An event can be presented from multiple different views. We denote the data matrices for each view by $\mathbf{A} = [a_1, a_2, \dots, a_N]$, $\mathbf{B} = [b_1, b_2, \dots, b_N]$ with N samples. We consider paired observations from two views, denoted $(a_1, b_1), (a_2, b_2), \dots, (a_N, b_N)$ for $i = [1, N]$. We also denote \mathbf{f} function to map inputs by kernel machines or DNNs with a corresponding set of learning parameters \mathbf{W}_f . For example, the projection of view 1, and view 2 are as follows $\mathbf{f}(\mathbf{A}) = [\mathbf{f}(a_1), \dots, \mathbf{f}(a_N)]$, $\mathbf{f}(\mathbf{B}) = [\mathbf{f}(b_1), \dots, \mathbf{f}(b_N)]$, respectively. The dimensionality of the projection is denoted L . The deep canonical correlation analysis (DCCA) (Andrew et al. 2013) is a DNN extension of canonical correlation analysis (CCA) (Hardoon et al. 2004). Inspired by DCCA, we propose the deep sensor-fusion learning approach based on DCCA. Instead of feed-forward neural networks in DCCA, we use two autoencoders (AE) combined with CCA. The schematic diagram of the deep sensor-fusion learning is described in Figure 2. Both two feature extraction networks \mathbf{f} , \mathbf{g} , and the two reconstruction networks \mathbf{q} and \mathbf{p} are separate for each view to get reconstruction errors $\mathbf{R}_A, \mathbf{R}_B$. The objective of this model is optimized as follows:

$$\min_{\mathbf{w}_f, \mathbf{w}_g, \mathbf{w}_q, \mathbf{w}_p, \mathbf{U}, \mathbf{V}} \frac{-1}{N} \text{tr}(\mathbf{U}^\top \mathbf{f}(\mathbf{A}) \mathbf{g}(\mathbf{B})^\top \mathbf{V}) + L_{AE} \quad (2)$$

$$L_{AE} = \frac{\lambda}{N} \sum_{i=1}^N (\|\mathbf{a}_i - \mathbf{q}(\mathbf{f}(\mathbf{a}_i))\|^2 + \|\mathbf{b}_i - \mathbf{p}(\mathbf{g}(\mathbf{b}_i))\|^2), \quad (3)$$

where $\lambda > 0$ is a trade-off parameter, two CCA directions \mathbf{U}, \mathbf{V} with L dimensions. L_{AE} is the sum of reconstruction errors. Similar to the optimization of DCCA, we also use stochastic optimization for the deep sensor-fusion objective.

4 PROPOSED FRAMEWORK

We present a novel vehicle detection framework based on the deep sensor-fusion approach using multiple sensor signal data for BWIM. In particular, we utilize two strain signal sensors

Figure 2. Schematic diagram of deep sensor-fusion approach.

at different positions on the bridge. We observe that two views corresponding to the two strain sensors can identify a passing vehicle event. The flowchart of the proposed framework is depicted in Figure 3. Our framework includes three phases. The first phase (in a gray area), *data pre-processing*, collects sensor signal datasets from the BWIM database. Then, we apply the Wavelet denoising methods (El-Dahshan 2011, Wink and Roerdink 2004) to get two denoising signals S_1 and S_2 . The second phase (in a blue area), *signal transformation*, uses Wavelet transform methods (Vuong et al. 2022) to decompose a denoised signal sequence from 1D frequency space into 2D scale-time space to obtain coefficient results in C_1 , and C_2 . In the final phase (in a yellow area), *vehicle detector*, the coefficient matrix is fed into the deep sensor-fusion learning as Figure 2 to find the sharing representations for each view. Then, the output results of deep sensor-fusion learning are used to train with a simple classifier (Quinlan 1996) to detect vehicles.

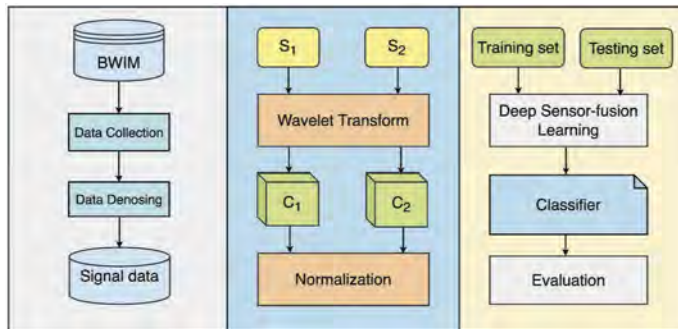

Figure 3. The general flowchart of the proposed framework.

We further depict a strain signal sequence as Figure 4(a) and its coefficients of CWT using Morlet Wavelet and Mexican Hat Wavelet (Vuong et al. 2022) in Figure 4(b) and Figure 4(c), respectively. It can be easily seen that the coefficients at time scales, where the oscillations appear in the original signal, are larger than those at the other time scales. Thus, the coefficients matrix is an informative representation of the signal. In addition, it also owns sequential nature as its columns are sequentially related.

Figure 4. (a) strain signal sequence, (b) CWT by Morlet, (c) CWT by Mexican Hat.

5 EXPERIMENTS

5.1 Data pre-processing and transform

We evaluate the performance of the proposed framework on two real-world strain signal datasets. These data are collected from BHMS on two bridges in Japan. One is a prestressed concrete bridge (Bridge A) and the other is a metal bridge (Bridge B). Note that the two selected sensors on the same bridge are installed at different positions. These sensors require synchronization. The sampling frequency of the strain meters is 100Hz and 200Hz, respectively. We use 50K samples for signals in these experiments. The length of each sample is 128 time steps. The ground-truth data are collected from the surveillance cameras installed on the bridge. We use the TSS proposed in (Kawakatsu et al. 2017) to retrieve the number of vehicles along with the time epochs that they pass over the sensors. Then, the raw signals are reduced noise. For example, the denoising sensor signal is illustrated in Figure 5 (a), 5 (b), respectively, for the first and second sensor positions in Bridge A.

Figure 5. Example of raw signals and denoised signals at different positions in Bridge A.

After denoising signal data, we use CWT to transform the inputs into scale-time space to obtain coefficients. For strain signals, we use the Mexican Hat Wavelet or the Morlet Wavelet. In many experiments, we set up scale parameters from 10 to 200. With a scale equal to 200, we obtain the meaning coefficients with an accuracy of the classifier is more than 92 %. Therefore, we use a scale parameter equal to 200 for each sensor signal data. The coefficient results are used as inputs to feed the deep sensor-fusion learning for vehicle detectors.

5.2 The compared methods

To evaluate the performance of the deep sensor-fusion learning in our proposed framework, we employ many experiments with the compared methods, which are based on the multi-view representation approach as follows:

- *Traditional CCA-based methods:* CCA, Kernel CCA (Hardoon et al. 2004, Kawano et al. 2019) are foundation techniques for finding a common space between two views without DNNs.
- *AE-based methods:* SplitAE (Ngiam et al. 2011), CorrAE, DistAE (Wang et al. 2015) find a sharing representation by reconstructing errors for each view. These methods use two autoencoders without CCA to find a common subspace for multiple views.
- *Hybrid CCA and DNN methods:* Both DCCA and deep sensor-fusion learning use hybrid DNNs and CCA. However, we propose two autoencoders for deep sensor-fusion learning instead of using two feed-forward neural networks as in DCCA.

Deep sensor-fusion learning has hyperparameters that are selected by using the tuning set. The final dimensionality L is selected from $\{5, 10, 15, 20, 25, 30, 35, 40, 45, 50\}$. The feature mappings (\mathbf{f}, \mathbf{g}) are implemented by networks of 4 hidden layers and a linear output layer of L units; reconstruction mappings (\mathbf{q}, \mathbf{p}) are implemented by networks of 4 hidden layers and an output layer of L units. We use SGD for optimization with minibatch size, learning rate, and momentum tuned on the tuning set. Then, we use a very simple decision tree classifier (Quinlan 1996) for embeddings of views to train efficiently on low-dimensional projections and achieve high accuracy for vehicle detection.

5.3 Evaluation metric

The ground truth consists of the number of vehicles and sequence samples. The i -th sample is described as triplet $\{\mathbf{s}_{1i}, \mathbf{s}_{2i}, \mathbf{g}_i\}$. Here, \mathbf{s}_{1i} is a sequence of the first sensor signal input, \mathbf{s}_{2i} is a sequence of the second sensor signal input. \mathbf{g}_i indicates the presence of a vehicle at the bridge entrance at the observation time. We estimate the length of a sequence input based on the average speeds and bridge length. Each dataset in our experiments is divided into training, tuning, and test sets according to the ratio of 80%, 10%, and 10%, respectively. The trained model is used to classify the label of test data. To evaluate the performance of the deep multi-view models, we use metrics such as accuracy (Acc), precision (P), recall (R), and F_1 scores for the classification problem. The main standard parameters include True Positive (TP), False Positive (FP), True Negative (TN), and False Negative (FN) are defined in the confusion matrix (Susmaga 2004). Based on the confusion matrix, Acc, P, R, and F1 are defined as follows:

$$Acc = \frac{TP + TN}{TP + FP + TN + FN}, \quad (4)$$

$$P = \frac{TP}{TP + FP}, R = \frac{TP}{TP + FN}, F1 = \frac{2 \times P \times R}{P + R}. \quad (5)$$

We use five folds cross-validation with ten experiment times for each fold to evaluate the proposed method and the compared methods, particularly the averaged Acc, P, R, and F1 scores.

5.4 Results

The averaged accuracy results of the proposed framework and the compared methods on two bridges are given in Table 1. The mean accuracy along with standard deviation on the training data and testing data by our proposed framework are $97.87 \pm 1.41\%$ and $93.62 \pm 1.73\%$ on Bridge A, respectively, $96.76 \pm 1.53\%$ and $94.24 \pm 1.85\%$ on Bridge B. It can be clearly observed that the deep sensor-fusion learning in our proposed framework surpasses the compared methods. More specifically, our framework achieved better accuracy on both two bridges than those of the traditional CCA-based methods (CCA, Kernel CCA) from 10% to 20%. In comparison with the AE-based methods, they could not beat our proposed framework. In particular, the performance of our framework is higher than SplitAE, Corre AE, and DistAE from 10% to 22% for Bridge A and from 5% to 15% for Bridge B. Results also show that our framework is more effective than the DCCA method about 5%. The results also validate the importance of the deep sensor-fusion model in our framework. The reason may be that the peak detection procedure in our framework is more effective than the compared methods. In addition, reconstruction errors computed by the AEs model integrating with the CCA objective can account for different types of anomalies. As we can observe, substituting it with the two separate autoencoders significantly degenerates the performance of the proposed framework by the SplitAE method. The deep sensor-fusion learning can leverage complementary information between the two signals to compute more discriminative reconstruction errors. The outputs of deep sensor-fusion learning make classification much easier on vehicle detector. So, we only use a simple classifier that can be trained efficiently on low dimensional projections that already achieve high accuracy instead of using a heavily nonlinear classifier on the original inputs. Deep sensor-fusion learning plays an important role in improving the framework's performance.

The mean P, R, and F1 results, along with standard deviation for five folds cross-validation of the proposed framework, are described in Figure 6 (a), and Figure (b), for Bridge A, and Bridge B, respectively. Performance of our proposed framework obtains from 90% to 95% with F1 score on two datasets. Both P and R results are high over five folds. In Bridge A, the mean P results obtained more than 95%, and the mean R results are about 90% on five folds. For Bridge B, we also observe that the similarity results of P and R are from 90% to 95%. The results show that the deep sensor-fusion approach is the effective method for finding a sharing projection between two views for both strain signals datasets. Therefore, the proposed framework can be generalized for multiple strain signal datasets on bridges. Furthermore, it can be integrated and improve the accuracy of vehicle detection task for BWIM systems.

Table 1. Comparison of the proposed method with the compared methods.

Method	Mean Acc (%)			
	Bridge A		Bridge B	
	Training data	Testing data	Training data	Testing data
CCA	78.72 ± 2.24	74.47 ± 2.83	82.01 ± 2.45	80.94 ± 2.64
Kernel CCA	85.11 ± 2.24	80.85 ± 2.45	85.49 ± 2.64	80.16 ± 2.82
SplitAE	89.36 ± 1.41	85.36 ± 2.24	91.37 ± 1.95	89.93 ± 2.24
CorrAE	82.56 ± 1.73	75.36 ± 2.24	87.46 ± 2.24	81.35 ± 2.45
DistAE	75.62 ± 2.24	72.36 ± 2.45	84.96 ± 1.85	80.81 ± 2.24
DCCA	93.62 ± 1.73	89.36 ± 2.23	94.96 ± 1.73	92.81 ± 1.75
Proposed framework	97.87 ± 1.41	93.62 ± 1.73	96.76 ± 1.53	94.24 ± 1.85

Figure 6. Averaged P, R, and F1 score of 5 folds cross-validation both bridges.

Figure 7. Comparison the proposed method and the compared methods at the different L.

Each algorithm has hyper-parameters that are selected using the tuning set. We evaluate the mean accuracy of the proposed method and the compared methods with the different L parameters from $\{5, 10, 15, 20, 25, 30, 35, 40, 45, 50\}$ on two strain sensor datasets. The averaged accuracy results at different L are described in Figure 7. In Figure 7 (a) for Bridge A, the results show that the performance of our proposed method is better than the compared methods at the different values L. Similarly, our proposed method surpasses the compared methods in Figure 7 (b) for Bridge B. Both the traditional CCA methods without DNNs and AE-based methods without CCA can not find an effective subspace to share between views when lower L from 5 to 40. The proposed framework based on deep sensor-fusion learning can improve the performance of vehicle detection by integrating CCA and AEs. The performance of the proposed framework significantly increases along with increasing L values from 5 to 40. When L is from 45 to 50, the implementation of the proposed framework has almost no increase and is stable. The experiment results show the effectiveness of the proposed framework when we choose L equal to 50.

6 CONCLUSIONS

In this paper, we propose a novel vehicle detection framework for multiple strain sensors of BWIM systems based on deep sensor-fusion learning. The proposed framework transforms the signal into a scale-time space by CWT. Then, we propose a deep sensor-fusion learning approach based on AEs and CCA for multiple sensors. It extracts complex features through multiple neural layers and can detect vehicle properties from the multi-view sensor signals. The performance of the proposed framework is evaluated on two real-world datasets collected from bridge health monitoring systems. The results of the experiments show that the proposed framework is reliable and effective for vehicle detection in the BWIM system.

After detecting vehicles on bridges, we consider how to estimate the heavy vehicles and detect overload vehicles by multiple strain sensor signals in future work. The overload vehicle detection task may reduce the costs of both installation and system maintenance for BHMS.

Masonry design for extended life-time usage by implementing joint behaviour

T. Molken, J. Smits & S. Van Hout

Department of Civil Engineering, Materials and Constructions division, KU Leuven, De Nayer Campus, Sint-Katelijne-Waver, Belgium

R. Meuleman

Product developer, Wienerberger Belgium nv, Kortrijk, Belgium

ABSTRACT: New structures are designed for a specified design working life according to (EN 1990, 2015). Facing sustainability requirements, designers need to account for extended lifetime usage beyond the original purpose of the building. Increasing the spans of the floors is one way to do so. Though, it significantly limits the use of masonry structures. (EN 1996-1-1, 2012) states that the designer should account for out-of-plane eccentricities of the masonry wall. Annex C of this document allows for a simplification with a fully restrained connection between floor and wall elements. Therefore, the eccentricity is directly related to the span of the neighbouring elements. Though, in the same annex, it is acknowledged that this is too conservative so a reduction is allowed. Nevertheless, they are not able to implement the stiffness of mortar joints or bearing paths. To take these interface materials into account, an easy-at-hand analytical approach is developed and tested.

1 INTRODUCTION

For centuries, masonry structures have shown a proven adaptability to new occupations and even resilience. Up till now, old masonry structures are still a valid research subject throughout all of Europe as they can still be found in existing structures (Bertolesi, et al., 2019; Vitti, 2021). Figure 1 shows some examples of repurposed masonry buildings in Europe. From that point of view, masonry structures can be seen as sustainable structures.

Leopoldskazerne, Ghent

La Piscine, Roubaix

LX factory, Lisbon

Figure 1. Repurposed masonry buildings in Europe.

Currently, the design of masonry bearing wall structures is carried out uniformly throughout Europe and certain other countries in accordance with the Eurocodes (EN 1996-1-1, 2012) or the American code (ACI 530-13, 2013) in Northern America. However the simplified rules of annex

C out of (EN 1996-1-1, 2012) will lead to conservative results in the case of unreinforced masonry. In combination with rather limited normal forces, the negative influence of eccentricities on the bearing capacity is a handicap for the application of big spans. However, in the future, the demand is rising for masonry in combination with big spans to apply adaptable design (Malabi-Eberhardt, et al., 2021) where a building during his lifetime could facilitate different occupations.

One common way of limiting eccentricities and obtaining equally distributed load transfers is by the application of bearing paths made out of elastic material. Loads are not anymore concentrated near the borders of the brick but distributed over the width which should lead to smaller eccentricities. This paper presents the results of some theoretical approaches and the results of experiments on a two-storey high scaled model of a masonry structure. Further, it can be noted that the bearing path also has the advantage to limit the transfer of vibrations through the building.

2 HANDLING ECCENTRICITIES

2.1 Code provisions out of EN 1996-1-1 together with annex C

The verification of unreinforced masonry walls in the ultimate limit state uses a reduction factor Φ applied on the product of the thickness of the wall t and the design compressive strength of the masonry f_{db} see Eq. (1). The reduction factor accounts for the effects of slenderness and the eccentricity caused by the loading. While for the thickness of the wall, the bearing length t_b may be taken at the top and bottom of the wall in the case of a partial support of the floor. On the other hand, it is known that with small values of t_b stresses will increase rapidly, and plasticisation will occur. Reason why a rectangular stress block in the code is proposed (EN 1996-1-1, 2012) with an upper limitation of $0.33 \cdot t$ (or level arm $\geq 0.33 \cdot t$ to the gravity centre, Figure 2).

$$N_{Ed} \leq N_{Rd} = \Phi_i \cdot t \cdot f_d = \left(1 - \frac{2e_i}{t}\right) \cdot t \cdot f_d \leq 0.9 \cdot t \cdot f_d \quad (1)$$

The eccentricity e_i is the sum of the eccentricities due to: the floor load M_{id}/N_{id} , horizontal loads mostly coming from the wind e_{he} , and imperfections e_{init} . A minimum value of $0.05t$ should be respected, see Eq. (2). Note that in the American code (ACI 530-13, 2013) the reduction factor is depending on the square of the slenderness ratio defined by the height of the masonry and the radius of gyration without the impact of out-of-plane loads (for unreinforced masonry).

$$e_i = \frac{M_{id}}{N_{id}} + e_{he} + e_{init} \geq 0,05t \quad (2)$$

Where M_{id} : Design value of the bending moment caused by the eccentricity of the floor load at the support (at the top as M_1 and at the bottom as M_2).

N_{id} : Design value of the vertical load at the top middle or bottom of the wall.

e_{he} : Eccentricity resulting from horizontal loads.

e_{init} : Initial eccentricity due to construction imperfections $\geq h_{ef}/450$

The information needed to calculate the out-of-plane eccentricity M_{id}/N_{id} from Eq. (2) can be found in Annex C of (EN 1996-1-1, 2012). It is a simplified method applicable to masonry walls supporting concrete floors. The end moment is given by Eq. (3) for M_1 (and likewise for M_2) and can be used for local analysis of the wall-floor joint and starts from an uncracked wall-section assuming elastic behaviour of materials. This implies that normal forces should be sufficiently high to guarantee full contact without cracking. For non-timber joist floors the moment distribution can be found in Figure 2. On the other hand, it is also stated that when the bearing length is limited to $t_b < t$, the relevant moments of inertia need to be used. As it is known that true fixity will not occur, the moments obtained may be reduced by a semi-empirical factor η varying between 0.5 and 1, depending on the bending stiffness ratio k_m of the adjacent floor to the upper and lower walls, see Eq. (4) valid for slabs loaded with uniform distributed loads.

$$M_1 = \frac{n_1 \frac{E_1 I_1}{h_1}}{n_1 \frac{E_1 I_1}{h_1} + n_2 \frac{E_2 I_2}{h_2} + n_3 \frac{E_3 I_3}{l_3} + n_4 \frac{E_4 I_4}{l_4}} \cdot \left[\frac{w_3 l_3^2}{4(n_3 - 1)} - \frac{w_4 l_4^2}{4(n_4 - 1)} \right] \quad (3)$$

$$\eta = 1 - \frac{k_m}{4} = 1 - \frac{1}{4} \cdot \left[\frac{n_3 \frac{E_3 I_3}{h_3} + n_4 \frac{E_4 I_4}{h_4}}{n_1 \frac{E_1 I_1}{h_1} + n_2 \frac{E_2 I_2}{h_2}} \right] \geq 0.5 \quad (4)$$

Where:

w_i = distributed load on element i

n_i = stiffness factor equal to 4 with both ends fixed, 3 for members simply supported at the end, 0 for the stiffness term for the cantilever and 1.5 for the loading

Figure 2. Simplified presentation for moment distribution (a) and maximum values (b) out of (EN 1996-1-1, 2012).

2.2 Önorm B 3350.

The old Austrian masonry code (Pauser, 1993) presents another interesting structural model, based on a strut mechanism, which makes horizontal stiff bracings needed. Nevertheless, the final outcomes in the meaning of stress fields at the contact surface are not meaningfully different.

Figure 3. Structural model out of the old Austrian code (a) and proposed stress distributions at the contact surface (b), following (Pauser, 1993).

It can be highlighted that in the presented structural model an indication is made of the effects of higher loads and therefore higher bending moment capacities of the joints. Decreasing rotations (and linked to this also deflections) are marked: $\alpha_1 > \alpha_2 > \alpha_3$.

2.3 Literature

Most, if not all, of the experimental research has been devoted to refining the reduction factor η from Eq. (4) to obtain a more consistent relation between the results following from Eq. (3) with observations based on experiments. Sahlin (Sahlin, 1959) was one of the first to carry out a study of wall-floor connections in which the influence of crack formations at connection sites was investigated using tests on frameworks. This study laid the foundation for further research into the behaviour of floor-wall connections. Decades later, Hendry A.W (Hendry, 1998) conducted real-size tests to derive the same joint fixity factor η (= moment reduction

factor). Lewicki (Lewicki, et al., 2004) published similar research at different loads. This was done for both hollow clay bricks and aerated concrete walls.

2.4 Proposed theoretical model

Despite the considerable efforts made by the cited researchers so far a methodology based on fundamental mechanics is missing which allows for including the beneficial effect of elastic bearing paths. In practice, neoprene is often inserted between the hollow core slab and the masonry wall to distribute the load (avoiding local failure of the wall), limit acoustic emissions and avoid the transition of vibrations. This neoprene also inhibits the transition of a bending moment between the slab and the wall. In a first step, the rotational stiffness of a wall against an externally applied constant moment M is written as a function of the rotation angle φ , see Eq. (5). With σ a constant bending stress in the masonry and b , t and h respectively the length, the thickness and the height of the masonry wall.

$$C_{constant} = \frac{M}{\varphi} = \frac{\sigma \frac{bt^2}{6}}{\frac{\Delta h}{t/2}} = \frac{\sigma \frac{bt^3}{12}}{\varepsilon \cdot h} = \frac{\sigma \frac{bt^3}{12}}{\frac{\sigma}{E} \cdot h} = \frac{E * I}{h} \quad (5)$$

As already shown in Figure 2 (a), the bending moment is varying over the height in such a way that $M_1 = -M_2$ in the case of equal loads, heights and spans. The shortening Δh is now due to the averaged strain or half value of the maximum strain (corresponding with the maximum stress or moment at the top and bottom) which develops only over half of the height. In a next step, a reasonable assumption is made that the bending moment is not varying over the limited thickness of the bearing path h_n , width t_n and Young modulus E_n . As before, but accounting for the varying moment, Eq. (6) can be found where the stress in the bearing path is related to the one in the masonry wall by the square of the width.

$$\begin{aligned} C_{wall+bp} &= \frac{M}{\varphi} = \frac{\sigma \frac{bt^2}{6}}{\frac{\Delta h_n + \Delta h}{t/2}} = \frac{\sigma \frac{bt^3}{12}}{\varepsilon_n \cdot h_n + \varepsilon/2 \cdot h/2} = \frac{\sigma \frac{bt^3}{12}}{\sigma \left(\frac{t}{t_n}\right)^2 / E_n \cdot h_n + \sigma/E \cdot h/4} \\ &= \frac{EI}{\left(\frac{E}{E_n} \left(\frac{t}{t_n}\right)^2 \frac{h_n}{h} + \frac{1}{4}\right) h} = \frac{1}{n_i \frac{E}{E_n} \left(\frac{t}{t_n}\right)^2 \frac{h_n}{h} + 1} n_i \frac{EI}{h} = \alpha_i n_i \frac{EI}{h} \end{aligned} \quad (6)$$

To account for the presence of a bearing path in the equation of Annex C (EN 1996-1-1, 2012) a new reduction factor α_i is introduced depending on the geometrical, material parameters of the bearing path and the boundary condition by the stiffness factor n_i , without the need for η -factor. Previous Eq. (3) can be rewritten as Eq. (7) by introducing the corresponding α_i -factors. To adjust this formula for concentrated loads (P) instead of distributed loads (w), the calculation of the load effect changes from factor $1/4 \cdot w l^2$ to $3/8 \cdot P l$.

$$M_1 = \frac{\alpha_1 n_1 \frac{E_1 I_1}{h_1}}{\alpha_1 n_1 \frac{E_1 I_1}{h_1} + \alpha_2 n_2 \frac{E_2 I_2}{h_2} + \alpha_3 n_3 \frac{E_3 I_3}{h_3} + \alpha_4 n_4 \frac{E_4 I_4}{h_4}} \cdot \left[\frac{w_3 l_3^2}{4(n_3 - 1)} - \frac{w_4 l_4^2}{4(n_4 - 1)} \right] \quad (7)$$

3 EXPERIMENTAL PROGRAM

3.1 Development of a scaled model.

Typical multi-purpose buildings are characterized by spans of 8.1 m and free heights of at least 3.0 m. The masonry wall thickness is in such cases about 0.30 m to obtain a sufficient acoustic performance. In the case of multi-span applications, the slab thickness will be about 0.25 m for an in-situ casted concrete floor slab.

Out of practical reasons, a test set-up was developed at a scale of 1/3 respecting the same slenderness ratio (h/t) or a storey height of 1 m with a brick width of only 0.10 m. A single-span standard reinforced hollow core precast floor element with a free span of 2.8 m and thickness of 0.13 m was used. A two-storey building was realized to capture differences in deformation at both levels as mentioned in section 2.2, see Figure 3. Two types of execution have been tested. In the first one, no bearing path or even mortar joint was used. A practice which is frequently seen on smaller single-house sites in Belgium. Secondly, bearing paths (width limited to 80 mm instead of 100 mm of the brick) are inserted at the top and bottom to facilitate the best possible distribution of forces. The depth of the test set-up was fixed to 0.60 m, the width of the hollow core element used. Horizontal stability was guaranteed by wooden beams attached to the hollow cores in the middle of the span, supported by the stiff testing frame (allowing vertical deformations). Dimensions of the test set-up and measuring devices can be found in Figure 4, together with a picture of both test set-ups in the laboratory.

Figure 4. Test set-up of the scaled model (Meylemans, 2023).

3.2 Geometrical and material properties.

Material properties have been derived based on material tests, with stress levels equal to the one applied under the real testing conditions, see Table 1. Adhesives have been used by a professional (from the Wienerberger factory) for the bricklaying of the glued bricks.

Table 1. Mechanical material properties.

Component	Producer	Type	ρ	f_{ck}	f_{cm}	E
			[kg/m ³]	[N/mm ²]	[N/mm ²]	[N/mm ²]
Bricks	Wienerberger	PLS500-15N	850*	5.94	15*	15000°
Adhesive	Wienerberger	Dry-fix	1*	-	-	-
Mortar	Handmade	C300	1800	-	12°	27000°
Hollow core	Vets	V13-60GL	1653	40*	48°	35000°
Bearing path	Hakron	Neoprene 60	-	-	5*	18

* Out of datasheet of the producer, °based on information out of (EN 1992-1-1, 2005) or (EN 1996-1-1, 2012) and - = not relevant. Characteristic values based on tests on wall elements EN1025-1.

3.3 Measuring devices

Up-to-date measuring techniques have been used with a differentiation between the ones related to the slab, loadcells and Linear Variable Differential Transformers LVDT's, and the ones related to the vertical wall elements. For these latter elements, Digital Image Correlation (DIC) techniques have been used with front and side views in combination with classic DEMEC strain measurements as validation of the DIC (gauge length of 150 mm and an accuracy of 0.02 mm).

Three-dimensional digital image correlation (3D-DIC), an optical-numerical contactless technique, is used for measuring the strain distribution and full-field displacement at the surface of a specimen. Two synchronized stereovision cameras (Manta G-895B cameras with Kowa LM12XC lenses) take images of a speckled object in the undeformed and deformed state (20 images at each load step). The images are post-processed in DuoDIC, an open source MATLAB toolbox (Solav & Silverstein, 2022). In the undeformed state of the specimen, some images are taken of a flat checkerboard pattern. DuoDIC uses these images for calibrating both cameras.

The DIC measurement, see *Figure 5*, consists of a two-step approach. The first step includes the full view of the specimen. The field of view in step two is concentrated on the region just above and just below the hollow core slab. In such a way, displacements over the thickness of the wall are obtained by DIC measurements on the headers of the masonry.

Figure 5. DIC test-setup (a) full view of the specimen and, (b) detailed concentrated view.

3.4 Numerical simulation

With the aid of the Finite Element Method (FEM), shell elements, and contact elements (avoiding the transition of tensile stresses) first insight can be obtained. Figure 6 shows, by the aid of the principal stresses, and a concentrated load of 14.4 kN applied at each floor level, a huge influence of the bearing path. Compression stresses are divided by a factor of about 10, parasitic stresses are disappearing and stresses are introduced more centrally with an elastomer bearing path. Additionally, the inclined strut (almost disappearing with the elastomer) of Figure 3 can be visualized by the principal stresses of Figure 6.

Figure 6. FEM simulation - hard contact left (minimum -3,98 N/mm²), elastomer right (-0,41 N/mm²).

4 RESULTS AND VALIDATION

A concentrated load was applied to achieve the ultimate bearing capacity of the hollow core slab based on the mean values of the material properties (JCSS, 2001) and a rectangular stress distribution in the concrete. Three characteristic moments can be derived (EN 1992-1-1, 2005) the cracking moment $M_{cr} = 4.54$ kNm; the design moment for the ultimate limit state (ULS) $M_{Rd} = 7.78$ kNm; and the expected failure moment $M_u = 11.69$ kNm. For a simply supported element, the corresponding concentrated loads are respectively: $P_{cr} = 4.5$ kN, $P_{Rd} = 9.0$ kN, and $P_u = 14.4$ kN or 30, 63 and 100% of the estimated failure load. During the tests, no failure was observed which made it possible to repeat the tests several times.

4.1 Deformations of the wall elements

The DIC measurements on the headers of the wall show the displacements at the location of the connection at the lower floor level, Figure 7. Due to a recording error, only the displacements at a load level of 7.2 kN/ each level can be shown, in the figure also some noise can be seen due to the tongue-and-groove shape of the blocks. Unfortunately, the measurements during the experimental testing are not accurate enough to compare them with the results of the finite element model in the linear-elastic FE software. Though, when looking more generally at displacements, similar trends and magnitudes can be observed between test results and numerical modelling.

Figure 7. Results out of the FEM model (central) and DIC measurements (outer sides) at 7.2 kN of the header parts on top and bottom of the lower floor, respectively without and with elastic bearing path. Different scales have been used.

The results of the LE-FE model can then be compared to the analytical approaches as shown in Table 2. The first three columns show the outcome of applying the formula (Eq. (3)) and the reduction (Eq. (4)) proposed in Eurocode 6. As stated before, these formulas do not account for interface materials such as neoprene. The two following columns, ‘New-Neoprene’, apply the newly proposed factor α (Eq. (6)). It is seen that the obtained compression stresses are relatively close to each other for the lower wall. However, the tensile stresses are more deviating which is also the case for all stresses at the level of the upper wall with limited normal forces.

Table 2. Comparison analytical and numerical results.

	EC6 – non incl. interface material			New - Neoprene		LE-FEM*	
	$M_{1,EC6}$ [kNm]	$M_{1,EC6,red \eta}$ [kNm]	$\sigma_{zz, ana, red \eta}$ [N/mm ²]	$M_{1,red \alpha}$ [kNm]	$\sigma_{zz, ana, red \alpha}$ [N/mm ²]	$\sigma_{zz, num, neoprene}$ [N/mm ²]	$\sigma_{zz, num, cold}$ [N/mm ²]
Upper wall	-0,323	-0,162	-0,27/0,13	-0,134	-0,23/0,10	-0,14/0,02	-0,22/0,09
Lower wall	-0,287	-0,143	-0,31/0,04	-0,127	-0,29/0,02	-0,23/0,00	-0,42/0,16

* Values not obtained in the joint, but slightly lower since the boundary conditions of the joint were adjusted to avoid the floor slab pulling on the wall.

4.2 Deformations of the hollow cores

In the end, also a comparison is made between the deformations (compensated for the settlements of the supports) of the hollow cores, see Figure 8. On the left hand side, the data out of the first loading cycle is shown, some scatter is seen due to the cracking and a loading and unloading cycle. This scatter is completely disappeared in the second loading cycle (only the A and E series are shown), at the right hand side, except for the lower one with an elastic bearing path (N).

Figure 8. Measured deformations of the hollow core slab at the top (T), lower (L), with rigid (R), neoprene (N) bearing paths, after a first (1) and second test cycle (2). Measurements of L_N_2 are presented dotted, due to the high scatter.

It is noted that the deformation of the upper hollow cores is always more important than the ones of the lower floor, indicating that the double clamping moment of the lower floors plays a role, see also section 2.2. A reset was done of the deformations between the first and subsequent loading cycles, reason why no residual deformations (after the first loading cycle) in the

right graph of Figure 8 can be found. Residual deformations of 5.9 (rigid)/- (neoprene) mm of the lower and about 7.9 (rigid)/7.5 (neoprene) mm of the top slabs have been measured. In the reloading phase, it is remarkable that no difference can be found between the system with rigid supports and with elastomer, which is clearly the case during the first loading cycle.

5 CONCLUSIONS

A new approach was presented to handle the influence of elastic bearing paths in the formulation of Annex C out of (EN 1996-1-1, 2012). Based on more advanced FEM approaches it seems that the proposal works well and there is no need more for a semi-experimental joint fixity factor. For the experimental setup, a reduction factor of more than 10 can be achieved.

Experimental results clearly indicated that there is still a certain ‘fixity’ in the connections even with the application of an elastic bearing path. However, no important bending strains could be observed which is an indication that the actual code is far too negative. This is the reason why other researchers cited launched the semi-empirical so-called joint fixity reduction factor η . The α -factor proposed in this contribution is based on mechanical sound engineering principles and allows to take into account the beneficial effects of bearing paths. Results shows an even better performance than the actual fixity-factor out of the code provisions. Nevertheless, further improvements should be made to obtain full correspondence with FEM- and test-results.

ACKNOWLEDGEMENTS

This research would never have been possible without the question raised by the company Wienerberger, who also delivered the needed material together with Vets (Belgium) for the hollow cores. Our master thesis student Miro performed all the described experiments together with Luc our lab technician. This work will be continued in the near future.

This work was supported by FWO – Research Foundation of Flanders [grant number 1SG3523N].

Data-driven life-cycle risk assessment of bridge networks using Bayesian network

M. Cheng & H.O. Gao

Cornell University, Ithaca, NY, USA

ABSTRACT: Bridge failures within the transportation network can lead to significant losses. Such failures are attributable to many factors from design to usage, internal to external, historic to present. It is therefore important to monitor and assess these risks in a holistic life-cycle approach. Generally, life-cycle risk assessment involves the evaluation of bridge failure probability over time and the associated consequences/losses. With increasing capabilities to harvest big data from various sources, the risk profile can be updated by integrating the power of data into the assessment. This paper presents a framework based on Bayesian network to perform data-driven life-cycle risk assessment for bridge networks. The life-cycle risk is updated with data from count stations and the bridge monitoring data. 13 bridges in a bridge network in New Jersey is used to demonstrate how the framework fuses the data and complex model of the system for risk assessment of the bridge network.

1 INTRODUCTION

Bridges are vulnerable assets in a transportation network and infrastructure systems. Failures of bridges can lead to significant losses such as injuries, casualties, traffic delays, and lost productivity. Such failures are attributable to many factors such as natural hazards, deterioration, and overloads (Frangopol et al. 2017). The failure analysis is further complicated by confounding factors changing over time such as the increasing traffic loads and failure consequences due to stressors such as population growth in urban areas and the increasing magnitudes and frequencies of natural hazards exacerbated by climate change (Yang and Frangopol 2019). Hence, it is important to monitor and assess these risks in a holistic life-cycle approach across the bridge network. In general, life-cycle risk assessment (LCRA) of a bridge network involves evaluating the failure probability profiles of bridges and the corresponding failure consequences within the transportation network. In existing studies, LCRA has been performed for bridge networks under different hazards such as earthquakes (Bocchini and Frangopol 2011) and riverine floods (Zhang and Alipour 2022). The outputs of risk assessment can then be used for decision-making such as life-cycle management (Liu et al. 2020) and recovery optimization (Bocchini and Frangopol 2012).

Recently, the ability to harvest big data to support the risk assessment of the transportation network has been advanced significantly. The newly available data can better reflect the capacity of and demand for the transportation network. For example, data from sensors embedded in the bridges and pavements can indicate bridge performance and diagnose road conditions, respectively (Frangopol et al. 2017; Guerrero-Ibáñez et al. 2018), which provides key information for up-to-date network capacity evaluation, while radar sensors and cameras can capture traffic flows (Guerrero-Ibáñez et al. 2018) that reflect demands over the network. The power of big data offers LCRA of bridge networks new improvement opportunities as the data/information on the network capacity and demand can be continuously acquired to update the failure probability profiles and the associated consequences. Structural health monitoring (Sun et al. 2020), intelligent transportation systems (Zhu et al. 2018), and smart manufacturing systems (Qu et al. 2019) are some examples of efforts in related fields that started incorporating the

power of data in their respective practices (i.e., structural engineering, transportation, and manufacturing). However, these existing endeavors tend to work in silos without taking a comprehensive systems approach. It is therefore important to develop a general methodology that accounts for different analyses and integrates disparate sources of data as a leverage for complex system level analysis and decision making.

This paper presents a framework based on Bayesian network (BN) to incorporate data from various sources into LCRA of bridge networks. BN presents an intuitive graphical framework that can model the relationships among random variables (i.e., nodes) using conditional probabilities. With recent advances, it's made its way into risk assessment (Marcot and Penman 2019). More specifically, the proposed framework uses BN to (1) model the interdependencies across and correlations within sub-systems analyses and (2) update the probability distributions of variables of interest when data is available for any nodes and subsystems. The framework also classifies the nodes into either data nodes or analysis nodes to guide Bayesian inference. In this paper, reliability analysis of the bridges and traffic prediction are joined together to perform data-driven LCRA of the bridge network. Using the framework, the life-cycle risk of the bridge network is updated when data from count stations and/or bridge monitoring devices is available. A bridge network located in Camden County, New Jersey, is used as an illustrative example to demonstrate how this framework can unify different analyses and disparate sources of data into LCRA for better informed and educated decision.

2 DATA-DRIVEN LIFE-CYCLE RISK ASSESSMENT (LCRA) OF A BRIDGE NETWORK

The risk of a bridge network is the joint risk of bridges in the network, usually summation of the individual bridge risks under reasonable independency assumption across bridge failures. For each evaluation time interval, typically a year, it involves the evaluation of the bridge failure probabilities and the corresponding consequences, which is expressed as

$$R_{netw}(t) = \sum_{i=1}^{N_b} P_{f,i}(t)C_{f,i}(t) \quad (1)$$

where N_b is the number of bridges considered in the bridge network, $P_{f,i}(t)$ is the failure probability of the i th bridge in year t , and $C_{f,i}(t)$ is the failure consequence associated with bridge i .

The performance function of a bridge to determine $P_{f,i}(t)$ is (Cheng et al. 2020)

$$g(t) = \alpha_m \alpha_a R_n(t) - a_{dl} L_{dl} - \alpha_{ll} L_{ll}(t) \quad (2)$$

where α_m and α_a are the uncertainty factors associated with material strength and the analysis, respectively, $R_n(t)$ is the nominal resistance in year t , a_{dl} and α_{ll} are the uncertainty factors associated with the dead load and live load, respectively, L_{dl} is the nominal dead load, and $L_{ll}(t)$ is the nominal live load for year t . Due to deterioration from different stressors, $R_n(t)$ decreases over years, while the live load effects can increase due to the increase in the truck weight and volume (Yu et al. 2019). The specific formulation of Equation 1 depends on various factors, such as the configurations of the bridge and the axle spacing of the trucks. Since the focus of this paper is not on the reliability analysis of bridges, we let L_{dl} and L_{ll} be normalized by $R_n(0)$ and only focus on the time-varying factors. A general form of the performance function is

$$g(t) = \alpha_m \alpha_a F_d(t) - a_{dl} A_{dl} - \alpha_{ll} A_{ll} F_{trk,W}(t) F_{trk,V}(t) \quad (3)$$

where $F_d(t)$ (<1) is the deterioration factor in year t , A_{dl} and A_{ll} are normalized factors associated with the dead load and live load, respectively, and $F_{trk,W}(t)$ and $F_{trk,V}(t)$ are the time-varying factors associated with the truck weight and truck volume, respectively. The effect of the truck volume on the failure probability is minimal, so $F_{trk,V}(t)$ is set to 1. $F_d(t)$ is modeled using a linear function

$$F_d(t) = 1 - B_d t \quad (4)$$

where B_d is the linear factor for deterioration. $W_{trk}(t)$ is modeled using an exponential decay function (Yu et al. 2019)

$$F_{trk,W}(t) = 2 \cdot \exp(-0.15t) \quad (5)$$

In this paper, $C_{f,i}(t)$ is estimated as the indirect loss due to detour cost after the closure of the bridge. The indirect loss is the summation of the running costs and the time loss associated with the vehicles supposed to pass the bridge (Dong et al. 2013). The running cost is

$$C_{run}(t) = L_d V_{ADT}(t) T_d [c_{r,car}(1 - r_{trk}) + c_{r,trk} r_{trk}] \quad (6)$$

where L_d is the detour length of the bridge, $V_{ADT}(t)$ is the annual average daily traffic (AADT) volume at year t , T_d is the time duration of the detour, $c_{r,car}$ and $c_{r,trk}$ are running costs for car and trucks, respectively, and r_{trk} is the ratio of truck traffic. The time loss is

$$C_{time}(t) = \frac{L_d V_{ADT}(t) T_d}{S_d} [c_{w,car} O_{car}(1 - r_{trk}) + c_{w,trk} O_{trk} r_{trk}] \quad (7)$$

where S_d is the speed of detour, $c_{w,car}$ and $c_{w,trk}$ are wages for car and truck drivers, respectively, and O_{car} and O_{trk} are average occupancies per car and truck, respectively.

In traditional risk assessment, some model parameters (e.g., V_{ADT} and W_{trk}) are treated as constants across years. Their values can be either taken from some existing sources (e.g., national bridge inventory database) or pre-determined using established models (e.g., linear extrapolation). However, such values are not necessarily best representations of the real conditions. Data-driven LCRA can address this caveat by utilizing data from monitoring devices. Newly available data can help reduce the discrepancy between the values adopted in risk assessment modeling and the true conditions. This in turn reduces the uncertainty when evaluating the risk.

In this paper, the deterioration factor F_d is estimated through data from bridge monitoring devices. Since the devices are usually embedded in the bridges, it is assumed that $F_d(t)$ can be obtained each year. V_{ADT} and $F_{trk,W}$ are estimated using the data from count stations in the traffic monitoring program operated by Department of Transportation (DOT). The traffic data mainly comes from continuous count stations (CCSs) and the short term count stations (STCS). The goal of the CCS is to understand the temporal pattern of traffic flow by installing permanent sensors to collect data all year round, while the goal of the STCS is to understand the spatial pattern of the investigated area by using portable sensors to measure traffic flow on road segments for one to three days. Specifically, the truck weight is monitored by CCSs and it is assumed that $F_{trk,W}(t)$ is perfectly observed. The estimation of V_{ADT} of a bridge is more complicated. Though the number of STCSs are large, it is still not enough to cover all the roads and bridges. Therefore, $V_{ADT}(t)$ of a bridge is approximated by the nearby STCSs (Wang and Kockelman 2009)

$$V_{ADT}(t) = \frac{1}{2} [V_{STCS,1}(t) \alpha_{iv,s1} + V_{STCS,2}(t) \alpha_{iv,s2}] \quad (8)$$

where $\alpha_{iv,s1}$ and $\alpha_{iv,s2}$ are uncertainty factors for traffic volume due to the spatial interpolation for the first and second STCSs, respectively, and $V_{STCS,1}(t)$ and $V_{STCS,2}(t)$ are AADT measured at the two nearby STCSs. It should be noted that if there is only one nearby STCS, then $V_{ADT}(t) = \alpha_{iv,s} V_{STCS,1}$. Besides, if the nearby count site is a CCS, then the acquired data $V_{CCS}(t)$ can be used to calculate $V_{ADT}(t)$. When data is provided for all nearby STCSs, $V_{ADT}(t)$ can be immediately determined. However, missing data complicates the problem as the STCSs do not have measurements every year. In that case, $V_{STCS}(t)$ is estimated using temporal extrapolation (Huynh et al. 2021)

$$V_{STCS,1}(t) = \alpha_{iv,t} \cdot V_{STCS,1}(t-1) F_{C,V}(t) \quad (9)$$

where $\alpha_{tv,t}$ is the uncertainty factor for traffic volume due to the temporal extrapolation, $V_{STCS,1}(t-1)$ is the AADT measured in the previous year, and $F_{C,V}(t)$ is the annual growth factor for the traffic volume measured at CCSs in year t . $V_{STCS,2}(t)$ is calculated in the same way. The underlying assumption is that growth rates are the same for all locations in the investigated area. Overall, F_d , $F_{trk,W}$, $F_{C,V}$, and V_{CCS} are observed every year, while V_{STCS} are obtained every few years. The data from these sources are used to update the failure probability profiles and the associated failure consequences of the bridge network.

3 FRAMEWORK FOR DATA-DRIVEN LCRA USING BAYESIAN NETWORK (BN)

BN is a directed acyclic graph (DAG) consisting of nodes that represent random variables and links that connect the nodes showing the dependencies and statistical correlations. BN models a joint probability distribution as the product of marginal distributions and conditional probability distributions. Consider a BN with four nodes in Figure 1. X_1 and X_2 , both random variables, represent root nodes and are described by marginal distribution $P(X_1)$ and $P(X_2)$, respectively. X_3 is a child node of X_1 and X_2 and is described by conditional probability $P(X_3|X_1, X_2)$, while X_4 is the child node of X_2 and is described by conditional probability $P(X_4|X_2)$. The joint distribution is then

$$P(X_1, X_2, X_3, X_4) = P(X_1)P(X_2)P(X_3|X_1, X_2)P(X_4|X_2) \quad (10)$$

More information regarding BN can be found in Straub and Der Kiureghian (2012).

Constructing a BN involves (1) building the graphical model (i.e., DAG) and (2) eliciting and storing the conditional probability tables (CPT) that define the relationships among nodes (Bensi 2010). The first step is related to the system one wants to analyze, while for the second step, conditional probability tables can be established based on expert knowledge tables (Marcot and Penman 2019), or determined using the simulation data (Bensi 2010). After constructing the BN, inference can be efficiently performed via query from the distributions of a set of random variables given the evidence of another set of random variables. Classical algorithms for inference include the variable elimination algorithm and junction tree algorithm (Bensi 2010).

Figure 1. Example BN with four nodes.

Here we propose a framework for data-driven LCRA using BN. Based on the function of the nodes in system analysis, we define three types of nodes: performance nodes (PN), data nodes (DN), and analysis nodes (AN). Performance nodes are represented by random variables that are considered as the performance indicators that can be monitored and/or quantified for a system or a subsystem. The PNs depend on the system and the analysis objectives. For LCRA of the bridge network, the PN represents risk in each year. Data nodes are the random variables with data coming in reflecting conditions of a system. In the model discussed in Section 2, F_d , $F_{trk,W}$, $F_{C,V}$, and V_{STCS} are DNs that can be further categorized as continuous or intermittent DNs. If the updating frequency of a DN is higher than that of the monitoring frequency of the system PN, then it is a continuous DN (CDN); otherwise, it's an intermittent DN (IDN). Analysis nodes (AN) are the random variables representing the outputs from certain analyses or models. The analysis can be as simple as estimating V_{ADT} using nearby STCSs (i.e., Equation 9), or as complicated as the reliability analysis of a bridge (i.e., Equations 2 and 3).

Based on the temporal property, the framework also classifies the nodes as time-dependent or not. Suppose a non-time-dependent node is the child node of a list of parent nodes in the

graph, then a time-dependent node depends not only on this list of nodes, but also on itself in the previous time step. In this paper, for a time-dependent node, a virtual root node representing itself in the previous step is added. When PN, IDN, and AN are time-dependent, they are denoted as PN-T, IDN-T, and AN-T, respectively. An example of IDN-T is traffic volume from short term count stations (STCS) V_{STCS} . When they are not time-dependent, they are denoted as PN-NT, IDN-NT, and AN-NT, respectively.

Once the classification of nodes in a BN is done, Bayesian inference can be made. An inference consists of query variables and evidence variables. Query variables include PN-T, PN-NT, IDN-T when receiving no data, and AN-T, while evidence variables include IDN-T and IDN-NT when receiving data, and CDN.

4 ILLUSTRATIVE EXAMPLE

Thirteen bridges in a transportation network in Camden county, New Jersey, are used as an illustrative example. The bridges, STCSs, and the CCS are shown in Figure 2. There are 3 STCSs and 1 CCS on the road link. Based on the entrances and exits on the highways, these count stations are used to estimate the AADT of the 13 bridges (i.e., V_{ADT}). Gadda et al. (2007) investigated the errors in estimating AADT using count stations. Based on their results, the temporal uncertainty $\alpha_{t,v,t}$, is assumed to follow a triangular distribution with a mode of 1.0, a lower limit of 0.6, and an upper limit of 1.4, indicating an estimation error around 20%. For spatial uncertainty $\alpha_{t,v,s}$, it is also assumed to follow a triangular distribution with a mode of 1.0. The estimation error depends on the distance between the count sites and the bridge. It is 20% when the distance is smaller than 0.5 mile, otherwise, it is 40%. Please note that when there is no entrance or exit between the bridge and the count station, the error is 10% to reflect the error due to the adjustment from a two-day measurement to a one-year estimate. As mentioned previously, V_{ADT} is used for the calculation of failure consequence. The additional parameters for failure consequence evaluation are as follows (Cheng and Frangopol 2023). $c_{r,car} = 0.11$, $c_{r,trk} = 0.30$, $t_d = 180$, $r_{trk} = 0.04$, $c_{w,car} = 22.82$, $c_{w,trk} = 26.97$, $O_{car} = 1.5$, $O_{trk} = 1.05$, and $V = 50$. L_d of bridges are obtained from national bridge inventory database. The parameters to evaluate failure probabilities are based on the computation results in Cheng and Frangopol (2022). A_{dl} and A_{ll} are estimated to be 0.10 and 0.35, respectively, and are used for all bridges, while B_d varies from 0 to 0.002.

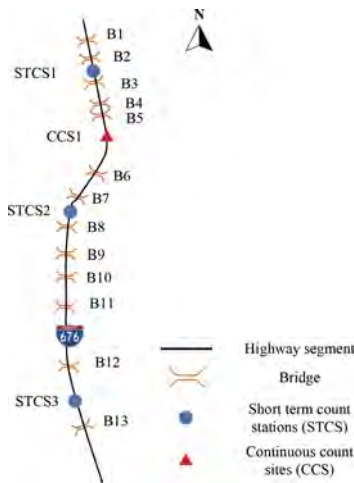

Figure 2. Bridges and traffic count sites in the transportation network in Camden County, New Jersey.

The graphical model of the BN is shown in Figure 3. On the right, the figure shows brief explanations of the nodes. On the left, the figure shows the relationships among the nodes. The graph mainly depicts the estimation of (1) AADT and (2) the reliability indices of the

bridges before the final bridge network risk assessment. For estimation of the AADT, the links between V_{Bi} and the measurements at count stations depend on the topography of the highway segments shown in Figure 2. For estimation of the reliability indices, the node $F_{Trk,W}$ affects the reliability indices of all bridges since the truck weight is only measured at the CCS. Deterioration of each bridge is measured to update its reliability index. As a result, a node $F_{d,Bi}$ is connected to β_{Bi} for each bridge. After the AADT and reliability index are estimated, the risk of each bridge can be determined. Finally, the risk of the network is the summation of the risk across all the individual bridges studied.

With the BN graphical model, next step is to construct marginal distributions and conditional probability tables. Monte Carlo simulation is used to generate the data for all the nodes (Bensi 2010). It should be noted that such simulation is different from those in reliability analysis where random data is generated according to the prescribed usually normal distribution. Instead, here the ranges of certain random variables are determined first; samples are then drawn uniformly from these while calculations are performed for other random variables. Before the learning of conditional probability tables of BN, discretization is carried out for all the nodes. The binning intervals for all traffic volume nodes are the same except that the ranges are different based on the current value. Specifically, the upper and lower limits are 1.8 and 0.8 times of the current AADT, respectively. The ranges of $F_{d,Bi}$, $F_{Trk,W}$, and β_{Bi} are from 0.93 to 1.0 with an interval of 0.01, from 1.0 to 1.8 with an interval of 0.01, and from 2.8 to 4.2 with an interval of 0.1, respectively. Since the risk of bridges can vary drastically, the ranges of the risk for all bridges are first determined using the simulated data for parameter learning. The interval is then set by calculating the 20th, 40th, 50th, 60th, 70th, 80th, 90th, 92th, 94th, 96th, 98th, 99th, 99.5th, and 99.9th percentiles. The reason for the irregular intervals is that higher risk should be paid more attention to.

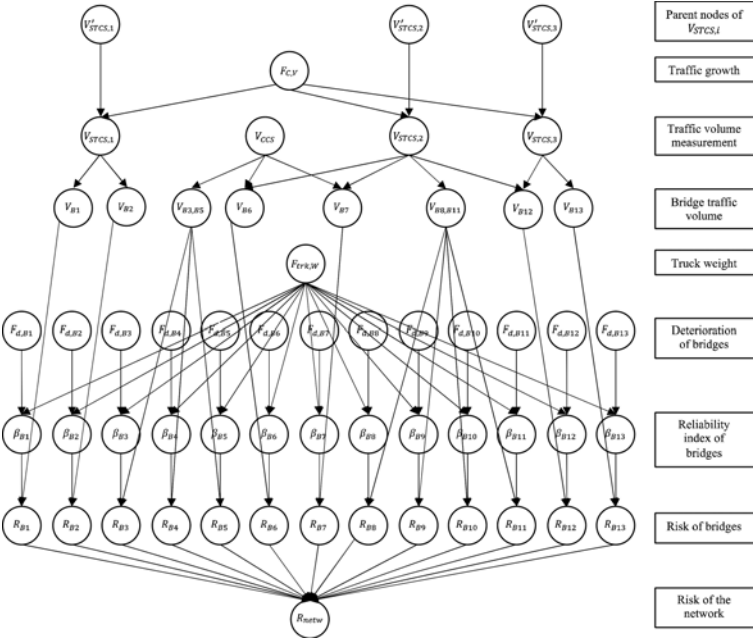

Figure 3. BN for the data-driven LCRA of the bridge network.

A future scenario is hypothesized to illustrate how BN can perform the risk assessment. As mentioned previously, LCRA is complemented by the available data from F_d , $F_{Trk,W}$, $F_{C,V}$, V_{CCS} , and V_{STCS} . Monte Carlo simulation is used to generate the profiles of data for these random variables. The deterioration profile of each bridge $F_d(t)$ is simulated by first randomly sampling B_d using a normal distribution with a mean of 0.001 and a COV of 0.2 and then calculate F_d in each year. $F_{Trk,W}(t)$ is calculated by Equation (5). Annual growth rate in each year $F_{C,V}(t)$ is

simulated using a normal distribution with a mean of 1% and a standard deviation of 1%. With a starting AADT of 62456 (i.e., $V_{CCS}(0) = 62456$), $V_{CCS}(t)$ is calculated by multiplying $V_{CCS}(t-1)$ and $F_{C,V}(t-1)$. $V_{STCS}(t)$ of the three STCSs are generated in the same way as $V_{CCS}(t)$. Specifically, $V_{STCS,1}(0) = 65436$, $V_{STCS,2}(0) = 67874$, and $V_{STCS,3}(0) = 85124$. $F_d(t)$, $F_{trk,W}(t)$, $F_{C,V}(t)$, and $V_{CCS}(t)$ can be observed at each year, while according to NJDOT, STCS measurements are generally conducted in a three-year cycle. Hence, it is assumed that data of $V_{STCS,1}(t)$, $V_{STCS,2}(t)$, and $V_{STCS,3}(t)$ are observed every three years with $V_{STCS,1}(0)$, $V_{STCS,2}(1)$, and $V_{STCS,3}(2)$ being first obtained at the three corresponding STCSs.

BN is implemented using the python package pgmpy (Ankan and Panda 2015). Figure 4 shows the total risk of the whole bridge network. As time elapses, the risk generally increases due to the deterioration of bridges and increases in the traffic volumes. However, we see decreases in total risk in years 15, 16, and 28, when $V_{STCS,3}$ are observed. This indicates that observed data helps adjust downward the overestimation of V_{B12} and V_{B13} . Figure 5 shows the risk of a selected bridge B2. Based on Figure 3, V_{B2} has only one parent node, $V_{STCS,1}$. Since the CDN $F_{c,v}$ and the failure probability are always increasing, the risk estimation can only be reduced when data from $V_{STCS,1}$ indicates a decrease in V_{B2} . In year 21, the risk significantly drops. This matches with the availability of observed $V_{STCS,1}$ in that year. Together, Figures 4 and 5 demonstrate the ability of the BN framework in using available observations to update the risk estimation of the bridge network.

Figure 4. Risk of the bridge network.

Figure 5. Risk of a representative bridge B2.

5 CONCLUSIONS

In this paper, a framework based on Bayesian network (BN) is proposed for data-driven life-cycle risk assessment (LCRA). Based on the function of the nodes in a BN, three types of nodes including performance nodes, data nodes, and analysis nodes are defined. The data nodes are further classified to be intermittent or continuous given the frequency of receiving data. Based on the temporal properties, these nodes can also be grouped as time-dependent or not. With the classification of nodes, the framework specifies the procedure to perform Bayesian inferences.

The framework is then applied to LCRA of bridge networks with the inclusion of data from three sources. Particularly, the traffics on the bridges are updated by data from traffic count stations and used to update the failure losses of bridges, while reliability of the bridges is updated by truck weight data fused with bridge monitoring data. A bridge network in Camden County, New Jersey, is used to demonstrate the ability of the framework in supporting life-cycle risk assessment and management of infrastructure systems.

Risk-based life-cycle loss assessment using statistical moments

Y. Zhang

Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

Y. Li

Department of Construction and Quality Management, Hong Kong Metropolitan University, Hong Kong, China

ABSTRACT: Evaluating the economic loss of civil infrastructure subjected to hazards can be significant for life-cycle risk assessment. In the past, the expected value of loss has been widely investigated during risk assessment and employed as a standard decision-making criterion. However, the inherent uncertainties may be neglected when focusing on the mean value. Hence, other statistical moments, especially the higher-order moments, and the probability density function of the long-term loss should be considered. In this paper, a probabilistic analysis framework is proposed for risk quantification to compute the probability density function of the long-term loss using statistical moments. By using the first-four statistical moments of the long-term loss, the maximum entropy method can construct the probability density function of the long-term loss effectively and accurately. The proposed method can enhance the computation efficiency during risk assessment and benefit the decision-making process.

1 INTRODUCTION

Over the past few decades, there were significant financial and social losses caused by various natural hazards, which have gained increasing awareness of the public to risk management of civil infrastructures. Risk assessment and life cycle performance of infrastructures are becoming key concerns of researchers to conduct risk management. Recently, the long-term loss of civil infrastructures subjected to hazards such as earthquakes, hurricanes and flooding have received special attention (Cheng & Frangopol, 2022, Giouvanidis & Dong, 2020, Zhu et al., 2021). The long-term loss is also known as risk during life-cycle risk assessment, and it refers to the cumulative financial loss of the civil infrastructures resulting from the damage under hazards over the service life. Previously, the expected long-term loss has been regarded as a standard decision criterion. However, more recent studies have stated that the expectation of long-term loss is not informative and other statistical indicators should be involved (Cheng & Frangopol, 2022, Goda & Hong, 2006, Goda & Hong, 2008). Then several studies started to investigate the statistical parameters of the long-term loss such as the standard deviation and higher-order moments. For instance, an analytical renewal model was proposed to assess the mean and standard deviation of the life-cycle cost (Pandey & Van Der Weide, 2017). Li et al. (2020) stated that the importance of evaluating the higher-order moments of the long-term loss under stationary and non-stationary hazard models. The higher-order moments of long-term loss under non-stationary hazards such as the skewness and kurtosis are of interest. Uncertainties arising from the stochastic occurrence and the intensity of hazards are taken into account.

In addition to statistical parameters, the probability distribution of the long-term loss could also be significant information for decision-making process (Pandey & van der Weide, 2018, Wang & Zhang, 2018). Although Monte Carlo simulation (MCS) is the most direct way to assess the probability distribution of the long-term loss, it could be time-consuming when considering different hazard conditions and scenarios. To address this research gap, a probabilistic approach incorporating the maximum entropy method and the statistical moments of the long-term loss is developed for capturing the probability density function (PDF) of long-term loss.

Maximum entropy method (MEM) refers to the moment method for deriving the unknown PDF of a random variable with its statistical moments (Rahman & Xu, 2004, Xu & Rahman, 2004, Zhao & Ono, 2001). Various distribution models were developed to fit the unknown PDF such as the Pearson system and Johnson system (Johnson et al., 1995, Xu et al., 2020). However, the MEM could be seen as the most unbiased one among different distribution models. The MEM originates from the maximum entropy principle (Jaynes, 1957), which can select the most possible distribution towards the underlying PDF of interest. In the field of structural reliability analysis, MEM has been widely utilized to derive the unknown PDF of structural responses (Li & Zhang, 2011, Xu & Kong, 2019). Overall, MEM could be a versatile tool for the derivation of the unknown PDF of a random variable. The computational effort of using MEM can be remarkably reduced compared with that of MCS. In this study, MEM with the first-four analytical statistical moments, i.e., mean, standard deviation, skewness and kurtosis, are employed for the derivation of the PDF and CDF of long-term loss. The following section introduces a stochastic hazard model to provide the stochastic model for risk assessment. Section 3 summarizes the theory of MEM and the analytical first-four statistical moments of long-term loss is also included. Section 4 presents a case study to validate the efficiency and accuracy of the proposed method. Finally, conclusions are stated in Section 5.

2 LIFE-CYCLE RISK MODEL

2.1 Stochastic hazard model

The risk assessment within the life-cycle is dependent on the stochastic hazard model. The homogeneous Poisson process has been widely utilized to model probabilistic uncertainties of hazards (e.g., earthquakes and typhoons) in previous studies. In this paper, the typhoon hazard and the homogeneous Poisson model is taken as an example for illustrative purposes. According to the Poisson process, the arriving time of a typhoon event is a random variable. If the life-cycle of the civil infrastructure is $(0, t_{\max}]$, the arriving times within the period can be denoted as a series of $\{T_1, T_2, \dots, T_k\}$, i.e., T_k is the arriving time of the k th typhoon event during the life cycle. The inter-arriving time between the two adjacent events is also a random variable and can be noted as S_k . The relationship between the arriving time and the inter-arriving time can be described as $T_k = S_1 + S_2 + \dots + S_k$. The homogeneous Poisson process specifies that the inter-arriving time follows exponential distribution

$$f_s(s) = \lambda \exp(-\lambda s) \quad (1)$$

where λ is the occurrence rate associated with the hazard.

The total number of occurrences can be given as $N(t_{\max})$ and let $N(t_{\max}) = n$. It follows a Poisson distribution

$$P[N(t_{\max}) = n] = \frac{(\lambda t_{\max})^n \exp(-\lambda t_{\max})}{n!}, \quad n = 0, 1, 2, \dots \quad (2)$$

2.2 Risk assessment within the life cycle

Given the stochastic hazard model, the risk-based economic loss of each typhoon event can be noted as L , which is a series of random variables $\{L_1, L_2, \dots, L_k\}$. For instance, the loss associated with the first typhoon event is L_1 . Herein, the investigated loss is restricted to the economic cost of civil infrastructure system due to repair or restoration. Other costs such as social impact are not investigated in this context. By quantifying the losses of all the typhoon events, the accumulated loss within the life cycle can be given as

$$AL(t_{\max}) = \sum_{k=1}^{N(t_{\max})} L_k e^{-rT_k} \quad (3)$$

where $AL(t_{\max})$ is the accumulated loss within the life cycle, r is the monetary discount rate, L_k and T_k are the loss and the arriving time associated with the k th typhoon event.

3 PROBABILISTIC LOSS USING STATISTICAL MOMENTS

3.1 Statistical moments

To compute the probabilistic distribution of the accumulated loss, the four statistical moments should be determined firstly. The statistical moments of the accumulated loss are the key inputs for the proposed probabilistic loss assessment framework. Herein, the first-four moments (i.e., mean, standard deviation, skewness and kurtosis) are calculated based on the moment generating function (MGF). The MGF of X about ϖ can be defined as

$$M_X(\varpi) = E[e^{\varpi X}] \quad (4)$$

The theory of the MGF gives that the m th order moment of X can be calculated by taking the m th order derivatives of the MGF. Based on this theorem, the MGF of the accumulated loss within the life cycle should be calculated and can be given as

$$M_{AL(t_{\max})}(\varpi) = \exp\left[\lambda \int_0^{t_{\max}} [M_L(\varpi e^{-rx}) - 1] dx\right] \quad (5)$$

Subsequently, the first four statistical moments of the accumulated loss within life cycle can be computed analytically by taking the derivatives at zero. Accordingly, the first four analytical statistical moments can be calculated (Li et al. 2020).

3.2 Maximum entropy method

Once the first-four analytical statistical moments of long-term loss are obtained, the maximum entropy method can be employed to derive the probabilistic distribution of the long-term loss. The general idea of the MEM is presented as follows.

Given a random variable Y , the information entropy of Y can be expressed as

$$H(f_Y(y)) = - \int_y f_Y(y) \log(f_Y(y)) dy \quad (6)$$

On the basis of the maximum entropy principle, the underlying PDF of Y can be found by the following constrained optimization problem

$$\begin{cases} \text{Find:} & f_Y(y) \\ \text{Maximize:} & H(f_Y(y)) = - \int_Y f_Y(y) \log[f_Y(y)] dy \\ \text{s.t.:} & E[Y^i] = \int_Y Y^i f_Y(y) dy, \quad i = 1, 2, \dots, k \end{cases} \quad (7)$$

where $E[Y^i]$ is the i -th raw moment of Y . Hence, the MEM uses a series of statistical moments of Y as constrains to find an underlying PDF with the maximum information entropy, which can be seen as an unbiased estimation of the unknown PDF. Conventionally, the number of the commonly used statistical moments is adopted as four, which refers to the first-four statistical moments.

To solve the optimization problem in Equation (7), the Lagrangian function is introduced first

$$\begin{aligned} L[\varphi, f_Y(y)] = & - \int_Y f_Y(y) \log[f_Y(y)] dy - (\varphi_0 - 1) \left[\int_Y f_Y(y) dy - 1 \right] - \\ & \sum_{i=1}^k \varphi_i \left[\int_Y y^i f_Y(y) dy - \mathbb{E}[Y^i] \right] \end{aligned} \quad (8)$$

where $\varphi = [\varphi_0, \varphi_1, \dots, \varphi_k]^T$ is the vector of the Lagrangian multipliers. Given the following condition

$$\frac{\partial L(\varphi, f_Y(y))}{\partial f_Y(y)} = 0 \quad (9)$$

The underlying PDF of random variable Y is expressed as

$$\hat{f}_Y(y) = \exp\left(-\varphi_0 - \sum_{i=1}^k \varphi_i y^i\right) \quad (10)$$

where φ_0 is calculated as follows by using the normalization axiom in probability theory

$$\varphi_0 = \log \left[\int_Y \exp\left(-\sum_{i=1}^k \varphi_i y^i\right) dy \right] \quad (11)$$

However, the constrained optimization problem shown in Equation (7) is difficult to solve. To address this issue, K-L divergence can measure the discrepancy between the true PDF and the estimated one

$$K[f_Y(y), \hat{f}_Y(y)] = \int_Y f_Y(y) \log \left[\frac{f_Y(y)}{\hat{f}_Y(y)} \right] dy = \int_Y f_Y(y) \log[f_Y(y)] dy - \int_Y f_Y(y) \log[\hat{f}_Y(y)] dy \quad (12)$$

By substituting Equation (10) into Equation (12), we can obtain

$$K[f_Y(y), \hat{f}_Y(y)] = -H(f_Y(y)) + \varphi_0 + \sum_{i=1}^k \varphi_i \mathbb{E}[Y^i] \quad (13)$$

Minimizing the K-L divergence can be an alternative way to find the underlying true PDF. Likewise, the objective function can be revised as

$$\Gamma(\varphi) = \varphi_0 + \sum_{i=1}^k \varphi_i E[Y^i] = \log \left[\int_Y \exp\left(-\sum_{i=1}^k \varphi_i y^i\right) dy \right] + \sum_{i=1}^k \varphi_i E[Y^i] \quad (14)$$

Then, the hyper parameters φ can be determined by the following un-constrained optimization problem

$$\begin{cases} \text{Find:} & \varphi = [\varphi_0, \varphi_1, \dots, \varphi_k]^T \\ \text{Minimize:} & \Gamma(\varphi) = \log \left[\int_Y \exp\left(-\sum_{i=1}^k \varphi_i y^i\right) dy \right] + \sum_{i=1}^k \varphi_i E[Y^i] \end{cases} \quad (15)$$

3.3 Probabilistic distribution of life-cycle loss

Before using the maximum entropy method for deriving the probabilistic distribution of the long-term loss, a standardized transformation is employed to transform the long-term loss (i.e., AL) into a standard random variable Y

$$Y = \frac{AL - u_1}{u_2} \quad (16)$$

By solving the un-constrained optimization problem shown in Equation (15), the underlying probabilistic distribution of the long-term loss can be estimated as

$$\hat{f}_{AL}(l_t) = \frac{1}{u_2} \hat{f}_Y(y) = \frac{1}{u_2} \exp\left(-\varphi_0 - \sum_{i=1}^k \varphi_i \left(\frac{l_t - u_1}{u_2}\right)^i\right) \quad (17)$$

where l_t is the long-term loss of interest.

4 ILLUSTRATIVE EXAMPLE

To validate the accuracy and efficiency of the proposed method. A coastal bridge subjected to the hurricane hazard is investigated. The bridge is a multi-span simply girder bridge, which is vulnerable to deck unseating failure encountering hurricanes. The occurrence of hurricanes is modelled by the homogeneous Poisson process over the service life of the bridge. The relevant parameters that dominate the long-term loss of the bridge are the occurrence rate λ , the parameter of the loss severity L , the monetary discount rate r and the service life of the bridge t_{\max} .

Note that the occurrence rate λ is determined as 0.245 by the annual number of hurricanes in a specific region (Li et al., 2020). The loss severity L is calculated by the product of the failure probability and the corresponding repair loss caused by the failure events (i.e., unseating failure of the bridge). In this paper, the loss severity is assumed as exponential distribution and the expected loss severity is 1.283 million USD (Li et al., 2020). The service life is 75 years of this bridge.

The first-four statistical moments can be calculated as 12.2099×10^6 USD, 4.3773×10^6 USD, 0.61 and 3.54 on the moment generating function given in Equation (5). Then, the maximum entropy method can be employed to derive the long-term loss of the coastal bridge under hurricanes by using these statistical moments as constraints. The Lagrangian multipliers of the MEM are determined as (0.3459, 0.5015, -0.1287, 0.0164). Figures 1 and 2 show the PDF and CDF in logarithm scale of the long-term loss by 10^6 MCS and the proposed method, respectively. It can be seen that the PDF and CDF by the proposed method are in good accordance with those by MCS, which reveals that the proposed method can be an alternative way to fit the unknown probabilistic distribution of loss of civil infrastructures instead of MCS. Thereby, the proposed method can significantly improve the efficiency of deriving the probabilistic distribution of the long-term loss under different scenarios.

Figure 1. PDF of the long-term loss (75 years, $r = 2\%$).

Figure 2. CDF of the long-term loss (75 years, $r = 2\%$).

5 CONCLUSIONS

In this paper, a probabilistic analysis method is developed for deriving the probability density distribution of the long-term loss of civil infrastructures. First, the analytical statistical moments,

including mean, standard deviation, skewness and kurtosis of long-term loss are calculated by using the moment generating function based on the stochastic Poisson process. Then, the maximum entropy method is employed to find an estimation of the unknown distribution of the long-term loss by fitting its first-four statistical moments. The proposed method can be an alternative way to derive the distribution of the long-term loss and achieve comparable accuracy compared with the conventional sampling technique, i.e., MCS. The proposed method will benefit the process of deriving distributions of long-term loss given different scenarios as well as the process of decision making.

ABSTRACT: In this paper, non-linear finite element models were developed for the web crippling of cold-formed lean duplex stainless steel (CFLDSS) square and rectangular hollow sections under the concentrated interior bearing loads at elevated temperatures (up to 950 °C). The interior bearing loads cover the loading conditions of Interior-One-Flange (IOF) and Interior-Two-Flange (ITF). The web crippling design rules in the current international specifications were examined. It was found that the predictions by the North American Specification were generally unconservative and not reliable, while the European Code provided reliable but very conservative predictions. New design method, the Direct Strength Method, was proposed for the web crippling strength of CFLDSS tubular sections at elevated temperatures under the loading conditions of IOF and ITF. The assessments indicate that the new method provides better strength predictions than the codified design rules. The new predictions are overall conservative and reliable.

1 GENERAL INSTRUCTIONS

The excellent properties of stainless steel, such as corrosion resistance with low life cycle costs, and fire resistance, make it suitable for a wide range of applications in engineering structures. The alloying elements of stainless steel have been continually developed for the goal of better mechanical properties, and higher corrosion resistance in high temperature application (Ronald et al. 2007). The relatively new stainless steel, lean duplex stainless steel is a high strength material with nominal 0.2% proof stress of 450 MPa. It offers higher strength than the traditional stainless steel, but has superior economic advantages due to its lower nickel content (around 1.5%), as the cost mainly depends on the nickel price. Therefore, it is becoming an attractive choice as a construction material in civil and structural engineering industry. In the last decade, great progress has been made in understanding the structural performance and design criteria of lean duplex stainless steel, including fundamental material properties (Saliba & Gardner, 2013), and structural members, such as beams (Huang & Young, 2014), columns (Zhao et al. 2015), and the bolted connections (Cai & Young 2014a).

However, it should be noted that these investigations were conducted at room (ambient) temperature condition instead of at elevated temperatures. It has been recognized that stainless steel has better strength and stiffness retention than carbon steel at elevated temperatures. This superior performance has been utilized in the high temperature industry for many years (Gardner et al. 2010). In the last few years, attention has been received to investigate the structural performance of stainless steel structures at elevated temperatures, for examples of tubular joints (Feng & Young, 2012), and bolted connections (Cai & Young, 2014b, 2018).

However, limited investigations have been conducted on stainless steel undergoing web crippling at elevated temperatures.

It is proposed herein to investigate the behavior of cold-formed lean duplex stainless steel (CFLDSS) tubular sections undergoing web crippling under interior loading conditions at elevated temperatures. The sections are under the interior loading conditions of Interior-One-Flange (IOF) and Interior-Two-Flange (ITF) at the nominal elevated temperatures ranged from 22 to 950 °C. The web crippling strength design rules at room temperature in the current codified design rules (EC 3-1.3, 2006, NAS, 2016) are examined for the possibility of application at elevated temperatures. The reduced material properties due to elevated temperatures were used in calculating the strength predictions. Finally, a new design method, the Direct Design Method (DSM), is proposed, which provide better strength predictions than the current codified design rules.

2 SUMMARY OF EXPERIMENTAL INVESTIGATION

The tests carried out by Cai and Young (2019b) for cold-formed lean duplex stainless steel (CFLDSS) tubular sections subjected to web crippling failure under concentrated interior bearing loads (IOF and ITF) were under room (ambient) temperature condition. The CFLDSS had square and rectangular hollow sections ($H \times B \times t$) with grades of EN 1.4162 (AISI S32101) and EN 1.4062 (AISI S32202), where H is the over height of the section web; B overall cross-sectional width, and t thickness of the section. The tensile coupon tests were carried out to obtain the material properties of the CFLDSS at room temperature condition, including the Young's modulus (E_r), 0.2% proof stress ($f_{0.2,r}$) and ultimate strength ($f_{u,r}$). Detailed descriptions of the coupon tests and web crippling tests are given in Cai and Young (2019a, b).

3 FINITE ELEMENT ANALYSIS

3.1 *Development of Finite element models*

The finite element (FE) models developed by the ABAQUS program of version 6.20 (2019) were used to simulate the web crippling tests of CFLDSS specimens. Four main components in the tests were modelled, namely, the section of CFLDSS, the steel bearing plates, the interactions between the steel bearing plates and specimen, and the boundary conditions.

The shell element type S4R, which is a four-node doubly curved element with reduced integration and hourglass control was selected to simulate the CFLDSS tubular sections. The CFLDSS members were modelled according to the centerline dimensions of the cross-sections. The solid element type C3D8R was chosen to simulate the steel bearing plates. The steel bearing plates were defined as rigid body as the steel bearing plates in the test program (Cai & Young 2019b) were fabricated by high strength steel with thickness of 50 mm, which are much thicker than the CFLDSS specimens. Contact pairs were used to model the interfaces between the CFLDSS sections and the bearing plates, with the bearing plates defined as master surface while the CFLDSS sections as slave surface. A coefficient of 0.4 was adopted to account for the friction penalty contact in the tangential direction. The geometrical nonlinearity of the FE models is considered by the NLGEOM command in ABAQUS (2019). Due to the symmetry of the geometries and failure modes of the test specimens, as well as the test setup under the IOF and ITF loading conditions (Cai & Young 2019b), half of the CFLDSS specimens and steel bearing plates were modelled by assigning appropriate symmetric boundary conditions.

The engineering stress-strain curves obtained from the tensile coupon tests were converted to true stress and logarithmic plastic strain curves. The true stress and logarithmic plastic strain curve was then imitated by means of a piecewise linear stress-strain model, especially, over the strain-hardening region. The material properties were assigned to the webs and flanges of the sections. Displacement control loading method and the general static analysis method were used in FE analysis. Detail of the development of FE models are described in Cai et al. (2021).

3.2 Validation of FE models

A total of 34 CFLDSS tubular sections tested by Cai and Young (2019b) at room temperature condition were analyzed. The comparisons of the web crippling strengths (P_t) per web obtained from the test program with those obtained from the finite element results ($P_{FE,r}$) are shown in Table 1. It is shown that a good agreement was generally achieved between test and FE strengths. The mean values of the $P_t/P_{FE,r}$ for the IOF and ITF specimens are 1.10 and 1.08, respectively; with the same corresponding coefficient of variation (COV) of 0.063. The test strengths are generally slightly higher than the predictions from the FE analysis. This could be due to the flat tensile material properties instead of the compressive material properties were used in the webs. The observed failure modes from the tests are well predicted by the FE analysis for the two different loading conditions are illustrated in Figure 1. In summary, the comparisons indicate that both the failure modes and the ultimate web crippling strengths from the test program could be replicated by the results of the FE analysis. Detail of the strength comparison between tests and FE analysis are presented in Cai et al. (2021).

Table 1. Overall comparison of test strengths with finite element predictions (Cai et al. 2021).

Loading condition	Number of tests		$P_t/P_{FE,r}$
IOF	16	Mean	1.10
		COV	0.063
ITF	18	Mean	1.08
		COV	0.063

Figure 1. Comparison of tests and FE models for IOF (*upleft*) and ITF (*upright*) (Cai, et al. 2021).

Table 2. Material properties at elevated temperatures (Cai & Young, 2014b).

Material properties	Nominal Temperature (°C)						
	22 [#]	200	350	500	650	800	950
E_T (GPa)	200	190	183	169	160	60.4	13.5
$f_{0.2,T}$ (MPa)	724	564	508	448	304	119	18.0
$f_{u,T}$ (MPa)	862	710	696	627	358	138	25.0

Note: “#” represents room (ambient) temperature.

4 PARAMETRIC STUDIES AND ANALYSIS

The validated FE models were used to generate numerical data for the CFLDSS tubular sections under the IOF and ITF loading conditions at elevated temperatures. The numerical investigation in this study generally simulates the test procedure of steady state tests, where the specimens is heated to a pre-determined temperature level without any preloading, the specimen will then be loaded until failure while the specimen temperature is maintained. The material properties of CFLDSS at elevated temperature conditions were used. The stress-strain curves of the tensile flat coupons in the longitudinal direction of CFLDSS (grade EN 1.4162) rectangular section at elevated temperatures were used. These stress-strain curves were measured at elevated temperature

using steady state test method by Cai and Young (2014b), including Young's modulus (E_T), 0.2% proof stress ($f_{0.2\%,T}$) and ultimate strength ($f_{u,T}$) at elevated temperatures are presented in Table 2.

A total of 140 specimens at elevated temperatures, i.e. 22 (room temperature), 200, 350, 500, 600, 800 and 950 °C were analysed in the parametric study. The design of the CFLDSS tubular sections was done by considering the key parameters in the web crippling design rules (EC 3-1.3, 2006, NAS, 2016) for steel tubular sections. These tubular sections include five rectangular and five square hollow sections ($H \times B \times t$). The variation of the key parameters in these sections cover a wide range, including $h/t = 21.0 \sim 145.0$ and $N/h = 0.36 \sim 1.24$, where h is the flat web height. The specimens were generally identified by three segments in the labelling, as shown in Table 3. For example of specimen IOF250×250×2.0N250, where the first segment "IOF" indicates the loading condition of "Interior-One-Flange"; the following segment of "250×250×3.0" means the section dimension of " $H \times B \times t$ " in the unit of mm; and the last segment "N250" indicates that the loading plate with bearing length (N) of $N = 60$ mm was used in the test specimen.

Table 3. Web crippling strength (kN) of specimens per web in parametric study (Cai et al. 2021).

ITF300×200×12.0N200	1254.1	1025.6	969.7	845.1	581.3	225.3	40.4

Note: "#" represents room (ambient) temperature.

The ultimate strengths ($P_{FE,T}$) of the CFLDSS specimens per web at elevated temperatures are shown in Table 3. The reduction factors of web crippling strengths for CFLDSS specimens were obtained by normalizing the strengths at elevated temperatures ($P_{FE,T}$) with that at room temperature ($P_{FE,r}$) for the same specimen at elevated temperatures. As shown in Figure 2, these reduction factors were compared with those of material properties of CFLDSS at elevated temperatures, i.e. the reduction factors of E_T/E_r and $f_{0.2,T}/f_{0.2,r}$. The reduction factors of E_T/E_r overestimated the residual strengths of the specimens, while those of $f_{0.2,T}/f_{0.2,r}$ underestimated the residual strengths of the specimens in the temperatures ranged from 200 to 950 °C. Nevertheless, both reduction factors of E_T/E_r and $f_{0.2,T}/f_{0.2,r}$ show similar reduction trends to those of $P_{FE,T}/P_{FE,r}$.

5 CURRENT DESIGN RULES AND ASSESSMENT

5.1 General

The current codified web crippling design rules of stainless steel members are mainly based on those of carbon steel members. The differences of the design rules in current design specifications are discussed in Cai and Young (2019a). In this study, the design rules in North

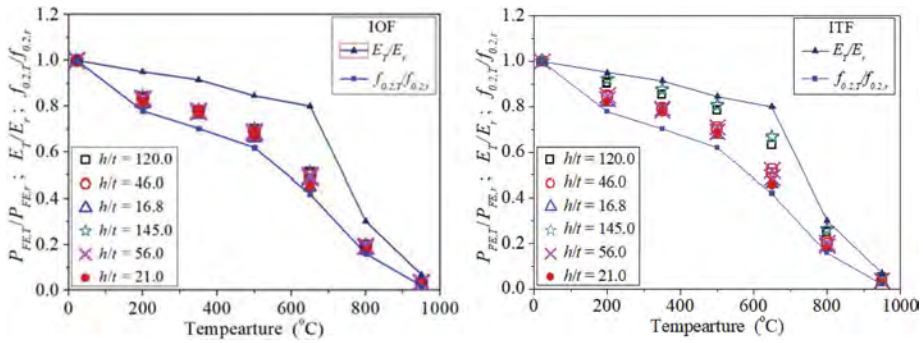

Figure 2. Comparison of reduction factors for IOF (*upleft*) and ITF (*upright*) loading conditions (Cai, et al. 2021).

American Specification (NAS, 2016) and European code (EC 3-1.3, 2006) were used. It should be noted that these design rules are only applicable for room temperature condition, but not for elevated temperature conditions. When calculating the nominal strengths, the reduced material properties (Table 2) of CFLDSS due to elevated temperatures were used. Reliability analysis was used to assess the web crippling design rules. The analysis was performed following the Commentary in the ASCE Specification (2002). The reliability index (β) of 2.5 was set in this study. The β was calculated by using the corresponding resistance factor (ϕ) specified in the design codes. Details of the analysis procedure are presented in Cai et al. (2021).

5.2 Assessment of current predictions

The ultimate strengths ($P_{FE,T}$) per web at elevated temperatures were compared with those predicted by the aforementioned design specifications. Table 4 summarizes the comparisons, where the comparisons were also presented at each temperature level.

Table 4. Comparison of test strengths with predicted strengths (Cai et al. 2021).

Temperature		IOF			ITF		
		P_{FE}/P_{NAS}	P_{FE}/P_{EC}	$P_{FE}/P_{DSM,T}$	P_{FE}/P_{NAS}	P_{FE}/P_{EC}	$P_{FE}/P_{DSM,T}$
22 °C [#]	Mean	0.80	3.27	0.95	0.63	6.30	0.90
	COV	0.109	0.152	0.163	0.095	0.165	0.116

	COV	0.155	0.193	0.041	0.117	0.150	0.099
950 °C	Mean	1.11	2.77	1.60	0.99	5.97	1.75
	COV	0.169	0.207	0.200	0.153	0.165	0.266
Overall	Mean	0.91	3.00	1.27	0.77	6.09	1.29
	COV	0.169	0.179	0.228	0.176	0.148	0.263
	ϕ	0.90	0.91	0.80	0.80	0.91	0.80
	β	1.79	5.56	2.92	1.59	8.43	2.75

Note: “[#]” represents room (ambient) temperature.

For the IOF loading condition at each temperature, the predictions by the NAS (2016) are unconservative except for the temperature level of 950 °C due to the mean values smaller than

1.0; while the predictions by EC 3-1.3 (2006) are conservative. The conservative predictions are mainly due to the web slenderness ratio (h/t) and the actual bearing lengths (N) are not considered in the design provisions of EC 3-1.3 (2006), as discussed by Cai and Young (2019a). Note that the CFLDSS specimen sections have different web slenderness (h/t) and were loaded by steel plates with different bearing lengths (N). Similarly, for the CFLDSS specimens subjected to ITF loading condition, the predictions by the NAS (2016) are unconservative while those by EC 3-1.3 (2006) are conservative at each temperature levels.

The overall mean value of FE strength-to-predicted strength with the corresponding COV are also illustrated in Table 4. For IOF loading condition, the overall mean value for the predictions by NAS (2016) is 0.91, with the corresponding COV of 0.169. The predictions by NAS (2016) are not reliable due to the values of $\beta = 1.79$ that is smaller than 2.5. The predictions by EC3-1.3 (2006) are very conservative but reliable. Similarly, for ITF loading condition, the mean value for the predictions by NAS (2016) is 0.77 and the predictions are not reliable due to the $\beta < 2.5$. However, the overall predictions by EC3-1.3 (2006) are reliable but very conservative.

6 PROPOSED DIRECT STRENGTH METHOD AND ASSESSMENT

6.1 General

The predictions by the NAS (2016) were generally unconservative and not reliable while those by EC3-1.3 (2006) were very conservative and reliable. Hence, improvements were made for the web crippling design of CFLDSS tubular sections at elevated temperatures. The Direct Strength Method (DSM) (2008) is an alternative way to determine the strength of cold-formed steel members. The DSM has been developed and documented in the design specifications, such as the NAS (2016) for the design of steel beams and columns. It should be noted that the current DSM in design specifications does not provide design rules for web crippling design of cold-formed steel members. In this study, efforts on the DSM modifications are made for its application to web crippling design of CFLDSS tubular sections at elevated temperatures,

6.2 Modified DSM

The presented format of DSM in Cai and Young (2021) for web crippling design of CFLDSS stainless steel sections at room temperature is illustrated in Equation (1), where different sets of coefficient for a , b , n , γ and λ_k in Equation (1) were proposed depending on the loading conditions. The two different types of web crippling failure for cold-formed stainless steel square and rectangular hollow sections are, web buckling, where the web crippling capacity mainly depends on the stiffness of the material, and yielding in the web, where the web crippling capacity mainly depends on the yield strength of the material (Zhou & Young 2013). As presented in Figure 2, the reduction factors of web crippling strength, $f_{0.2,T}/f_{0.2,r}$ and E_T/E_r of CFLDSS sections depicted similar reduction trends at elevated temperature. The factor χ as shown in Equation (2) was proposed to account for the effects of reduction factors of $f_{0.2,T}/f_{0.2,r}$ and E_T/E_r at elevated temperatures. To be consistent with the design at room temperature condition, the $f_{0.2,T}$ and E_T at elevated temperatures were considered in this study. The CFLDSS tubular sections subjected to web crippling ($P_{DSM,T}$) at elevated temperatures could then be calculated by χP_{DSM} , as shown in Equation (3).

$$P_{DSM} = \begin{cases} \gamma P_{y,T} & \lambda \leq \lambda_k \\ a \left[1 - b \left(\frac{P_{cr,T}}{P_{y,T}} \right)^n \right] \left(\frac{P_{cr,T}}{P_{y,T}} \right)^n P_{y,T} & \lambda > \lambda_k \end{cases} \quad (1)$$

$$\chi = \frac{1}{0.0036} \frac{f_{0.2,T}}{E_T} \quad (2)$$

$$P_{DSM,T} = \chi P_{DSM} \quad (3)$$

where $\lambda = (P_{y,T}/P_{cr,T})^{0.5}$ is the web crippling slenderness ratio. The $P_{cr,T}$ and $P_{y,T}$ are respectively the nominal bearing strengths per web for buckling and yielding at elevated temperatures. The

calculations of $P_{cr,T}$ and $P_{y,T}$ could be done manually by referring Clause 5.13 of the AS 4100 (1998), as shown in Equations (4)-(7). It should be noted that these equations are provided for the design at room temperature condition (AS 4100, 1998), but not for elevated temperatures. Therefore, the $f_{0.2,r}$ was replaced by $f_{0.2,T}$ at elevated temperatures in calculations.

$$P_{cr} = \alpha_c t N_m f_{0.2,T} \quad (4)$$

where α_c is the slenderness reduction factor as specified in Clause 6.3.3 of the AS 4100 (1998), N_m is the mechanism length for the loading conditions of IOF an ITF, which could be determined by the following Equation (5):

$$N_m = N + 5R + h \quad (5)$$

where R is the outer corner radius.

$$P_y = \alpha_p t N_m f_{0.2,T} \quad (6)$$

$$\alpha_p = \frac{0.5}{k_s} \left[1 + \left(1 - \alpha_{pm}^2 \right) \left(1 + \frac{k_s}{k_v} - \left(1 - \alpha_{pm}^2 \right) \frac{0.25}{k_v^2} \right) \right] \quad (7)$$

where $k_s = 2R/t - 1$, $\alpha_{pm} = 1/k_s + 0.5/k_v$ and $k_v = h/t$.

Table 5. Coefficients for the design by DSM (Cai et al. 2021).

Loading condition	a	b	n	λ_k	γ	ϕ
IOF & ITF	1.00	0.18	0.45	0.60	1.13	0.80

In this study, different values of a , b , n , λ_k , γ and ϕ were proposed, as shown in Table 5. These are applicable for CFLDSS square and rectangular hollow sections having stiffened or partially stiffened flanges with the limits for $10 \leq h/t \leq 145$, $r/t \leq 2.0$, $N/t \leq 150$ and $N/h \leq 1.5$.

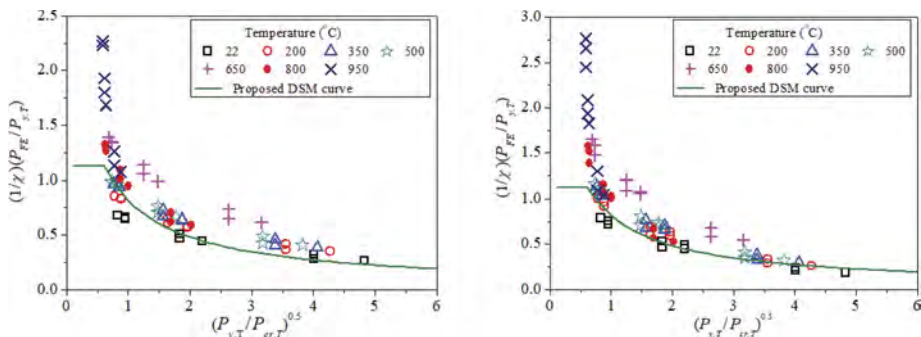

Figure 3. Comparison of FE results with proposed DSM curve for IOF (upleft) and ITF (upright) (Cai, et al. 2021).

6.3 Assessment of proposed DSM predictions

The strength predictions by the proposed DSM ($P_{DSM,T}$) were compared with those FE results, as shown in Table 4. The proposed DSM ($P_{DSM,T}$) for the web crippling strengths of CFLDSS tubular sections at elevated temperature generally provided conservative predictions at each temperature level, except at 22 °C. For each loading condition, the overall conservative predictions are mainly due to the very conservative predictions for the strengths at the temperature levels of 650 and 950 °C as reflected in the mean values of $P_{FE}/P_{DSM,T}$. The predictions by using the proposed DSM are reliable for the two loading conditions at elevated temperatures as the values of $\beta > 2.5$. The comparisons of the $P_{FE}/P_{DSM,T}$ at elevated temperatures together with the DSM curves (using Equations (1-3)) for the two loading conditions are shown in Figure 3. In each figure, the ratio of $(1/\chi)(P_{FE}/P_{y,T})$ were plotted against the web crippling slenderness ratio of $(P_{y,T}/P_{cr,T})^{0.5}$.

7 CONCLUSIONS

Non-linear finite element models were developed for the web crippling of cold-formed lean duplex stainless steel (CFLDSS) square and rectangular hollow sections under the loading conditions of Interior-One-Flange (IOF) and Interior-Two-Flange (ITF). After successful verification, an extensive parametric study of 140 CFLDSS tubular sections at elevated temperatures up to 950 °C was performed. The assessments showed the predictions by the NAS (2006) were generally unconservative and not reliable while those by EC3-1.3 (2006) were very conservative and reliable. The Direct Strength Method (DSM) was proposed. It is shown that the predictions by using the DSM are generally conservative and reliable. Therefore, the DSM is applicable for web crippling (loading conditions of IOF and ITF) design of CFLDSS tubular hollow sections at elevated temperatures with limits of $21 \leq h/t \leq 145$, $r_f/t \leq 2.0$, $N/t \leq 125$ and $N/h \leq 1.25$. The flanges of the CFLDSS tubular sections are stiffened or partially stiffened that unfastened to the supports.

ABSTRACT: The orthotropic steel deck (OSD) shows notable superiorities in bridge applications but is highly prone to fatigue cracking due to the use of massive welded connections, especially in the rib-to-deck (RD) connection. This study presents a risk-based approach to planning different management strategies for OSDs under fatigue, which is supported by the integrated fatigue assessment coupling test data, in-situ measurements and probabilistic simulations. RD connections are focused on since they account for the longest welding length, i.e., about 50 times the total bridge length. The probability-stress-life (P-S-N) curve is first derived for RD connections from fatigue test data. Meanwhile, a condition-based probabilistic model of vehicle loads is constructed using the site-measured data. The load model is then implemented with numerical simulations in a sampling-based manner to derive fatigue stress spectra of different fatigue-critical RD connections. Based on the derived P-S-N curve and stress spectra, the fatigue deterioration of RD connections is assessed in a probabilistic form. Moreover, the failure assessment diagram (FAD) is derived for OSDs considering the serviceability, in accordance with the estimation of associated consequences. Based on the probabilistic estimation, the risk assessment is carried out for the OSD by combining the probability of failure and associated consequences.

1 INTRODUCTION

The orthotropic steel deck (OSD) is a highly redundant and integrated deck system that is extensively employed in large-span bridges, in which the light self-weight is of the first priority (Zou et al., 2022). The OSD consists of massive components connected via a copious number of welded connections (Heng et al., 2022). Especially, the rib-to-deck (RD) welded joint can even account for 50 times the total bridge length. Under this situation, fatigue cracking is frequently observed in OSDs after several decades of exploitations (Connor et al., 2012). As a result, the normal operation of the bridge will be greatly affected in the presence of excessive cracks within the same lane.

The fatigue issue of RD joints in OSDs has already been investigated with great efforts in the past 20 years due to its prominence and notable influence, including both fatigue resistance (Cheng et al., 2016), life prediction (Ye et al. 2017), and repair methods (Wang et al., 2021). However, some further efforts are still lacking from the aspect of risk assessments, which helps to offer different insights into the recurring fatigue cracking issue of OSDs.

This work aims to offer novel insights into the fatigue-induced risk of lane closures in the OSD bridge, which can provide constructive supports for the further management of OSDs with massive welded joints. In section 2, stress spectra of RD joints in different lateral locations are derived by combing the finite element simulation and condition-based random vehicle model. In section 3, fatigue prognosis is carried out using a multi-level failure assessment diagram, followed by the associated risk assessment of lane closures. In section 4, the major result and findings are discussed. Finally, key conclusions are drawn in Section 5.

2 DERIVATION OF FATIGUE STRESS

2.1 Illustration of the investigated bridge

In this study, a typical OSD bridge in the urban network of Chengdu, China is selected as the prototype, as shown in Figure 1. The selected bridge consists of three spans of 45 m (side), 68 m (main) and 45 m (side). In the length, the bridge is divided into a total of 112 segments, each of which has a similar configuration except for the varying sectional height. The width of bridge (in a single direction) is 12.5 m, carrying one fast lane, one middle lane and one slow lane. Beneath the three lanes, a total of 15 longitudinal ribs (also called as U-ribs) are distributed. Each U-rib is connected to the deck by two RD joints on its left and right sides. For better illustration, the U-ribs are named as 1 to 15 from left (fast lane) to right (slow lane), e.g., U1. Accordingly, the associated RD joint is coded with L (left) or R (right), e.g., U1L or U1R.

Figure 1. The typical OSD bridge selected for investigation (courtesy of Dr Junlin HENG).

2.2 Site-specific random traffic modelling

Based on the site-specific traffic data, the random vehicle load (RVL) model (Heng et al., 2019) can be established to simulate the fatigue action on RD joints by vehicles, as shown in Figure 2. In the RVL model, vehicles are classified into a total of six categories, mainly depending on the configuration of axles and functions. It can be found that, the light-weight car accounts for the highest proportion in both the three lanes, i.e., 76.67% in total traffic. Meanwhile, it is worth noting that the heavy trucks V5 and V6 show a highly similar occupancy rate in the middle and slow lanes. As a result, equal concerns should be paid to the fatigue cracking in RD joints of both the middle and slow lanes.

Instead of the gross vehicle weight, the load of each vehicle type is modelled in detail from axle-to-axle. Due to the presence of multi-peaks in the distribution of axle weights, the Gaussian mixed model (GMM) model is leveraged. Meanwhile, the lateral distribution of vehicle within the lane is also considered by fitting the discrete distribution by Eurocode 1 (CEN, 2003) to a Gaussian distribution. Further details about the RVL model could be found in (Guo et al., 2015).

Based on the RVL model, random sampling of vehicles can be carried out in a conditional sampling manner, as illustrated by Equation 1,

$$p(W_i) = p(VC) \cdot p(W_i|VC) \quad (1)$$

where VC standards for the vehicle category; W_i is the weight of the i th axle.

Meanwhile, in terms of the average daily traffic (ADT), the mean value of 10,605 and standard deviation of 2,121 can be derived from the observation data.

Category	Illustration	Occupancy rate (%)		
		Fast	Middle	Slow
V1		41.23	25.74	9.70
V2		0.03	0.26	0.36
V3		0.1	0.87	0.6
V4		0.04	0.67	0.92
V5		0.06	1.17	1.31
V6		0.57	7.94	8.43

Figure 2. Configuration of different vehicle types and lane occupancy rate.

2.3 FE-based derivation of fatigue stress

Multi-scale finite element (FE) model of the bridge is constructed, as shown in Figure 3. The model includes the global model of the bridge structure, the sub-model of the interested segment, and the local refined model of the RD joint. The 3-dimensional shell element SHELL63 is employed in the FE modelling. Since the global modelling aims to simulate the boundary condition at the structural level, a relatively coarse meshing size is employed (i.e., 50 mm in width and 100 mm in length). Then, the segment at the mid-span is selected for the sub-model, which employs a fine mesh size of 20×20 mm at the outer edge. Further, the RD joint is highly refined with a very fine element size of 4 mm.

The global model and sub-model are connected using the interpolation of nodal displacement at the interface, which is realised by multi-point constriction (MPC). Meanwhile, the local refine model is embedded in the sub-model by sharing nodes directly.

Figure 3. Finite element model of the selected bridge.

Based on the constructed FE model, the sampled vehicle can be transformed into the stress spectra of RD joints in different lateral positions, as shown in Figure 4. In the derivation, a total of 5,000,000 samples of vehicles are generated based on the RVL model discussed in Section 2.2. The influence surface technology (Heng et al., 2019) is employed to improve the solution efficiency, via which the loading of vehicles can be achieved by vector calculus. As indicated by the result, the RD joints in the fast lane (e.g., U4r) shows a low level of stress spectra due to the rare presence of heavy trucks in the lane. On the contrary, the similar RD joint in the middle lane (i.e.,

U9R) suggest a high-level stress distribution. Moreover, a very notable feature of multi-peaks can be found in the stress spectra. Moreover, the stress spectra also vary significantly within the same lane due to the lateral distribution of the car footprint. For instance, the RD joint U14L shows a very limited stress level since it is very close to the centre of the lane.

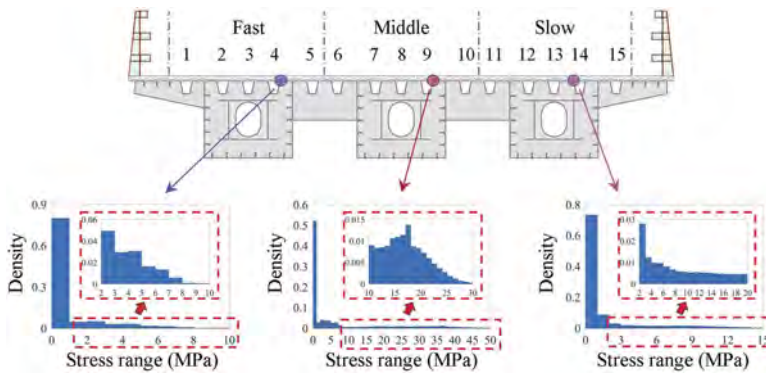

Figure 4. Stress spectra of different RD joints.

3 PROBABILISTIC PROGNOSIS AND RISK ASSEMENT

3.1 Fatigue damage model

The fatigue strength of RD joint is described using the probability-stress-life (P-S-N) curve, as illustrated by Equation 2,

$$\log(C) = m \cdot \log(\Delta\sigma_{ref}) + \log(N_{ref}) + \varepsilon \quad (2)$$

where C is a material constant marking the fatigue strength of RD joints; m is the power index, fixed as 3.0 in this work; $\Delta\sigma_i$ and N_i are respectively reference stress range and associated allowance number of loading cycle; ε stands for the uncertainty factor, which follows the lognormal distribution.

Based on the fatigue test data in (Zheng et al., 2019), the mean value of parameter C is determined as 2.27×10^{12} , while its coefficient of variance (COV) is solved as 0.59. For each RD joint, the fatigue limit state function (LSF) can be expressed by Equation 3,

$$g(D, t) = \Delta - D(t) \quad (3)$$

where $D(t)$ is the damage accumulation factor at time t ; Δ is the tolerance factor, assumed as 1.0 in this study.

Since the RD joint experience variant-amplitude fatigue action, the linear damage accumulation rule is employed in calculating the fatigue damage, as illustrated by Equation 4,

$$D(t) = \sum_i \frac{N_i \cdot \Delta\sigma_i^m}{N_{ref} \cdot \Delta\sigma_{ref}^m} \quad (4)$$

where $\Delta\sigma_i$ and N_i denote the i th applied stress range and number of loading cycle, respectively.

3.2 Failure assessment diagram and limit state functions

As aforementioned, the bridge is divided into 112 segments in the length direction. Accordingly, each lane can be also divided into 112 lane segments (LSs). Moreover, as depicted in Figure 4, each lane segment has five U-ribs and ten RD joints associated. To this end, the OSD system is idealized into a link-parallel mixed system, as indicated by the failure

assessment diagram (FAD) in Figure 5. In general, the OSD system consists of three parallel components, i.e., fast, middle and slow lanes. Then, each lane is further discretized into 112 LSs, which are also in the parallel relation. Finally, each LS is modelled by a linking system covering all the ten RD joints with the lane.

Figure 5. Failure assessment diagram of the OSD bridge.

As discussed earlier, excessive fatigue cracking within the same lane will result in mandatory lane closure due to its influence on the running safety of vehicles. To this end, after consulted with industrial colleague, the failure of the lane is assumed when the fatigue crack occurs in more than 10% of the 112 LSs, i.e., above 11 LSs. To this end, the possibility of occurrence can be further expressed for the closure in each lane, as illustrated by Equation 5,

$$p_{lc} = p(N_{f,LS} \geq 11) \quad (5a)$$

$$p_{f,LS} = \prod_{i=1}^{10} p_{f,joint}(i) \quad (5b)$$

where P_{lc} denotes the possibility of lane closure; $N_{f,LS}$ is the number of cracked lane segment; $P_{f,LS}$ is the failure probability of each lane segment; $P_{f,joint}(i)$ stands for the failure probability of i th RD joint in the lane.

3.3 Risk assessment model

Based on the above FAD, three scenarios are identified for potential risk of lane closures, i.e., one lane closure, two lanes closure and all the three lanes closure (i.e., the shutdown of the bridge). Accordingly, the associated costs can be estimated, as illustrated by Equation 6,

$$C_{LC} = (C_r + C_f + C_t) \cdot (1 + r_m)^t \quad (6)$$

where C_{LC} is the total cost for lane closure; C_r denotes the estimated repair cost; C_f is the fuel and abrasion cost of vehicles due to detour; C_t stands for the time value consumed by detour of vehicles; r_m is the annual discount rate of money, assumed as 1.5% in this study.

Detailed computation of the cost can be referred to a previous study (Zhu et al., 2016), while Table 1 lists the value considered in this study.

4 RESULT AND DISCUSSION

4.1 Fatigue reliability

Based on the proposed method, the fatigue reliability of each joint can be at first predicted, as shown in Figures 6a and b. Overall, the RD joints in the fast lane demonstrate the highest

Table 1. Key parameters for the consequence analysis.

Type	Symbol	Scenario of lane closure (in €)		
		One lane	Two lanes	Shutdown
Repair cost	C_r	93,000	166,183	230,247
Fuel cost	C_f	107,376	214,751	322,127
Time value	C_t	158,459	316,918	475,378

reliability due to the rare presence of heavy trucks. Meanwhile, very similar reliability can be found in the RD joints within the middle and slow lane, which is consistent with the distribution of heavy trucks V5 and V6. Figure 6b further plot a list of representative RD joints in the different lane. It is worth noting that the fatigue reliability of the RD joint is highly sensitive to its lateral position in the lane. For instance, the joint U14L shows the highest reliability while the nearby U14R suggests the third lowest reliability. Meanwhile, it is also revealed that the joint U12L in the slow lane is the most fatigue-critical detail. Based on the reliability prediction made using site-specific data, a tailored managing plan can be stipulated for the OSD bridge.

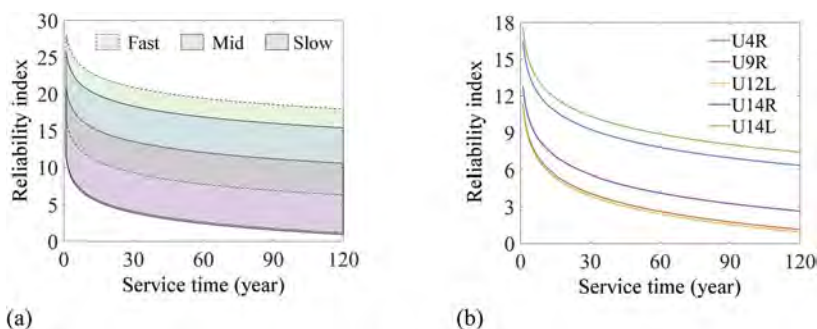

Figure 6. Reliability of welded joints: (a) distribution over lanes; (b) selected joints in different lanes.

Similarly, incorporating the FAD proposed in Figure 5, the fatigue reliability can be also assessed at the level of lane segments, as shown in Figure 7. Similar to the previous result, the middle and slow lanes show a very consistent evolution of reliability during the service life of the bridge. Meanwhile, a very prominent reliability is predicted for the fast lane due to the rare passing of heavy trucks.

In addition, the possibility of occurrence can also be estimated for the closure in different lanes, as shown in Figure 8a. Also, the fast lane is highly unlikely to closure due to the limited fatigue damage by light-weight cars. At the same time, the possibility of closure becomes very prominent in both the slow lane and middle lane as the bridge is approaching the end of its design life (i.e., 120 years in this study). Moreover, the three assumed scenarios are also investigated, as shown in Figure 8b. After about 80 years of service, the closure of a single lane becomes very notable. With the time further increase, the closure of two lanes is even apparent, while the closure of a single lane becomes unlikely. At the same time, the shutdown (i.e., the closure of all the three lane) seems to be a rare event during the entire service life.

4.2 Time-variant risk

The time-variant risk associated with the above different scenarios is also estimated, as shown in Figures 9a and b. Overall, the risk is relatively moderated before 80 years, indicating the guaranteed performance of OSDs as a highly integrated and redundant deck system. Meanwhile, it can be found that the largest risk originates from the scenario that two lanes are forced to closure. Figure 9b further investigates the contribution of the three scenarios.

Figure 7. Reliability of lane segment.

Figure 8. Probability of occurrence of lane closures: (a) different lane; (b) different scenarios.

Obviously, the “two lanes” event increase at a rapid rate and surpass the “one lane” event after roughly 100 years.

Figure 9. Time-variant risk due to fatigue: (a) different scenarios; (b) contribution of scenarios.

5 CONCLUSIONS

Based on the above investigation, the following key conclusions can be drawn.

- (1) The fatigue stress spectra in the rib-to-deck (RD) joints of orthotropic steel deck (OSD) bridges are controlled by both the lane type and lateral position within the lane. Due to the rare presence of heavy trucks in the fast lane, the stress level in all the RD joints is relatively low within the lane. Meanwhile, high fatigue stress is likely to occur in the RD joint close to the frequent foot print of vehicles. Accordingly, the fatigue damage of RD joints shows a very high sensitivity to the lane type lateral position within in the lane.

- (2) Both the middle lane and slow lane shows a similar possibility of closure, while it is a rare event for the closure of the fast lane. Different from the middle lane and slow lane, heavy trucks rarely select the fast lane. As a result, the mandatory closure of the slow lane is very unlikely to occur under the investigated traffic. To this end, more efforts are suggested to the slow lane and middle lane.
- (3) The one-lane and two lanes closure contribute remarkably to the risk of lane closure, while the shutdown scenario has little contribution. After about 80 years of service, the risk associated with the closure of a single lane becomes very notable, which is then surpassed by the closure of two lanes soon. Meanwhile, the risk of a shutdown is maintained at a very limited level during the entire service life.

Life-cycle management of offshore wind deteriorating structures under ship collision accidental events

P. Salazar L., J. Morán A. & P. Rigo

Department of Naval and Structural Engineering (ANAST), Liege, Belgium

P.G. Morato

Department of Wind and Energy Systems, Technical University of Denmark, Roskilde, Denmark

ABSTRACT: In conventional industrial practices, the structural performance is evaluated against deterioration mechanisms as well as extreme and/or accidental events. However, most existing approaches treat the aforementioned structural assessments separately. In this work, we identify system inspection and maintenance strategies by jointly modeling deterioration processes and accidental/extreme events within the overall life-cycle management optimization. In particular, the decision-making objective is formulated considering a system failure risk metric that depends on the damage caused by deterioration processes and accidental/extreme hazards. In order to enable efficient inference and uncertainty propagation, we propose an underlying probabilistic approach relying on dynamic Bayesian networks. The efficacy of the proposed approach is tested in a life-cycle management setting where the risk of an offshore wind frame substructure is controlled by timely allocating inspection and maintenance actions. Within the investigation, we also observe the influence of ship collision events frequency on the resulting asset management strategies.

1 INTRODUCTION

Civil and maritime infrastructures support societal development and are essential for economic growth. Among them, offshore wind turbines offer a sustainable solution towards the pursuit of achieving renewable energy generation. Engineering systems are, however, exposed to deterioration mechanisms throughout their service life along with occasional extreme and/or accidental events, thus inducing a risk of structural failure. There is a need, therefore, for life-cycle management capable of controlling structural failure risks while minimizing inspection and maintenance costs. Driven by modern data collection techniques, the development of decision-making methods has been intensified in the last decade (Frangopol & Soliman 2016). From a computational standpoint, the identification of life-cycle management strategies involves the solution of a challenging decision-making problem under uncertainty and imperfect information, in which the uncertainties associated with the estimation of deterioration processes and data collection systems should also be adequately quantified.

Early risk-based approaches frame the decision-making problem in a simplified decision tree, where inspections and maintenance decisions are selected based on static pre-defined heuristic rules, e.g. equidistant inspection intervals, and repairs undertaken following damage indications. Later on, heuristic-based methods are integrated with dynamic Bayesian networks (DBNs) via policy search simulations, thus providing more flexibility to the definition of the heuristic decision rules (Luque & Straub 2019). Heuristic-based policies are, however, limited by the fact that only a subset of the vast policy space is explored. Addressing this limitation, decision-making methods relying on Markov Decision Processes (MDPs) and Partially Observable MDPs (POMDPs) have been proven to provide optimal policies in high-dimensional space settings (Papakonstantinou & Shinozuka 2014, Morato et al. 2022a). In very high dimensional state, action, and observation spaces, normally characteristic of engineering systems planning problems, schemes integrating POMDP with deep reinforcement learning can efficiently identify optimal policies, resulting in substantial cost savings compared

to other heuristic-based and conventional management strategies (Andriotis & Papakonstantinou 2019, Morato et al. 2022b). The previously mentioned decision-making methods are usually applied so as to identify management strategies for deteriorating engineering components or systems. Yet, along with deterioration processes, engineering infrastructures are also occasionally exposed to extreme and/or accidental hazards. With respect to the latter, methods able to identify management strategies for engineering systems under extreme events have also been explored in the literature (Kumar et al. 2009). The severity and occurrence of extreme hazards are normally characterized as low-probability high-consequence events, (Stewart & Rosowsky 2022). In that case, the goal of adequate strategies generally involves controlling the vulnerability of affected structural systems, as well as mitigating human, social, environmental, and economic losses. However, high-probability low-consequence accidental events can also occur, and while they may be associated with less critical consequences, the structural reliability of the concerned engineering systems can be severely compromised. For example, offshore wind structures are exposed to multiple hazards throughout their lifetime, including extreme environmental loads and accidents, e.g. ship collisions. In conjunction with deterioration processes, damage due to high-probability low-consequence ship collisions detrimentally affects the capacity of offshore wind structural systems, rendering them potentially unable to withstand future hazards.

Most reported planning methods and conventional industrial practices deal with engineering systems exposed to either deterioration mechanisms or extreme events. In this work, we propose a probabilistic modeling framework based on dynamic Bayesian networks jointly treating deterioration processes and accidental/extreme events. Particularly, the system's structural reliability is formulated conditional on its components' reliability, whose evolution is modeled considering both probabilistic deterioration processes and accidental/extreme events. The proposed scheme constitutes the underlying probabilistic foundation, which integrated with heuristic- or POMDP- based decision-making methods, is able to provide management strategies for deteriorating engineering systems under accidental and/or extreme events. To test our approach, life-cycle management heuristic-based policies are identified for a structural system subject to fatigue deterioration and accidental ship collision events, also investigating the effect of accidental events occurrence and their intensity on the resulting strategies.

2 LIFE-CYCLE MANAGEMENT OF DETERIORATING STRUCTURES UNDER ACCIDENTAL AND/OR EXTREME EVENTS

In this section, we propose a probabilistic modeling approach based on dynamic Bayesian networks for the estimation and inference of the reliability of a structural system subject to both time-varying deterioration processes and accidental/extreme loads. Relying on computed system reliability metrics, along with inspection and maintenance costs, life-cycle management policies can then be identified via policy search simulations or Markov decision processes.

2.1 *Probabilistic modeling via dynamic Bayesian networks*

Encoding the conditional relationships among random variables, Bayesian networks are acyclic graphical models that enable robust inference based on observed information. Bayesian networks that track dependencies over time are commonly denoted temporal template models, or more generally, dynamic Bayesian networks (DBNs). By leveraging the inference capabilities featured by DBNs, the reliability of a structural system can be efficiently estimated. The overarching scheme for probabilistically modeling the reliability of a deteriorating structural system under accidental/extreme events over time is graphically shown in Figure 1. Chance nodes represent random variables and are bounded by circular edges in the graph, additionally filled with grey color if they are partially observable. Also, network template models are enclosed by a blue or green box, indicating whether they are repeated over components or intensity measures, respectively.

2.2 *Stochastic deterioration processes*

The damage condition state caused by a non-stationary deterioration process, e.g. fatigue or corrosion, can be updated over time based on collected information through a two-step

Figure 1. Overarching graphical representation of the proposed probabilistic approach. Damage evolution caused by both deterioration processes and accidental/extreme events is modeled over time through dynamic Bayesian networks. Each component's reliability is conditional on deterioration and accidental/extreme damage, whereas the system's reliability depends on the components' reliability.

process. Firstly, the joint state comprised of the damage condition, d_t , and the deterioration rate, τ_t while conditional on past observations, $\mathbf{o}_0, \dots, \mathbf{o}_t$, advances over time according to the transition model $p(d_{t+1}, \tau_{t+1} | d_t, \tau_t)$, as:

$$p(d_{t+1}, \tau_{t+1} | \mathbf{o}_0, \dots, \mathbf{o}_t) = \sum_{d_t} \sum_{\tau_t} p(d_{t+1}, \tau_{t+1} | d_t, \tau_t) p(d_t, \tau_t | \mathbf{o}_0, \dots, \mathbf{o}_t) \quad (1)$$

Based on the information collected from inspections or monitoring, the damage is then updated by applying Bayes' rule. The likelihood $p(\mathbf{o}_{t+1} | d_{t+1})$ can be directly defined from probability of detection curves or other observation uncertainty measures:

$$p(d_{t+1}, \tau_{t+1} | \mathbf{o}_0, \dots, \mathbf{o}_{t+1}) \propto p(\mathbf{o}_{t+1} | d_{t+1}) p(d_{t+1}, \tau_{t+1} | \mathbf{o}_0, \dots, \mathbf{o}_t) \quad (2)$$

2.3 Accidental and/or extreme events

Occasional accidental or extreme events can be categorized according to their severity and can be probabilistically modeled based on their occurrence rate. The frequency associated with an accidental event depends on the operational conditions, location, and specific characteristics of the structural system. Based on the specific frequency, annual event occurrences can be estimated, for example, through a Poisson random process. In Figure 1, the annual occurrence is depicted with the node n_I for each considered intensity measure, I , and graphically represented as a template model. The damage sustained due to accidental or extreme events, ϵ , can be then modeled conditional on annual event occurrence. In terms of reliability, a component or system limit state can be defined based on the structural damage, ϵ , and a case-dependent safety measure.

2.4 System structural reliability

At the system level, the failure event can be defined conditional on the component's failure probability, represented in Figure 1 with nodes F_{sys} and F , respectively (Morato et al. 2022b). And, as mentioned previously, the failure probability associated with each component depends, in turn, on the deterioration, d , and accidental, ϵ , damage condition.

2.5 Reliability-based robustness index

Along with reliability measures, quantifying the resistance of a structural system against accidental or extreme loads can also be informative for life-cycle management considerations. As explained by Biondini (2009), structural robustness can be measured by comparing the structural performance (e.g. reliability) of the system in a damaged state with respect to the system in an intact condition. A reliability-based robustness index, I_R , can be therefore formulated as (Frangopol & Curley 1987):

$$I_R = \frac{\beta_{sys,0}}{\beta_{sys,0} - \beta_{sys,d}} \quad (3)$$

where $\beta_{sys,0}$ and $\beta_{sys,d}$ correspond to the reliability index (i.e. $\beta_{sys} = -\Phi^{-1}[p_{F_{sys}}]$) estimated for the intact and damaged system, respectively.

2.6 Life-cycle management planning

As mentioned in Section 1, life-cycle strategies can be identified through heuristic-based policy search or via POMDP-based deep reinforcement learning, potentially including additional maintenance actions undertaken in response to damage caused by accidental or extreme events. In any case, the objective of the life-cycle management decision problem is stated as the minimization of the total expected cost, $\mathbf{E}[c_T]$:

$$\mathbf{E}[c_T] = \mathbf{E} \left[\sum_{t=0}^{t_N} [\gamma^t (c_{I,t} + c_{R,t} + r_{F,t})] \right] \quad (4)$$

where c_I and c_R , stand for inspection and repair costs, respectively; while the system risk, r_F , is defined as the system failure probability, $p_{F_{sys}}$, multiplied by the failure cost, c_F . Note that the total cost is discounted by the factor γ . By identifying policies on the basis of the aforementioned optimization objective, life-cycle management policies are able to jointly consider the risk induced by deterioration processes and occasional accidental/extreme events, both of them encapsulated in the system risk metric, r_F .

3 LIFE-CYCLE MANAGEMENT PLANNING FOR A DETERIORATING OFFSHORE WIND SUBSTRUCTURE SUBJECT TO SHIP COLLISIONS

The main goal of this study is to determine the influence of occasional accidental events on life-cycle management strategies. Specifically, life-cycle management policies are identified for a structural system subject to both fatigue deterioration and accidental ship collision events. A heuristic-based policy search is conducted in order to identify life-cycle strategies, evaluating each considered heuristic combination over 2,000 policy realizations on a 30-year decision horizon. In particular, a specified number of braces (and their corresponding fatigue hotspots) are inspected at equidistant inspection intervals, prioritized according to their brace failure probability. Besides, a brace is subsequently repaired if a crack is observed or once the brace failure probability exceeds 10^{-3} . The heuristic-based policy becomes the optimized heuristic combination that results in the minimum total life-cycle cost, among all evaluated heuristic rules. The inspection and repair costs are specified for each element as $c_I = 0.4$ and $c_R = 30$ monetary units, whereas the system failure cost is defined as $c_F = 50,000$ monetary units. Also, a discount factor is specified as $\gamma = 0.95$. Note that more optimal policies can be found via POMDP-based deep reinforcement learning approaches. As mentioned earlier, the primary aim of the study is not reaching policy optimality but observing the effect of considering both deterioration processes and extreme/accidental events on the retrieved life-cycle strategies.

3.1 Case study description

3.1.1 System structural reliability

The methodology proposed in Section 2 is tested for a typical engineering system in the structural reliability community, the Zayas frame, considered in this work as a 2-dimensional representation of an offshore wind substructure. The frame features 2 legs and 13 braces, with the characteristics shown in Figure 2. The failure of the system corresponds to the event in which the frame is not able to withstand a concentrated horizontal load applied at the upper-left corner, i.e. the probability of the external horizontal load exceeding the structural system

resistance $p_r[L_H > L_{push}]$. The horizontal load is characterized as a lognormal random variable with mean $\mu_{L_H} = 70$ kN and 25% coefficient of variation, while the system resistance is assumed deterministic. The system failure depends on the event of a potential brace failure, caused by fatigue deterioration and/or accidental collision damage. Particularly, a brace failure event is defined as a series system including one/two fatigue hotspots and a collision failure event, each of them estimated based on the limit states explained hereafter. To define the failure probability of the frame, pF_{sys} , conditional on all brace failure/survival state combinations, 8,192 ($= 2^{13}$) non-linear static push-over simulations have been run with the assistance of the computer code 'USFOS'. For a complete description of the frame structural reliability computation, the reader is referred to Morato et al. (2022b).

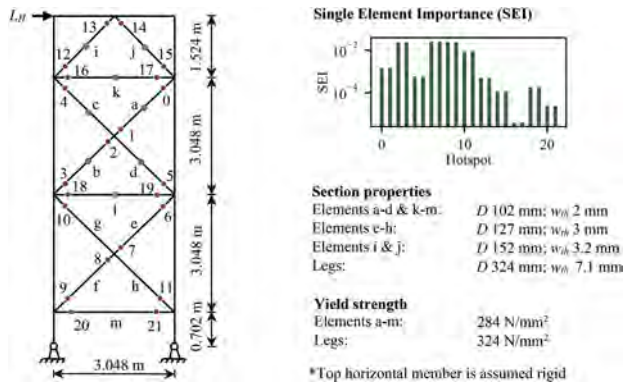

Figure 2. Zayas frame geometry and material properties, adapted from Morato et al. (2022b).

3.1.2 Fatigue deterioration

The deterioration condition of each fatigue hotspot is here described according to the Markovian model, originally proposed in Ditlevsen & Madsen (2007):

$$d_{t+1} = \left[\left(1 - \frac{m}{2} \right) C_{FM} S_R^m n^{m/2} + d_t^{1-m/2} \right]^{2/2-m} \quad (5)$$

where the evolution over time, t , of the crack depth, d , is formulated through a fracture mechanics law with material parameters $\ln(C_{FM}) \sim \mathcal{N}(\mu = -35.2, \sigma = 0.5)$ and $m = 3.5$, stress range $S_R \sim \mathcal{N}(\mu = 70, \sigma = 10)$ N/mm², $n = 10^6$ annual stress cycles, and initial crack depth $d_0 \sim \text{Exp}(\mu = 1)$ mm. At the hotspot level, fatigue failure p_{F_i} occurs once the crack depth, d , exceeds a critical size, $d_c = 20$ mm, formally defined as $p_{F_i} = \Pr[g_t \leq 0]$ and computed via a through-thickness failure criterion (Hlaing et al. 2022), i.e. $g_t = d_c - d_t$. Adopting the probabilistic methodology proposed in Section 2, the fatigue deterioration is encoded in a deterioration rate DBN model. The continuous crack depth, d , is adequately discretized into states conditional on $|\mathcal{S}_t| = 31$ fully observable deterioration rate states. In terms of the observational model, the inspection quality is quantified with a Probability of Detection curve $PoD(d) \sim \text{Exp}(\mu = 8)$. More details can be found in Morato et al. (2022a).

3.1.3 Ship collisions

The accidental event is defined as a ship bow impact on the midpoint of a brace and its damage is estimated by means of the absorbed energy. For the purpose of this study, only elements on the 'splash zone' are potentially subject to ship collisions, i.e. brace elements a-d and i-l. The mechanisms for energy absorption are assumed as plastic bending and plastic tensile strain. Local denting and global deflection of the installation, as well as local deformation of the vessel, are not accounted for. To determine the energy absorbed by the collided structure, a ship bow collision on a brace member is considered as a three-point centrally loaded beam bending problem, (Zhang

et al. 2019). The maximum capacity of energy absorbed by bending and tension, ϵ_{max} , corresponds then to the hinge rotation limit of the element, formulated as:

$$\epsilon_{max} = 4\sigma_y w_{th} (D - w_{th})^2 \alpha \left(\frac{w_{th}}{D}\right)^\beta + \pi\sigma_y w_{th} (D - w_{th}) \frac{L}{2} \left[\alpha \left(\frac{w_{th}}{D}\right)^\beta\right]^2 \quad (6)$$

where w_{th} , D , and L represent the wall thickness, outer diameter, and length of each tubular member, respectively, while σ_y corresponds to the yield strength. According to Marshall et al. (1977), a lower and upper bound solution can be specified for the plastic hinge rotation at failure for a tubular element, where the range for the multiplicative constant α may be defined between 122 and 12,800 and the exponent β may take values between 2.5 and 3. To account for the uncertainty associated with the previously mentioned parameters and defined for each considered element thickness and diameter, α is described as a uniform random variable, $\alpha \sim \mathcal{U}(122, 12800)$, and β is assumed as a Gaussian random variable, $\beta \sim \mathcal{N}(\mu = 2.75, \sigma = 0.25)$. Geometrical and material properties are treated here as deterministic variables.

Table 1. Occurrence frequency statistical description of all examined accident ship collision events, categorized according to their intensity measure (collision energy).

Occurrence frequency/intensity	0.625 kJ	3.125 kJ	6.250 kJ	9.375 kJ	12.5 kJ
Low (λ_{low})	10^{-2}	10^{-3}	$5 \cdot 10^{-4}$	10^{-5}	10^{-6}
Medium (λ_{medium})	$5 \cdot 10^{-2}$	$5 \cdot 10^{-3}$	10^{-3}	$5 \cdot 10^{-5}$	$5 \cdot 10^{-6}$
High (λ_{high})	10^{-1}	10^{-2}	$5 \cdot 10^{-3}$	10^{-4}	10^{-5}

During the computation of policy evaluations, the failure probability of an accidental event is estimated, at each time step, according to the limit state, $g_{col} = \epsilon_{max} - \epsilon_{col}$, with ϵ_{max} calculated following Equation 6. In terms of the collision energy, ϵ_{col} , which can be linked to the intensity measure of an accidental event, a set of collision intensities are here investigated ranging between 0.625 and 12.5 kJ. The intensities can be regarded as reasonable collision scenarios for the Zayas frame, corresponding specifically to a ship mass between 5 and 100 tonnes colliding at 0.5 m/s. In the numerical experiments, three collision occurrence event settings are tested, representative of low, medium, and high frequencies, all of them described as Poisson processes. Table 1 lists the mean annual frequency, λ , considered for each analyzed setting. While evaluating life-cycle policies, the number of ship collision events, $n_{I,col}$, is sampled at each time step, thereby enabling the computation of the collision energy ϵ_{col} and the accidental event failure probability.

3.2 Results and discussion

3.2.1 Robustness analysis

To better understand the ability of the analyzed frame to withstand potential ship collisions, the robustness of each brace is quantified according to Equation 3 and displayed in Figure 3. The intact reliability index, β_0 , corresponds to the case in which only deterioration damage is considered, whereas the damaged reliability index, β_{db} , also accounts for accidental events associated with a certain collision intensity, along with fatigue deterioration. As expected, more severe ship collisions lead to an overall robustness reduction, also accentuated by longer fatigue deterioration exposure. Interestingly, the observed robustness indices are clearly influenced by each brace's structural importance, defined according to Morato et al. (2022b).

3.2.2 Life-cycle costs and policies

The total expected cost, $\mathbf{E}[c_T]$, resulting from all examined accidental event frequency settings is reported in Table 2, also listing the corresponding expected inspection and repair costs along with the system failure risk, i.e. $\mathbf{E}[c_I]$, $\mathbf{E}[c_R]$, and $\mathbf{E}[r_F]$. Whereas more intense ship collision events naturally lead to higher life-cycle total expected costs, expected inspection and repair costs are also clearly influenced by the intensity of accidental events. Considering only

Table 2. Expected total cost resulting from the conducted numerical experiments for settings with varying frequency of collision event occurrence.

Occurrence frequency	$E[c_f](\% E[c_T])$	$E[c_R](\% E[c_T])$	$E[r_F](\% E[c_T])$	$E[c_T](95\% \text{ C.I.})$
Zero (λ_{zero})	15.31 (7.3 %)	55.99 (26.8 %)	137.35 (65.9 %)	208.65 (± 0.01)
Low (λ_{low})	15.29 (7.0 %)	59.75 (27.2 %)	144.41 (65.8 %)	219.45 (± 0.02)
Medium (λ_{medium})	11.99 (4.5 %)	66.01 (25.1 %)	185.08 (70.4 %)	263.08 (± 0.04)
High (λ_{high})	11.01 (3.4 %)	86.02 (26.5 %)	227.59 (70.1 %)	324.63 (± 0.05)

Figure 3. Reliability-based robustness index estimated for all Zayas' brace elements potentially subject to ship collision accidental events (darker colors represent major severity).

fatigue deterioration during the planning stage would have resulted in a higher failure risk for more severe collision scenarios, with negligible influence on inspection and repairs. To further investigate the effect of collision occurrence on the retrieved policies, an additional analysis is conducted comparing the heuristic decision rules evaluated for each occurrence setting against the baseline case, in which only fatigue deterioration is considered. The normalized difference between the $E[c_T]$ resulting from each evaluated heuristic rule combination h_i and the optimized heuristic-based policy h_{opt} is defined as the comparative proxy, formulated as:

$$\bar{h}_i = \frac{\mathbf{E}[c_T(h_i)] - \mathbf{E}[c_T(h_{opt})]}{\mathbf{E}[c_T(h_{opt})]} \quad (7)$$

The above-mentioned metric, \bar{h}_i , is compared in Figure 4 for three ship collision frequency settings (i.e. λ_{low} , λ_{medium} , λ_{high}) against the case where only fatigue deterioration is modeled, λ_{zero} . Additionally, optimized heuristic-based policies are marked with a plus marker for each considered collision event occurrence case and a circular marker for λ_{zero} . As seen in the figure, the optimized heuristic-based policy remains the same for λ_{low} setting, yet it is clearly different for the other two cases λ_{middle} and λ_{high} . As one could expect, the life-cycle policy is mainly driven by fatigue deterioration when the frequency of accidental events is very low. Nevertheless, life-cycle management strategies are influenced by both fatigue deterioration and ship collision for the other two examined ship collision frequency scenarios. Additionally, it can also be observed that the optimized heuristic-based policy for λ_{zero} setting is farther from the optimized life-cycle policy when considering higher frequency of ship collisions, thus demonstrating the importance of jointly modeling both fatigue deterioration and accidental events.

4 CONCLUSIONS

This study reveals the importance of accounting for the increased risk caused by accidental events in life-cycle management planning for deteriorating structural systems. In the numerical

Figure 4. Heatmap representation of the difference between the normalized expected total costs resulting from settings with varying frequency of ship accidental collision events and the baseline case, in which only fatigue deterioration is accounted for.

experiments, heuristic-based life-cycle management policies are identified for an offshore wind substructure subject to fatigue deterioration and ship collisions, and the results indicate that the retrieved strategies are highly sensitive to the intensity and occurrence frequency of the examined ship collision events. In terms of decision-making, further research efforts might explore the integration of the proposed probabilistic approach with deep reinforcement learning methods.

ABSTRACT: The paper presents selected results obtained in the continuous monitoring of the *Candia* bridge – a historical masonry arch bridge crossing the Sesia River in the north of Italy – to detect scour-induced effects. Generally speaking, hydraulic processes are the main cause of bridge failure, and masonry arch bridges are particularly vulnerable to scour-induced settlements. Consequently, the early detection of anomalies associated to scour is of outmost importance to ensure the safe operation of river bridges. In the present study, measurements of the piers rotation are performed using tiltmeters; in addition, environmental parameters, such as temperature, water level and riverbed changes, are measured to check possible correlation with the monitored rotations. The results from the first two years of monitoring highlight anomalous changes in the rotation-temperature correlation of various piers.

1 INTRODUCTION

Masonry bridges with shallow foundations on the riverbed are highly vulnerable to scour-induced settlements. Nevertheless, the number of studies addressing this issue is still limited. Some scholars have tackled the problem with refined numerical models (Zampieri et al. 2017, Tubaldi et al. 2018, Scozzese et al. 2019), limit analysis (George & Menon 2022) or laboratory testing of scaled-down models (Invernizzi et al. 2011). However, extensive studies on the long-term monitoring of scour effects in masonry arch bridges are still missing. The present paper summarizes the results collected in two years of continuous monitoring of the historical multi-span masonry bridge, called *Candia* bridge.

On-site inspections revealed that all pier footings resting on the riverbed underwent strengthening interventions, highlighting the vulnerability to scour actions. In addition, the bridge experienced an intense flood event in October 2020.

The quasi-static monitoring system of the *Candia* bridge was designed to measure the rotations at the top of the piers resting on the riverbed to eventually detect the onset of scour-induced settlement. In more detail, the system includes: (a) 15 MEMS tilt-meters; (b) 1 hydrometer and 1 echo-sounder; (c) 1 weather station; (d) 2 cameras. The tiltmeters measure the traverse rotation of piers at the arches skewback and 2 tilt-meters are installed on the piers that were most affected by the scour events since 2003. In addition, temperature, water level and riverbed variations are monitored by means of thermocouples, hydrometer and echosounder respectively. The system is active since November 2020.

The structure, along with other bridges has been investigated as part of a joint research between Politecnico di Milano and Regione Lombardia aimed at defining guidelines for monitoring key infrastructures (Limongelli et al. 2022) and the subsequent implementation in pilot sensing systems (see, e.g. Bianchi et al. 2022, Borlenghi et al. 2022b, D'Angelo et al. 2022).

After a concise description of the bridge and the Sesia River, the paper focuses on the data collected in the first two years of monitoring.

Figure 1. The *Candia* bridge: view from the upstream of Sesia River.

2 THE *CANDIA* BRIDGE: DESCRIPTION AND PRELIMINARY ANALYSIS

The investigated structure (Figure 1) – called *Candia* bridge (Borlenghi et al. 2022a) – is a multi-span masonry arch bridge that crosses the Sesia River between the small municipalities of Candia Lomellina and Casale Monferrato. The structure is 325 m long and it is composed of 16 segmental arches, 15 piers and end abutments. All structural components are built in brick masonry. The arches have a span – measured from the arch skewback – of 17.5 m. As shown in Figure 1, all the piers were subjected to the strengthening of the foundation. The deck width is equal to 10 m and includes a roadway and a railway track, with the latter being inactive since 2010.

2.1 *The interaction with the Sesia river*

The structure is located 5 km upstream of the confluence between Sesia River and Po River. The Sesia River has a meandering channel pattern, which appears planimetrically stable from aerial images observation since 1954. In addition, the flow regime of the Sesia River is rather torrential with flow discharges ranging between 70 m³/s and 5000 m³/s. In case of a 200-year flood event, water can reach an elevation of about 105 m above sea level (asl) and 1 m above the skewback of the bridge arches.

According to Pizarro et al. (2019), scour can be classified as (1) natural scour, (2) contraction scour, and (3) local scour. In case of *Candia* bridge, the natural scour is occurring due to a general degradation of the altimetric profile of the Sesia River: along the period 1960-2000, the river generally eroded for 2-3 m. In addition, local scour at the foundation piers may occur due to local flow turbulences induced by the obstructions in the riverbed: the large concrete plinths reduced the free flow cross-section to 13.5 m. The presence of wood debris can further intensify the local scour process and in the case of *Candia* bridge the presence of important accumulation of debris during floods is well-documented.

Armoring intervention of the riverbed were carried out on several occasions to stabilize the sediments around the foundations. To the authors' knowledge, the last intervention of riverbed stabilization - before the installation of the monitoring system - was performed after 2003 around the most eroded piers at the left side of the channel, where flow concentrates in normal condition. This operation, however, simply modified the local morphology of the riverbed, deviating the main flux - and therefore the scour process - from the left to the central-channel piers. Figure 2 shows a representation of this mechanism.

In October 2020 a serious flood of the Sesia River occurred. The maximum water level reached during the event can be estimated from available photos and it is almost equal to

105 m asl (the quota of the 200-year flood event). The flood caused severe damage to the streets, railway tracks and buildings in areas nearby the bridge. However, no evidence of damage was detected on the bridge. After the flood event, field measurements of water depth were performed with a stadia rod. The local measures on pier P05 – taken from the extrados of the foundation plinth – resulted in 5.5 m at the upstream side and 2.7 m at the downstream side.

Figure 2. Satellite images of the Sesia River before and after the armoring intervention.

2.2 Historical and documentary research

Due to the lack of available documentations, an intense historical research was performed to identify the construction period and the main structural interventions.

The bridge was conceivably built between 1868 and 1870. According to the original design drawings – found in a Thesis of the Royal Technical School for Engineers of Turin (Martinengo 1869) – the foundations of the piers were of two types: the piers most subject to the river flow, i.e. those on the river right (P01-P04), were founded at a depth of 2 m below the riverbed (96 m asl), while the remaining ones (P05-P15) were founded 1 m below the riverbed (97 m asl). Surprisingly, at the age of the construction, the main river channel was on the river right.

Between 1954 and 1955 the 9th arch – included among P08 and P09 – was reconstructed and the foundations of piers from P09 to P11 were strengthened a deepening of the foundation level (Figure 3a) up to 12 m below the riverbed. The reason of the heavy damage of the arch is still unknown but most likely it was connected to soil settlements. Subsequently, during the 1980s, a similar intervention on the foundations of piers P04-P08 was performed (Figure 3b), together with the strengthening of arches from 1 to 5.

Figure 3. Historical drawings of different strengthening interventions on the piers: (a) 1955 intervention on piers P09, P10 and P11; (b) 1984 intervention on piers from P04 to P08.

To the authors' knowledge and based on the results of the documentary research, the foundation level for piers from P04 to P11 is equal to 12 m (measured from the extrados of the foundation plinth) while the foundation level of piers P01-P03 and P12-P15 is equal to 6 m.

3 THE CONTINUOUS MONITORING SYSTEM

The monitoring system installed in the *Candia* bridge (Figure 4a) is composed by: (a) 15 uniaxial MEMS analog tiltmeters (SISGEO model 0S541MA0202, accuracy $\pm 0.008^\circ$); (b) 1 weather station (measuring temperature, humidity, rainfall intensity, wind speed and direction); (c) 1 hydrometer; (d) 1 echo-sounder and (e) 2 cameras.

Figure 4b shows typical installation of one tiltmeter (before the cable connection). The tiltmeters were installed at the skewback of the arches on the upstream side of the bridge, measuring positive transverse rotations along the direction of the river flow. It is worth noting that the pier rotation due to a scour-induced settlement is expected to occur in the opposite direction of the river flow (Tubaldi et al. 2018) and therefore with negative measured rotations. As shown in Figure 4a, the tiltmeters were installed only on the piers located in the riverbed and the piers from P04 to P08 – the ones most affected by the deviation of the main river flux from the left- to the central-channel (Figure 2) – are monitored with two tiltmeters: one for each skewback.

The environmental parameters are measured with the weather station, the hydrometer and the echo-sounder. In addition, the outdoor temperatures are also recorded by the internal thermistor of the tiltmeters. The water level is measured with a hydrometer positioned at the deck level while the evolution of scouring holes is performed with an echo-sounder. As shown in Figure 4c, the echo-sounder is installed on piers 5 at the downstream side: the ideal position of the sensor should be on the upstream side, where the scour hole might develop, however, the intense debris accumulation on the upstream side suggested the installation on the downstream side. The debris accumulation on the piers is detected with 2 cameras taking pictures of the river from the upstream side (Figure 5).

The continuous monitoring system has been active since November 22nd, 2020. The sensor network has a sampling frequency of 1 Hz with the only exception of the cameras that acquire pictures every 10 minutes. The recorded data are collected every hour in 1 binary file that is transmitted to Politecnico di Milano for the analysis. In the post-processing phase the recorded data are averaged to obtain a single observation every hour.

Figure 4. The quasi-static monitoring system: (a) sensors layout; (b) mounting of tiltmeter T12; (c) position of the echosounder.

4 DATA ANALYSIS

This section summarises the main results of the quasi-static monitoring system for a period of 2 years, from 31/12/2020 to 01/01/2023. During this time period 16,510 1-h dataset were collected and analysed together with the upstream side pictures taken with the permanent cameras in the daylight (e.g. Figure 5).

Firstly, the main environmental parameters, i.e. outdoor temperature and water level, are processed. Figure 6a illustrates the evolution of the outdoor temperature measured from the internal thermistor of one tiltmeter. The maximum and minimum recorded temperatures in the selected period are equal to 45.7°C and -7.3°C, respectively. However, the temperatures below -1.2°C were ignored in the present paper due to an occasional sensor malfunctioning.

Figure 6b presents the time evolution of the river water level measured with the hydrometer in terms of elevation above sea level (m asl). The average recorded value in the selected period is 97.0 m asl while the maximum value is equal to 100.6 m asl (12 May 2021). It is worth considering that during the expected 200-year event, the river water level can reach an elevation of about 105 m asl, namely, rising about 8 m from the average water level. In the selected period the maximum detected rising is about 3.6 m from the average water level.

Regarding the analysis of debris accumulation Figure 5a shows the important wood debris accumulated over the concrete foundation basement of pier P05 after the flooding of October 2020 (estimated water level reach during the event equal to 105 m asl). After six months an event with a water level of 100 m asl occurred in May 2021 and a substantial variation in the debris accumulation is visible from Figure 5b.

Figure 5. Pictures from the permanently installed cameras: (a) debris accumulation on P05 in November 2020 resulting from the important event of October 2020; (b) debris accumulation on P05 and P04 after the event of May 2021.

Figure 6. Time evolution of environmental parameters: (a) measured temperature and (b) water level.

Due to the limited length of the present paper only the results of the four most representative tiltmeters are reported: T3, T4, T7 and T8. The selected sensors belong to piers P04 and P06, namely two of the piers most affected by the deviation of the main river flux from the left-

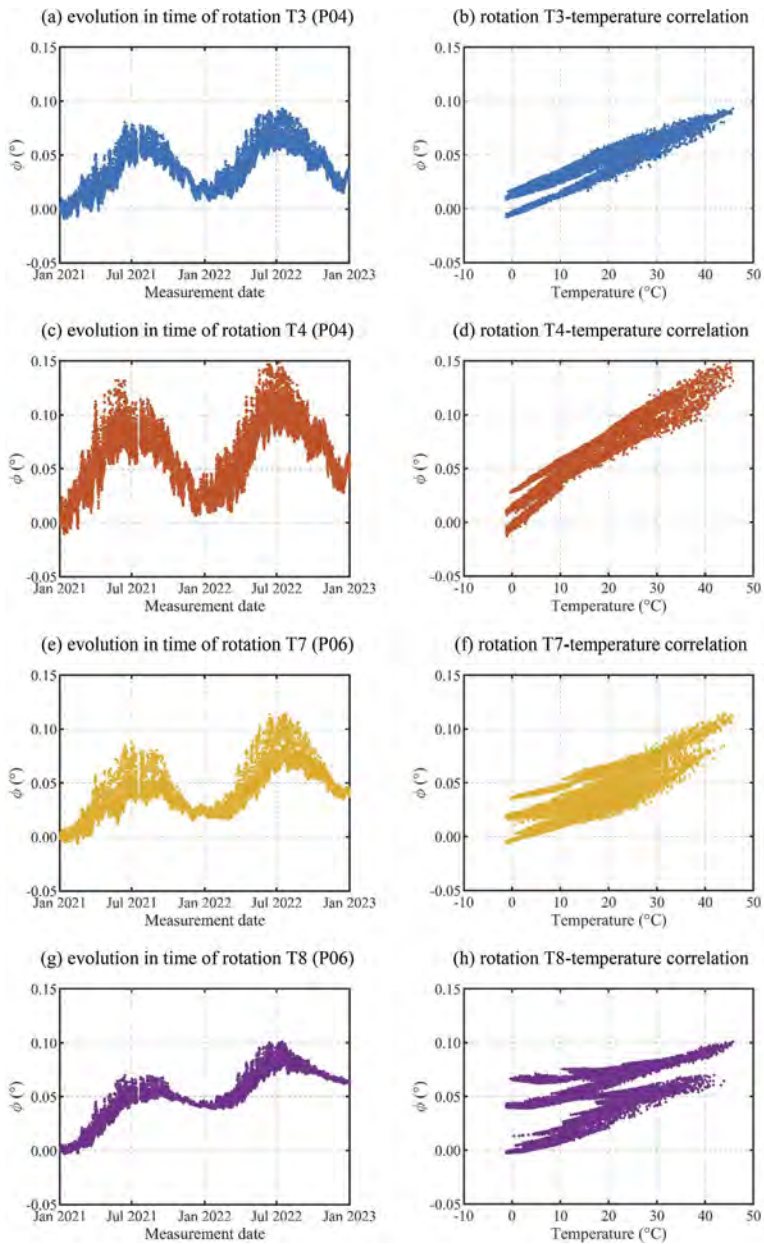

Figure 7. Time variation of rotations and rotation-temperature correlation of sensors T3 (P04), T4 (P04), T7 (P06) and T8 (P06).

Table 1. Statistics of the measured rotations from January 1st 2021 to January 1st 2023.

Tiltmeter	φ_{ave} (°)	φ_{min} (°)	φ_{max} (°)	σ_x (°)	CV (%)
T3	0.036	-0.008	0.093	0.020	56.0
T4	0.060	-0.013	0.148	0.030	50.5
T7	0.039	-0.006	0.114	0.022	57.0
T8	0.050	-0.003	0.101	0.023	46.6

the central-channel after 2003 (Figure 2). Table 1 reports the statistical analysis of the measured rotations. φ_{ave} , φ_{min} and φ_{max} denotes the average, minimum and maximum values of recorded respectively; σ_x represents the standard deviation and CV the coefficient of variation. The maximum daily variation – experienced during the summer – ranges between $\pm 0.028^\circ$ for T8 and $\pm 0.075^\circ$ for T4, while the seasonal variations are about two times larger, ranging from $\pm 0.06^\circ$ for T8 and $\pm 0.14^\circ$ for T4.

Firstly, the qualitative comparison of Figures 7a, c, e, g and Figure 6a suggest that the fluctuations of the measured pier rotations approximately follow the temperature variations with a direct correlation: the rotations increase with the increase of temperature. However, the inspection of the time evolution of measured rotations (Figure 7a, c, e, g) reveals that between January 2021 and January 2023 – periods in which temperatures are similar – there is a clear accumulation of rotation, ranging from $+0.02^\circ$ for T3 to $+0.06^\circ$ for T8. In addition, as shown in Figures 7b, d, f, h, the rotation-temperature correlation exhibits various changes during the monitoring period, highlighting the presence of different anomalies.

Tubaldi et al. 2018 analyzed scour effects on a two-span masonry bridge with a novel modelling procedure. The research highlight that: (a) the effects of scouring-induced settlements are related with pier-foundation rotations in the opposite direction of the river flow; (b) the pier displacements start to increase beyond the values induced by vertical loads only after the maximum scour depth exceeds the foundation depth. The previous considerations can be related to the present work as follow:

- The tiltmeters of *Candia* bridge experienced an accumulation of rotation in the direction of the river flow; therefore, the phenomenon that caused the residual rotations should be related to a soil settlement of the downstream side. It is worth considering that the distribution of vertical loads is not symmetric: the railway track – decommissioned in 2010 – is on the upstream side while the roadway is on the downstream side, causing an asymmetric distribution of service loads.
- According to the blueprints of the different interventions (Figure 3) the foundations depth for all the piers should be equal to approximately 12 m (measured from the extrados of the foundation plinth). During an onsite survey a local measure of the scour hole depth on the upstream side of pier P05 was equal to 5.5 m. Consequently, the system should record the negative rotation residuals only if new important hydraulic events will occur.

5 CONCLUSIONS

The paper illustrates the first two years of results from the continuous monitoring system recently designed and installed on the historical masonry arch bridge of *Candia* over the Sesia River.

The main aim of the monitoring system is to detect scour-induced pier settlements. Variations in the structural behavior of the bridge are measured with a series of MEMS tiltmeters installed on top of the bridge piers. To account for the hydraulic actions, and for the scour in particular, a hydrometer, an echo-sounder, and two cameras were installed. It is worth noting that relevant flood events – which would induce scour – did not occur during the first two years of recording. Due to the limited length of the paper, only four tiltmeters are analyzed in the presented research (i.e. T3, T4, T7 and T8).

From the analysis of the recorded data, the following conclusions can be drawn:

- The tilt variations in the considered monitoring period range from -0.013° to $+0.148^\circ$.
- The outdoor temperature is confirmed as the dominant driver for the tilt variations; however, the rotation-temperature correlation changes different times during the monitoring period.
- Between January 2021 and January 2023 there is a clear accumulation of rotation, ranging from $+0.02^\circ$ for T3 to $+0.06^\circ$ for T8.
- The water elevation does not show any correlation with the pier rotations. However, the recorded water level variations are negligible in respect to the flood events experienced by the structure in October 2020, before the monitoring system installation.

The physical phenomenon that caused the identified permanent shifts in the rotation- temperature correlation is still not clear. To this purpose onsite visual inspections are periodically performed to detect the onset of possible cracks in the arches. However, it is worth considering that the detected anomalies are not directly correlated with scour-induced settlements: the scour action induces a rotational mechanism at the base of the piers on the upstream side, while the identified permanent rotations occurred (most likely) due to settlements in the downstream side.

Within the following months, new investigations are planned using drones, laser-scanner surveys and local measures of scour hole depth at central pier foundations.

ABSTRACT: This paper presents an overview of Global Navigation Satellite System (GNSS) technology for Structural Health Monitoring (SHM) of bridges. Peculiarities and requirements related to GNSS technology, installation features, data management, signal processing and significance of the results to ultimately support life-cycle frameworks for optimal management of critical bridge assets are discussed. A case study of GNSS-based SHM of an existing bridge is also presented. The investigated bridge is part of a group of pilot bridges equipped with different SHM systems within a project for risk-based bridge management and monitoring at regional scale. Results of the GNSS-based SHM of the bridge, with emphasis on data processing and correlation analysis, are presented for a monitoring time interval of about two years.

1 INTRODUCTION

Bridges are critical assets within infrastructure systems and their operability is fundamental to guarantee efficient mobility within transportation networks and suitable levels of system functionality and resilience (Biondini & Frangopol 2019). However, bridges are exposed to aging and deterioration processes and many countries are facing with the need of significant repair and maintenance activities on large stocks of existing bridges that are approaching the end of the service life, with huge social and economic impacts (ASCE 2021). It is therefore essential for bridge managers and owners to establish efficient management procedures to prioritize maintenance and rehabilitation interventions for a rational allocation of the available economic resources at infrastructure scale. To this purpose, Structural Health Monitoring (SHM) is an important support to bridge condition assessment procedures.

Among other SHM techniques, Global Navigation Satellite System (GNSS) technology allows to monitor three-dimensional displacements of structures and infrastructural facilities for long-term observations of the structural behavior and damage detection to inform the optimal maintenance and management planning. This paper provides a short overview of the GNSS-based monitoring systems of critical infrastructure systems, including peculiarities and requirements related to GNSS technology, installation features, data management, signal processing and results significance to ultimately support life-cycle frameworks for optimal management of bridge assets at infrastructure scale. An application to GNSS-based SHM of an existing bridge is also presented (Bianchi et al., 2021, 2022a).

The investigated bridge is part of a group of nine bridges selected as pilot case studies for the design and installation of different SHM systems (Borlenghi et al. 2021, Zani et al. 2021, Bianchi et al. 2022b, Capacci et al. 2022, D'Angelo et al. 2022) within a joint project established in Italy between Regione Lombardia and Politecnico di Milano for risk-based

management and monitoring of the regional roadway infrastructure (Biondini et. al. 2022, Limongelli et. al. 2022). The bridge is a seven-span structure with grillage deck made by pre-cast Prestressed Concrete (PC) I-beams and simply supported on each span and Reinforced Concrete (RC) piers. The bridge is crossing a river and two of the central spans have been instrumented with a GNSS-based SHM system aimed at assessing the long-term structural behavior. The system is complemented by a weather station to monitor the environmental conditions. As the bridge is exposed to hydraulic actions, a camera and a hydrometer have been integrated into the monitoring system for detecting floating debris in front of the piers and monitoring of water elevation, respectively (Bianchi et al. 2021). This paper focuses on the GNSS-based SHM system and presents some selected results over a monitoring time interval of about two years, with emphasis on data processing and correlation analysis.

2 GNSS-BASED MONITORING SYSTEMS

Permanent GNSS-based system is a well-known and reliable solution to monitor three-dimensional displacements of selected points located on structures, infrastructural facilities, and ground surface (DeLoach et al. 1989, Bock et al. 1990, Lovse et al. 1995). This system is based on the processing of GNSS satellite signals, received by ground antennas located permanently on the points of interest (Teunissen et al. 2017). There are various GNSS strategies available for signal analysis, broadly categorized into two groups: Absolute Positioning (AP) and Relative Positioning (RP). Precise Point Positioning (PPP) is an example of an AP strategy, where the position of a monitored point is calculated using only the data collected by its GNSS antenna (Zumberge et al. 1997). In contrast, RP is performed by computing the positions of a monitored point using its data together with those collected by one or more reference antennas. This approach is the most suited for SHM purposes, because it allows to compute displacements of points with the highest accuracy. In fact, accuracies in the estimation of displacements up to the millimeter level can be achieved over short baselines of a few kilometers or less (Caldera et al. 2022). Moreover, the advent of new generation and cost-effective GNSS hardware, along with improvements in data processing software, and the introduction of new satellite constellations and features, have made GNSS technology more accessible for permanent monitoring purposes. This development is significant since the use of traditional geodetic hardware was previously limited mainly by budgetary constraints (Caldera et al. 2016).

In using the RP approach for SHM purposes, it is essential to install one antenna on an unaffected point to serve as the reference monitoring point, also referred to as the Local Master (LM). The displacements of all other points are calculated with respect to this reference point. For instance, when monitoring the movements caused by a landslide on the piers of a bridge, LM should be positioned nearby, in a stable position outside the landslide area. The monitored points are then located on the piers. Notably, one advantageous feature of GNSS is that the LM position can be monitored with respect to a third-part Continuously Operating Reference Station (CORS) or a regional and/or national GNSS positioning services, if available. Although with slightly worse accuracy, this approach helps avoid a misinterpretation of the monitoring project resulting from apparent movements of the monitored points caused by LM movements. This is a unique characteristic of GNSS technology, that usually is not applicable when using other permanently installed instruments like robotic total station or Ground-Based Synthetic Aperture Radar (GBSAR).

Another characteristic of GNSS is that the displacements are provided in all weather conditions, including snowfall, fog, and heavy rain. In this way, the continuity of the monitoring is not compromised especially during weather events that can trigger anomalous structural responses. In contrast, optical instruments such as total stations or collimators may not be as well-suited for such bad weather monitoring periods.

A GNSS-based monitoring network provides straightforward and easy-to-interpret results, consisting of three-dimensional displacements of monitored points in a customized local reference system. For example, when dealing with a bridge, it is generally useful to define it with

an axis in the direction of the bridge, an axis perpendicular to this direction and the third one accordingly for the height component.

In addition, the antennas in a GNSS network do not require line-of-sight visibility, making it a flexible approach suitable for scenarios with artificial or natural obstructions, such as mountainous areas or urban environments, where the use of other monitoring techniques is difficult. It is also worth highlighting that GNSS processing is session-independent, which prevents errors from accumulating over time and avoids the slow drifts that may affect other instruments, such as MEMS-based sensors.

Although GNSS antennas collect raw GNSS data at a 1-5 second rate, computing GNSS displacements requires processing a larger temporal window to achieve higher accuracy (the rule is: the wider the window, the better the accuracy). For instance, hourly displacements are computed by processing data collected over a 1-hour window to achieve 2-3 mm accuracy, while daily displacements require processing data collected over a 24-hour window to achieve 1 mm accuracy or better. Due to latency, the technology may not be suitable for extreme real-time applications, such as collapses.

Moreover, accuracy depends on the distance of the monitoring point from the LM, with shorter baselines achieving millimeter-level accuracy, particularly within 1 km of distance (the rule is: the shorter the baseline, the better the accuracy).

Finally, the main GNSS requirement is that the antenna should have a good sky visibility, to be able to collect the signals coming from GNSS satellites. This is why GNSS is not applicable in scenarios with absent sky visibility (i.e., inside tunnels) and can suffer in urban canyons or in points with a lot of vegetation covering the sky.

3 CASE STUDY: ISOLA DOVARESE BRIDGE

The bridge considered as a case study in this paper is located in Isola Dovarese, a small town in Cremona province, Italy. This structure has a prominent role in the regional transportation systems since it overpasses the Oglio River, an affluent of the Po River, and guarantees the link with Mantova province. The two-lane SP11 road runs on the bridge, and it carries an average daily traffic of 4292 vehicles characterized by 24% of heavy trucks, up to 20 tons.

Figure 1. Map of Lombardy region with location of Isola Dovarese bridge.

Figure 2 shows a view of the bridge. Built in 1969, the Isola Dovarese bridge is a seven-span structure with total length of 107,00 m, including end spans of 8,40 m long and five central spans of 18,00 m. The bridge deck is simply supported on each span and is made by a grillage of precast PC I-beams with top RC slab and transversal stiffening RC beams. Geometry of the deck cross-section for one of the central spans is shown in Figure 3. Cast-in-situ RC piers are supported by pile foundations, each consisting of 35 circular piles 8 m deep, as shown in Figure 4.

Figure 2. View of the Isola Dovarese bridge.

Figure 3. Bridge deck cross-section.

Figure 4. Bridge foundation [m]: (a) vertical and (b) plan views.

4 DESIGN AND IMPLEMENTATION OF THE GNSS-BASED SHM SYSTEM

To support the design of the monitoring system, an in-depth study of the bridge condition state was developed. Historical technical drawings and reports were provided by Cremona Province. In 2018 an experimental campaign aimed at the mechanical characterization of material was performed by means of destructive and non-destructive tests. In 2019 a detailed visual inspection activity was carried to check information gathered from available design documents and verify the current bridge condition. Visual inspection highlighted a fair condition state of the bridge characterized by extensive portions of exposed corroded reinforcement of the piers. Over the same year, a rehabilitation intervention aimed at the steel bar passivation and restring of the concrete cover was performed. Finally, in order to optimally design the monitoring network, any operational constraints related to the installation, deployment and maintenance of the GNSS monitoring system were identified (e.g., power supply availability, sky visibility of the GNSS antennas for the selected monitoring points, on-field sensors configuration to optimize deployment costs, cable routing, among other features and requirements).

The preliminary studies and observations suggested to implement a GNSS-based SHM system for the observation of the long-term structural response of the bridge. The primary objective was to evaluate the behavior of the decks and piers by monitoring the absolute displacements of selected points. GeoGuard solution (<https://www.g-red.eu/geoguard>) was selected for the implementation of the GNSS monitoring of the bridge. It is a state-of-the-art end-to-end solution that provides IoT GNSS sensors, the Brevia GNSS processing software and a web interface to access the monitoring results. A network of ten GNSS antennas was strategically positioned at representative points on two of the five central spans of the bridge that spanned the river, as shown in Figure 5a. Additionally, the LM was installed on one of the abutments, which is not affected by the movements under investigation (Figure 5b). To ensure adequate coverage and minimize the number of GeoGuard Monitoring Units (GMU) required, 6 GMUs were employed. One of them was used in a single GNSS antenna configuration (LM) and the remaining five were used with a GNSS dual-antenna configuration. This approach allowed for optimal hardware costs since fewer GMUs, that connect two GNSS

antennas instead of only one, were deployed. Each GMU was powered by a photovoltaic panel. The data gathered are displayed on a system user interface with options for setting filtering parameters, a localization map, and highlighted displacements (Figure 5c). System notifications alert users when displacement thresholds are exceeded.

The GNSS-monitoring system was installed in July 2020. In order to reach the locations of interest on the piers, the installation was carried out by a team of rock climbers who rappelled beneath the bridge deck using a rope (Figure 6a). Steel supports were specifically designed to anchor the GNSS antennas to the bridge, ensuring optimum sky visibility. The supports were carefully sized to ensure their displacements are at least an order of magnitude lower than those that can be measured with GNSS signals from the satellite constellation (Figure 6b).

Figure 5. GNSS-based SHM system. (a) Location of ten GNSS antennas on both bridge deck and piers. (b) Plan view with location of antennas, LM, and reference system. (c) System user interface.

Figure 6. (a) Installation phase (b) GeoGuard Monitoring Units and steel supports.

The GNSS system steadily recorded from October 2020. The GNSS antennas collected raw satellite data at a rate of 0.2 Hz, which were subsequently sent to a dedicated processing cloud for elaboration over various time intervals ranging from 1 to 24 hours. The resulting solutions were displayed on the system user interface (Figure 5c). The monitoring system has been dismissed in July 2022, at the end of the planned period of investigation of this specific pilot study within the project for risk-based management and monitoring of the regional roadway infrastructure.

5 RESULTS OF DATA PROCESSING AND CORRELATION ANALYSIS

Time histories for longitudinal, transversal, and vertical displacement can be accessed in the system user interface for each point over different time intervals. Figure 7a shows the longitudinal, transversal, and vertical displacements with respect to the LM for one monitored pier point (ID11) over the entire monitoring period of almost two-year, using 24-hour time interval, along with a spline interpolation of the results. Figure 7b represents the hourly movements of the same point (ID11) for a representative period of two weeks. In general, recorded bridge movements were below 5 mm and primarily resulted from seasonal variations during the observation period, especially in the transversal direction.

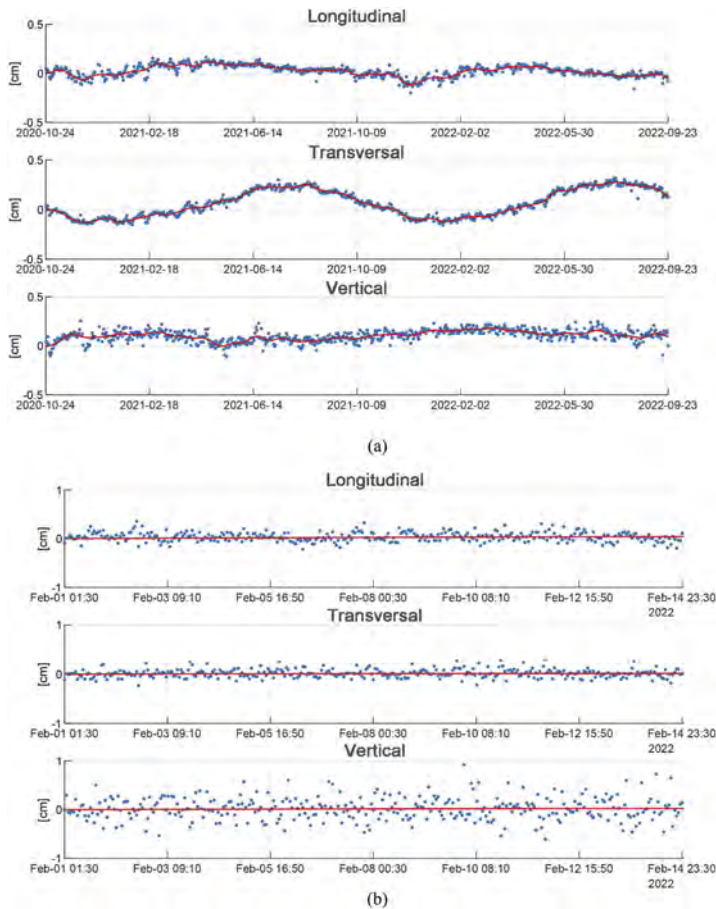

Figure 7. Longitudinal, transversal, vertical displacement components of antenna ID11 with respect to the LM (blue dots), compared with a spline interpolation of the dataset (red line): (a) Daily displacements for a monitoring period of about two years; (b) Hourly displacements for a monitoring period of two weeks.

A multiple linear regression model has been implemented to filter the effects of temperature variations on the computed displacements. Environmental temperature data has been collected by the GNSS receivers that recorded also their internal temperature at 20 minutes interval. The decorrelation of GNSS signals has been performed based on the daily average internal temperature of the reference receiver ID01. The residual displacement time-series have been then computed after decorrelation for longitudinal, transversal, and vertical displacement components of the ID11 receiver using a 24-hour time interval, as shown in

Figure 8. The decorrelated time series exhibit a stable trend over time, confirming that the detected periodic movements are mainly due to the thermal effects affecting the structure.

Figure 8. Temperature-decorrelated daily longitudinal, transversal, vertical displacement components of antenna ID11 with respect to the LM (blue dots) compared with a spline interpolation of the dataset (red line) and temperature time-history (green dots) for a monitoring period of about two years.

6 CONCLUSIONS

An overview of GNSS technology for permanent displacement monitoring, including its benefits and limitations, as well as some recommendations for optimal use, has been provided. An innovative GNSS-based SHM system utilizing new generation, cost-effective receivers, with application to an existing bridge, has been also presented. The SHM system designed and implemented on the investigated bridge has been active for two years as a pilot case study of a project for risk-based management and monitoring of a roadway infrastructure system at regional scale. The SHM system was intended to monitor the short-term and long-term structural behavior of the bridge, providing support for early detection of anomalous movements and maintenance planning.

The results show that the monitored points displacement accuracy is less than a millimeter for daily solutions and approximately one millimeter for hourly solutions. Analysis revealed limited bridge movements, with periodical displacements less than 5 mm primarily caused by thermal effects. Decorrelation of the measures from temperature confirms that the movements result from thermal effects on the structure and that the bridge exhibits stable behavior over time. Based on these results, it can be concluded that the good performance of the GNSS SHM system is suitable to facilitate a timely identification of damage initiation and propagation and support the bridge condition assessment to inform a proper planning of maintenance and rehabilitation interventions.

ACKNOWLEDGEMENTS

The research activities presented in this paper, including the design, installation, implementation, and management of the GNSS-based SHM system of the Isola Dovarese bridge, have been funded by a research agreement between Regione Lombardia and Politecnico di Milano for the development of criteria and guidelines for maintenance and management of the regional road infrastructure network.

Remote monitoring of a concrete bridge through InSAR and GNSS measurements

O. Lasri, P.F. Giordano & M. Previtali

Politecnico di Milano, Milan, Italy

M.P. Limongelli

Lund Technical University, Lund, Sweden

ABSTRACT: Structural Health Monitoring (SHM) can support decision makers in structural integrity management by providing information about occurrence of damage and its evolution in time. Nevertheless, the adoption of traditional SHM systems, e.g., vibration-based SHM systems employing accelerometers, involves laborious installations and maintenance of the instrumentation (e.g., sensors, cables, acquisition systems), which is typically directly installed on the monitored structure. Recently, thanks to new Synthetic Aperture Radar missions, remote sensing provides promising methodology capable of monitoring infrastructure assets. This paper investigates the use of Multi-Temporal Interferometric Synthetic Aperture Radar (MT-InSAR) processing as a suitable tool for monitoring the structural health of bridges. The full interferometry processing chain is based on Sentinel-1 radar data and a combination of open-source routines. The feasibility of the remote monitoring strategy is assessed on a concrete bridge on which GNSS receivers are installed. To validate the methodology, MT-InSAR-derived time histories are verified against the GNSS-derived ones.

1 INTRODUCTION

Bridges and viaducts play a key role in transportation networks. An anomaly or a collapse of these structures could compromise the economy of entire communities (Clemente 2020). Due to the ageing of these infrastructures and the evolution of traffic demand, structural degradation is becoming a serious matter of concern. Furthermore, climate change is exacerbating the frequency and intensity of extreme flood events as flood-induced scour is among the main causes of the riverine bridge collapse (Wardhana 2003). According to this, a proper plan of management and security becomes crucial to avoid wasting resources. Structural Health Monitoring (SHM) systems provide a valid resource to decision-makers and nowadays there is a wide choice of instrumentations and methods (Karbhari 2009). In several geoscience fields, Synthetic Aperture Radar Interferometry (InSAR) is already a well-established monitoring technology and enables the study of geophysical processes (Milillo 2019a, Davalillo 2014). Recently, due to the development of Multi-Temporal InSAR (MT-InSAR) techniques and the increase in the temporal and spatial resolution of SAR products, InSAR technology can provide measurements of deformations of human artefacts like bridges (Giordano 2022, Milillo 2019b, Selvakumaran 2020). Selvakumaran et al. (2018), by processing 48 TerraSAR-X scenes over the Tadcaster Bridge (England), highlight the reliability of MT-InSAR to detect movements in the region of the bridge where the collapse occurred due to the scouring action. As aforementioned, several works in the literature highlight the potential for this technology to provide measurements of assets that are difficult to access for conventional SHM systems. Nevertheless, while traditional monitoring methods provide only limited and point-like

displacement data, MT-InSAR strategies facilitate coverage of wide areas with a high frequency, saving time and money (Milillo 2019b, Huang 2017, Qin 2019). Furthermore, due to the availability of SAR images relevant to past periods, MT-InSAR strategies allow for studying the past behaviour of the infrastructure. Nowadays, establishing the link between MT-InSAR outcomes in terms of displacement time histories and the structural health of bridges remains a key topic of investigation. Besides, one of the main barriers to the wide use of MT-InSAR is the scarce accessibility of relevant software and hardware tools. Most MT-InSAR software packages are patented, only available through expensive licenses, and they perform a black box processing preventing a clear understanding of all steps.

In this paper, a workflow based on SNAP-StaMPS open-source tools (Mancini 2021) is adopted to perform a PSInSAR analysis using Sentinel 1 data. Sentinel Application Platform (SNAP) is a software distributed by ESA which incorporates utilities for interferogram generation. The interferograms are the input for the free Stanford Method for Persistent Scatterers (StaMPS) package which generates the displacement time series and the displacement velocity estimated over the analysed PSs. The MT-InSAR workflow is run on ordinary hardware (a 16 GB RAM laptop) and tested on a real case study. A bridge monitored by a GNSS system is selected to carry out a comparison between MT-InSAR and GNSS results.

In the following sections, the GNSS (Section 2.1) and InSAR (Section 2.2) techniques are presented highlighting the basic concepts of each technique. The case study, a concrete bridge crossing the Oglio river, Northern Italy, is described in Section 3.1. A description of the application of the MT-InSAR and the GNSS techniques to the case of the study is presented in Sections 3.2 and 3.3, respectively. Section 3.4 reports the discussion and comparison of the results of the two techniques.

2 REMOTE MONITORING THROUGH GPS AND INSAR

2.1 GNSS

In the 1970s, the U.S. Department of Defense began developing satellite navigation systems, commissioning the design and construction of the first satellite, NAVSTAR GPS (Navigation Satellite Timing and Ranging Global Positioning System), which was launched in 1978. A Global Navigation Satellite System (GNSS) is composed of three segments: the control segment, the space segment, and the user segment. The control segment is composed of a network of monitoring stations and ground antennas that assure the proper operation of other segments. The GNSS satellites represent the space segment: satellites orbiting the Earth at a height of more than 20,000 kilometres and broadcasting an electromagnetic signal that contains ranging codes and navigation data. This data allows users (user segment) to compute both the travel time from the satellite to the receiver and the satellite coordinates at any epoch. A GNSS receiver is required to properly use the information contained in a GNSS satellite signal. The main elements of a generic GNSS receiver are an antenna and a microprocessor which allow for analyzing the information contained in the GNSS signal and obtaining the position of the antenna phase centre in a geocentric reference system (i.e., for GPS, in the WGS84 reference system). GNSS signals can be processed and analyzed in several ways with different levels of accuracy (Roberts 2015). In the civil engineering context, numerous applications replicate to some extent the traditional nature of static engineering surveying, such as coordinating control points and monitoring deformation. In the last decade, also dynamic applications and deflection monitoring of large structures have been proposed (Roberts 2015, Xinpeng 2021). Nowadays, the static methods based on Differential-GNSS strategies allow for a high-precision positioning providing coordinates of ground locations with millimetric precision, both in the horizontal and in the vertical components (Correa-Muños 2018).

2.2 InSAR

In addition to the GNSS constellations that provide navigation and geo-referencing services, there are other constellations of satellites for Earth observation purposes. These satellites orbit nearly 800 kilometres from Earth and fall into two broad categories: optical satellites and radar

(Radio Detection And Ranging) satellites. Radar satellites are active devices that irradiate electromagnetic waves at different bands of the microwave domain towards a certain area of interest or target. A fraction of the signal is backscattered and returned to the sensor, where amplitude and phase are recorded. The amplitude of the backscattered signal depends on the amount of electromagnetic field backscattered towards the satellite which depends on acquisition geometry, radar carrier frequency, radar resolution, wavelength and polarization, size of the scatterers, surface roughness and orientation. Typically, signals backscattered from exposed rocks and urban areas show strong amplitudes, whereas smooth flat surfaces (like water basins) show low amplitude. Instead, the phase of the signal is affected by the target-sensor distance, thereby it is proportional to surface topography, ground displacement along Line Of Sight (LOS), atmospheric pressure, water vapour and soil moisture (Cusson 2018). In the ideal case where the phase alteration is correlated only to the target-sensor distance, analyzing phase variations among two radar images of the same area of interest can inform about the area movement. Based on this concept, Differential Interferometric Synthetic Aperture Radar (DInSAR) techniques allow for obtaining the deformation rate of the target by analyzing radar images acquired over the same area at different times. A simple phase difference between two images cannot properly assess the target displacement, mainly because the phase change is perturbed by some decorrelations due to variations in atmospheric properties and by errors in satellite orbit and surface elevation determination (Ferretti 2001, Hooper 2012). The phase change among two images which generate the i -th interferogram can be described as follows (Ferretti 2001):

$$\Delta\varphi_i = \frac{4\pi}{\lambda} \Delta r_{Ti} + \Delta\alpha_i + \Delta n_i + \varepsilon_{topo,i} \quad (1)$$

where Δr_{Ti} is the phase change due to the movement in the LOS direction, $\Delta\alpha_i$ is the atmospheric phase contribution, Δn_i is the decorrelation noise and $\varepsilon_{topo,i}$ is the phase contribution due to possible errors in the Digital Elevation Model (DEM). According to Equation (1), the main challenge of any DInSAR technique is to assess the phase change Δr_{Ti} . An essential condition to accomplish this separation is to analyze pixels characterized by small Δn_i typically related to two types of reflectors: those where the response to the radar is dominated by a strong reflecting object and is constant over time (Permanent Scatterer, PS) and those where the response also remains constant but due to different small scattering objects (Distributed Scatterers, DSs). The first pioneer work based on Permanent Scatterer Interferometry (PSInSAR) was proposed by Ferretti et al. (2001). This strategy uses an algorithm patented and developed by a spin-off company founded by Politecnico di Milano and called Tele-Rilevamento Europa, TRE (Ferretti 2001). In the last few years, other strategies have been developed, such as the Small Baseline Subset (SBAS) technique (Crosetto, 2016) and the SqueeSAR algorithm (an extension of the PSInSAR) that allows for using both PSs and DSs (Ferretti 2011). Some validations of PSInSAR highlighted that, in ideal conditions and by exploiting high-resolution data, sub-millimeter accuracy can be obtained (Ferretti 2007). However, these performances cannot be generalized to all possible scenarios since the accuracy strictly depends on the quality of images and processing strategy. Another important PSInSAR contribution was given by Hooper et al. who proposed a novel PS selection method based on the use of phase characteristics and suitable to find low-amplitude natural targets with phase stability that cannot be identified by amplitude-based algorithms (Hooper 2004). This work originated one of the most widely used PSInSAR software packages, StaMPS (Hooper & Zebker 2007, Hooper 2008). Nowadays, due to data availability and some freely available SAR services, such as European Space Agency (ESA) services and Sentinel 1 images, PSInSAR processing becomes more accessible, and it can be run also by open-source processing chain (Mancini 2021).

3 CASE OF STUDY

3.1 *The Isola Dovarese bridge*

The case study is a concrete bridge situated in Isola Dovarese, a municipality of the Cremona province, Italy (Bianchi et al. 2022a, Bianchi et al. 2022b, Limongelli et al. 2022). The Isola

Dovarese bridge, shown in Figure 1, was built in 1969 and has a total length of 107 m including two lateral spans of 8.40 m and five central spans of 18 m. By overpassing the Oglio River, an affluent of the Po River, this bridge provides a key asset for local and regional traffic. The bridge deck is made of precast prestressed concrete I-beams with top concrete slab and transversal stiffening beams. The deck is simply supported on cast-in-situ reinforced concrete piers with a hexagonal profile. In 1979, to tackle a general scour of the riverbed, the foundations were strengthened. Recently, an extensive visual inspection activity of the river-bridge system highlighted the good condition state of the bridge but a massive woody debris accumulation in front of a couple of piers.

Figure 1. The Isola Dovarese bridge.

3.2 Processing of GNSS data

The GNSS-based SHM system designed for the Isola Dovarese Bridge consists of ten receivers mounted on the deck and the piers of two central spans (Bianchi et al. 2022a, Bianchi et al. 2022b). Each slave receiver is anchored through a special steel support guaranteeing the continuous visibility of the satellite constellation. Satellite observations are made by the receiver every 5 seconds and sent in almost real-time to the cloud where they are processed with two different rates: hourly and daily position solutions. The software used by the survey company is the BREVA GNSS Software, developed by GRd, which allows higher estimation accuracy because it is specifically made to process low-receiver data. With an accuracy of up to 1 mm for 24-hour time intervals, the GNSS monitoring system provides the relative vertical displacement with respect to the master receiver ID01, at ten key points of the bridge (Figure 2).

In previous works, findings indicate limited movements of the bridge with small upward vertical displacements likely related to water level variations (Bianchi et al. 2022b). It was also observed that the bridge's displacements are primarily caused by thermal effects and water level variations (Bianchi et al. 2022a). In this study, data relevant to the receivers mounted on deck are considered, namely ID04 and ID08 mounted on the eastern side of the bridge, and ID05 and ID09 mounted on the western side (Figure 2). Figure 3b shows the GNSS time histories of the vertical displacement in the observation period (October 2020 – August 2022). All GNSS receivers anchored on the deck show similar vertical displacement and present a clear seasonal trend. Figure 3b displays the mean value of the four vertical displacement time series.

3.3 Processing of InSAR data

In this analysis, 18 scenes covering the period from October 2020 to December 2021 and freely provided by the European Space Agency (ESA) (through Sentinel-1 satellite mission), were processed. The 18 Single Look Complex (SLC) images, acquired through the Interferometric Wide (IW) swath mode with a geometric resolution of approximately 5 m x 20 m, were processed through an open-source workflow (based on SNAP and STAMPS software) run in

Figure 2. GNSS monitoring: (a) planimetric location of GNSS receivers; receivers mounted on the (b) West and (c) East sides of the bridge.

Figure 3. (a) GNSS vertical displacement of the deck receivers; (b) GNSS average vertical displacement of the deck receivers.

a consumer-grade laptop with 16 GB of RAM. To compare the outcomes of the PSInSAR and the GNSS analyses (Figure 3), an estimation of the vertical component of the InSAR LOS displacement is required. By assuming negligible planimetric displacements of the deck, an estimation of the vertical displacement is obtained as follows:

$$d_{UP} \sim \cos \tilde{\theta} d_{LOS} \quad (2)$$

where θ is the incidence angle between the LOS displacement d_{LOS} and the vertical direction, $\tilde{\theta}$ is its average value, and d_{UP} is the vertical component of the LOS displacement. In Figure 4, the available PSs in the area of interest are shown Figure 4a. The InSAR time series, in terms of LOS displacement and vertical displacement, are reported in Figures 4b and c, respectively.

3.4 Comparison of results

To compare InSAR and GNSS results, a zone idealization is carried out (Figure 5). The planar displacement of the PSs observable in Figures 4 and 5 may be due to the low accuracy of the Digital Terrain Model (DTM) used for topographic phase removal (Equation 1).

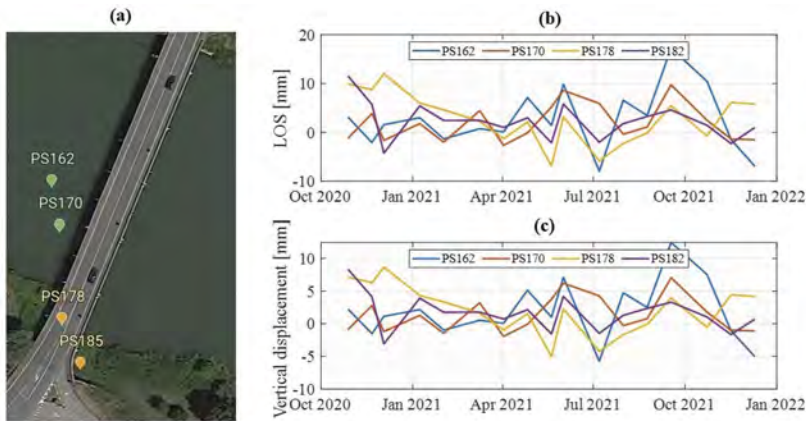

Figure 4. The PSs in the area of interest: (a) location of PSs; (b) LOS displacement of the PSs; (c) vertical components of the LOS displacements of the PSs.

According to PSs location, it is reasonable to assume that PS162 and PS170 belong to the deck portion already monitored through the GNSS system (Z1 in Figure 5b). Similarly, PS178 and PS185 are assumed to belong to the zone of GNSS master receiver ID01 (Z2 in Figure 5b). The InSAR displacement of the two zones (Z1 and Z2) are estimated each as the average displacement of the PSs in the zone.

Figure 5. (a) The GNSS receivers; (b) Zone idealizations.

The GNSS system provides the relative vertical displacement of the deck (Z1) with respect to the master receiver ID01 (Z2). To make results comparable, the InSAR relative displacement of the deck is obtained by subtracting the Z1 displacement from the Z2 displacement. As shown in Figure 6a, the time histories of the vertical component of the displacements computed with the two sets of data are consistent. A downward movement of the bridge in the warmest period (July 2021) is highlighted by both time histories. Even if the entity of InSAR displacement is quite different (Figure 6a), the trend of the deck movement is consistent with the GNSS evidence. The correlation analysis between the GNSS and the InSAR displacement shows a high consistency corresponding to a Pearson Correlation Coefficient (R in Figure 6b) of $\sim 71\%$ (Figure 6b).

Figure 6. (a) Relative displacement of zone Z1 with respect to zone Z2: InSAR vs GNSS; (b) Correlation study among InSAR and GNSS output.

4 CONCLUSION

One of the main barriers to the use of InSAR processing is the scarce accessibility of relevant software and hardware tools as well as satellite images. In this study, a consumer-grade laptop (16 GB RAM), open-source software and low-resolution radar images (freely available) are used. The results are then validated against the GNSS-derived time histories. Despite the limited number (18) of low-resolution images and the short bridge length, some PSs have been identified in the study area. The GNSS and InSAR vertical components of the bridge displacements present different values; however, the two-displacement series shows a trend correlation. This study presents preliminary evidence suggesting a possible correlation between GNSS and InSAR vertical components. However, due to the limited number of images and potential confounding variables, it is not possible to draw definitive conclusions. Further studies utilizing a larger number of radar images and higher resolution images are necessary to thoroughly assess the PSInSAR workflow based on open-source software. Future works will aim to boost the PSInSAR processing by using high-resolution images to increase the number of PSs, as well as utilizing both ascending and descending images to improve the accuracy of vertical displacement measurements.

ACKNOWLEDGEMENTS

The installation and the management of the GNSS system on the Dovarese bridge were funded by Regione Lombardia–Politecnico di Milano agreement, 2018–2020. This study was partially funded by the Lombardy Region and by the Italian Civil Protection Department within the project RELUIS 2022–2024 WP6 “Structural Health Monitoring and Satellite Data”.

ABSTRACT: The progressive aging of civil infrastructures makes it essential to develop managerial tools and instrument for planning maintenance activities. As public entities, typically in charge of the management of infrastructures, have limited resources, it is crucial to define clear prioritization criteria. Addressing this need, this work introduces the usage of a functional priority index for ranking infrastructures on the basis of the impact of their closure. The impact is expressed in terms of induced travel delay for people due to path detour. To estimate this delay an analytical strategy is introduced and applied to assess the priority index on a sample of 290 bridges in Lombardy. Relevant information are gathered integrating two data sources providing information on the transportation network and on the travel demand, i.e. road network data and Origin Destination matrices. The results of this application show that the method enables the identification of the most critical infrastructures and the detection, for each bridge closure, of the most impacted areas of the region and the most impacted hours of the day.

1 INTRODUCTION

Maintaining civil infrastructures and ensuring their functioning is a crucial problem for those entities that are responsible for their management as these structures are naturally subject to both obsolescence and deterioration caused by the effects of natural hazards, operational and environmental conditions (Wang, Zhang, & Li 2017). Among civil infrastructures, bridges are crucial elements characterized by high vulnerability in terms of both natural and man-made risk. The impact of aging and natural deterioration processes could be detrimental to the infrastructure system performances under service loadings or extreme events, such as earthquakes. Moreover, considering their relevance for the transportation network system, they often represent bottlenecks as they are designed to cross obstacles as water flows or highways. Hence, the detour of these infrastructures could result in substantial extra travelling time (Biondini & Frangopol 2016). Given the importance of infrastructures for transport network users, the reliability of nodes of the network represents a key element for evaluating the quality of transport. In order to allow infrastructure reliability and safety for transportation network management purpose, maintenance activities are necessary. In the current economic context, resources available to public entities, that are typically in charge of the management of these infrastructures, are limited, making crucial the identification of some criteria for planning maintenance activities based on clear priorities (Frangopol & Liu 2007).

The evaluation of the priority of intervention and the development of an adequate maintenance planning is a complex task, because it requires to take into considerations many different variables characterizing the level of risk, that range from the age of the infrastructure, its technical characteristics, the operating conditions, and also the consequences of the unavailability

of the infrastructure (Arena, Bianchi, Biondini, Torti, & Vantini 2020). It is worth to highlight that concepts of vulnerability, risks and reliability are still not uniquely defined (see Jenelius et al., 2006 and Pan et al., 2021 for discussions on the definitions of these concepts). In this study, we adopted the definitions provided by Simmons et al., in 2017. The authors identified three different components influencing the level of risk: i) hazard, ii) vulnerability and iii) exposure (Simmons, Corbane, Menoni, Schneiderbauer & Zschau 2017). The first component refers to detrimental events that may cause losses or damage, such as long-term gradual stress events and shock events (Hughes & Healy 2014). Vulnerability refers to the likelihood of occurrence of disruptive events. Exposure is related to the consequences of the hazard on the social community; hence it requires the assessment of the impact on the societal needs. Loss of functionality or temporary closure of an infrastructure is an example of the exposure of the system.

In this paper, we will focus on the system functionality and, more specifically, on the consequence of the unavailability of the infrastructure in terms of impact on users. More in details, we will propose a methodology to evaluate the impact of a bridge closure in connection to its function of maintaining a proper connectivity between all areas of a region, allowing users to move from one point to another and reach their destinations. Despite concepts of vulnerability, reliability and risks do not have widely accepted definitions, authors agree on the usage of the increased cost of travel (measured through time, distance or money) for the users as a reasonable measure of the reduced function of the network (Jenelius et al., 2006). Therefore, this work will assess the impact of the closure of a bridge on the users in terms of delays induced on traveling people. First, a global index, measuring total travel cost in terms of travel time will be presented; second, the variability of the additional travel time along time and space will be evaluated, in order to understand within day variability and identify areas that are most affected by the closure of an infrastructure.

The rest of the manuscript is organized as follows. In Section 2 we introduce a brief review of related literature. The sample and the data sources follow in Section 3. In Section 4, we present the methodology used to evaluate the impact of a bridge closure. In Section 5 we report the results of the analysis on the selected sample. In section 7 we illustrate our conclusions and some of the potential future research paths.

2 RELATED RESEARCH

The assessment of transport failure has recently drawn the attention of both scholars and practitioners. The increasing vulnerability of infrastructures due to climate change (Schneider, Semenov, Patwardhan, Burton, Magadza & Oppenheimer 2007) and the recent collapses of transportation infrastructures, contributed to the enhancement of the relevance of the topic. Several measures of impact assessment have been introduced in the literature, looking at different indicators, such as generalized costs, user costs, efficiency measures, network topological features and congestion effects (Jenelius, Petersen, & Mattsson 2006, Taylor, Sekhar, & D'Este 2006, Stein, Young, Trent, & Pearson 1999). Jafino, Kwakkel and Verbraeck in 2020 reviewed the different measures that have been introduced in prior studies for ranking transport infrastructures on the basis of the consequences deriving from the closure of the infrastructure. Referred to as criticality analysis measures, seventeen measures have been described and compared. A first set of metrics are built on the concept of generalized travel costs derived from an infrastructure disruption. Total travel cost can be assessed only in terms of additional travel time or can be weighted according to the travel demand. A second set of measures is based on the concept of accessibility of the geographical area. In these cases, the impact is assessed in terms of reduced accessibility characterizing the area. Authors often used the Hansen's index for measuring accessibility index (Taylor et al., 2006; Hernández & Gómez, 2011; Taylor & D'Este, 2007). The third set of criticality measures are built for measuring connectivity among different places. A decrease in connectivity implies that some places of the network become unreachable from other places of the network, due to disruption of

single or multiple infrastructures. However, it is worth to highlight that these measures are highly sensitive to inaccuracies in the network data (Jeulieus et al., 2006).

These approaches allow to estimate, in different ways, the consequences of the closure of an infrastructure, generally evaluating the impact of a disruption, in terms of travel costs for the users, accessibility or connectivity of the area. However, all these approaches do not address one element crucial to the understanding of the consequence of a damaged network: the temporal variability of the effects. Since daily traffic profiles are characterized by a large within-day variability, analyzing mobility flows between an origin and a destination during the 24 hours is fundamental to investigate the consequences of closing a transportation infrastructure over the day. In this paper, the object of the analysis is the additional travel cost considering both the induced delay and the travel demand on the network. Regarding the former we represented the induced delay by means of a point belonging to a space of continuous functions defined on the time domain $(0,24)$. As for the latter, the spatial aggregation is the network wide aggregation. This approach allows to estimate the impact of the closure of one infrastructure on the overall transportation network. The impact will be assessed considering the additional delay for the trips of the whole set of origin destination pairs, hence capturing inter-dependencies among elements of the transportation infrastructure (Scott, Novak, Aultman-Hall, & Guo, 2006).

3 DATA

3.1 *The sample*

In this manuscript, for supporting the development of the methodology, we will focus on a reduced sample of road infrastructures, made of 290 bridges, selected in accordance with regional authorities from Lombardy Region. This area is characterized by a large and heterogeneous territory with an area of 23,844 square kilometers and a resident population of about 10 million inhabitants. The road network of Lombardy counts 70,000 km of roads. On this transport network there are almost 10,000 infrastructures, including bridges, tunnels and overpasses. The sample will allow us to test the methodology, understand potential criticisms and limitations before extending the approach to all the 10,000 infrastructures of the road network. The sample includes the most relevant bridges located in the twelve provinces which the region is divided into: Bergamo (BG), Brescia (BS), Milano (CMM), Como (CO), Cremona (CR), Lecco (LC), Lodi (LO), Monza Brianza (MB), Mantova (MN), Pavia (PV), Sondrio (SO) and Varese (VA). Each bridge is identified by an identification code of the road network section, the province it belongs to, and its GPS position.

3.2 *The datasets*

As follows we describe the datasets available for developing the project: the regional road network model and the regional OD matrices, both provided by the regional government of Lombardy. The road network model is a spatial network made of about 37,000 nodes and 82,000 directional edges, which model all types of roads of the real network. Nodes represent the intersections between two or more roads, whereas edges are segments of road between two intersections. For each directed edge of the network, an identification code of the road section, the type of the road (e.g. highway, regional, provincial, local) the length (km), the typical travel time (hour) and the velocity without traffic (km/h) are known.

Regione Lombardia, the administrative body of Lombardy, publishes every few years an OD matrix, containing the number of trips across different mobility areas during a typical working day. OD matrix has been estimated starting from survey data on travel behavior and merging this information with data related to the socioeconomics features of the different areas of the region. The OD matrices of Lombardy contain the number of hourly trips between 1,450 internal mobility areas. Trips are classified according to eight modalities (car driver, car passenger, motorbike, bus, train, bike, foot and others) and five purposes (work,

study, business, occasional and return home). For the scope of our analyses, we aggregated all trips with respect to their purpose and we considered only those of people moving with a motor vehicle on the road, hence aggregating the modalities car driver, car passenger, motorbike and bus, while disregarding the trips related to the other modalities. In this way, we obtain a total of almost 12.4 million of trips distributed over the day, accounting for almost 75% of the total trips contained in the matrix. For the scope of our analyses, we integrated our two sources of information, the road network data model and the OD matrices.

4 METHODOLOGY

In this section, we illustrate the main methodological choices made in this work in connection to the selection of the indicator used to measure the impact and the methodology for the assessment of the impact for the selected bridges. Specifically, we propose an approach that relies on prior literature focusing on the evaluation of consequences of the closure of the infrastructure in terms of additional travel cost, but enriches prior research, considering how this delay changes over time and space, i.e. time and space variability.

4.1 *The calculation of the global index*

The first step of analysis is the so-called traffic assignment step and consists in the estimation, for each trip, of the route on the road network. First, for each mobility area, its centroid is associated to the closest node of the road network data model. The assignment of the centroid is computed by minimizing the Euclidean distance in kilometers between the two. Next, for every OD couple the shortest time path $O \rightarrow D$ on the road network data model is found by means of the Dijkstra's algorithm (Newman 2018). Through this algorithm, the number of trips passing through it is computed. This latter is obtained by summing over all OD pairs whose shortest connecting path goes through e . The relevant indicator could either be the flow function describing the number of trips passing from e at any time t of the day:

$$f_e(t) = \sum_{(O,D):e \in O \rightarrow D} f_{(O,D)}(t - t_{(O,e)}) \quad (1)$$

where $f_{(O,D)}(t)$ is a standard function indicating the number of travelers departing from O at time t and heading at D , $t_{(O,e)}$ indicates the travel time necessary for reaching the midpoint of edge e starting from O , and $f_{(O,D)}(t - t_{(O,e)})$ the number of travelers at time t on edge e departed from O and heading at D . Coherently with previous studies we define an index on the basis of the importance of bridges in maintaining a proper connectivity between all origin and destination couples of the OD matrices in order to measure the impact of the bridge closure (Berdica & Mattsson 2007, Sullivan, Aultman-Hall, & Novak 2009, Rupi, Bernardi, Rossi, & Danesi 2015). We evaluate the effects of a bridge closure on the movement of people, by estimating an index expressed in terms of extra person-hours traveled. To measure the consequences of the closure of a bridge belonging to the edge e of the road network data model, we virtually remove the edge e from the network. Then, for every OD pair we measure the increase in travel time of the shortest time path connecting O and D after the removal of the edge e . Hence, to obtain the extra traveled person-hours we simply multiply this extra travel time by the number of trips associated to edge e :

$$I_e = \sum_{(O,D):e \in O \rightarrow D} \left[t_{(O,D)}^- - t_{(O,D)} \right] \int f_{(O,D)}(t - t_{(O,e)}) dt. \quad (2)$$

I_e is measured in person-hours and indicates the cumulative extra-time, spent on road in the typical working day by people traveling within the area, due to the closure of a bridge belonging to the edge e .

4.2 Spatial-temporal indexes

The global index I_e has the benefit of providing an estimate of the total impact of a bridge closure but does not consider the spatio-temporal variability, i.e. how this impact spreads during the hours of the day and across geographical areas of the region. To this purpose, we provide a novel two-way approach exploring both the temporal and the spatial dimensions. From a temporal perspective, we estimate how the impact of a bridge closure changes along time. To this end, we follow the same argument used above to build the global impact index I_e , but separately for each time $t \rightarrow [0, 24]$. Hence, to measure along time the impact of the closure of a bridge belonging to the edge e , we measure the temporal impact function

$$i_e(t) = \sum_{(O,D):e \in O \rightarrow D} \left[t_{(O,D)}^{-e} - t_{(O,D)} \right] f_{(O,D)}(t - t_{(O,e)}) \quad (3)$$

From a spatial perspective, we want to estimate how the impact of a bridge closure is distributed across the region, namely the most impacted areas of Lombardy. Hence, we apply again the same argument used above for the construction of I_e (2) but now we fix the origins or the destinations:

$$I_e^O = \sum_{D:e \in O \rightarrow D} \left[t_{(O,D)}^{-e} - t_{(O,D)} \right] \int f_{(O,D)}(t - t_{(O,e)}) dt \quad (4)$$

And

$$I_e^D = \sum_{O:e \in O \rightarrow D} \left[t_{(O,D)}^{-e} - t_{(O,D)} \right] \int f_{(O,D)}(t - t_{(O,e)}) dt. \quad (5)$$

5 RESULTS

5.1 Analysis of the global index

Figure 1 shows the value of I_e for each bridge. In this, each bridge is colored according to its global impact in terms of person-hours per day using a log-scale. Looking at the Figure 1, it

Figure 1. Distribution of the global impact (person-hours) of the 290 bridges for each province.

appears that the most critical bridges are located in the north side of the region in the provinces of Bergamo and Brescia, which are mainly in a mountain area with a sparse road network made of few main roads mostly located at the valley bottom with very time-consuming alternative paths. Moreover, the values of I_e in the different provinces follow a strongly right-skewed distribution characterized by few bridges with high values and many bridges with low values.

5.2 Analysis of the spatio-temporal effects

We now investigate the impact of each bridge closure by its temporal and spatial effect during the day using the functions $i_e(t)$. An illustrative example related to a one-way bridge is reported in Figure 2 which shows the spatio-temporal effects due to the closure of the most critical afternoon-peak bridge: on top left, the geographical position of the selected bridge is highlighted; in the top right we show the temporal impact function of its closure; at the bottom, the spatial impacts on both origins (left) and destinations (right) are reported. Results reveal a clear difference between the impacted origins, all of them located west of the bridge, and the impacted destinations, all of them located east of the bridge. This is due to the fact that the selected bridge is on a one-way road going from west to east. Looking at the temporal impact function, the afternoon peak appears to be higher than the morning peak, due to the fact that people moving on this road are likely to be mostly commuters coming back home after going west to work in the morning.

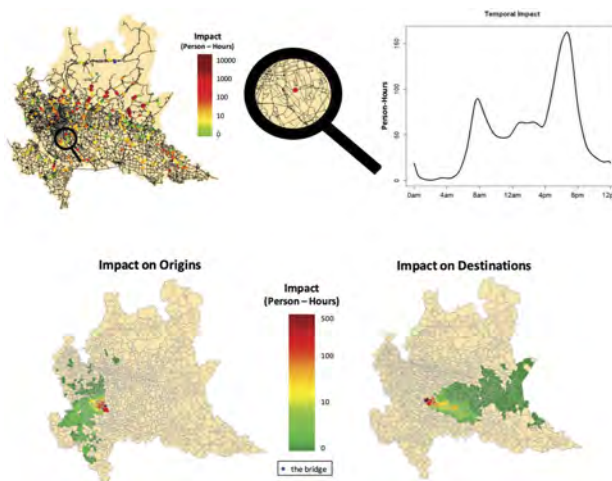

Figure 2. Top: the selected bridge on the road network of Lombardy and its temporal impact function. Bottom: the spatial impacts of the bridge closure, highlighted with a blue point, on both origins and destinations.

6 MONETARY QUANTIFICATION

Delays caused by the unavailability of an infrastructure can be expressed in monetary terms through the Value of Time (VOT), also called the value of travel time savings. The Value of Time is defined as “*the monetary value attached to the possibility of save a determined amount of travel time*” (Zamparini & Reggiani 2007). In other words, the VOT can be seen as willingness-to-pay indicator (Hess 2005), that links time to the cost that individuals have to face in order to accomplish their mobility activities (Zamparini & Reggiani 2007). The VOT is of central interest in transportation research, because it is one of the most relevant components in

the evaluation of mobility and infrastructural investments and it is a very important parameter for explaining travel behavior and modal choices.

Obviously, the VOT is not unique as it depends significantly on the characteristics of the individual, the means of transport and, more generally, the conditions in which a trip is made. In the literature, very different VOTs, estimated on the basis of the various studies are available. One relevant example is the meta-analysis provided by (Wardman, Chintakayala, & de Jong 2016), that covers more than 3100 monetary valuations deriving from 389 studies conducted in Europe between 1963 and 2011. The valuation of VOT also refer to the Italian transportation context, in line with the geographical scope of this analysis. Moreover, the study introduces different segmentation factors including travelling mode and travelling purpose, hence enabling the estimation of the VOT for people using the car as transportation mean.

7 CONCLUSIONS

This work proposes a methodology aimed to assess the functional priority of one critical infrastructure in a transport network, bridges. Specifically, we focused on the exposure risk addressing the impact of the closure of the infrastructure in connection to its function of ensuring the accessibility of an area, connecting different geographical areas. From a methodological point of view, we provided different levels of impact assessments. First and foremost, we introduced the global index for estimating the impact of a bridge closure, hence providing a means for ranking infrastructures.

Secondly, we explored both temporal and spatial variability. From a temporal point of view, we evaluated how the impact of a bridge closure varies according to the hour of the day. From a spatial point of view, we evaluated how the impact of a bridge closure is distributed over origins and destinations of trips. The analysis of the temporal results allows to identify the most critical bridges of the region and to highlight for each bridge the most impacting hours of the day. These results can be used by decision makers for communication or planning purpose. Regarding the former, decision makers can anticipate the damage on the users caused by maintenance interventions on road infrastructures. Moreover, the information on the temporal variability of the consequences of bridge closure can be instrumental in optimizing the road maintenance schedule. The impact of bridge closure is also assessed in economic terms. Using the concept of the value of time (VOT), the hours of delay for the users have been translated into monetary value, hence highlighting the socio-economic cost for one hour of infrastructure disruption for people using the examined infrastructure.

The developed methodology has proved to be scalable and repeatable, thus providing possibility for application on a larger set of bridges or to other contexts. Specifically, the proposed methodology can be applied to other geographical areas and extended to any other transportation infrastructure that can be modeled as a directional edge, such as tunnels and overpasses. In conclusion, we want to highlight some of the potential paths for future research. First, the proposed methodology focuses on one specific impact dimension, that is the impact on users. This dimension has to be complemented in order to consider the broader socio-economic impact, including the impact on the economic activities operating in the area related to supply chain management (Bell, 2000; Smith et al., 2003). The proposed approach could also be enhanced by considering elastic demand function. Further research could also be directed towards the consideration of other maintenance strategies, such as the reduced capacity due to closure of one of the two road directions.

ABSTRACT: The analysis of the bond properties of plain rebars to concrete is of great significance for the identification and strengthening of historic buildings. This study investigates the bonding mechanism of plain rebars to concrete through theoretical analysis of pull-out tests. The normal stress at the contact interface due to the difference in Poisson's ratio between reinforcement and concrete and the resulting bond stress are quantified through the combination of elastic mechanics and fracture mechanics. The energy release rate is introduced in the analysis to elucidate that when the crack extension force is greater than the frictional resistance at the debonding interface, the bond-slip curve will drop precipitously after reaching the peak point (cliff type), and conversely the curve decreases slowly under abrasive wear (slope type). According to the theory, the bond-slip curve of plain rebar and concrete can be predicted.

1 INTRODUCTION

Plain rebars are used as reinforcement in historic buildings; therefore, the analysis of the bond properties of plain rebars to concrete has positive implications for the identification and strengthening of historic buildings (Cairns 2021, Mo & Chan 1996, Robuschi et al. 2021, Xu et al. 2019). The study of the bond performance of reinforcement and concrete has been accompanied by the application of reinforced concrete structures, however, due to the complexity of the factors and the change of the impact with different stress states, the research on the bond properties is still limited. The current research methods for bond behavior mainly include experimental studies, numerical analysis and analytical solutions. Among the experimental studies, axial pull-out tests (Darwin et al. 1996, Gao et al. 2018) and beam tests (Gao et al. 2022, Mo & Chan 1996) are the main test types where the concrete strength and component including the addition of various fibers such as CF, SF, PF, etc., the confining pressure effect such as stirrups and concrete cover depth, the longitudinal reinforcement such as the surface shape, diameter and anchorage length are the key factors; and the magnitude of the load, the strain and slip of the reinforcement are the main physical quantities measured in the tests owing to limitations of measurements.

Compared to the large number of experimental studies on the bond properties, the research on the bonding mechanism at the interface of reinforcement and concrete need to be further studied. The consensus on the bond mechanism is chemical adhesion at the interface at the

initial stage, and with the emergence of relative slip at the interface of reinforcement and concrete, mechanical interlock force and frictional force come into play. In terms of numerical analysis, the bond behavior is simulated by adding zero-thickness tangential and normal spring elements (Ngo & Scordelis 1967, Erfanian & Elwi 2019, fib 2022), or indirectly by adjusting the constitutive relations of reinforcement and concrete (Liu et al. 2020, Feng et al. 2018, Jendele & Cervenka 2006). For the study of the mechanical behavior of the bond mechanism, some researchers considered it as an axisymmetric plane strain problem based on elastic mechanics, and solved the bond stress in the limit state by using the elastic mechanical characteristics of thick-walled cylinders (Tepfers & De Lorenzis 2003, Gao et al. 2019). Ouyang & Shah (1994) analyzed the bond-slip properties of reinforcement and concrete based on fracture mechanics, and the damage caused by concrete cracking was considered to correct the bond-slip model (Phan et al. 2015).

The interfacial interaction between plain rebar and concrete is a dynamic process of bonding, damage and frictional state with the change of loadings. In this paper, considering the bond mechanism of reinforcement and concrete, the normal stress at the interface due to the difference in Poisson’s ratio between reinforcement and concrete and the resulting bond stress are quantified through the combination of elastic mechanics and fracture mechanics. By comparing the crack extension force and the frictional resistance at the debonding interface, the bond-slip curve can be judged as a cliff type with a precipitous drop after reaching the peak point and a slope type with a slow decrease under abrasive wear.

2 BASIC ASSUMPTIONS OF PULL-OUT SPECIMENS

The pull-out test of plain rebars in concrete matrix is the main test method to study the bond properties between plain rebars and concrete. A detailed theoretical analysis of the pull-out process of the rebar helps to correctly understand the bonding behavior. In most of the pull-out tests of plain rebars, the fixed end of the matrix (i.e. concrete) is at the loading end (Figure 1a). Since the bond properties of plain rebars and concrete is mechanically identical to that of fiber and concrete, Gao et al (1988) analyzed the debonding process of fiber and matrix based on elasticity and fracture mechanics, as shown in Figure 1b where the loading end is free and the other end of the matrix is fixed. In addition, there are some assumptions were used: the stress distribution of interface between fiber and matrix are uniform; the stress at the fiber-matrix bonding interface away from the crack tip is ignored; and the stress distribution length at the crack tip is ignored. Comparing Figure 1a and 1b, it found that the boundary conditions of the two are not consistent. Therefore, based on the study by Gao et al (1988), the theoretical equations are derived in this paper using the boundary conditions shown in Figure 1a, which conform to the boundary conditions of pull-out test of plain rebars.

The initial bond length of the plain rebar is s . Assuming a debonding zone of length l already exists between the fiber and matrix, the length of the bonded region is $s-l$. The radius of the plain rebar is r , its elastic modulus and Poisson’s ratio are E_f and ν_f , respectively; and the radius of the matrix is R , its elastic modulus and Poisson’s ratio are E_m and ν_m , respectively.

Figure 1. Specimen of pull-out test: (a) plain rebar; (b) fiber.

3 INTERFACIAL NORMAL STRESS

3.1 Basic equations

For a cylindrical pull-out specimen with the plain rebar embedded on the center line, the stress state of the plain rebar in the axial plane with its surrounding concrete can be simplified to an axisymmetric plane strain problem. Polar coordinates are used for computational simplicity in which the distance from the origin is ρ and the angle is φ , and the expressions for each stress component when the body force is ignored are:

$$\begin{cases} \sigma_\rho = \frac{A}{\rho^2} + B(1 + 2 \ln \rho) + 2C \\ \sigma_\varphi = -\frac{A}{\rho^2} + B(3 + 2 \ln \rho) + 2C \\ \tau_{\rho\varphi} = 0 \end{cases} \quad (1)$$

where σ_ρ = radial stress; σ_φ = hoop stress; and $\tau_{\rho\varphi}$ = tangential stress.

The expressions for each displacement component are:

$$\begin{cases} u_\rho = -\frac{1+\nu}{E} \left[\frac{A}{\rho} - 2B\rho(\ln \rho - 1) - (1 - 4\nu)B\rho - 2(1 - 2\nu)C\rho \right] \\ u_\varphi = \frac{4B\rho\varphi(1-\nu^2)}{E} \end{cases} \quad (2)$$

where u_ρ = radial displacement and u_φ = hoop displacement.

Based on the assumption of complete contact between the plain rebar and concrete at the initial stage, which means the plain rebar should not detach from its surrounding concrete at the normal direction, and there is no relative sliding at the tangential direction, the normal stresses of the plain rebar and the concrete at the interface ($\rho = r$) are equal, and the tangential stresses are also equal. In addition, the normal and tangential displacements of the plain rebar and the concrete at the contact interface are also equal, respectively.

3.2 Stress and displacement of the plain rebar and concrete

According to the boundary conditions, the stress and displacement components of the plain rebar can be expressed respectively as:

$$\sigma_{\rho,f} = \sigma_{\varphi,f} = q^* \quad (3)$$

$$u_{\rho,f} = \frac{1 + \nu_f}{E_f} (1 - 2\nu_f)q^*\rho \quad (4)$$

Similarly, the stress and displacement components of concrete can be expressed respectively as:

$$\sigma_{\rho,m} = \frac{\frac{R^2}{\rho^2} - 1}{\frac{R^2}{r^2} - 1} q^* \quad (5)$$

$$\sigma_{\varphi,m} = -\frac{\frac{R^2}{\rho^2} + 1}{\frac{R^2}{r^2} - 1} q^* \quad (6)$$

$$u_{\rho,m} = -\frac{1}{E_m} \left[\frac{1 + \nu_m}{\rho} \frac{r^2 R^2 q^*}{R^2 - r^2} + (1 + 2\nu_m)(1 - 2\nu_m) \frac{r^2 q^* \rho}{R^2 - r^2} \right] \quad (7)$$

3.3 Interfacial normal stress

Based on Equation 4 for the radial displacement of the plain rebar and Equation 7 for the radial displacement of the concrete, combined with the assumption of complete contact, an equation is obtained:

$$\alpha(1 - \nu_f)q^* - 2\alpha\nu_f^2q^* = -(1 + 2\gamma + \nu_m)q^* + 2\gamma\nu_m^2q^* \quad (8)$$

where $\alpha = E_m/E_f$ and $\gamma = r^2/(R^2-r^2)$.

In the plane strain problem, the out-of-plane strain can be ignored, so the axial strain of the plain rebar and concrete can be considered equal to zero, and the relationship between the out-of-plane axial stress and the in-plane stress of the plain rebar and concrete are:

$$\begin{cases} \sigma_f = \nu_f(\sigma_{\rho,f} + \sigma_{\varphi,f}) \\ \sigma_m = \nu_f(\sigma_{\rho,m} + \sigma_{\varphi,m}) \end{cases} \quad (9)$$

By substituting Equations 3, 5 and 6 into Equation 9, the relationship between the axial stress of the plain rebar and concrete and the normal stress q^* at the interface can be obtained:

$$\begin{cases} \sigma_f = 2\nu_fq^* \\ \sigma_m = -2\gamma\nu_mq^* \end{cases} \quad (10)$$

The expression of normal stress at the interface can be obtained by substituting the above Equation 10 into Equation 8:

$$q^* = \frac{\alpha\nu_f\sigma_f - \nu_m\sigma_m}{\alpha(1 - \nu_f) + 1 + \nu_m + 2\gamma} \quad (11)$$

According to the assumption that the stress distribution of both plain rebar and concrete is uniform in the cross section, the axial stress of plain rebar and concrete can be obtained directly by dividing their axial cross-sectional resultant forces (T_m , T_f) by the cross-sectional area.

The relationship between the normal stress q^* at the interface and the axial cross-sectional resultant forces (T_m , T_f) can be obtained:

$$q^* = \frac{1}{\pi r^2} \left[\frac{\alpha\nu_f T_f - \gamma\nu_m T_m}{\alpha(1 - \nu_f) + 1 + \nu_m + 2\gamma} \right] \quad (12)$$

4 SOLUTION OF THE TENSILE FORCE AND DISPLACEMENT

Take a micro-element dy in the debonding zone for analysis, the rebar is under tension, one end of the tension is T_f and the other end is $T_f + dT_f$; the concrete is under compression, one end of the resultant force is T_m and the other end is $T_m + dT_m$, the interface between concrete and rebar has a tangential stress τ_s . The equilibrium equation of the micro-element can be established:

$$\frac{dT_m}{dy} = -\frac{dT_f}{dy} = 2\pi r\tau_s \quad (13)$$

The interfacial tangential stress τ_s is generated by friction, so it can be obtained from the following equation:

$$\tau_s = \mu(q_0 - q^*) \quad (14)$$

where μ = friction factor at debonding interface.

Considering the tension force of the rebar is P at the loading end, and the compression force of the concrete is $-P$, the resultant forces of the rebar and the concrete can be obtained by substituting Equations 12 and 14 into Equation 13:

$$T_m = (\tilde{P} - P)e^{\lambda y} - \tilde{P} \quad (15)$$

$$T_f = -T_m \quad (16)$$

where

$$\tilde{P} = \frac{\pi r^2 q_0}{\alpha \nu_f + \gamma \nu_m} [\alpha(1 - \nu_f) + 1 + \nu_m + 2\gamma] \quad (17)$$

$$\lambda = \frac{2\mu}{r} \left[\frac{\alpha \nu_f + \gamma \nu_m}{\alpha(1 - \nu_f) + 1 + \nu_m + 2\gamma} \right] \quad (18)$$

According to Equation 17, when $P = \tilde{P}$, the resultant force of concrete section is equal to $-\tilde{P}$ ($T_m \equiv -\tilde{P}$), the resultant force of rebar section is equal to \tilde{P} ($T_f \equiv \tilde{P}$), the resultant force in the debonding zone does not vary with the change of cross-sectional position, which indicates that there is no tangential stress at the debonding interface, and the Poisson effect at this moment has completely offset the initial normal stress q_0 . therefore, \tilde{P} is considered as the characteristic tension force value that can completely offset the initial pressure at the interface caused by the Poisson effect.

The strains of the rebar and concrete in the debonding zone can be calculated by the following equations:

$$\frac{du_f}{dy} = \frac{T_f}{\pi r^2 E_f} - \frac{2\nu_f}{E_f} q^* \quad (19)$$

$$\frac{du_m}{dy} = \frac{\gamma T_m}{\pi r^2 E_m} + \frac{2\nu_m}{E_m} \gamma q^* \quad (20)$$

where u_f = the axial displacement of the rebar and u_m = the axial displacement of the concrete.

The axial displacement of the rebar and concrete can be obtained by substituting Equation 18 into Equation 19 and Equation 15 into Equation 20 and integrating. The displacement difference between the rebar and concrete can be obtained thereby:

$$\begin{aligned} \nu(y) &= |u_f(y) - u_m(y)| \\ &= \left[\frac{1 - 2k\nu_f}{\pi r^2 E_f} + \frac{\gamma(1 - 2k\nu_m)}{\pi r^2 E_m} \right] \cdot \left[\tilde{P}(l - y) - (\tilde{P} - P) \frac{1}{\lambda} (e^{\lambda l} - e^{\lambda y}) \right] \end{aligned} \quad (21)$$

where

$$k = \frac{\alpha \nu_f + \gamma \nu_m}{\alpha(1 - \nu_f) + 1 + \nu_m + 2\gamma} \quad (22)$$

5 LOAD-DISPLACEMENT CURVE OF PULL-OUT SPECIMENS

5.1 Threshold value of initial normal stress

Assuming the cracked body is always in the elastic state, the equilibrium equation can be established according to the energy conservation:

$$\int_{S_T} \mathbf{T} d\mathbf{u} ds = \zeta dA + \int_{S_T} \tau_s d\mathbf{v} ds + dU \quad (23)$$

where ζ = the energy release rate and U = the elastic strain energy.

The left side of Equation 23 is the mechanical work done by external forces during crack extension, the first term on the right side of Equation 23 is the energy consumed by crack extension, the second term is the energy consumed by interface friction, and the third term is the change in the elastic strain energy of the system. The elastic strain energy U of the cracked body can be directly expressed as:

$$dU = \frac{1}{2} \int_{S_T} \mathbf{T} d\mathbf{u} ds - \frac{1}{2} \int_{S_T} \tau_s d\mathbf{v} ds \quad (24)$$

The energy release rate can be obtained by substituting Equation 24 into Equation 23:

$$\zeta = \frac{1}{2} \frac{\partial}{\partial A} \int_{S_T} \mathbf{T} d\mathbf{u} ds - \frac{1}{2} \frac{\partial}{\partial A} \int_{S_T} \tau_s d\mathbf{v} ds \quad (25)$$

The pull-out specimen can be regarded as a special case of the cracked body, the external force \mathbf{T} is the loading end tension force P , and its displacement $-u_f(0)$ is the displacement of rebar at the loading end, and the minus sign here means the displacement direction of rebar at the loading end is opposite to the positive direction of the coordinate system. The relative slip between the crack surfaces is the displacement difference $v(y)$ between the rebar and concrete, the crack area A is the area of the debonding zone ($2\pi rl$), and the micro surface area ds is $2\pi r dy$. When the above-mentioned parameter is substituted into Equation 25, the energy release rate can be obtained.

$$\zeta = \frac{-P \partial u_f(0)}{4\pi r \partial l} - \frac{1}{2} \int_0^l \tau_s \frac{\partial v(y)}{\partial l} dy \quad (26)$$

The following equation can be obtained by substituting Equation 21 into Equation 26:

$$4\pi^2 r^3 E_f \zeta = (1 + \beta)(1 - 2k\nu_f)(P - Q)^2 \quad (27)$$

where

$$Q = T_m(l) + P = (\tilde{P} - P)(e^{\lambda l} - 1) \quad (28)$$

According to Equation 27, the expression of the tension force P at the loading end can be obtained:

$$P = 2\pi r^{3/2} \left[\frac{E_f \zeta}{(1 + \beta)(1 - 2k\nu_f)} \right]^{1/2} + Q \quad (29)$$

When there is no friction force at the interface of the debonding zone, i.e. $\mu = 0$, then the coefficient $\lambda = 0$ according to Equation 18, and followed by $Q = 0$ according to Equation 28. Therefore, only the first term remains on the right side of Equation 29, and P is defined as P_0 at this moment:

$$P_0 = 2\pi r^{3/2} \left[\frac{E_f \zeta}{(1 + \beta)(1 - 2k\nu_f)} \right]^{1/2} \quad (30)$$

P_0 indicates the tensile force without friction at the debonding interface, which is the force required for crack expansion. The tension force P can be simplified by substituting Equations 28 and 30 into Equation 29:

$$P = \tilde{P} - (\tilde{P} - P_0)/e^{\lambda l} \quad (31)$$

Threshold value of initial normal stress can be obtained according to Equation 31 if $P_0 = \tilde{P}$.

5.2 Typical load-displacement curves

There are two typical load-displacement curves during the pull-out process of plain rebar (Figure 2). When the initial normal stress q_0 is greater than the threshold value of initial normal stress q_{th} , the peak of the load-displacement curve of the pull-out test occurs when the rebar is about to be completely debonding from concrete ($y = s$), and before that, the force $P(s)$ at the loading end can be expressed as:

$$P(s) = \tilde{P}(1 - e^{-\lambda s}) + P_0 e^{-\lambda s} \quad (32)$$

Figure 2. Two typical load-displacement curves: (a) slope type; (b) cliff type.

After complete debonding, there is only friction force at the interface between plain rebar and concrete, defining the tension force at this moment as:

$$P^*(s) = \tilde{P}(1 - e^{-\lambda s}) \quad (33)$$

When the difference between $P(s)$ and $P^*(s)$ is small, which is reflected in the load-displacement curve as a slow decline after reaching the peak (Figure 2a), and this curve is named as slope type curve. When $P(s) > P^*(s)$, the load-displacement curve will drop precipitously to $P^*(s)$ after reaching the peak (Figure 2b), this curve is named as cliff type curve.

6 CONCLUSIONS

This study analysis the reasons for two typical types load-displacement curves during the pull-out tests of plain rebar. The following conclusions were determined:

- The normal stress at the interface due to the difference in Poisson's ratio between plain rebar and concrete is quantified, and the expression of the characteristic tension force that can completely offset the initial pressure at the interface caused by the Poisson effect is derived.

- The energy release rate is introduced to elaborate the load-displacement curve. The reaction force at the loading end is divided into two parts, the friction force at the debonding interface and the crack extension force at the crack tip. When the crack extension force is greater than the frictional force, the curve, named as cliff type curve, shows a steep drop after reaching the peak point; on the contrary, the curve belongs to slope type and decreases slowly after reaching the peak under abrasive wear.
- The verification of the theory is not presented due to the page limit, and the service-life of the bond due to the corrosion of plain rebar needs further study.

Residual bearing capacity of corrosion-damaged reinforced concrete columns with annular cross sections

Y. Jiang, Hua-Peng Chen & W.B. Li

School of Transportation Engineering, East China Jiaotong University, Nanchang, Jiangxi, China

ABSTRACT: This paper aims to analyze the residual bearing capacity of the corroded reinforced concrete (RC) columns with annular cross sections to provide useful information for maintenance and repair. The materials and structural strength degradation models are constructed by investigating the deterioration mechanism of the corroded structures. Based on these deterioration models, the analytical models are presented to evaluate the residual bearing capacity of the corrosion-damaged annular columns. Then, the moment-axial force (M-N) interaction diagram is plotted to analyze the influences of various corrosion levels and different loading conditions on the residual bearing capacity of the corroded columns. Finally, a numerical example is applied to verify the effectiveness of the presented method. The obtained results conclude that the proposed approach can be used to quantitatively analyze the bearing capacity of the corroded annular RC columns, which grows as the compression zone area develops but decreases as the rebar corrosion level increases.

1 INTRODUCTION

The annular RC columns are often employed in bridges and port engineering structures as load-bearing components (Wang et al. 2019), prone to be attacked by aggressive environments. Research (Huang et al. 2020) shows that chloride-induced steel corrosion is one of the most critical factors leading to the degradation of RC structures. Recently, many analytical methods have been established to predict the residual strength of the corroded RC structures (Wang & Liu 2009, Jnaid & Aboutaha 2016, Chen 2018, Chen & Nepal 2018, Chen et al. 2022). Jnaid & Aboutaha (2016) developed the finite element modelling and analytical models to estimate the residual flexural strength of the corroded RC beams by accounting for the deterioration of rebar bond strength and the reduction of the rebar capacity. Moreover, the residual bearing capacity models of the corroded RC columns were constructed by analyzing the degradation of materials and structural strength by Chen et al. (2022). However, the existing studies mainly focus on analyzing the effects of rebar corrosion on RC beams and columns with rectangle cross-sections, and there are very limited investigations for the corroded annular columns.

This paper presents an analytical method to assess the performance deterioration of the corroded annular RC columns. By investigating the degradation of materials and structural strength, the residual bearing capacity models are constructed to evaluate the effects of corrosion levels and loading conditions on the residual capacity of the corroded annular columns.

2 DEGRADATION MODELS OF MATERIALS AND STRUCTURAL STRENGTH

2.1 Rebar corrosion

Chloride-induced steel reinforcement corrosion changes the yield strength and the cross-sectional area of rebar (Du et al. 2005). Generally, the corrosion level can be defined as the mass ratio between the corroded rebar and the original rebar, then expressed as the residual area ratio of the rebar cross-section. Therefore, the residual bearing capacity of the corroded rebar F_{sx} can be written as

$$F_{sx} = f_{yc} A_{sc} \quad (1)$$

where f_{yc} is the residual yield strength of the corrosion-damaged rebar, calculated from $f_{yc} = (1-\gamma X)f_{y0}$, in which f_{y0} is the yield strength of the uncorroded rebar, and γ is the influence coefficient of nonuniform corrosion obtained from experimental results (Du et al. 2005), taken as 0.5; A_{sc} is the residual area of the corroded rebar, estimated from $A_{sc} = (1-X)A_{s0}$, in which A_{s0} is the cross-sectional area of the original rebar.

2.2 Concrete cracking and spalling

The rust expansion exerts the hoop stress on the surrounding concrete. When the tensile stress of the concrete cannot bear the hoop stress from the rust expansion, the cracks generate at the rebar bond interface and then propagate to the concrete cover surface with rebar corrosion growth. Based on the thick-walled cylinder model, the crack width at the concrete surface w_c can be expressed as a function of the radial displacement at the bond interface \bar{u}_b (Chen 2018), namely

$$w_c(X) = \frac{W_u G_f}{\eta_1 f_t} \left(\frac{E_c}{f_t} \bar{u}_b(X) - \eta_2 \right) \quad (2)$$

where the radial displacement \bar{u}_b depends on the rebar volume expansion factor ζ_r , calculated from $\bar{u}_b = (\zeta_r - 1)D_b X/4$; D_b is the original diameter of rebar; G_f , f_t , and E_c are the fracture energy, tensile stress and elastic modulus of the intact concrete, respectively; W_u is the normalized value of the ultimate cohesive crack width; and coefficients η_1 and η_2 can be defined as

$$\eta_1 = (l_0 - R_b)(1 - R_{sc}(l_0 - R_{sc})\delta(R_{sc}, R_b)); \quad \eta_2 = R_b + R_{sc}(l_0 - R_b)(l_0 - R_{sc})\delta(R_{sc}, R_b) \quad (3)$$

where l_0 is the material constant estimated from $l_0 = n_c W_u l_{ch}/(2\pi)$, in which l_{ch} is characteristic length given by $l_{ch} = E_c G_f / f_t^2$; n_c is the total number of concrete cracks, $n_c \approx 2\pi R_{sc} / L_c$; L_c is the spacing of crack bands; R_{sc} is the distance from the centroid of the rebar to the concrete cover surface. Moreover, $\delta(R_{sc}, R_b)$ is the crack width coefficient associated with the radial distance between rebar surface R_b and concrete cover surface R_{sc} , expressed as

$$\delta(R_{sc}, R_b) = \frac{R_{sc} - R_b}{l_0(l_0 - R_b)(l_0 - R_{sc})} + \frac{1}{l_0^2} \ln \frac{R_{sc}|l_0 - R_b|}{R_b|l_0 - R_{sc}|} \quad (4)$$

After the cracks connect each other, the concrete cover peels off. This paper simplifies the irregular spalling of the concrete cover as uniformly damaged. Then, the residual outer radius r_c of the annular columns can be evaluated from the crack width at the concrete surface (Chen et al. 2022), as

$$r_c = r - y_c = r - \min(cw/T, c) \quad (5)$$

where r is the outer radius of the intact concrete cross-section; y_c is the average loss of the concrete cover thickness due to corrosion; w is the cumulated crack width, given by $w = w_c n_c$; c is the thickness of the concrete cover; T is the coefficient estimated from the load capacity tests of the corroded RC columns (Hui et al. 1997), taken here as $T = 0.003\text{m}$.

2.3 Rebar bond strength deterioration

Corrosion-induced rebar deformation and concrete cracking seriously weaken the rebar bond strength and affect the load transmission, leading to reduction of the bearing capacity of RC structures. Research indicated that the residual bond strength ratio ζ is strongly related to the crack width propagation at the concrete cover surface (Chen 2018), namely

$$\zeta(X) = \tau_{ux}(X)/\tau_{i0} = 1/(1 + \lambda_\eta w(X)/D_b) \quad (6)$$

where τ_{i0} and τ_{ux} are the bond strength of the rebar before and after corrosion, respectively; the coefficient λ_η is determined by the fitting of experimental results (Cairns et al. 2006), taken as $\lambda_\eta = 15\text{-}20$. When the rebar anchorage failure occurs before yielding failure, the bearing capacity of the corroded rebar F_{ux} is determined by the residual bond strength τ_{ux} (Fib 2010), expressed as

$$F_{ux} = \pi D_{bc} l_a \tau_{ux}(X) \quad (7)$$

where the residual diameter of the corroded rebar D_{bc} is given by $D_{bc} = (1-X)^{0.5}D_b$, and l_a is the rebar anchorage length. Then, the residual strength f_{ux} of the corroded rebar after bond failure can be calculated from $f_{ux} = 4\tau_{ux}l_a/D_{bc}$. Moreover, the deterioration of the rebar bond strength can also lead to the deformation incompatibility between the rebar and the concrete. Here, by introducing the bond strength interpolation factor G_d (Wang & Liu 2009), the stress-strain relationship between the rebar and the concrete under severe corrosion can be compatible, defined as

$$G_d = \frac{\varepsilon_{sx}}{\varepsilon_{sc}} = \frac{2(\varepsilon_{end} - \varepsilon_{start})Y_{xc}}{\tan(17.5^\circ)\varepsilon_{end}L_{ub}} \quad (8)$$

where ε_{sx} and ε_{sc} are the strain of the rebar and the surrounding concrete, respectively; the initial and final strains ε_{end} and ε_{start} are taken as 0.006 and 0.002, respectively; Y_{xc} is the residual height of the concrete compression zone; and L_{ub} is the unbonded length of the tensile rebar.

2.4 Buckling of corroded compressive rebar

For the corroded columns bearing the vertical loads, the longitudinal rebar has the potential failure of buckling due to the stirrup corrosion and the spalling of the concrete cover. The critical buckling stress f_{cr} of the longitude rebar can be estimated from the improved Euler's formula, as

$$f_{cr} = \pi^2 E_s I_{sc} / (L_p^2 A_{sc}) \quad (9)$$

where E_s is the elastic modulus of the steel bars; I_{sc} is the inertia moment of the corroded rebar calculated from $I_{sc} = \pi D_{bc}^4 / 64$; and the laterally unbraced length L_p of the longitude rebar is given as $L_p = n_r s$, in which s is the stirrup spacing; and $(n_r + 1)$ is the number of the failure stirrups.

3 MODELS FOR RESIDUAL BEARING CAPACITY

3.1 Basic assumption of reinforcement

The bearing capacity of the corrosion-damaged RC columns consists of the strength contributions of both concrete and steel reinforcement. For an annular concrete column with steel bars exceeding six ($n_s \geq 6$) and uniformly distributed arrangement, the stress state of the rebar can be analyzed by converting the independent steel bars into an equivalent steel ring (Wang et al. 2019) with an area of A_{nsc} and a thickness of t_{sc} , as shown in Figure 1, given as

$$A_{nsc} = \sum_{i=1}^{n_s} A_{sc}(i); \quad t_{sc} = A_{nsc} / (2\pi r_s) \quad (10)$$

where A_{sc} is the residual area of one of the corroded steel bars in the concrete section, given by Equation 1; and r_s is the distance from the centroid of the rebar to the center of the ring section.

Figure 1. Basic assumption of reinforcement: (a) independent steel bars; (b) the equivalent steel ring.

3.2 Parameter definition

The typical annular cross-section of RC columns is plotted in Figure 2(a), where r_1 and r are the inner and outer radii of the ring section, respectively; r_c is the residual external radius of the ring section after corrosion damage. When $r_1/r \geq 0.5$, the area A_Y of the concrete compression zone can be approximately taken as the area of the ring section formed by a central angle of $2\pi\theta_{ac}$, where θ_{ac} is defined as $\theta_{ac} = A_Y/A_{cc}$, in which A_{cc} is the residual area of the corrosion-damaged

concrete cross-section $A_{cc} = \pi(r_c^2 - r_l^2)$, and A_{c0} is the intact concrete section area $A_{c0} = \pi(r^2 - r_l^2)$. Moreover, the area ratio θ_c is calculated from $\theta_c = A_y/A_{cc}$, in which A_y represents the equivalent compressive zone area of the concrete; the area ratio θ_{ccs} is taken as $\theta_{ccs} = A_{cs}/A_{nsc}$; A_{cs} is the area of the rebar failure under compression; θ_{cts} is equal to $1 - \theta'_{cts}$ in which the area ratio θ'_{cts} is defined as $\theta'_{cts} = A_{ts}/A_{nsc}$; and A_{ts} is the area of the rebar failure in tension.

In Figure 2(b), h_{0c} is the effective height of the damaged concrete cross-section, given by $h_{0c} = r_c + r_s$; the ratio ζ_c is defined as $\zeta_c = Y_{xc}/h_{0c}$, in which Y_{xc} is the residual compression zone height of the concrete column calculated from $Y_{xc} = y_{xc}/\beta_1$; y_{xc} is the equivalent compression zone height of the concrete; β_1 is the reduction factor of the concrete compression zone height; y_c is the average loss of the height in the concrete compression zone, estimated from Equation 5; ε_{cu} is the ultimate compressive strain of the concrete; ε_c is the concrete compressive strain corresponding to y_{xc} ; ε_{acs} is the failure strain of the corroded compressive rebar; ε_{ats} is the failure strain of the corroded tensile rebar; y_{acs} and Y_{acs} are the distances from the position of the strain ε_{acs} to the X -axis and the neutral axis, respectively; y_{ats} and Y_{ats} are the distances from the position of the strain ε_{ats} to the X -axis and the neutral axis, respectively.

The relationship between ζ_c and parameters θ_c , θ_{ac} , θ_{ccs} , and θ_{cts} associated with the cross-sectional strain distribution can be established from the plane-section assumption, as listed in Table 1. In addition, r_{tc} is equal to $(r_c + r_l)/2$; the coefficient β_c is expressed as $\beta_c = (f_{sc}/E_s)/\varepsilon_c$; the coefficient β_c is estimated from $\beta_c = (f_{szc}/E_s)/\varepsilon_c$; f_{sc} and f_{szc} represent the failure stresses of the tensile and compressive rebar, respectively, where the tensile stress f_{sc} is a negative value.

Table 1. Model parameters definition.

Coordinate position*	θ ($0 \leq \theta \leq 1$)
$r_c - Y_{xc}$	$\theta_c = \arccos(r_c/r_{tc} - \beta_1 \zeta_c (r_c + r_s)/r_{tc})/\pi$
$r_c - Y_{xc}$	$\theta_{ac} = \arccos(r_c/r_s - \zeta_c (1 + r_c/r_s))/\pi$
$y_{acs} = Y_{acs} - Y_{xc} + r_c$	$\theta_{ccs} = \arccos(r_c/r_s + (\beta_c - 1)\zeta_c (1 + r_c/r_s))/\pi$
$y_{ats} = Y_{ats} - Y_{xc} + r_c$	$\theta_{cts} = \arccos(r_c/r_s + (\beta_c - 1)\zeta_c (1 + r_c/r_s))/\pi$

* Below the X -axis gives the negative values, while above the X -axis gives positive values.

Figure 2. Stress block and parameters definition of corroded annular RC columns: (a) typical cross-section; (b) strain distribution; (c) equivalent stress distribution of concrete; (d) stress distribution of rebar based on the equivalent steel ring assumption.

3.3 Residual bearing capacity of concrete

From Figure 2(c), the axial force of the concrete F_c can be calculated from the residual area of the concrete cross-section and the compressive strength of the concrete f_c , and the concrete bending moment M_c can then be calculated by assuming the X -axis as the moment axis, namely

$$F_c = a_1 f_c A_{cc} A ; M_c = a_1 f_c A_{cc} r_s B / \pi \quad (11)$$

where a_1 is the reduction factor of the concrete compressive strength, parameters A and B are defined, respectively, as

$$A = \theta_c ; B = \sin \pi \theta_c r_{tc} / r_s \quad (12)$$

3.4 Residual bearing capacity of rebar

From the stress distribution of the rebar, as shown in Figure 2(d), the stress states of the equivalent steel ring can be divided into four parts. Based on the materials and structural strength degradation models, the axial force of the corroded rebar for different stress states can be calculated from the residual stress and area. Moreover, the bending moment of rebar for various states can be obtained by taking the moment of the X -axis.

3.4.1 Case 1: Rebar reaching the compressive failure stress ($0 \leq \theta \leq \theta_{ccs}$)

In Case 1, the failure stress of the compressive rebar f_{szc} is governed by the smaller value of the yield strength f_{yc} and the critical buckling strength f_{cr} , expressed as $f_{szc} = \min(f_{yc}, f_{cr})$. Meanwhile, the residual cross-section area can be calculated from the area ratio θ_{ccs} . Then, the force F_{cs} and moment M_{cs} of rebar can be expressed, respectively, as

$$F_{cs} = f_{szc} A_{nsc} k_{cef} ; M_{cs} = f_{szc} A_{nsc} r_s k_{cem} / \pi \quad (13)$$

where parameters k_{cef} and k_{cem} can be calculated from

$$k_{cef} = \theta_{ccs} ; k_{cem} = \sin \pi \theta_{ccs} \quad (14)$$

3.4.2 Case 2: Rebar under compression but not reaching the failure stress ($\theta_{ccs} \leq \theta \leq \theta_{ac}$)

In the case of the rebar not reaching the compressive failure stress ($\theta_{ccs} \leq \theta \leq \theta_{ac}$), the strength of the rebar can be estimated from the stress-strain relationship. In addition, the residual cross-section area can be calculated from the difference between the area ratios θ_{ac} and θ_{ccs} . The axial force F'_{cs} and bending moment M'_{cs} of rebar in Case 2 can then be expressed as

$$F'_{cs} = f_{szc} A_{nsc} k'_{cef} ; M'_{cs} = f_{szc} A_{nsc} r_s k'_{cem} / \pi \quad (15)$$

where parameters k'_{cef} and k'_{cem} are defined as

$$k'_{cef} = \frac{\mu_{acs} + \eta_{cs} \nu_{acs}}{\pi (\cos \pi \theta_{ccs} + \eta_{cs})} ; k'_{cem} = \frac{\nu_{acs} / 2 + \mu_{2acs} / 4 + \eta_{cs} \mu_{acs}}{\cos \pi \theta_{ccs} + \eta_{cs}} \quad (16)$$

in which μ_{acs} is taken as $\mu_{acs} = \sin \pi \theta_{ac} - \sin \pi \theta_{ccs}$; μ_{2acs} is calculated from $\mu_{2acs} = \sin 2\pi \theta_{ac} - \sin 2\pi \theta_{ccs}$; ν_{acs} is equal to $\pi(\theta_{ac} - \theta_{ccs})$; and the factor η_{cs} associated with the cross-section properties is given by

$$\eta_{cs} = \zeta_c (1 + r_c / r_s) - r_c / r_s \quad (17)$$

3.4.3 Case 3: Rebar in tension but not reaching the failure stress ($\theta_{ac} \leq \theta \leq \theta_{ctis}$)

The residual cross-section area of rebar in Case 3 can be calculated from the difference between the area ratios θ_{ctis} and θ_{ac} . Then, the force F'_{ts} and moment M'_{ts} of the corroded rebar can be determined by the stress-strain relationship, namely

$$F'_{ts} = f_{szc} A_{nsc} k'_{ctf} ; M'_{ts} = f_{szc} A_{nsc} r_s k'_{ctm} / \pi \quad (18)$$

When the bond effect between the rebar and the surrounding concrete is adequate, the parameters k'_{ctf} and k'_{ctm} can be defined, respectively, as

$$k'_{ctf} = \frac{\mu_{tsa} + \eta_{cs} \nu_{tsa}}{\pi (\cos \pi \theta_{ccs} + \eta_{cs})} ; k'_{ctm} = \frac{\nu_{tsa} / 2 + \mu_{2tsa} / 4 + \eta_{cs} \mu_{tsa}}{\cos \pi \theta_{ccs} + \eta_{cs}} \quad (19)$$

where μ_{tsa} is taken as $\mu_{tsa} = \sin \pi \theta_{ctis} - \sin \pi \theta_{ac}$; μ_{2tsa} is calculated from $\mu_{2tsa} = \sin 2\pi \theta_{ctis} - \sin 2\pi \theta_{ac}$; and ν_{tsa} is given by $\nu_{tsa} = \pi(\theta_{ctis} - \theta_{ac})$. However, the deformation of the tensile rebar and the surrounding concrete is incompatible after rebar bond failure. Here, the bond strength interpolation factor G_d is introduced to construct a new stress-strain relationship between the corroded rebar and the cracked concrete. Then, the parameters k'_{ctf} and k'_{ctm} can be rewritten as

$$k'_{ctf} = G_d \frac{\mu_{tsa} + \eta_{cs} \nu_{tsa}}{\pi (\cos \pi \theta_{ccs} + \eta_{cs})} ; k'_{ctm} = G_d \frac{\nu_{tsa} / 2 + \mu_{2tsa} / 4 + \eta_{cs} \mu_{tsa}}{\cos \pi \theta_{ccs} + \eta_{cs}} \quad (20)$$

3.4.4 Case 4: Rebar reaching the tensile failure stress ($\theta_{cts} \leq \theta \leq 1$)

For the case with part of the steel ring failure in tension, the stress of the corroded rebar f_{sc} depends on the smaller value of the yield strength f_{yc} and the residual bond strength f_{ux} , expressed as $f_{sc} = \min(f_{yc}, f_{ux})$, and the residual cross-section area is equal to $\theta'_{cts} A_{nsc}$. Then, the axial force F_{ts} and bending moment M_{ts} can be expressed, respectively, as

$$F_{ts} = f_{sc} A_{nsc} k_{ctf}; \quad M_{ts} = f_{sc} A_{nsc} r_s k_{ctm} / \pi \quad (21)$$

where parameters k_{ctf} and k_{ctm} are estimated from

$$k_{ctf} = \theta'_{cts}; \quad k_{ctm} = -\sin \pi \theta_{cts} \quad (22)$$

3.5 Residual bearing capacity of the corroded columns

Based on the stress state analysis, consequently the residual axial force N_{res} and bending moment M_{res} of the corroded annular RC columns can be calculated by summing the concrete load capacity and the rebar load capacity, namely

$$N_{res} = F_c + F_{cs} + F'_{cs} + F'_{ts} + F_{ts}; \quad M_{res} = M_c + M_{cs} + M'_{cs} + M'_{ts} + M_{ts} \quad (23)$$

4 NUMERICAL EXAMPLE

In this section, a short RC column of annular cross-sections is employed to illustrate the applicability of the residual bearing capacity models described above. The cross-section of this column has an inner radius of $r_I = 125\text{mm}$, an outer radius of $r = 175\text{mm}$, and a radius of $r_s = 150\text{mm}$. Nine rebars of a diameter of 10mm are uniformly distributed in the concrete section, with a tensile strength $f_{y0} = 340\text{MPa}$ and an elasticity modulus $E_s = 200\text{GPa}$. The concrete compressive strength f_c is 40MP, with the cover thickness c of 20mm. Moreover, other material properties of the concrete can be estimated from the concrete compressive strength (Fib 2010). In addition, the stirrups have a spacing of 100mm, and the total crack number n_c is taken as 4.

In Figure 3, the equivalent crack width at the concrete surface as a function of corrosion level is analytically predicted, matching well the experimental results (Vidal et al. 2004, Coronelli et al. 2013, Banba et al. 2014, Khan et al. 2014). The predicted results demonstrate a well-defined trend in which the cracks widen as the corrosion level increases.

Figure 3. Predicted equivalent concrete crack width versus corrosion level, compared with experimental results from various sources.

Based on the results of crack width evolution, the normalized residual bond strength can be estimated from Equation 6. In Figure 4, the normalized residual rebar bond strength declines as the crack width increases, matching well the experimental data (Rodriguez et al. 1994, Fischer 2010, Law et al. 2011, Banba et al. 2014). Compared with the later crack propagation stage, the normalized residual bond strength has a more rapid drop in the earlier stage.

Figure 5 shows the influences of rebar corrosion and the relative compression zone area ratio θ_c on the residual bearing capacity of the corroded annular concrete columns, where the normalized

Figure 4. Predicted normalized residual bond strength versus surface crack width, compared with experimental data from various sources.

axial force n is calculated from $n = N_{res}/a_1f_cA_{c0}$. As expected, the residual bearing capacity of the corroded columns largely depends on the loading conditions and the corrosion levels, which grows as the compression zone area increases but decreases with the corrosion level increases.

To further investigate the effects of the corrosion level on the mechanical performance of the annular RC columns, various values of the corrosion level ranging from 0 to 50% are adopted to predict the residual bearing capacity of the corroded columns, as shown in Figure 6, where the normalized bending moment m is calculated from $m = \pi M_{res}/a_1f_cA_{c0}r_s$. From the results, the bearing capacity of the corroded RC column reduces obviously at the corrosion level between 4 and 15%. For corroded columns with smaller eccentricities, the loss of the concrete cross-section is the main reason causing the significant decline of the residual capacity. However, for the corroded columns with larger eccentricities, the degradation of rebar bond strength is the critical factor, leading to the rapid drop of the residual capacity.

Figure 5. Normalized bearing capacity n of the corroded annular columns with various rebar corrosion levels and different relative compression zone area ratios θ_c .

Figure 6. The M-N interaction diagram of the annular RC column with various corrosion levels.

5 CONCLUSION

This paper presents an analytical method for assessing the residual bearing capacity of the corroded RC columns with annular cross-sections. The materials and structural strength degradation models are constructed by investigating the deterioration mechanism of the corroded

columns, which consider the decrease of rebar bearing capacity, the cracking and spalling of concrete cover, rebar bond strength reduction, and the buckling of the compressive rebar. The residual bearing capacity models are then constructed to quantitatively analyze the coupling effects between corrosion levels and loading conditions on the bearing capacity of the corrosion-damaged annular columns. According to the results obtained from the numerical example, the following conclusions are drawn: (1) the developed models can effectively predict the concrete crack width growth, rebar bond strength degradation and residual bearing capacity of the corroded annular columns; (2) the effects of rebar corrosion on the residual bearing capacity of the annular concrete columns increase significantly as the compression zone area develops; (3) at the corrosion level of 4-15%, the residual bearing capacity of the corroded annular columns reduces more obviously due to concrete cover loss and rebar bond strength deterioration.

Steel liner corrosion and its effects on the leak-tightness of the nuclear containment structure

X.B. Li, X.Y. Wu & J.X. Gong

State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, Dalian, China

ABSTRACT: To evaluate the aging effect of the steel liner on the nuclear containment structure, uniaxial tensile tests are conducted on 36 steel liner specimens with 0% to 50% corrosion rate. The corrosion effect on the degradation of the mechanical properties of the steel liner is investigated. Based on the experimental results, the stress-strain model of the corroded steel liner is established, and a corrosion simulation method for the steel liner is proposed. Combined with the finite element method, the effect of steel liner corrosion on the leak-tightness of the containment is evaluated. Finally, the proposed corrosion simulation method is compared to the Nuclear Regulatory Commission (NRC) method, and recommendations for the corrosion factor in the NRC method are made.

1 INTRODUCTION

The nuclear containment structure (containment, hereafter) serves as the ultimate physical barrier in the defense-in-depth system of the nuclear power plant. The steel liner anchored on the inner wall of the containment plays a pivotal role in ensuring the leak-tightness of the containment. As the service time increases, the containment will suffer from aging-related degradation, and steel liner corrosion is one of the major forms of degradation (Dunn et al., 2011, Petti et al., 2011). A series of large-scale experiments on the containment demonstrated that concrete cracking occurred prior to the tearing of the steel liner, and thus the leak-tightness of the containment under severe accidents is directly determined by the steel liner (Hanson et al., 1987a, Hanson et al., 1987b, Hessheimer and Dameron, 2006). Given the critical role of the steel liner as a leak-barrier, it is of great importance to investigate the mechanical properties of the corroded steel liner and the corrosion effect on the leak-tightness of the containment.

Due to the particularity of the containment, the effect of steel liner corrosion on the containment was generally carried out by testing the mechanical properties of corroded steel liner specimens and then conducting a numerical simulation of the containment based on the test results. Cherry et al. (Cherry, 1999) conducted a series of corrosion tests on A516 GR70 steel liners, and found that the ultimate strength and ultimate tensile strain of the steel liners were significantly reduced by corrosion. Based on the experimental results, the NRC proposed a simulation method and a tearing criterion for the corroded steel liner (Cherry and Smith, 2001, Spencer et al., 2006). According to research conducted by the NRC, the leak-tightness of different types of containment under steel liner corrosion conditions has been extensively studied (Spencer et al., 2006, Petti et al., 2008, Li and Gong, 2023). In general, there are few studies on the steel liner corrosion. The corrosion test carried out by Cherry et al. (Cherry, 1999) only considered the steel liner with a maximum corrosion level of 20%, and the test data were not sufficient to obtain the degradation law of the mechanical properties of the steel liner under different corrosion levels. The corrosion simulation method proposed by the NRC considered the weakening of the bearing capacity of the steel liner by reducing its thickness but ignored the degradation of the material properties of the corroded steel liner. Additionally, the tearing criterion for the

corroded steel liner proposed by the NRC is to introduce a corrosion factor that can characterize the corrosion effect on the ductility of the steel liners. However, the suggested value for the corrosion factor given by the NRC fails to reflect the corrosion level.

In the present work, the mechanical properties of the corroded steel liner are investigated by corrosion and uniaxial tensile tests, and the mechanical properties of the corroded steel liner under different corrosion rates are analyzed. Based on the experimental results, the constitutive model for the corroded steel liner is established, and a corrosion simulation method for the steel liner is proposed. Combined with the nonlinear finite element analysis method and sub-model analysis techniques, the effect of different levels of steel liner corrosion on the leak-tightness of the containment is evaluated. Finally, the proposed corrosion simulation method is compared to the NRC method, and recommendations for the corrosion factor in the NRC method are made.

2 UNIAXIAL TENSILE TESTS

2.1 Specimen preparation

In this study, P265GH steel with a thickness of 6 mm, which is widely used for containment steel liners, is selected as the test material. The tensile specimens used in this study were designed in accordance with Chinese standard GB/T228.1–2010. Six groups of corrosion rates (from 0% to 50%) are considered by using the electrochemical accelerated corrosion method, and each group includes six specimens. It should be mentioned that the corrosion level of steel liners in nuclear power plants is usually assessed by the corrosion depth and area. Therefore, the reduction in average cross-sectional area is used in this study to calculate the corrosion rate.

2.2 Test results

The tensile stress-strain curves of representative specimens are shown in Figure 1, and the detailed test results are shown in Table 1.

Figure 1. Tensile stress-strain curves of steel liner specimens.

Table 1. Uniaxial tensile test results of steel liner specimens.

Specimen group	η (%)	E_s (MPa)	f_y (MPa)	ϵ_{sh}	f_p (MPa)	ϵ_p	ϵ_u
L-0%	0	203958	310.57	0.02079	431.14	0.2657	0.4363
L-10%	10	201631	290.42	0.01976	394.12	0.2105	0.3009
L-20%	20	202142	264.10	0.01460	379.22	0.1792	0.2414
L-30%	30	200109	267.21	0.01108	364.65	0.1425	0.1935
L-40%	40	201966	248.34	0.00712	361.25	0.1413	0.1899
L-50%	50	199694	231.02	0.00469	335.07	0.1095	0.1464

Note: η is the corrosion rate; E_s is the elastic modulus; f_y is the yield strength; ϵ_{sh} is the strain of the steel liner for hardening initiation; f_p is the peak strength; ϵ_p is the peak strain; ϵ_u is the fracture strain.

Combined the contents in Figure 1 and Table 1, the following points can be concluded:

- (1) The elastic modulus of the steel liner is not affected by corrosion, but the yield strength, peak strength, peak strain, and fracture strain are degraded as the corrosion rate increases.
- (2) At a corrosion rate of 50%, the mean fracture strain of the steel liner is reduced by 66.45%, indicating that the ductility of the corroded steel liner is significantly degraded.
- (3) When the corrosion rate is low, the steel liner exhibits an obvious yield point and yield platform. However, when the corrosion rate reaches 30%, the yield point is no longer obvious and the yield platform gradually becomes shorter or even disappears.

To reflect the corrosion effect on each mechanical property parameter of the steel liner, statistical analysis is performed for f_y , f_p , ϵ_p , and ϵ_u , as shown in Figure 2. Moreover, regression analysis of the test results revealed that the remaining mechanical parameters of the steel liner approximately satisfy the following linear degradation law as the corrosion rate increases:

$$M(i) = 1 - k(i)\eta \quad (0 \leq \eta \leq 50\%) \quad (1)$$

where $M(i)$ represents the non-dimensional quantity for the mechanical parameter of the steel liner, i.e., $M(f_y) = f_y/f_{y0}$, $M(f_p) = f_p/f_{p0}$, $M(\epsilon_p) = \epsilon_p/\epsilon_{p0}$, $M(\epsilon_u) = \epsilon_u/\epsilon_{u0}$; f_{y0} , f_{p0} , ϵ_{p0} , and ϵ_{u0} represent the mean values of the corresponding mechanical parameters of the uncorroded steel liner, respectively; $k(i)$ represents the degradation coefficient (see Figure 2).

Figure 2. Degradation law of mechanical properties of steel liner specimens.

3 CONSTITUTIVE MODEL OF CORRODED STEEL LINERS

As shown in Figure 1, the tensile constitutive relationship of the steel liner generally includes four stages, a linear elastic stage, a yielding platform, a strain hardening stage, and a necking stage. Through statistical analysis of the test curves, the constitutive model of the corroded steel liner is established in this study, which has the following form:

$$\sigma_s = \begin{cases} E_s \epsilon_s & 0 \leq \epsilon_s < \epsilon_y \\ f_y & \epsilon_y < \epsilon_s \leq \epsilon_{sh} \\ f_y \left[1 + \frac{\epsilon_s - \epsilon_{sh}}{\epsilon_p - \epsilon_{sh}} \left(\frac{f_p}{f_y} - 1 \right) \exp \left(1 - \frac{\epsilon_s - \epsilon_{sh}}{\epsilon_p - \epsilon_{sh}} \right) \right] & \epsilon_{sh} < \epsilon_s \leq \epsilon_u \end{cases} \quad (2)$$

The present constitutive model considers that the modulus of elasticity of the steel liner remains constant under different corrosion rates, and thus the yield strain can be calculated from the yield strength. The f_y , f_p , ϵ_p , and ϵ_u at different corrosion rates can be calculated by Equation (1). Additionally, the mechanical property parameter ϵ_{sh} has a large dispersion due to the impact of uneven corrosion. To develop a uniform mathematical model, a linear relationship is fitted to ϵ_{sh} , and it has the following form:

$$M(\epsilon_{sh}) = \frac{\epsilon_{sh}}{\epsilon_{sh0}} = 1 - 1.48\eta \quad (3)$$

Figure 3 shows the comparison between the model curves and the test curves under different corrosion rates, which are in good agreement.

Figure 3. Comparison between the model curve and the test curve.

4 FE ANALYSIS OF THE CONTAINMENT

4.1 Global model of the containment

The containment studied in reference (Zhou et al., 2018) is adopted in this study, as shown in Figure 4. The total height of the containment is 61.7 m, and the height of the base slab is 5.5 m. The inner radius of the dome is 24 m with a wall thickness of 0.8 m, and the inner radius of the cylinder wall is 18.5 m with a wall thickness of 0.9 m. The entire inner surface of the containment is lined with a 6 mm steel liner to provide the required leak-tightness at the pressure boundary. To meet functional requirements, many penetrations are provided in the containment, such as equipment hatches and personnel airlocks. Furthermore, a complete pre-stressing tendon system is arranged in the containment.

Figure 4. Schematic diagram and FE model of the containment.

In this study, a global FE model of the containment is established by ABAQUS. The modeling details of the global model are referenced in the literature (Jin and Gong, 2021). The mechanical behavior of the concrete is simulated using the plastic damage model in

ABAQUS, and the uniaxial compressive and tensile constitutions of concrete are modeled using stress-strain relationships suggested in the literature (Li and Gong, 2023). The isotropic elastic-plastic model is applied to simulate the mechanical behavior of the rebar and the prestressed tendons. For this study, we focused on the steel liner corrosion, and the mechanical behavior of the steel liner is modeled by the constitutive model proposed in Equation (2) to simulate the real corrosion situation. In addition, the nonlinear FE analysis of the global model of the containment is divided into two analysis steps. In the first step, the gravity load and the prestressing load of the tendons are applied simultaneously. In the second step, the pressure is applied uniformly to the inner surface of the containment.

4.2 Sub-model for corroded steel liners

A series of aging investigations into the containment revealed that the steel liner corrosion is strongly localized, and the corroded area is usually small (Dunn et al., 2011, Petti et al., 2011). Therefore, the FE model requires a refined mesh to reflect the strain concentration in the corroded area of the steel liner. However, due to the large size and complex structural form of the containment, the use of a refined mesh for the global model will make convergence difficult. To overcome this limitation, we performed the local corrosion analysis of the steel liner using the sub-model technique of ABAQUS, and the specific implementation process can be found in a previous work (Li and Gong, 2023). To reduce the influence of the singular zones of the containment on the calculation, the current zone of the containment, which is away from the buttress and the penetration, is selected for the sub-model. To consider the most unfavorable scenario, the sub-model for the corroded steel liner is selected at the location where the maximum strain of the steel liner is generated in the current zone of the global model, as shown in Figure 5. The corrosion region is set at the center of the sub-model, and its dimensions and shape are described in the NRC report (Spencer et al., 2006). Through mesh convergence analysis, the global mesh size of the sub-model is taken as 200 mm. Additionally, the mesh size of the corrosion area is taken as 8 mm, and a transition zone is provided around it to reduce the effect of variation in mesh size.

Figure 5. FE model of the sub-model.

4.3 Failure criterion

In the nuclear engineering community, it is widely acknowledged that the tearing of the steel liner means that the containment loses its leak-tightness function. The tearing of the steel liner is determined by its fracture strain, and the NRC has proposed a failure criterion for steel liners with consideration of corrosion effects in the FE analysis (Spencer et al., 2006):

$$\varepsilon_{pe} = f_m f_{cor} f_g \varepsilon_{p,eff} \quad (4)$$

where ε_{pe} is the uniaxial equivalent strain of the steel liner; f_m is the multiaxial stress factor; f_g is gauge length factor; $\varepsilon_{p,eff}$ is the effective plastic strain of the steel liner from the FE analysis.

The corrosion factor in Equation (4) reflects the corrosion effect on the ductility of the steel liner, and three suggested values of the f_{cor} are recommended by NRC (Cherry and Smith, 2001). However, these recommended values cannot directly reflect the effect of different corrosion levels on the ductility of the steel liner. Based on the test results, we propose a calculation method for the corrosion factor that takes the corrosion rate into account:

$$f_{\text{cor}}^* = \frac{1}{1 - 1.28\eta} \quad (0 \leq \eta \leq 50\%) \quad (5)$$

Therefore, an improved failure criterion for the corroded steel liner can be expressed as:

$$\varepsilon_{\text{pe}} = f_{\text{m}} f_{\text{cor}}^* f_{\text{g}} \varepsilon_{\text{p,eff}} \quad (6)$$

According to the failure criteria, when ε_{pe} exceeds the ε_{u0} of the steel liner, tearing occurs, and thus the containment is considered to lose its leak-tightness function (or functional failure).

5 SIMULATION METHOD AND ANALYSIS RESULTS

5.1 Simulation methods for corroded steel liners

The previous studies for the numerical simulation of the corroded steel liner mainly used the simulation method proposed by the NRC, which was to reduce the thickness of the steel liner in the corroded zone, and the uncorroded material properties were still adopted in the corroded zone (Cherry and Smith, 2001, Spencer et al., 2006, Petti et al., 2008, Alhanaee et al., 2018). This simulation method assumes that the substrate material properties of the steel liner after removing the corroded layer are consistent with those of the uncorroded material. However, the corrosion morphology of the steel liner shown in Figure 1 indicates that the corroded steel liner has many corrosion pits on its surface caused by the non-uniformity of corrosion. Due to the stress concentration effect, the mechanical parameters of the substrate material of the corroded steel liner are also significantly degraded. Therefore, the corrosion simulation method proposed in this study is to reduce the thickness of the corroded steel liner according to the corrosion rate and then impart the corresponding stress-strain relationship of the corroded steel liner in the corroded zone according to the proposed constitutive model. The proposed method can consider both the cross-sectional loss and the degradation of the mechanical properties of the corroded steel liner. Therefore, it is closer to the actual performance of the corroded steel liner.

To investigate the leak-tightness performance of the containment under different corrosion degrees of the steel liner, six groups of corrosion conditions with corrosion rates ranging from 0% to 50% are considered in this study. Meanwhile, the same corrosion conditions are simulated according to the NRC method to compare the differences between the proposed corrosion simulation method and the NRC method. In addition, Equations (4) and (6) are used to determine the tearing of the steel liner under the NRC method and the proposed method, respectively.

5.2 FE analysis results and discussion

A plot of the ratio of ε_{pe} to ε_{u0} as a function of pressure is shown in Figure 6, and a horizontal line is drawn at a ratio of 1.0 to indicate the failure occurs. The functional failure pressure corresponding to the tearing of the steel liner gradually decreases as the corrosion rate increases. Compared with the uncorroded condition, the functional failure pressure of the containment is reduced by 29.06% at a corrosion rate of 50%, indicating that the steel liner corrosion can easily lead to leakage of the containment at low pressures under accident conditions.

Taking the simulated condition with corrosion rate of 50% as an example, Figure 7 shows the comparison of the relationship curves between steel liner strain and pressure under the proposed corrosion simulation method and the NRC method. It should be mentioned that the corrosion factor in the failure criterion is taken as $f_{\text{cor}} = 2$ for the corrosion rate of 50% according to relevant literature (Spencer et al., 2006, Petti et al., 2008). At low pressure, the steel liner strains calculated by the proposed method and the NRC method are essentially the same. However, at

high levels of pressure, the steel liner strain calculated by the NRC method is lower than our proposed method. What's more, the NRC method overestimates the functional failure pressure corresponding to the tearing of the steel liner. Additionally, it is not conservative enough to use $f_{cor} = 2$ to determine the tearing of the steel liner in the case of a 50% corrosion rate.

Figure 6. Failure functions under different corrosion rates.

Figure 7. Comparison of corrosion simulation methods.

Figure 8. Comparison of functional failure pressure.

Following the three suggested values of the corrosion factor recommended by the NRC, the functional failure pressure under different corrosion rates is calculated, as shown in Figure 8. Comparing the NRC method with the proposed method, it is obvious that the proposed method can directly reflect the variation of the corrosion factor with the corrosion rate. Meanwhile, the corrosion factor obtained by our proposed method basically conforms to the value interval of the corrosion factor recommended by the NRC. Moreover, the corrosion factor

recommended by the NRC can be specified as follows: when the corrosion rate is less than 20%, the upper bound value can be selected; when the corrosion rate is 20% to 40%, the best estimate value is recommended; and when the corrosion rate exceeds 40%, the lower bound value should be adopted.

6 CONCLUSIONS

Combined with corrosion test and numerical simulation, the mechanical properties of the corroded steel liner and the corrosion effect on the leak-tightness of the containment are systematically analyzed. The following conclusions can be drawn:

- (1) The corrosion effect on the elastic modulus of the steel liner is not significant, but as the corrosion rate increases, the yield strength, peak strength, peak strain, and fracture strain show linear degradation.
- (2) The constitutive model of the corroded steel liner established in this study agrees well with the experimental results.
- (3) Functional failure pressure of the containment decreases with the increase in the corrosion degree of the steel liner, and when the corrosion rate is 50%, the functional failure pressure decreases by 29.06%.
- (4) The proposed simulation method can directly reflect the impact of corrosion on the steel liner and is closer to the actual corrosion situation. Additionally, the corrosion factor recommended by the NRC is clarified. When the corrosion rate is less than 20%, the upper bound can be chosen; when the corrosion rate is 20% to 40%, the best estimate is recommended; and when the corrosion rate exceeds 40%, the lower bound should be used.

ABSTRACT: Carbonation resistance has received prevalent attention from academia as well as industry during the last few decades. The single influence of carbonation on reinforced concrete structures has been widely considered. However, the combined effect of cyclic loading and carbonation still need to be investigated. Therefore, an optimized test procedure was proposed to simulate the damage mechanism of reinforced concrete beams with combined corrosion. The results showed different carbonation process of tensile concrete corresponding to two different test procedures, which indicated that combined corrosion was more serious than separated effects. And a carbonation model of tensile concrete under combined corrosion was proposed. Subsequently, the model was validated by comparing the prediction results with data from past literature. The research findings are significant for improving the accuracy of evaluation of residual carbonation life of reinforced concrete bridges and early warning of durability protection.

1 INTRODUCTION

Carbonation is of major concern to researchers and engineers, as the reaction of CO₂ with calcium-bearing phases in concrete infrastructure components is known to decrease alkalinity of pore water, introducing steel reinforcements corrosion in concrete (Morandea, et al. 2014, Tang, J.Z., et al. 2018). Thus, carbonation is typically considered to be a major cause of performance deterioration of reinforcement concrete (RC) structures in the atmospheric environment.

Numerous researchers have investigated the influence of material components and ambient conditions on concrete carbonation, including various mineral additions (Sisomphon, et al. 2007), mix proportions (Leemann, et al. 2015), recycled aggregates (Zhang, et al. 2021), relative humidity and temperature (Bary & Sellier, 2004, Chen & Ho, 2013), and CO₂ concentration (Visser, 2014). Considering that concrete in structures is constantly subjected to both carbonation and loads, the influences of static loads and visible cracks on concrete carbonation have also been investigated (Castel, et al. 1999, Song, et al. 2006, Talukdar, et al. 2015) and corresponding carbonation models were established (Wang, et al. 2018, Tang, et al. 2020). It is generally believed that the tensile stress had a positive association on the carbonation depth; conversely, there were thresholds existing for the influence of the compressive stress level. In large-scale concrete bridges, prestressed reinforcements are used to avoid cracking of concrete during their service life, but traffic loading cycles will promote the expansion of microcracks and pores (Jiang, et al. 2017). Compared with uncracked concrete, the diffusion of CO₂ is more likely to start in damaged concrete (Chen, et al. 2008). For example, Wang et al. (2018) observed that flexural cracks clearly affected the upward propagation of the carbonation front. Therefore, the combination of the mechanical load and environmental actions was more severe than the sum of those individual factors (Yao, et al. 2017).

However, few studies in carbonation model that accounted for the effects of fatigue damage were reported. Song, et al. (2020) proposed a numerical model for prefatigued concrete and further revealed the effects of environmental factors on the carbonation process of concrete.

Jiang, et al. (2018) established a general carbonation equation for three common damage patterns occurred in pier, the top and bottom of girders at mid-span, respectively. Nevertheless, those experimental specimens were subjected to fatigue damage before carbonation, which was inconsistent with the actual service condition of bridges. Therefore, an improvement in test process is necessary for accurate corrosion initiation prediction of steel reinforcements in reinforced concrete structures.

In this study, the environmental chamber with a loading equipment was used to realistically simulate the coupling effects of cyclic loading and carbonation on RC beams. The distribution of cracks and carbonation process of the flexural tensile concrete under combined corrosion was revealed. Furthermore, the influence of test procedure on concrete carbonation was also studied. Finally, on the basis of experimental data and theoretical analysis, the corresponding carbonation model was established and verified. The outcome of this study can provide important references for evaluation of residual carbonation life and durability protection of RC structures in atmospheric environment.

2 EXPERIMENTAL METHODS

2.1 Materials and specimens

The Chinese standard ordinary Portland cement (P.O 42.5) was used in this study with a specific surface of 363 m²/kg. And natural river sand obtained from Weihe river was chosen as the fine aggregate with a fineness modulus of 3.40 and an apparent density of 2700 kg/m³. As for the coarse aggregate, continuous graded crushed gravel was used with a size of 5-15 mm and an apparent density of 3100 kg/m³.

A total of 5 RC beams was designed and cast. One beam was loaded monotonically to failure to determine the static capacity of the beam. Two beams were carbonated after loaded cyclically and the other two beams were exposed to combined corrosion. In addition, several cubic concrete specimens were cast for carbonation. The concrete mix proportion is shown in Table 1, and the dimension of RC beams as well as the details of reinforcements are given in Figure 1. All specimens were cured for 28 days in a standard curing room, in which the temperature and relative humidity were kept at 23 ± 2°C and 95%, respectively.

Table 1. Mix proportion of Concrete.

Water	Cement	Fine Aggregate	Coarse Aggregate	
kg/m ³	kg/m ³	kg/m ³	kg/m ³	w/c
161	460	684	1116	0.35

Figure 1. Dimension and reinforcement detailing of RC beams.

2.2 Load application

2.2.1 Equipment for loading test

The equipment can simulate the mechanical properties of specimens corresponding to various working conditions, either for static load or cyclic load. There were three parts to the load equipment: the loading system, the control system and the data collection system. As shown in Figure 2, the loading system was composed of a reaction frame, hydraulic jack, load distributing girder, fixture, and load sensor, etc. The base of the hydraulic jack was fixedly connected with the reaction

frame, and the lifting part was connected with the load distribution girder through the fixture. The length of the distribution girder was 500 mm and the RC beams were tested under four-point flexural loading. Furthermore, the control system can adjust the load through controlling the hydraulic jack with the automatic pressure circulation device and the maximum load that can be applied by the equipment is 300 kN. Real-time data during the test, such as displacement, strain could also be collected by the stress and strain testing and analysis system (DH3818Y).

The loading system was placed in the environmental chamber while the other two systems were placed outdoors, connecting through oil-pressure pipes and sensor lines. This was convenient for operation and could prevent it from being interfered by the high temperature and humidity in the chamber as well.

2.2.2 Calculation of loading in test

Considering that actual vehicle loads are usually variable-amplitude fatigue loads which is difficult to simulate, constant amplitude sinusoid was selected in this paper. The details of the groups and loads are given in Table 2. The maximum load F_{max} and minimum load F_{min} applied to the RC beams in the fatigue tests are presented in this table. The maximum loads were determined based on S_{max} : a percentage of the yield strength of the reference beam, which was determined from the static tests. At the beginning, the beams were first subject to the mean load between F_{max} and F_{min} , and then, the fatigue damage was accumulated under constant amplitude sinusoidal cyclic loading at a frequency of 4 Hz.

Table 2. Summary of the specimens and corrosion condition.

Spec.	Procedure	Cyclic Load	
		F_{min}/F_{max} (kN)	S_{max}
A	Carbonation	-	-
B1	Static failure	-	-
B2	SC*	4.6/13.8	0.3
B3	SC	4.6/23	0.5
B4	CC**	4.6/13.8	0.3
B5	CC	4.6/23	0.5

* SC stands for separated corrosion; **CC stands for combined corrosion.

Figure 2. Equipment for loading test.

Figure 3. Carbonation chamber.

2.3 Accelerated carbonation test

After curing for 28 days, R2 and R3 were first applied to specified cyclic loads. Then the undamaged specimens R4 and R5 were successively placed on loading devices in the carbonation chamber (Figure 3) for 28 days combined corrosion. The cubic concrete specimens and damaged beams R2 and R3 were also put into the chamber for carbonation at the same time. According to the China National Standard (GB/T 50082-2009), the concentration of CO_2 was kept at $(20 \pm 3) \%$, and the values of the relative humidity and temperature were kept at $(70 \pm 5) \%$ and $(20 \pm 2) ^\circ C$, respectively.

In this study, a phenolphthalein indicator was used to measure the carbonation depth, which was an important index to evaluate the carbonation resistance of concrete. The sampling locations on the tension surface of RC beams are presented in Figure 4 and the carbonation depth was measured by a concrete carbonation depth ruler. At each location, two sample holes were dry drilled using an 8 mm diameter rotary impact drill. And the mean value of the measured carbonation depths of sample holes corresponding to different carbonation durations was chosen as the final carbonation depth of concrete.

Figure 4. Measurement of carbonation depth.

3 TEST RESULTS AND ANALYSIS

3.1 Crack width of RC Beams

The maximum flexural crack width of tensile zone of RC beams is shown in Figure 5, where the crack widths of B2 and B3 were measured under individual action of cyclic loading. The graph presents that the crack width increased rapidly in the first 14 days. This increase is due to the tensile stress being greater than the tensile strength of concrete, which accelerated the appearance of new microcracks and the propagation of the existing cracks. Thereafter, the crack width only exhibited a slight increase due to the further rising load cycles. The first reason for the downward trend of cracks width development lies in that the tensile stress was mainly borne by the steel bars rather than the concrete with the increase in the number of loading cycles. Secondly, the carbonization products may also result in the partial blocking of internal pores and cracks of concrete after 14 days.

Figure 5 also illustrates that the bending cracks were mainly concentrated in the pure flexural zone of RC beams, and they expanded from the bottom of the beams to the center after thousands of loading cycles. Besides, the number and space of cracks distributed in the bottom of B4 was obviously less than that of B5, and the maximum crack width of B5 (0.12mm) was about 3 times that of B4 (0.05mm) after 28 days. The same applied to B2 and B3, which indicated that both the number and width of flexural cracks increase with the increase of the load level.

In addition, it can be found that the crack width curve of B2 lay above that of B4 for equal carbonation ages, and the same happened with B3 and B5. Further, the crack width differences between combined corrosion specimens and separated corrosion specimens increased with the increase of carbonation durations, which gave a further verification on the point that carbonation slowed down the expansion of crack.

Figure 5. The maximum flexural crack width and distribution of specimens.

3.2 Carbonation depth of concrete

For the RC beams subjected to flexural loads, their lateral section could be divided into flexural tension zone and flexural compression zone by a neutral plane. The compressive load borne by

the flexural compression concrete was very low in this paper, which inhibited the carbonation. Considering that the tensile strength of concrete was much lower than the compressive strength, there existed difference in carbonation rate, which further affected the corrosion of steel in concrete. Therefore, the carbonation depth of tensile concrete should be investigated separately.

Figure 6 shows the carbonation depth of flexural tensile concrete under the combined effects of carbonation and cyclic loading, as well as that of zero-load cubic specimens. Generally, the carbonation depth of all specimens showed an increased trend, but that of fatigue-damaged specimens were all greater than that of non-damaged concrete. After 28 days of coupled corrosion, the carbonation depth of B2, B3, B4, B5 were 7.45, 12.75, 8.68, 14.36 mm, respectively, which were 22.5%, 109.7%, 42.8%, and 136.2% higher than that of A (6.08 mm). And the carbonation rate for unstressed specimens was 1.16 at 28 days, and that of B4 and B5 were 41.26% and 133.76% higher, respectively. This was consistent with previous reports (Jiang, et al. 2017, Song, et al. 2020) that fatigue damage decreased the carbonation resistance of concrete.

Under the same load level, the difference in carbonation depth of B2 and B4 increased with carbonation durations. However, that of B3 and B5 could be divided into two phases, i.e. the carbonation depth of B5 developed from less than that of B4 initially to a final exceedance. The reasons for this phenomenon are as follows. Firstly, when the load level was low, some cracks in separated corrosion specimens closed due to creep of concrete, which hindered the transportation of CO₂. In the meantime, carbonation-introduced autogenous healing also had the same effect. Secondly, compared with the combined corrosion, the separated corrosion specimen under high load level produced large unrecoverable plastic deformation earlier, so its carbonation depth was higher at the beginning. However, the carbonation rate of specimen with initial fatigue damage decreased with the decrease of hydration products. Thirdly, both length and width of flexural cracks in the combined corrosion specimens were gradually expanded, resulting in the faster growth of carbonation depth. Therefore, the difference of carbonation depth between the separated corrosion specimens and the combined corrosion specimens continued to increase.

Figure 6. The carbonation depths of specimens.

Figure 7. Comparison of mathematical models.

4 CARBONATION MODEL OF FATIGUR DAMAGED CONCRETE

According to the previous researches, fatigue damage did not change the proportional relationships between carbonation depths of concrete and square roots of carbonation ages (Jiang, et al. 2018). On this basis, an influence coefficient of cyclic load K_D was introduced in order to analyze qualitatively the effect of cyclic load on the carbonation depth of concrete, as shown in Eq. (1).

$$x_D = k\sqrt{t} = K_D \cdot K_0 \cdot \sqrt{t} = K_D \cdot x_0 \quad (1)$$

Where x_D is the carbonation depth of fatigue-damaged concrete (mm); x_0 is the carbonation depth of non-damaged concrete; k is the carbonation rate coefficient; t is the carbonation age (d); K_0 is the carbonation coefficient of non-damaged concrete; K_D is the influence coefficient of cyclic loading.

4.1 The carbonation depth of non-damaged concrete x_0

To date, various prediction models for the carbonation depths of non-damaged concrete have been proposed, such as semi-theoretical model (Zhang & Jiang, 1998), multi-coefficient model (Gong, et al. 1985) and stochastic model (Niu, 2003), as shown in as shown in Eq.(2), (3), and (4), respectively.

$$x_0 = 839(1 - RH)^{1.1} \sqrt{\frac{C_0 \cdot (w/c \cdot \gamma_c - 0.34)}{c \cdot \gamma_{HD} \cdot \gamma_c}} \sqrt{t} \quad (2)$$

where RH is the relative humidity (%); C_0 is the volume concentration of CO_2 (%); w is the water mass per volume (kg/m^3); c is the cement mass per volume (kg/m^3); γ_c is the coefficient of cement type, γ_{HD} is the coefficient of cement hydration.

$$x_0 = K_1 K_2 K_3 K_4 K_5 K_6 a \sqrt{t} \quad (3)$$

in which, K_1 is the coefficient of cement content; K_2 is the coefficient of water-cement ratio; K_3 is the coefficient of fly-ash content; K_4 is the coefficient of cement type; K_5 is the coefficient of aggregate type; K_6 is the coefficient of curing method; a is the carbonation rate.

$$x_0 = 2.56 K_{mc} K_j K_{CO_2} K_p K_s \sqrt[4]{T} (1 - RH)^4 RH (57.94 m_c / f_{cu} - 0.76) \sqrt{t} \quad (4)$$

where K_{mc} is the random variable for calculation pattern indeterminacy, K_j is the coefficient of carbonation location, K_{CO_2} is the coefficient of CO_2 concentration, K_p is the coefficient of casting surface, K_s is the coefficient of stress, T is the average annual ambient temperature, f_{cu} is the cube compressive strength of concrete, m_c is the ratio between the mean and standard values of the concrete cube compressive strength.

The predicted carbonation depth of those models and experimental results is compared in Figure 7. By comparison, it can be found that the model proposed by Zhang had advantages on calculated precision and the average value of the relative error was 0.75. Hence, Zhang's model was selected as the base carbonation model of non-damaged concrete and the relative error was introduced as the adjustment coefficient, as Eq. (5) described.

$$x_0 = 0.75 \times 839 \cdot (1 - RH)^{1.1} \cdot \sqrt{C_0 \cdot (w/c \cdot \gamma_c - 0.34) / (c \cdot \gamma_{HD} \cdot \gamma_c)} \cdot \sqrt{t} \quad (5)$$

4.2 The influence coefficient of cyclic loading K_D

In order to accurately describe the accumulation and development process of fatigue damage in concrete under cyclic flexural loading, it is necessary to define an appropriate fatigue damage variable and establish the relationship between the variable and load history. Tanaka, k. et al. (1999) defined a parameter to quantitative described the damage degree of specimens which was related to the stress amplitude and loading cycles, as shown in Eq. (6).

$$D_F = \sigma / f + 0.0431 (\lg N)^{1.24} \quad (6)$$

where D_F is the degree of fatigue damage, σ is the tensile stress (MPa), f is the flexural strength (MPa), N is the number of cyclic loading.

Fitting process is conducted on test data of carbonation depth of non-damaged concrete, indicating that K_0 was 1.1056. Hence, Eq. (1) can be described as follows:

$$K_D = x_D / (1.1056 \cdot \sqrt{t}) \quad (7)$$

According to Eqs. (6) and (7), the corresponding least-square regression line of the coefficient K_D versus the variable D_F can be obtained, thus, K_D can be rewritten as Eq. (8).

$$K_D = 0.6243 + 0.0350 e^{4.67 D_F} \quad (8)$$

By introducing Eqs. (5) and (8) into Eq. (1), the carbonation depth of concrete under cyclic loading can be obtained:

$$x_D = (390.14 + 22.02e^{4.67Df}) \cdot (1 - RH)^{1.1} \cdot \sqrt{C_0 \cdot (w/c \cdot \gamma_c - 0.34) / (c \cdot \gamma_{HD} \cdot \gamma_c)} \cdot \sqrt{t} \quad (9)$$

4.3 Model validation

Experimental data that collected from literature (Zhou, 2016) in which the accelerated carbonation tests on fatigue-damaged concrete beams were carried out were used to validate the proposed carbonation model in this paper. After curing for 90 days, all specimens were subjected to repeated loads to reach the specified fatigue damage degree (D) through controlling the number of load cycles. Finally, these damaged concrete specimens were moved into the environmental chamber for 7, 14, 28, and 56 days, and the reported exposure conditions for those specimens were the same as those in this study.

Figure 8 shows the carbonation depths of fatigue-damaged concrete beams calculated by the proposed model and it is obvious that the carbonation depths obtained by different methods were almost identical when $D \leq 0.6$. When the fatigue damage degree was 0.2, 0.4, and 0.6, the average relative errors between the predicted carbonation depth and the experimental results reported by Zhou were 7.52%, 9.68%, 7.80%, respectively. In the initial stage of the test, the test results were generally greater than the prediction values, but with the increase of exposure time, the carbonation depth of the proposed model came from behind to exceed test one at 56 days when $D = 0.6$. This phenomenon was more obvious as for the specimen with fatigue damage of 0.8, and the test procedure was responsible for the increase of relative error between the measured depths and model results, as illustrated in Section 3.2.

Figure 8. Comparison between predicted results and those reported by Zhou.

5 CONCLUSION

An innovative accelerated carbonation test of RC beams under the action of cyclic flexural loading was conducted in this study. Within the scope of our experiments, the following conclusions are drawn:

- (1) The decrease of carbonation resistance of concrete was related to the increase of cracks introduced by cyclic loading. The flexural crack width was positively correlated with load level and cycles, and carbonation depth was easily affected by load. However, the growth rate of the two was decreased. The carbonation process of concrete under the combined corrosion and separated corrosion was different. Hence, in the carbonation analysis of fatigue-damaged reinforced structures, the influence of test procedure should be considered.
- (2) By introducing the coefficient of fatigue damage and establishing the relationship between the coefficient and the degree of fatigue damage, a carbonation model of tensile concrete

- considering the effect of cyclic flexural loading is proposed based on Zhang 's model. It is found that the carbonation depths predicted by the theoretical carbonation model were in good agreement with the results reported by Zhou, and thereby demonstrated its validity.
- (3) Although 28 days of combined corrosion can reveal the carbonation mechanism of fatigue-damaged concrete to some extent, the degradation mechanism of mechanical properties of RC beams can be better investigated if the corrosion durations are longer. Furthermore, there are some differences between natural condition and accelerated tests, further experimental research is required.

Large-scale experimental testing of 50-year-old prestressed concrete bridge girder

P. Savino, A. Quattrone, D. Sabia, B. Chiaia & F. Tondolo
Politecnico di Torino, Turin, Italy

M. Anghileri, F. Biondini & G. Rosati
Politecnico di Milano, Milan, Italy

ABSTRACT: This paper reports on large-scale loading tests survey carried out on 50-year-old prestressed concrete girders as part of the BRIDGE|50 research project (www.bridge50.org). The girders were retrieved from an existing viaduct in Turin, Italy. The prestressed concrete elements were 19.2 m long and had an I-shaped cross-section with a cast-in-situ slab. Variable damages were found, due to in-service deterioration and/or subsequent lifting operations during the demolition phase. Each specimen was subjected to static tests using monotonic or cyclic loading up to the ultimate load. This paper reports the results of tests on the second group of four girders, comparing their load-deflection responses and strains with those of the first group subjected to a different static scheme. The experimental findings highlight the global structural response from bending to bending/shear failure; the outcomes will define a valuable reference database for assessing the residual structural performance of existing girder bridges.

1 INTRODUCTION

Civil infrastructures operate under adverse service conditions, which may cause durability problems at different levels and, in the worst cases, the decrease or total loss of load-carrying capacity. Meanwhile, traffic demand is continuously growing, both in terms of number and weight of vehicles. However, as civil infrastructures age, uncertainties on the prediction of structural response increase due to the deterioration mechanisms. As a result, structural assessment has received much attention in recent decades from different perspectives. Structural health monitoring technologies have been developed to report the structural health status and early warning in presence of structural damage. Indeed, full-scale load tests are conducted to better understand the structural behavior of existing structures and to calibrate structural models. However, large-scale tests on civil infrastructures, are not always straightforward. In order to learn more about non-linear behavior and the ultimate capacity of bridges, the load test involves irreversible damages which led to the dismissing of the structure. Furthermore, huge human, financial, and material efforts are required, and as reported in Recupero & Spinella (2019), only few studies have been carried out on full-scale prestressed concrete (PC) girders from decommissioned bridges around the world (Wang et al. 2020). Assessment of existing bridges requires a thorough understanding of their structural behavior. However, the investigation usually concerns few structural members, equipped to study mainly the flexural behavior. Full-scale experiments should include more variables to be controlled. A systematic assessment of several specimens should be conducted under different loading test setups for a better understanding of the failure mechanism and thus develop more reliable estimates of the residual capacity.

In this scenario, the BRIDGE|50 research project was established to study the residual structural performance of a 50-year-old viaduct and provide a framework for safety assessment and residual lifetime evaluation of existing bridges (Biondini et al. 2020, 2021). A wide experimental campaign was planned to investigate 25 prestressed concrete (PC) I-girders, 4 PC box girders, and 2 pier caps recovered from the C.so Grosseto viaduct, a viaduct built in Turin in 1970 and

decommissioned in 2018. After demolition, the structural members were stored in a testing site properly equipped to conduct a detailed structural assessment including visual inspection, deterioration mapping, and non-destructive tests (Anghileri et al. 2020). Furthermore, a large reaction steel frame of the Interdepartmental Center for the Safety of Infrastructures and Constructions (SISCON) of Politecnico di Torino was used to perform full-scale load tests up to failure. Several load test setups were considered to study the failure mechanisms under flexural, mixed flexural/shear, and shear loading modes. The first group of four PC beams was tested under three-point bending configuration and detailed in Tondolo et al. (2021, 2022) and Savino et al. (2023). This paper reports the experimental results of the second group of four beams tested under four-point bending configuration up to failure. The reported parameters not only extend the database aimed at providing further knowledge on the structural response of 50-year-old PC beams but could be used to evaluate developed theories on resisting mechanism. The observed response is also compared with the structural behavior recorded for the first group of beams.

2 DESCRIPTION OF THE C.SO GROSSETO VIADUCT

The C.so Grosseto viaduct was a multilevel road bridge located in Turin, Italy. It was built in 1970 and decommissioned in 2019 for a new urban redevelopment plan (Savino et al. 2020). Its structural topology represents a typical solution widespread in the Italian motorway heritage and consists of two structurally independent decks, one for each traffic way, with simply supported span. Each span comprised ten PC I-shaped girders and two PC box girders at the edges, with a length averaging from 16.0 to 24.0 m. Two diaphragms connected the longitudinal girders at the third points. The superstructure was completed by a cast-in-situ slab of 140 mm. The infrastructure was 1.4 km long and achieved a maximum vertical clearance of 12.4 m.

During the decommissioning works in 2018, a total of 31 structural elements were removed and stored in a testing site of about 6000 m², located in Turin. A detailed layout of the preserved structural member in the original deck configuration is shown in Figure 1. The coloured elements represent the girders recovered for BRIDGE|50 research project; the elements depicted in blue belong to the first group of tests whereas the elements highlighted in red refer to the girders investigated and reported in this work. All the elements were properly identified with a code, according to the original configuration. The PC beams studied in the present work were identified as B7-P47/46, B6-Ab/P47, B6-P48/49, and B10-Ab/P47 according to classification reported in Savino et al. 2023.

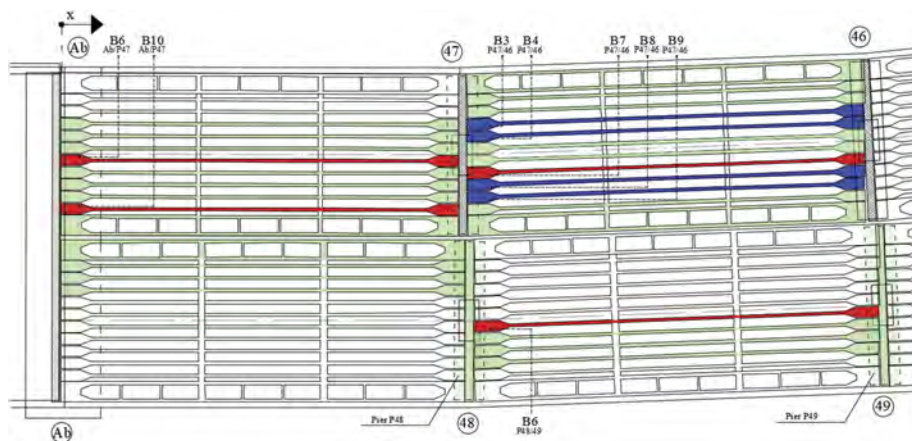

Figure 1. In-service layout of the investigated structural members (first group of tested girders in blue, second group of tested girders in red).

2.1 Details of the tested girders

All the girders were 19.5 m long, with an I-shaped cross-section of 580 x 900 mm. Cover depths were 45 mm for prestressed strands and were variable up to a minimum of 10 mm for

ordinary reinforcement. According to the design documentation, prestressing reinforcement was composed of seven-wire strands with a nominal diameter of 12.7 mm and tensile strength of 1638 MPa. The prestressed reinforcement consisted of 17 strands concentrated in the lower part of the beam and 3 strands located in the top flange as pictured in Figure 2. The stirrups are made by 8 mm ribbed steel spaced of 250 mm. The 14 cm cast-in-situ slab was reinforced with a square mesh of rebars. The maximum allowable stress for the strands at the tensioning stage was 1400 MPa. The concrete compressive strength at 28 days was designed to be 30 MPa. No specific requirements were reported for the cast-in-situ slab. The arrangement of the reinforcement as well as the cross-section geometry is given in Figure 2.

Figure 2. I-beam cross-section (units in mm).

According to the diagnostic campaign performed before the load tests session, the beams investigated in the present work were considered in good condition except for B6-P48/49 and B10-Ab/P47 girder which presented controlled damages induced by dismantling operations (Savino et al. 2023). The B6-P49/48 beam had two strands cut on both sides of the lower flange, at distances 3.7, 9.6, and 15.5 m from the end section. The B10-Ab/P47 girder had two strands cut on one side at distances of 3.8 and 15.5 m. Relying on the results provided by the preliminary diagnostic campaign, the load test program was properly planned, starting from the undamaged beams, considered as a benchmark for the subsequent beams with different degrees of damage.

3 FULL-SCALE LOAD TESTS SETUP

For the purpose of testing the PC girders with variable load configurations, a proper reaction steel frame was used (SISCON). Each beam was simply supported and loaded under a four-point bending configuration adopting shear spans of 650 cm. The loading system consisted of two couple of hydraulic jacks which transfer the load to the specimens through transverse steel beams. The loading process was conducted in two loading cycles. In the first phase, the load was increased until the opening of cracks, followed by the complete unloading of the girder. In the second loading phase, the specimens were loaded up to failure. The load tests were performed with a fixed loading rate by controlling the force and were stopped when the concrete in the compression zone crushed. The double loading cycles allowed also to perform the dynamic characterization of the specimens at different level of damages (Quattrone et al. 2020, Sabia et al. 2021, 2022).

As it is unusual to have full-scale elements of existing bridges loaded to collapse, the data gathered during such tests are of extreme interest to understand their structural response. For this reason, a proper measurement plan has been designed for each beam to measure several parameters involving displacements, strains, loads, vibrations, and acoustic emissions. This section summarizes only the equipment used to measure the parameters reported in this work and detailed below. Arrangement of the monitoring system is shown in Figure 3.

The layout of the monitoring system has been defined according to the load test setup, considering two main zones: the shear span and the bending span. Along the shear span, linear variable displacement transducers (LVDTs) were installed on aluminum frames oriented at 45° with a measurement base of 707 mm. Such sensors were denoted by the code “SHxxA/B”,

where “xx” indicates the progressive number, “A” refers to the frames with a negative slope, and “B” refers to the frames with positive slopes. In the bending zone, the LVDTs were installed on horizontal frames with a measurement base of 400 mm. Those were denoted by “BxxT/C” where “xx” indicates the progressive number, “T” refers to the LVDTs installed on the bottom flange, and “C” refers to the remaining positions. Furthermore, two electrical strain gauges were mounted on the bottom and upper flanges of the precast beam along the left vertical alignment of the B01T and B01C LVDTs.

Figure 3. Layout of the monitoring system (units in cm).

Three displacement transducers were installed at each end of the girder to measure vertical and horizontal displacements at the supports, and the potential slipping of one strand. A displacement transducer was installed along the shear span to measure potential sliding of the cast-in-situ slab. The vertical deflections along the shear span were measured by nine potentiometer transducers connected to the bottom of the girders (“D01-09” in Figure 3). For the B7-P47/46 girder, the LVDTs along the shear span, in positions 2-4 and 5-7, were moved 50 cm from the transverse diaphragms. The LVDTs in positions B02/03C and B05/06C were used along the shear span, close to positions 1 and 8. The two strain gauges were moved to the same alignment as the B03T. For B10-Ab/P47 girder, the two strain gauges have been moved to the midspan.

4 TEST RESULTS

Some of the most representative results of the full-scale load tests have been reported in the present paper. These diagrams were chosen to show the overall structural response of the girder as a consequence of simultaneous shear and bending actions during the mechanical tests. All the diagrams have been obtained by referring to the load applied by a single jack. Therefore, to consider the total load applied to the specimen, the load should be multiplied by 4. Furthermore, the self-weight and the weight of the loading system (estimated as 11.82 kN per actuator) need to be considered.

The Figure 4 presents the midspan deflection versus the applied load. The diagrams highlight a similar behaviour for all the specimens, which can be described by three phases: a linear elastic relationship, a cracking-induced reduction of the stiffness and the failure after reaching the maximum load due to the crushing of the upper slab.

The failure mode was similar with that registered in the first group of specimens (Savino et al. 2023). However, a different resistance mechanism was involved, as it will be shown in the following based on the crack pattern.

The B7-P47/46 reached its maximum capacity with a load of 120.1 kN, inherent to an applied bending moment of 1561.3 kNm. The B6-Ab/P47 showed a failure load of 126.5 kN; this load

Figure 4. Load vs deflection: (a) B7-P47/46, (b) B6-Ab/P47, (c) B6-P48/49, and (d) B10-Ab/P47 girder.

corresponds to a maximum applied bending moment of 1644.5 kNm. The B6-P48/49 was loaded up to a failure load of 105.6 kN, corresponding to a bending moment of 1372.8 kNm. The B10-Ab/P47 was loaded up to a failure load of 124.0 kN, corresponding to a bending moment of 1612.0 kNm. At these load levels, the B7-P47/46, B6-Ab/P47, B6-P48/49, and B10-Ab/P47 specimen exhibited maximum midspan deflections of 179.9, 191.3, 184.3 and 205.5 mm, respectively. Referring to the load-midspan deflection diagram of the specimens tested under three-point loading configuration, the maximum bending moment and midspan deflection were 1492.2 kNm (B8-P47/46) and 167 mm (B3-P47/46) respectively (Savino et al. 2023).

Since the load-deflection curves are function of the global behavior of the specimens, the first cracking load was detected from the load-tensile strain curves recorded by local transducers installed at the bottom flange of the PC girders near the midspan. The cracking load was determined in the sections that firstly began to deviate from the linear trend. As an example, Figure 5a shows a comparison between the LVDT readings and the strain gauge sg2, which shows the lowest cracking load. The estimated cracking loads for B7-P47/46, B6-Ab/P47, B6-P48/49, and B10-Ab/P47 beam were 20.7 kN, 25.5 kN, 17.2 kN, and 22.1 kN, respectively.

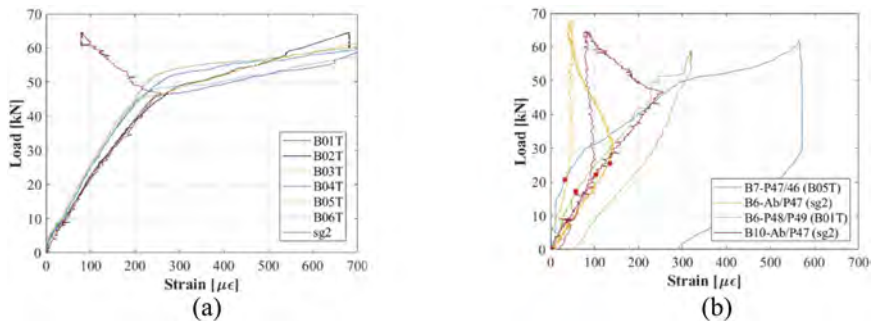

Figure 5. Load versus tensile strains: (a) signals comparison for B10-Ab/P47, (b) cracking load for B7-P47/46, B6-Ab/P47, B6-P48/49, and B10-Ab/P47 girder.

All curves start with a linear branch followed by a change in strain distribution when the applied load determines the first cracking. For B6-Ab/P47 and B10-Ab/P47 specimen, as the tensile strains were recorded by the strain gauges, a reduction in strain is observed: this can be associated to a crack opening in the nearby of the strain gauge location.

The compressive strains recorded in the top region have been reported in Figure 6. The green curves refer to the strain of the cast in situ slab recorded by strain gauges, and the other two curves refer to the top flanges of the I-beams, according to the layout in Figure 3. Furthermore, the images of the failure zones are also reported. The maximum compressive strain recorded on the top slab of the B7-P47/46 beam was -2.2‰. From Figure 6b, the failure occurred close to the strain gauge position in the midspan. For the other specimens, the compressive strains on the top slab resulted -1.4‰, -1.1‰, and -1.7‰, respectively.

Figure 6. Load versus top compressive strain and failure zones: (a)-(b) B7-P47/46, (c)-(d) B6-Ab/P47, (e)-(f) B6-P48/49, and (g)-(h) B10-Ab/P47 girder.

During the loading process, the average strains recorded by the LVDTs installed on the diagonal frames along the shear span were considered representative of the shear strains. As an example, the shear strain curves recorded on the left side (Figure 3) of the B7-P47/46 beam are shown in Figure 7. According to these curves after the load reaches approximately 50 kN, diagonal cracks formed with an inclined angle from the longitudinal axis, and basically orthogonal to the principal tension direction.

Figure 7. Load versus shear strain for B7-P47/46 beam.

The development of flexure-shear cracking for beam B7-P47/46 as representative of the four tests is reported in Figure 8a. The cracking pattern registered for girder B8-P47/46, as a representative of the previous three-point bending configurations, is reported in Figure 8b which reveals shear cracking along the whole length of the beam. Figure 8a reveals no shear strains in the constant moment region and a higher number of diagonal cracks in the shear span.

Figure 8. Crack pattern after the load tests: (a) B7-P47/46 (4-P bending test), and (b) B8-P47/46 (3-P bending test) girder.

5 CONCLUSIONS

An extensive experimental investigation has been conducted to study the structural behavior of 50-year-old PC girders at both service and ultimate load levels. The present paper summarizes the experimental part of the investigation concerning the tests involving both flexural and shear mechanisms. Specimens with different level of damage were tested, undamaged and damaged by dismantling operations, resulting in strands cut. The test results were analyzed considering deflections, strains, and cracks evolution, as well as ultimate capacities. Furthermore, the structural responses were compared with the results of specimens previously tested in three-point bending configuration. All the tests have shown a flexural compression failure with brittle crushing of the cast in situ slab.

Experimental tests for mechanical characterization of prestressed concrete bridge deck beams

M. Anghileri, G. Rosati & F. Biondini
Politecnico di Milano, Milan, Italy

P. Savino & F. Tondolo
Politecnico di Torino, Turin, Italy

ABSTRACT: This paper presents the preliminary results of extensive experimental activities for mechanical characterization of 50-year-old prestressed concrete bridge deck beams within the BRIDGE|50 research project (<http://www.bridge50.org>). The experimental campaign includes non-destructive diagnostic tests (e.g. sclerometer and ultrasonic tests) carried out on several prestressed concrete deck beams and laboratory mechanical tests on concrete cores extracted from both precast beam and cast-in-situ slab. The results of these activities have been used for calibration and validation of structural analysis models and to support a proper planning of full-scale load tests up to collapse to be performed on the deck beams.

1 INTRODUCTION

Aging and deterioration processes, combined with poor durability and lack of maintenance and repair activities, may drastically affect in time the load bearing capacity reducing the structural lifetime of bridges. This is nowadays an urgent problem in many countries, including Italy, since there is a large number of bridges built over the past 50 years that are approaching the end of the service life and a significant percentage of them are in a state of moderate to severe deterioration (Malerba 2014, ASCE 2021). The amount of maintenance and repair activities necessary to restore or increase the structural capacity and functionality of deteriorated bridges is huge and represents a relevant obstacle to infrastructure facilities management for owners and public authorities. This critical situation is made more evident by recent bridge and viaduct collapse events that have occurred with alarming frequency. It is therefore of paramount importance to establish effective life-cycle criteria, methods, and tools for bridge assessment, maintenance and management under uncertainty (Biondini and Frangopol 2016, 2019).

Despite significant developments accomplished in the last decades, life-cycle approaches still need to be consolidated by robust validation and accurate calibration and gathering new information and data from existing bridges and experimental tests is key to this purpose. BRIDGE|50 is a research project established jointly by Politecnico di Milano and Politecnico di Torino as part of a research agreement with public authorities and private companies to collect data from inspection activities and experimental tests on deteriorated bridge components and investigate the residual structural performance of existing bridges. This project includes a wide experimental campaign on a set of 29 Prestressed Concrete (PC) deck beams (25 PC I-beams and 4 PC box beams) with top Reinforced Concrete (RC) slab and 2 PC pier caps stored in a testing site after the dismantling of a viaduct in service for about 50 years (Biondini et al. 2021a, 2021b, 2022, Savino et al. 2022). The on-site activities include non-destructive diagnostic tests, full-scale load tests up to collapse, and concrete samples collected for laboratory tests. This paper presents the preliminary results of the non-destructive tests and laboratory tests for mechanical characterization of the PC bridge deck beams. The results of these activities have been used for calibration and validation of structural analysis models

(Anghileri and Biondini 2022) and to support a proper planning of full-scale load tests up to collapse to be performed on the PC deck beams (Tondolo et al. 2022).

2 PRELIMINARY ON-SITE INVESTIGATION

The experimental campaign of the research project started with a series of preliminary activities conducted on-site before the dismantling of the viaduct. These activities included visual inspections of the bridge components. Visual inspections have been conducted according to national and international standards with the participation of public authorities and private managing bodies. The large and diversified amount of data gathered through these activities has been elaborated according to inspection models typically used in practice (Beltrami et al. 2021).

Concrete coring from a bridge pier and carbonation tests have been conducted to investigate the aging and deterioration effects. Concrete split cores have been extracted from a bridge pier and carbonation depth has been assessed using a phenolphthalein solution as an indicator of the location of the depassivation front. A dynamic tests campaign has been also carried out on the bridge decks to characterize the dynamic behavior of the decks under service condition. Dynamic measurements have been acquired by using instrumented hammer and free-falling mass devices. The collected data have been analyzed in order to extract the principal modal components. The comparison of these results with those provided by full-scale experimental tests conducted in the testing site have been used to investigate the effectiveness of dynamic identification procedures in the assessment of damaged bridges. A detailed description of this activity and a critical appraisal of the results are reported in Quattrone et al. (2021) and Sabia et al. (2021, 2022).

3 PC BRIDGE DECK BEAMS

The dismantling of the viaduct at the end of its service life allowed the opportunity to investigate the residual capacity of several PC elements. In particular, 29 PC deck beams and 2 PC pier caps of the viaduct have been moved and stored in a testing site. The preliminary activities of the experimental campaign started with the study of the I-shaped PC bridge deck shown in Figure 1. The beams are characterized by a total length of about 19.40 m and made of a precast PC beam with top cast-in-place RC slab.

Figure 1. PC bridge deck beams stored at the testing site.

The I-shaped bridge deck beams are reinforced with twenty 7-wire prestressing strands with straight longitudinal profile. The nominal diameter of the steel strands is 12.7 mm (effective area 99 mm²). The initial prestressing stress, net of instantaneous and estimated long-term losses reported in the technical design documentation is $\sigma_{pd}=836$ MPa. However, based on the results of full-scale load tests and diagnostic activities aimed at evaluating the residual prestressing, the actual prestressing level after a lifetime of 50 years resulted significantly lower with respect to the design value, with a prestressing stress level $\sigma_p=614$ MPa estimated to best fit the experimental results of full-scale load tests (Anghileri 2022).

4 NON-DESTRUCTIVE TESTING

Rebound hammer tests and ultrasonic tests have been conducted on several PC bridge deck beams to characterize the concrete mechanical characteristics. The tests have been carried out

by subdividing the beams in five sample portions representative of the longitudinal beam profile. Longitudinal steel bars and stirrups are detected by means of pacometer and marked on the beam surface. This allowed to define a grid of 3×3 points on both the rear and front side used for sclerometer and ultrasound emission and reception points.

Ultrasonic tests have been conducted to measure the propagation velocity of compressive mechanical waves along the beam. This method can allow to detect internal cracking and other defects as well as damage in concrete such as environmental deterioration due to aggressive chemicals and inadequate concrete cast. It is worth noting that the outcomes at beam lateral regions might be characterized by a lower accuracy with respect to the measurements over the beam web in the inner regions due to both larger irregularities in the material volume when larger distances are covered by the ultrasound waves and interaction with denser reinforcement pattern.

The ultrasonic test measures the time required by the ultrasonic waves to cross the beam depth which is converted to concrete elastic modulus assuming concrete density $\rho=25 \text{ kN/m}^3$ and Poisson ratio $\nu =0.2$, as reported in the design technical documentation. Figure 2 shows mean and standard deviation values of concrete elastic modulus E measured in correspondence of the support lateral regions and over the beam web regions for 11 PC I-shaped beams.

Figure 2. Mean and standard deviation values of elastic modulus E for 11 beams: (a) support regions, and (b) beam web regions.

The results show a quite large variability at the same sample zones, particularly for the elastic modulus over the beam web. This effect might be attributed to differences in local concrete composition and/or deterioration state. The overall sample mean \bar{x} and sample coefficient of variation (CoV) of the concrete elastic modulus E are 29.89 GPa and 0.17, respectively. Moreover, assuming a Student's t-distribution for the standard variate associated to concrete elastic modulus sample mean \bar{x} , the two-sided 95% and 99% confidence interval are $(\bar{x} \pm 1.54 \text{ GPa})$ and $(\bar{x} \pm 1.95 \text{ GPa})$, respectively. These statistical confidence intervals can provide a quantitative measure of accuracy of point estimates of the sample mean (Ang and Tang 2007). Also, considering the total set of samples $n=55$, Figure 3 shows the results of the χ^2 and Kolmogorov-Smirnov (K-S) statistical tests conducted to estimate the validity of probability distribution models associated to the considered random variable and discriminate the relative goodness-of-fit among assumed distribution models. The χ^2 test compares the empirical probability mass function and the theoretical probability density functions by assuming normal and lognormal distributions. The K-S test compares the experimental cumulative frequency with a lognormal cumulative distribution function. Both statistical tests are passed with a significance level of 5%.

The rebound hammer test is used to estimate the compressive concrete strength based on the correlation between material surface hardness and residual strength. In fact, the sclerometer includes a sliding mass coupled with a spring. The mass is in contact with a swinging rod used to strike the material surface. The rebound distance of the mass is converted by a graduated scale into the rebound number S , which is then converted into the estimated concrete strength through a correlation curve calibrated by the device manufacturer using standard specimens.

Figure 3. Concrete elastic modulus E distributions: (a) χ^2 and (b) Kolmogorov-Smirnov statistical tests.

The rebound test is carried out after the ultrasonic test because the hammer blows may leave small marks on the beam that may affect the concrete surface roughness. The sclerometer test has been applied to three PC bridge deck beams collected in the testing site for a total of 15 sampling points. The rebound number S is converted into concrete compression strength. The overall sample mean and CoV of compressive concrete strength f_{cm} are 48.25 MPa and 0.20, respectively. The rebound hammer method generally provides a good estimate only of concrete cover strength. Even though concrete carbonation may lead to steel reinforcement corrosion, it generally increases the concrete strength. Therefore, the results of rebound tests may overestimate concrete strength. A more accurate estimate of the concrete strength has been evaluated based on SonReb method, with mean value $f_{cm}=31.88$ MPa and $CoV=0.25$. A detailed description of this activity is reported in Anghileri et al. (2021).

5 LABORATORY MECHANICAL TESTS

Laboratory mechanical tests have been performed on several concrete cores extracted from the PC bridge deck beams (Figure 4) after full-scale load tests have been performed. The concrete strength has been evaluated with uni-axial compressive tests on cylindrical samples characterized by aspect ratio 1:1 or 1:2 (Figure 5) and different diameter values (i.e., $\varnothing 75$, $\varnothing 100$, and $\varnothing 150$ mm). The results showed a small variability between the samples extracted from three PC deck beams. Considering a set of $n=17$ samples, the overall sample mean and CoV of the concrete compressive strength f_c are 29.94 MPa and 0.15, respectively, showing a good agreement with the results of non-destructive tests processed through the SonReb method.

Figure 4. Coring of samples from PC bridge deck beams.

The tensile concrete strength has been evaluated through splitting tensile strength test (Figure 6). The experimental results showed a small variability between samples extracted from three PC deck

Figure 5. Uni-axial compressive strength tests on concrete samples.

beams also for the tensile concrete strength. Considering a set of $n=9$ samples, the overall sample mean and CoV of the concrete tensile strength f_{ct} are 3.33 MPa and 0.13, respectively.

Figure 6. Splitting concrete tensile strength test.

The concrete elastic modulus has been also evaluated with uni-axial compressive strength test (Figure 7). Considering a set of $n=8$ samples, the overall sample mean and CoV of the concrete elastic modulus E_c are 27.22 GPa and 0.07, respectively. Moreover, the same eight samples have been used for uni-axial compressive tests to evaluate the complete stress-strain curves (Figure 8).

The level of concrete carbonation depth has been measured on the samples spraying a solution of phenolphthalein on concrete surfaces. Figure 9 shows the concrete carbonation depth assessment through a bar graph for concrete cores extracted from the support regions (rectangular cross-section) and beam web regions (I-shaped cross-section) of three PC deck beams.

Two tensile concrete strength tests have been also performed on concrete cores extracted from the top RC slab of the deck beams. Moreover, tensile tests have been conducted on samples of both prestressing strands and reinforcing bars. Table 1 and Table 2 summarize the mechanical properties of materials for both precast PC bridge deck beams and cast-in-situ RC slab, respectively, as evaluated from the complete set of information collected from available technical documentation, results of laboratory tests on samples, and results of on-site non-destructive testing.

The deck beams, particularly in the end regions, exhibit local damage due to corrosion with steel mass loss and concrete spalling. These effects can be attributed to the inadequacy of the bridge water conveyance system and use of road salts during the service life of the bridge.

Figure 7. Uni-axial concrete compressive test for elastic modulus assessment.

Figure 8. Uni-axial stress-strain curves of concrete in compression.

Figure 9. Concrete carbonation depth assessment.

However, based on visual inspections of the tested beams in the failure regions after the full-scale load tests, no significant corrosion of the prestressing strands has been observed. This indicates a relatively good attention during the construction phase of the precast PC beams.

The results of visual inspection activities, non-destructive and destructive tests, and laboratory tests have been also used for validation and calibration of structural modeling for non-linear analysis (Anghileri and Biondini 2021, 2022, Anghileri 2022) and a proper plan of the full-scale load tests (Tondolo et. al 2022, Savino et. al 2023).

Table 1. Nominal material characteristics of precast PC bridge deck beam.

Material characteristic	Value
Compressive concrete strength, f_c	-29.94 MPa
Tensile concrete strength, f_{ct}	3.33 MPa
Concrete elastic modulus, E_c	27.22 GPa
Steel bar yielding strength, f_{sy}	450 MPa
Steel bar ultimate strength, f_{su}	540 MPa
Steel bar elastic modulus, E_s	200 GPa
Steel strand yielding strength, f_{py}	1486 MPa
Steel strand ultimate strength, f_{pu}	1722 MPa
Steel strand elastic modulus, E_p	195 GPa

Table 2. Nominal material characteristics of cast-in-situ RC slab.

Material characteristic	Value
Compressive concrete strength, f_c	-26.00 MPa
Tensile concrete strength, f_{ct}	2.35 MPa
Concrete elastic modulus, E_c	27.00 GPa
Steel bar yielding strength, f_{sy}	450 MPa
Steel bar ultimate strength, f_{su}	540 MPa
Steel bar elastic modulus, E_s	200 GPa

6 CONCLUSIONS

Experimental activities based on non-destructive and laboratory tests carried out on concrete samples extracted from several 50-year-old PC bridge decks beams with cast-in-situ RC slab have been presented. Non destructive diagnostics included rebound hammer tests, ultrasonic tests, pacometer tests, sclerometric tests, and ultrasonic tests. The results of the non-destructive tests have been elaborated based on confidence intervals and statistical tests. The mechanical properties of materials have been estimated based on laboratory tests on concrete cores and samples of prestressing strands and reinforcing bars. For concrete, the results of laboratory tests show good agreement with the results of non-destructive tests processed through the SonReb method. Furthermore, concrete carbonation has been measured with higher carbonation depths in the web regions of the PC deck beams. For prestressing strands, no significance corrosion has been found based on visual inspections of the tested beams in the failure regions after the full-scale load tests.

The results of these experimental tests will be continuously updated based on the ongoing activities of the BRIDGE|50 research project and will be used for calibration and validation of structural analysis models and corrosion deterioration models to support a proper planning and interpretation of full-scale load tests to be performed on the deck beams.

Experimental campaign for corrosion assessment of 50-year-old PC deck beams

M. Carsana, E. Redaelli, D.O. Valoti & F. Biondini
Politecnico di Milano, Milan, Italy

ABSTRACT: Several prestressed concrete (PC) deck beams, stored in a testing site after dismantling a 50-year-old viaduct, have been subjected to inspection and diagnostics activities within the BRIDGE|50 research project. This paper discusses the results of field and laboratory tests carried out on these structural elements. Based on visual observations and magnetic and electrochemical tests, concrete samples have been collected from different PC deck beams in order to understand the cause of their degradation conditions. Chemical, physical, and microstructural properties of samples from selected beams are investigated based on laboratory tests focusing on the measurement of the actual carbonation penetration, chloride penetration profiles, and other durability-related parameters that are fundamental for corrosion assessment of PC deck beams.

1 INTRODUCTION

Reinforced concrete (RC) and prestressed concrete (PC) structures are exposed to multiple aging and deterioration processes, especially due to corrosion of steel reinforcement (Bertolini 2008, Biondini & Frangopol 2016). The impact of these damage processes is high, particularly for the large stock of existing RC/PC structures and infrastructural facilities, such as bridges and viaducts, built around the middle of last century. A proper and effective maintenance of RC/PC structures under corrosion needs to be supported by suitable criteria, methods and procedures for the characterization of the state of materials degradation (Bertolini et al. 2013) and condition structural assessment (Biondini & Frangopol 2019). A strong impulse for advances along these lines is given by the ongoing BRIDGE|50 research project - Residual structural performance of a 50-year-old bridge (Biondini et al. 2020), conducted within a research agreement established among Politecnico di Milano, Politecnico di Torino, and several public authorities and private companies (www.bridge50.org). This project provides a wide experimental campaign to be carried out on a group of PC deck beams obtained from a viaduct demolished in Turin in 2019 after a lifetime of about 50 years. Two adjacent spans of the viaduct have been preserved and deconstructed, including 29 precast PC beams (25 I-beams and four box beams) and two PC pier caps. These structural members are currently stored in a testing area dedicated to full scale load tests up to collapse, field investigations, and collection of samples for laboratory tests.

This paper reports an overview of the ongoing research activities devoted to field diagnostics and laboratory tests for corrosion characterization. More in detail, based on results from visual observations and non-destructive testing (NDT) made through magnetic and electrochemical methods (such as those for measuring corrosion potential of steel bars and electrical resistivity of concrete), concrete samples have been collected from selected structural elements (Figure 1) in order to better understand the cause of their degradation conditions. Chemical, physical, and microstructural properties of samples collected from different PC deck beams have been investigated. Laboratory tests have been focused on the measurement of the actual carbonation depth, chloride penetration profiles, sulphates content and microstructural features of concrete for a proper degradation assessment of PC beams.

Figure 1. View of different types and condition degradation state of PC structural elements preserved in the testing area. (a) Northern and eastern fronts of I-beam 46-T9-47; (b) Southern and eastern fronts of box-beam 47-C2-SP; (c) Eastern front of pier cap 48; (d) Southern and eastern fronts of I-beam 46-T1-47.

2 FIELD TESTS

The analysis of the PC deck beams started with an accurate visual survey which has been carried out in order to assess visible signs of deterioration and to locate areas for field measurements consisting of NDT described in §2.1. The preliminary inspection of the beams has highlighted their different conditions depending on the structural type. Cracking and spalling of concrete took place on wide zones of the structural elements, especially for pier caps and box beams. The pier caps exhibit evident signs of deterioration from corrosion of the reinforcing bars with wide detachments of the concrete, often even for layers of thickness larger than the concrete cover. Moreover, parts of the reinforcement are no longer embedded in concrete and they are heavily corroded (Figure 1c). Box-beams show signs of degradation especially in the bottom parts (Figure 1b). Moreover, some zones of concrete surface are interested by phenomena of efflorescence that could be due to the use of deicing salts. Overall, most of I-beams seem to be under fair conditions as documented in Figure 1a (except for damages caused by the demolition operations). Some of I-beams present signs of concrete segregation, limited to the end zones; only two I-beams show in such end parts wide detachments of concrete cover and steel bars heavily corroded (Figure 1d). A detailed inspection has been documented in Carsana et al. (2021) in order to assess the presence of visible signs of degradation. Based on visual inspection activities, NDT have been carried out in field on selected elements (Carsana et al. 2022), one for each type of PC beams.

2.1 Methodology

In order to verify the degradation state of steel bars on different types of PC beams, the cover depth of the outermost reinforcing bars has been detected with a magnetic-type covermeter. The concrete surface has been investigated by using re-bound hammer test. The corrosion behaviour of the steel reinforcement has been investigated by means of electrochemical measurements. The corrosion potential of steel has been mapped on the concrete surface using a CSE (Cu/CuSO₄) reference electrode. The electrical resistivity has been measured by placing a resistivity probe connected to a conductivitymeter on the outside surface. Preliminary measurements of corrosion rate have been also made in some localized zones of inspected PC elements.

2.2 Preliminary results

Inspection of selected PC beams has been made along several fronts (E=East; N=North; W=West, and S=South) by means of measurements of concrete cover thickness, surface strength (R_{scler}), corrosion potential (E_{corr}) and corrosion rate (i_{corr}) of steel bars and electrical resistivity of concrete (ρ). Results of inspection are summarized in Table 1, where the minimum (m), maximum (M) and average values (ave) obtained from each measurement are shown; the number of measurements (#) is also reported.

In order to assess the quality of the concrete, Schmidt hammer tests have been carried out. It should be observed that this test can be characterised by a great scatter of results, due to not only the variability of the compressive strength of concrete but the influence of several parameters related to the surface hardness of concrete (which is the parameter actually measured by the Schmidt hammer). Overall, the mechanical performance of the concrete of different PC beams seems comparable; the average values of the estimated strength of concrete ranged from 43 MPa (pier cap 48) to 57 MPa (I-beam 46-T9-47). Major variability has only been found for pier caps due to presence of zones where the concrete is weak, such as those close to cracking and spalling of surface. In fact, Schmidt hammer tests, being a NDT measurement, can extensively be carried out throughout the elements and can be used as an index of the homogeneity of the concrete. Electrochemical measurements have been carried out to investigate the corrosion conditions of the reinforcement at the moment of inspection (Table 1). On average, the corrosion potential measured on east front of pier cap 48 is -282 mV vs CSE. In several parts of east front corrosion potential reached also minimum values of -423 mV vs CSE, lower than -350 mV vs CSE (i.e., the threshold according to American Standard ASTM C876 below which the probability of corrosion is higher than 90%). Thus, such values highlight that, at the time of the measurements, the corrosion state of steel bars was not negligible. It should however be observed that electrochemical measurements refer to the active conditions of the steel at the moment in which the measurement is carried out and they could change based on electrical resistivity of concrete. Since the survey has been carried out after a rather dry period, the concrete was dry and had high values of electrical resistivity ($>1000 \Omega m$), as reported in Table 1. Comparable conditions have been also observed on the north front of pier cap 48 that has showed average values of electrical resistivity and corrosion potential respectively equal to 614 Ωm and -334 mV vs CSE. Overall, corrosion rate values of 301 and 5.35 mA/m² have been measured on pier cap 48. Certainly, the corrosion propagation of steel bars in this structural element could increase further during wet periods and more negative corrosion potentials could be reached.

Corrosion evaluation has been carried out in the same period also both on south and west fronts of the box beam 47-C2-SP. The reinforcement potential of the box beam 47-C2-SP showed average values of -136 and -220 mV/CSE and minimum values of -351 mV and -371 mV vs CSE (Table 1), while the electrical resistivity of concrete ranged between 700 and 1080 Ωm . The corrosion risk seems comparable to that of pier cap 48 as confirmed by a value of corrosion rate of 5.31 mA/m². For comparison, electrochemical measures have been carried out also on I-beam 46-T9-47 which showed corrosion potentials (between -59 mV and -119 mV vs CSE), significantly higher than those measured on box beam and pier cap. A negligible corrosion probability is also confirmed by a corrosion rate of 0.14 – 1.19 mA/m². In order to better investigate the causes of corrosion of inspected structural elements, different samples have been collected and subjected to laboratory tests.

3 LABORATORY TESTS

Table 2 summarizes structural elements that have been considered for more detailed inspection through by collecting several samples and doing laboratory tests. Such samples have been derived from different zones selected by taking into account their representativeness and exposure conditions with respect to the original location in the dismantled viaduct.

3.1 Sampling and analysis

Initially, several small fragments of concrete (indicated as *Fi*) have been collected during inspection phases. In few cases cores of diameter 45.5 mm and length of at least 160 mm have been also taken from the longitudinal or transversal front of structural elements (*Ci*). Moreover, several samples of concrete powders (*Pi*) have been collected directly by drilling at several depth with a tip of 10 mm diameter being this method considered much less invasive than taking a concrete core. The depth of carbonation has been measured by spraying a phenolphthalein indicator on concrete powders collected at increasing depth. Same test has been repeated also in lab on concrete cores derived from PC beams.

Chloride analyses have been carried out both on concrete powder samples as well as on 10 mm concrete slices in which each core has been divided in order to determine total chlorides profile as a function of depth. Both powder samples and concrete slices, the latter once ground, have been digested in hot nitric acid. The chloride content has been measured by means of potentiometric titration and expressed as percentage of the dry concrete. Chloride content has been measured also on single concrete fragments collected from outside surface of several PC beams. The content of sulphates has been measured with traditional chemical analysis of the samples dissolved in hydrochloric acid. Moreover, the microstructure of some samples has been observed under scanning electron microscope with an EDS X-ray spectrometer.

3.2 Analysis of results

The SEM image of concrete sample collected from I beam 46-T9-47 (Figure 2a) highlights the typical features of hardened cement paste. The compact morphology of cement paste is not much different from those of concrete fragments collected from other PC beams (F28 and F27) and may justify the high strength values measured by Schmidt hammer tests (Table 1). Moreover, the presence of certain chemical elements, such as calcium (Ca), oxygen (O) and silicon (Si) in major amounts, in addition to magnesium (Mg), aluminum (Al) and sodium (Na), is associated to typical compounds of calcium silicate and aluminate hydrates (Figure 2b). Traces of chlorine (Cl) and sulfur (S) have been found in this cement matrix as well as in those of samples F27 and F28 (Table 2). These traces suggest possible contaminations in concrete which could be responsible of chemical attacks (Neville 2011). Therefore, additional chemical tests have been carried out to verify degradation state of concrete of different PC beams.

Sulphate attack of concrete has been excluded for each type of PC beams. Samples C2, C3, F35, F36 and P28 show a content of SO_3 negligible, ranging between 0.12-0.81% (Colleparidi 2006). Further analyses have been carried out in order to value carbonation and chlorides penetration in concrete elements. Figure 3 compares the results of phenolphthalein test. Concrete core named C2-SN, which crossed the entire thickness of I-beam 46-T9-47, shows a depth of carbonation of 29-30 mm on the northern and the southern fronts.

On the southern front powder concrete samples (*P1-S*) have been also collected near concrete core C2-SN by obtaining comparable values, even if less accurate. For a depth of 20 mm concrete powder turned out to be carbonated, while for an increasing depth, ranging between 20 and 40 mm, not all powders turned out to be carbonated and showed grey-pink color. Phenolphthalein test made on this second layer of the *P1-S* sample indicates that the depth of carbonation shall be considered between 20 and 40 mm. From the comparison of the average value of the carbonation depth with the average value of the concrete cover thickness (Table 1), it follows that steel reinforcement of southern front of I beam 46-T9-47 should be in contact with an alkaline concrete.

On the east front of the same structural element the carbonation depth shows a major variability, likely related with different local properties of concrete. In fact, concrete core C3-E shows a depth of carbonation of 23 mm while powder concrete samples *P2-E*, collected in a zone near segregation (Figure 3b), turned out to be carbonated up to a depth of 40 mm. Therefore, the reinforcement, for which the concrete cover is minimum (as for reinforcing bars present in the bottom part, Figure 3b) and carbonation front has reached them, are no longer in passive conditions and the risk of concrete cracking due to corrosion is present.

On other inspected structural elements (48 and 47-C2-SP) carbonation depth has been measured only by means of drilling of powder concrete. Box beam 47-C2-SP has been tested

in terms of carbonation thickness in two zones of southern front (*P5* and *P6*), showing values of the order of 7-17 mm, and in a zone of western front (*P7*) which results to be in alkaline condition. For pier cap 48 the carbonation depth was less than 20 mm on eastern front (sample *P3*). Conversely, sample *P4* of the northern front of pier cap 48 was alkaline although it was collected near the zone with evident signs of deterioration from corrosion (Figure 1c). Concrete of pier cap 48 and box beam 47-C2-SP showed to be less carbonated than that of I beam 46-T9-47. Since their carbonation front is lower than the average depth of the reinforcement (22-23 mm), it appears that rebars were corroding at the time of inspection for other causes. Thus, several samples have been subjected to the measurement of chlorides content (Table 2). Figure 4 shows, separately for type of inspected beams, the chloride profiles measured on concrete samples. Each graph reports the chloride profiles measured on both

longitudinal and transversal fronts of inspected beams (distinguished respectively by means of filled and empty symbols) and the critical threshold of chlorides (dotted line) for carbon steel (0.05-0.125% in mass of concrete).

Chloride profiles have been interpolated based on the “erf function” obtained from the analytical solution of the one-dimensional Fick’s second law of diffusion. Often the first analysis, i.e. the outermost point (red border), has been not considered in the fitting procedure. Figure 4a shows chloride profiles obtained both from concrete cores (C2, C3) and powder concretes (P1, P2) collected from I beam 46-T9-47. In particular, comparable chloride contents have been obtained for specimens from southern front (P1) and from top part of eastern front (C3), where no segregation phenomena are visible, with negligible values (around 0.01% in mass of concrete).

Figure 2. (a) SEM image, and (b) EDS analysis of the cement matrix of concrete sample F12 collected from I beam 46-T9-47.

Figure 3. (a) Results of phenolphthalein test carried out both on concrete powder (P_1) and core (C_i) samples (grey = carbonated concrete; pink = alkaline concrete; mix color grey/pink = alkaline/carbonated concrete). Average concrete cover for each structural element is indicated with a yellow line. (b) View of east front of 46-T9-47 and collection positions of the samples C3-E and P2-E.

Chloride content appears only slightly higher in the first 20 mm of the eastern front of I-beam 46-T9-47 (P2, Figure 3b), although it is lower than the critical threshold of chlorides. Chloride profiles have been calculated also on powder samples derived from other I-beams (Figure 4d). Overall, it can be deduced that chlorides content is always negligible on longitudinal front (south or north) of I-beams. Only in sample P11, chlorides content has reached the critical threshold at the average concrete cover thickness (Figure 4d). Moreover, in the concrete fragment F16, collected at a depth of 25-30 mm from I-beam 46-T1-47, a high chlorides content (0.09% vs concrete mass) has been found. Thus, it can be deduced that the risk of chloride-induced corrosion should be considered for I-beams only on transversal fronts, as confirmed for I-beams 47-T5-SP and 46-T1-47 and by preliminary observations (Figure 1d).

Same analyses have been repeated on pier cap 48 and box beam 47-C2-SP. Chloride profiles measured on pier cap 48 (Figure 4c) overcome the critical chlorides threshold also far beyond

average concrete cover thickness, both on eastern and northern fronts, with maximum values of 0.14% vs concrete mass. Chloride penetration in box-beam 47-C2-SP is comparable on western and southern fronts, with values intermediate between the maximum obtained on pier cap 48 and the minimum of I-beam elements; chlorides content is higher than the critical threshold beyond steel depth.

4 CORROSION ASSESSMENT

Pier caps and box-beams present evident signs of deterioration from corrosion of reinforcement (Figure 1). Conversely, no clear signs of corrosion-induced damage have been observed on I-beams, except in their end parts where evidences of concrete segregation are visible (Figure 3b). The presence of macro-voids, observed on the concrete surface especially of eastern and western fronts of I-beams, suggests that concrete was not properly vibrated during casting phases. This phenomenon might have caused in some cases premature corrosion initiation with consequent detachments (Figure 1d) towards the ends of the I-beams or in their lower parts. However, based on chemical analyses carried out on several concrete samples collected from all inspected PC beams, both chlorides and carbonation penetration seem to be the main causes of corrosion.

As far as pier cap 48 is concerned, the depth of carbonation, measured on eastern and northern fronts, ranges between 0 and less of 20 mm. From the comparison with the values of the concrete cover thickness (Table 1), it follows that a part of steel reinforcement of the pier cap 48 could be in contact with alkaline concrete. However, where the concrete cover is low (Table 1) and carbonation has reached the steel rebars, these are no longer in passive conditions. In addition, a chloride content higher than the critical threshold has been found in pier cap 48 at average steel depth (0.14% vs concrete mass). Certainly, high corrosion probability to which steel reinforcement of pier cap 48 might be subjected is confirmed by the electrochemical measurements obtained in terms of corrosion potential (until -424 mV vs CSE) and of corrosion rate (with a value of 5.35 mA/m²) at the moment of inspection. Overall, better conditions for steel reinforcement have been observed in the I-beams. For example, I-beam

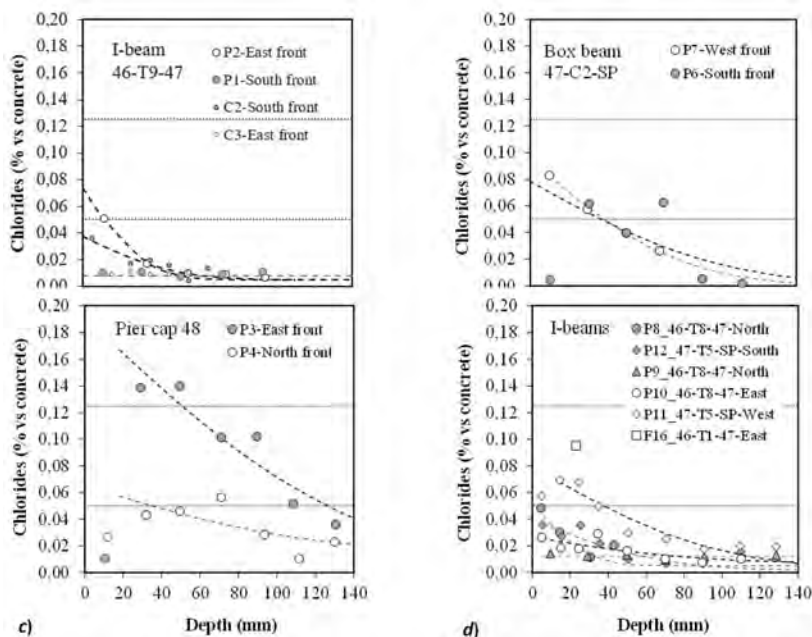

Figure 4. Chloride profiles measured on the different fronts of structural beams: (a) I-beam 46-T9-47; (b) box beam 47-C2-SP; (c) pier cap 48; (d) I-beams 46-T8-47, 46-T1-47 and 47-T5-SP. The dotted horizontal line indicates the critical chloride threshold.

46-T9-47 shows average corrosion potentials of -59 and -119 mV vs CSE respectively on southern and eastern fronts (Table 1). A negligible corrosion probability is also confirmed by an average corrosion rate ranging between 0.74 and 1.19 mA/m².

For these I-beams the risk of corrosion shall be considered high only towards their ends or in the lower parts, where the presence of macro-voids in case of segregation or an inadequate concrete cover could have favored the penetration of carbonation and chlorides (Figure 4d).

The conditions of box beams appear intermediate between those of pier caps and I-beams. Box-beam 47-C2-SP shows corrosion potentials ranging between -371 and +2 mV vs CSE with an average value of corrosion rate around 5.34 mA/m². The risk of chloride-induced corrosion from de-icing salts for box-beam 47-C2-SP is confirmed by chloride profiles.

5 CONCLUSIONS

In the framework of the multipartner project BRIDGE|50, a wide campaign of field and laboratory tests concerning real scale PC elements, such as those deriving from the viaduct demolished in Turin in 2019 after 50 years of service life, is ongoing. The results of the experimental study already carried out are allowing to evaluate statistically various electrochemical, chemical, physical and microstructural parameters of the inspected structural elements with the aim of defining an adequate procedural approach for corrosion assessment of RC/PC structures and infrastructure facilities. In particular, the results presented in this paper has highlighted that the main causes of deterioration of RC/PC elements are associated to concrete carbonation and chloride penetration due to de-icing salt especially for pier caps and box beams. Further experimental research along these lines is in progress to investigate the main factors affecting carbonation and chloride-induced corrosion of structural elements by considering different exposure conditions.

Experimental validation of nonlinear finite element analysis of PC bridge deck beams based on the results of full-scale load tests

M. Anghileri & F. Biondini
Politecnico di Milano, Milan, Italy

ABSTRACT: Full-scale load tests on prestressed concrete (PC) deck beams extracted from a dismantled bridge have been performed within the ongoing BRIDGE|50 research project. The results of this experimental activity, along with the outcomes of non-destructive tests and laboratory tests for mechanical characterization of materials, are considered in this paper for the validation of computational structural analysis models based on PC beam finite elements with distributed nonlinearity and plane-stress finite elements formulated in accordance with the Modified Compression Field Theory. The accuracy of numerical versus experimental results is evaluated under four-point bending for different shear span ratios and by taking into account the contribution of the top concrete slab on the structural response of the tested beams.

1 INTRODUCTION

Life-cycle-oriented design, assessment, maintenance, and management of deteriorating structures and infrastructural facilities should rely on structural analysis frameworks capable to account for time-variant structural performance, loading scenarios, environmental exposures, deterioration processes, and effects of maintenance and repair interventions (Biondini and Frangopol 2016). Availability of efficient and accurate life-cycle models is particularly important for bridge structures to properly address the significant amount of maintenance and repair activities necessary to restore or increase the structural capacity and functionality of huge stocks of existing bridges and viaducts worldwide that are currently rated as structurally deficient (ASCE 2021). However, although life-cycle models are well established for some of the most detrimental damage processes, such as corrosion and fatigue, robust validation and accurate calibration are still needed (Ellingwood 2005, Biondini and Frangopol 2018). In fact, deterioration models are sensitive to change of the probabilistic parameters of the input random variables and their validation is a difficult task because of the limited availability of information about long-term performance of in-service structures. Gathering new data from both inspection of existing structures and experimental tests is therefore of essence for a successful implementation in practice of life-cycle methods.

Based on these needs, the BRIDGE|50 research project has been established by Politecnico di Milano and Politecnico di Torino as part of an agreement with public authorities and private companies for a wide experimental campaign on a prestressed concrete (PC) viaduct dismantled after a lifetime of about 50 years (Biondini et al. 2021a, 2021b). A set of 29 PC deck beams, including 25 I-beams and four box-beams with top reinforced concrete (RC) slab, and two PC pier caps have been moved and stored in a testing site. The experimental activities include non-destructive diagnostic tests, full-scale load tests, and laboratory tests. These activities are complemented by extensive numerical analyses to further investigate the structural behavior of the tested beams and support a proper planning of the ongoing load tests (Anghileri and Biondini 2021, 2022). This paper presents recent project advances aimed at validating computational structural analysis models based on RC/PC beam finite elements with distributed nonlinearity and plane-stress finite elements formulated in accordance with the Modified Compression Field Theory (MCFT).

2 EXPERIMENTAL CAMPAIGN

2.1 PC bridge deck I-beams

The PC bridge deck beams investigated in this paper have a total length of about 19.40 m and consist of precast PC I-beams with twenty 7-wire prestressing strands and top cast-in-place RC slab, as shown in Figure 1. The nominal diameter of the steel strands is 12.7 mm (effective area 99 mm²). The initial prestressing stress, net of instantaneous and estimated long-term losses reported in the technical design documentation is $\sigma_{pd}=836$ MPa. However, based on the results of full-scale load tests and diagnostic activities, the actual prestressing level after a lifetime of 50 years resulted lower of about 25-30% with respect to the design value. This reduced value can be associated to larger instantaneous and/or long-term prestressing losses and steel corrosion effects. The I-beams, particularly in the end regions, exhibit local damage due to corrosion with steel mass loss and concrete spalling. These effects can be attributed to inadequacy of the bridge water conveyance system and use of road salts during the bridge service life. However, no significance corrosion of the prestressing strands has been observed based on visual inspections of the tested beams in the failure regions after the full-scale load tests. The effects of steel corrosion are therefore not considered in the structural analysis of the beams investigated in this paper.

Figure 1. PC deck beams: (a-b) views, (c) longitudinal profile, and (d) cross-section at mid-span.

2.2 Non-destructive diagnostics and laboratory tests

Non-destructive tests, including rebound hammer tests and ultrasonic tests, have been conducted on the PC beams to assess the concrete elastic modulus and compressive strength. Laboratory tests have been also carried out on several concrete cores extracted from the beams after full-scale load tests have been performed. The concrete compressive strength has been evaluated with uni-axial compressive tests on cylindrical samples with aspect ratio 1:1 or 1:2 and different diameter (i.e., Ø75, Ø100, and Ø150 mm). The results of the laboratory tests are in good agreement with the results of non-destructive tests based on the SonReb method. Uni-axial compressive strength tests have been also adopted to evaluate complete stress-strain curves. The tensile concrete strength has been evaluated through splitting tensile strength tests (Anghileri et al. 2023). Table 1 summarizes the nominal material mechanical properties evaluated based on the data reported in the available technical documentation complemented by the results of the experimental testing.

Table 1. Nominal material mechanical characteristics of the precast PC I-beams.

Material property	Value
Compressive concrete strength, f_c	-29.94 MPa
Tensile concrete strength, f_{ct}	3.33 MPa
Concrete elastic modulus, E_c	27.22 GPa
Steel bar yielding strength, f_{sy}	450 MPa
Steel bar ultimate strength, f_{su}	540 MPa
Steel bar elastic modulus, E_s	200 GPa
Steel strand yielding strength, f_{py}	1468 MPa
Steel strand ultimate strength, f_{pu}	1722 MPa
Steel strand elastic modulus, E_p	195 GPa

2.3 Full-scale load tests

Full-scale load tests are performed using the testing framework and the four-point loading scheme shown in Figure 2 (Tondolo et al. 2021, Savino et al. 2023). The loading system includes four actuators, two for each point load. The applied load is transferred by two transverse steel beams to the PC beam simply-supported at both ends by the steel reaction frame through bridge bearings. The setup of the experimental sensors installed to monitor the beam structural response during the full-scale load tests is shown Figure 2a (Tondolo et al. 2021, 2022). The reaction steel frame has been designed to allow for variable distance between the applied forces and reproduce the in-service span of the deck beams. Multiple load tests with different shear span ratio $\alpha=all$ are planned to investigate bending and shear failures.

Figure 2. Full-scale load tests. (a) Loading scheme and experimental sensors setup: load cells (LC), transducers to control the bending (LVDT_B) and shear (LVDT_S) behavior, displacement potentiometers (DP), transducers for strand slip and bearing settlements (LVDT_D), and transducer for beam-slab connection (LVDT_I). (b) View of the testing framework with a deck beam ready to be tested.

The testing program is ongoing. In this paper, the results obtained on the first six I-beams in the series are considered. The first four load tests have been carried out with shear span ratio $\alpha \approx 1.00$ (i.e., three-point loading) to favor a pure bending failure. Two additional tests have been performed with $\alpha \approx 0.68$ (i.e., four-point loading). The experimental load protocol consists of a preliminary loading phase up to concrete cracking, a stop under loading for the assessment of the cracking pattern, a subsequent unloading and final reloading up to collapse. The first three PC beams with top RC slab, namely beams #1, #2, and #3, have been tested under a three-point loading. They showed very similar structural behavior with collapse loads $Q_1=156$ kN, $Q_2=161$ kN, and $Q_3=144$ kN, respectively (Tondolo et al. 2022, Savino et al. 2023). In order to investigate the structural capacity of the PC beam only, the beam #4 has been tested after the removal of the top RC slab, leading to a collapse load $Q_4=129$ kN. Finally, beams #5 and #6 have been tested with the top slab under four-point bending with $\alpha \approx 0.68$. The experimental results obtained for these two beams showed a similar structural response with collapse loads $Q_5=244$ kN and $Q_6=254$ kN, respectively (Savino et al. 2023). The six beams exhibited a structural failure which started with full crushing in compression of the top RC slab in the critical regions, i.e., at mid-span or close to the applied loads, and then propagated through the entire PC beam cross-section.

The experimental test on beam #2 covers the entire load protocol and the results of this test are then considered in the following for the numerical validation under three-point bending, along with the results on beam #4 without the top slab and beam #6 under four-point bending.

3 NONLINEAR ANALYSIS AND EXPERIMENTAL VALIDATION

3.1 Finite element modeling

Several finite element formulations for nonlinear analysis of concrete structures have been proposed in literature with distinctive features based on several factors, including element discretization and formulation and solution process. In this paper, a RC/PC beam finite element (BFE) is considered since it allows for a trade-off among multiple factors including robustness of the formulation, accuracy of the solution process, and computational cost. The BFE

assumes the linearity of the cross-sectional strain field and neglects shear failures and bond-slip of steel reinforcement. The formulation accounts for the material nonlinearities associated with the constitutive laws of materials. The structure is discretized into beam finite elements (Figure 3a), the member cross-section is subdivided into four-node isoparametric subdomains, and numerical integration based on the Gauss-Lobatto rule is adopted to handle material nonlinearities (Bontempi et al. 1995).

Figure 3. Structural modeling: (a) BFE model: nodal displacements, isoparametric discretization, and Gauss-Lobatto integration scheme; (b) MCFT model: nodal displacements and element discretization.

A plane-stress finite element model, formulated in accordance with the MCFT, is also considered to better account for shear effects and local stress-diffusion phenomena. MCFT allows for a general approach to nonlinear plane-stress analysis of concrete structures (Vecchio and Collins 1986). It is based on a smeared rotating crack approach (i.e., cracks change orientation according to the direction of principal strains) and considers the cracked RC medium as an orthotropic material with its own constitutive laws. Equilibrium, compatibility, and constitutive laws are formulated in terms of average stresses and average strains and principal stresses and strain directions are considered coincident. The structure is discretized into constant strain triangle (CST) finite elements (Figure 3b) with smeared reinforcement (Bontempi et al. 1994).

Detailed information about formulation and modeling criteria adopted for the structural modeling of the tested beams can be found in Anghileri (2022) and Anghileri and Biondini (2022).

3.2 Nonlinear analysis of a PC deck beam without top RC slab

In the construction process of the bridge, the RC slab was cast after the PC beams were already assembled and in place under the effects of beam self-weight and prestressing action. Therefore, the deck beams can be considered as characterized by a composite cross-section (i.e., precast PC beam and cast-in-situ RC slab). In order to investigate the residual capacity of the PC deck beam only, a full-scale load test has been carried out on a PC beam after the removal of the RC top slab.

The BFE-based structural modeling of the PC I-beam exploits the symmetry and it is based on a discretization with 13 elements for the half beam, with one outer element with rectangular cross-section at the support region, one adjacent element with linearly varying width of the beam web, and eleven inner elements with I-shaped cross-section. The beam cross-section is subdivided in nine quadrilateral isoparametric subdomains. Numerical integration is based on a Gauss-Lobatto integration scheme with 8x8 Gauss-Lobatto sampling points. Moreover, eight sampling cross-sections are considered for each finite element. The constitutive laws of the materials are defined based on uniaxial stress-strain relationships. Saenz’s law in compression and elastic-perfectly plastic model in tension are assumed for concrete, while a bilinear hardening model is assumed for both reinforcing and prestressing steel with the material characteristics listed in Table 1.

The MCFT-based structural modeling of the PC I-beam exploits the symmetry and it is based on a discretization with 940 CST finite elements for the half beam. Based on the available technical documentation and results of non-destructive diagnostic test (e.g., pacometer), stirrups with diameter of 8 mm and spacing of 250 mm and 100 mm for the inner I-shaped

cross-section and outer rectangular cross-section, respectively, are considered. Stirrups are modeled as smeared reinforcement over the beam volume. Longitudinal reinforcing steel bars and prestressing strands are modeled as truss elements built over the CST finite element mesh. Constitutive relationships of the materials are defined to link average stresses and average strains based on uniaxial stress-strain relationships with the material characteristics listed in Table 1. For concrete in compression, the stress-strain relationship in the principal directions is the Hognestad parabola with compressive strength f_c related to the transversal principal strain to account for cracking effects. The behavior of concrete in tension is linear up to cracking with a post-cracking softening branch accounting for the tension stiffening effect. A bilinear hardening constitutive law is assumed for both reinforcing and prestressing steel.

The loss of the initial prestressing can be associated to several factors, including elastic shortening at prestress transfer, time-dependent losses, corrosion of steel strands, among others. The role of prestressing is firstly investigated considering different levels of residual prestressing. Figure 4a shows the load Q versus mid-span displacement d (net of the effects of self-weight and prestressing) of the PC deck beam under three-point bending ($\alpha=1.00$) for different prestressing $P=\eta P_0$ ($\eta=1.00, 0.80, 0.60$), where P_0 is the nominal prestressing force as reported in the design technical documentation ($\sigma_{pd}=836$ MPa). As expected, prestressing mainly impacts the serviceability stage. After calibration of the material mechanical characteristics, the numerical results have been compared with the outcomes of the load tests and a residual prestressing level $\sigma_p=614$ MPa has been estimated to best fit the experimental results. It is worth noting that this reduction of prestressing is in line with the ongoing diagnostic measurements on the residual prestressing (Savino et al. 2023).

Figure 4b compares experimental and numerical results obtained with $\sigma_p=614$ MPa based on MCFT. The experimental results consist of a preliminary loading phase up to $Q=107$ kN, a stop under loading for the assessment of the cracking pattern and dynamic testing, a subsequent unloading, and final reloading up to collapse ($Q=129$ kN). The nonlinear finite element analysis is carried out under monotonic loading. The backbone curve of the load versus displacement diagram is reproduced with high accuracy by the MCFT-based structural model. Similar results are obtained with a BFE-based structural model, as shown in Figure 5a. Moreover, Figure 5b indicates high accuracy also in terms of load versus the concrete axial strain at mid-span region recorded through transducers located at the top and bottom slab of the beam.

The close correspondence of the results obtained with BFE and MCFT is mainly due to the pure bending failure of the tested beam. However, significant deviations may occur under four-point bending with reduced shear span ratios because of possible shear failures that the BFE formulation is unable to capture. This will be further investigated in future load tests.

Figure 4. Load Q versus mid-span displacement d of PC deck beam without RC slab (MCFT): (a) Different prestressing levels $P=\eta P_0$ ($\eta=1.00, 0.80, 0.60$); (b) Experimental vs numerical results.

3.3 Nonlinear analysis of PC deck beams with top RC slab

Key factors to be investigated for the PC deck beams are the influence of the construction phases of the viaduct and the actual degree of collaboration between PC I-beam and RC slab. In fact, the RC slab has been cast with the PC deck beams already assembled and in place under

Figure 5. Experimental vs numerical results for the PC deck beam without RC slab (BFE): (a) Load Q vs mid-span displacement d ; (b) Load Q vs axial strain ε at mid-span.

the effects of beam self-weight and prestressing action. Moreover, the shear connectors of the slab to the beam just consist of transverse stirrups extended from the beam web. A steel wire mesh is also placed at the beam-slab interface. Therefore, considering also the type of structural failure, obtained in the experimental tests with full crushing in compression of the top slab and lack of connection between beam and slab at mid-span at incipient collapse, the effects of a possible lack of collaboration between beam and slab should be taken into account.

To this purpose, separate MCFT models are considered for beam and slab and a possible slip at the beam-slab interface is taken into account by means of a set of elastic links. The construction process and load stages are considered in a two-level approach. Beam self-weight and prestressing are applied in a first stage to the beam only and the slab contribution to self-weight and overall structural stiffness is evaluated incrementally in a second stage.

The MCFT-based structural modeling of the PC deck beam with top RC slab exploits the symmetry and is based on a discretization with 1128 CST finite elements for the half beam. Stirrups are modeled as smeared reinforcement over the beam volume. Longitudinal reinforcing bars and prestressing strands are modeled as truss elements built over the CST finite element mesh. Constitutive relationships and material properties are the same as for the PC beam without RC slab. Separate nodal points are considered at the beam-slab interface. The nonlinear structural analysis is based a two-level incremental approach. In a first stage, the beam only is loaded with self-weight and prestressing action. In a second stage, the two separate sets of CST finite elements (i.e., PC beam and RC slab) are connected at each pair of nodal points at the beam-slab interface by rigid links in the direction normal to the beam axis. For what concerns the interaction in the longitudinal direction, the beam-slab connection is modeled by means of a set of longitudinal elastic links to be activated in a second stage only. The link is considered rigid up to concrete cracking. This is confirmed by the results obtained in case of a full collaborating beam-slab system which accurately capture the experimental results in terms of initial stiffness of the uncracked beam (Anghileri and Biondini 2021, Anghileri 2022). After concrete cracking, the links are elastic with stiffness estimated to best fit the experimental results. This modeling strategy is also confirmed by the data recorded by the LVDT located at the beam-slab interface. Based on this structural modeling, the self-weight of the slab and the testing loading are applied incrementally in a second stage. The displacements of the beam nodal points are cumulated over both loading stages, while the displacements of the nodal points of the slab derive from the second stage only.

The experimental results of both three-point loading ($\alpha \approx 1.00$) and four-point loading ($\alpha \approx 0.68$) are considered to validate the finite element formulations and the modeling strategies. Figure 6a compares experimental and numerical results for the three-point bending test ($\alpha \approx 1.00$), in terms of load Q versus mid-span displacement d net of self-weight and prestressing, for the PC beam with and without RC slab. This comparison allows to quantify the role of the top slab in the structural response. For the case of beam with slab, the experimental results show a preliminary loading phase up to $Q=100$ kN, a subsequent unloading and final reloading up to the collapse load $Q=161$ kN. The nonlinear finite element analysis is carried out under monotonic loading. The best-fit stiffness value at beam-slab interface for the three-point loading scheme is $k=3000$ N/mm. Figure 6b compares the results for the four-point bending test ($\alpha \approx 0.68$). The experimental results show a preliminary loading phase up to $Q=134$ kN, a subsequent unloading and final reloading up to the collapse load $Q=254$ kN which occurred with full crushing in compression of the top slab in

the critical in the region close to the applied load. The best-fit stiffness value at beam-slab interface for the four-point loading scheme is $k=11500$ N/mm. Finally, a crack pattern survey has been performed on the tested beams after the load tests. As an example, Figure 7 compares the experimental crack pattern at collapse (line thickness proportioned to crack width) and the numerical crack pattern (half beam) obtained for the three-point loading scheme.

Overall, the good agreement between experimental and numerical results obtained for both BFE and MCFT validates the finite element formulations and related modeling strategies under flexural failures. Further investigations are necessary based on future load tests with reduced shear span ratios to investigate the accuracy of the proposed modeling under shear failures.

Figure 7. Load test under three-point bending. (a) Digital model; (b) Experimental crack pattern (crack width $\times 10^{-1}$ mm); (c) MCFT-based crack pattern of half beam for load $Q=161$ kN (line thickness proportioned to crack width).

4 CONCLUSIONS

The validation of the finite element models for nonlinear analysis of concrete structures based on BFE- and MCFT-based formulations has been presented through the outcomes of full-scale load tests on the PC bridge deck beams extracted from a dismantled bridge within the BRIDGE|50 research project. The structural and material characteristics and the modeling strategies have been calibrated based visual inspections, non-destructive tests, and laboratory tests. The role of the cast-in-situ RC slab on the structural capacity of bridge deck beams is also investigated considering the structural response of the PC beam with and without the top RC slab with different shear span ratio. The good agreement between numerical and experimental results allows to validate the finite element formulation and the modeling strategies and to support a proper planning of future full-scale load tests.

Future developments will be devoted to further investigate the accuracy of the proposed models to reproduce a shear-dominant structural behavior and failures and to gather additional information about material properties, residual prestressing, degree of collaboration and shear strength at the beam-slab interface, and corrosion damage based on non-destructive testing and laboratory tests on samples from the tested beams.

Dynamic response of PC bridge beams under different damages

D. Sabia, A. Quattrone, P. Savino & F. Tondolo

Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino, Italy

ABSTRACT: The present paper describes the dynamic test campaign on prestressed concrete bridge beams taken from a dismantled viaduct in Turin, Italy after a service life of 50 years in the framework of BRIDGE|50 research project. Dynamic measurements were previously performed on the decks from which the 29 beams were taken to characterize the behaviour of the viaduct in service condition. Successively the single beams are tested to analyse and evaluate the effects of the different damage levels on the dynamic properties. The vibration data have been collected before the application of static load, after the first cracking condition and after the maximum load applied on the beam to extract the principal modal components. The results highlight the correlation among the evolution of the damage and the dynamic response of the beam and then the effectiveness of vibration tests to identify the occurrence of damages and follow their evolution. The experimental findings could be used in future works to explore the effects of damages of the single beams on the global response of this bridge typology. This work presents the results of the experimental tests on the first eight beams tested.

1 INTRODUCTION

The progressive obsolescence of infrastructures requires to face challenging issues related to the assessment of their residual performances, the increase of the loading conditions, the extension of their service life and how to monitor the evolution of the health state over the years. Nevertheless, the effectiveness of the monitoring strategies requires to deepen the knowledge of the way the combination of different factors, such as corrosion or deterioration, extreme weather events, increase of loads, material ageing, that may influence the structural reliability.

The BRIDGE|50 research project, started in 2020, aims at deeply investigate the behaviour of aged structural elements approaching the end of their service lives (Biondini et al. 2021). The research activities will be devoted to accurately investigate the structural performances and characterize the material properties of a representative portion of a viaduct dismantled after 50 years of service life, namely 25 prestressed concrete beams, 4 box girders and 2 pier caps. The experimental campaign should represent a great source of information to be used in developing predictive models and calibrating monitoring techniques.

Vibration-based methods are widely applied in structural health monitoring techniques to follow the evolution of structural integrity, due to the direct dependence between the dynamic behaviour and the structural stiffness. Moreover, their appeal has increased due to the ease of managing the continuous streaming of large amount of data and inferring information by means of data mining algorithms (Demarie, Sabia, 2019).

In literature, several studies report the results of experimental dynamic investigations on beam-like prestressed structures, focusing on their use as symptoms of the onset of damage or the evolution of deterioration over time forces (Quattrone et al. 2012, Guiglia et al. 2014). In several cases, the authors have pointed out the low sensitivity of modal parameters to identify the reduction of prestressing. For this reason, tests under controlled conditions on end-of-life structures can contribute to supply more accurate definition of sensitivity limits and the thresholds to be transferred to monitoring systems.

The girders of Bridge|50 project were tested both in their current conditions and after the induction of defined damage steps. The aim is to estimate the contribution of the single beams on the global response of the decks, previously tested before the dismantling, and to investigate the influence of damages of the single beams on the global behaviour.

In this paper the results of the dynamic test campaign on a set of five beams are reported. The beams have the same nominal geometrical and material characteristics but some different damage. The dynamic data have been collected before the execution of the static tests, in cracked state and at the end of static tests, after the application of the ultimate loading condition.

2 THE CORSO GROSSETO VIADUCT

The Corso Grosseto viaduct was built in 1970. It was originally constituted by 80 concrete decks having variable spans, from 16 m to 24 m, and a total length of 1400 m (Figure 1). The structural elements which are investigating in BRIDGE|50 research project belong to the first four decks of the southern part of the viaduct. Each deck was composed of 10 precast prestressed concrete I-beams and 2 external precast prestressed concrete U-beams, simply supported at piers, and completed by two transverse beams at the thirds of the span and the 0.14 m thick upper slab were both casted on site. The dimensions of the I-beams cross section and the on-site casted slab, object of the present work, are shown in Figure 2. A set of 25 prestressed concrete beams constituting the decks have been dismantled and collected in a testing area, where a bench test has been realized to perform both static and dynamic tests.

Figure 1. An historical view of the Corso Grosseto viaduct.

3 STATIC TEST CAMPAIGN

According to the preliminary visual inspection carried out to map the presence of corrosion, cracks, and spalling, the beams have been classified in good structural condition (Table 1). The beams B07 and B08 have been damaged during the dismantling phases, when strands at the bottom flanges were cut. The B07 had two strands cut on both sides of the lower flange, at distances 3.7, 9.6, and 15.5 m from the end section. The B08 girder had two strands cut on one side at distances of 3.8 and 15.5 m.

The static test procedure consists in applying an incremental static load up to the reaching the ultimate load capacity by means of four hydraulic jacks. An intermediate unloading phase was made to evaluate the residual prestressing load and the effects of the opening of the cracks on the dynamic parameters (Savino et al. 2023). The test on B02 beam has been

Figure 2. Drawing of the first four decks of the southern part of the viaduct. In green, the beams collected to be tested. On left, the I-shaped beam cross section (measures in mm).

performed in a three-point bending scheme (shear span 9.3 m), whereas a four-point scheme (shear span 6.5 m) was adopted for testing B05 to B08 aimed at investigating the maximum flexural capacity and the shear-bending interaction, respectively. The beams have been loaded up to reach the ultimate condition highlighting a brittle rupture due to the crushing of the upper slab. The principal results are summarized in Table 1. The ultimate flexural strengths M_R take into account the load applied by the hydraulic jacks and the weight of the steel elements used to apply the load to the tested girder.

Table 1. Results of the static tests.

Beam	Position on the deck	Test configuration	M_R (kN m)	Condition
B02	B8 – P47/46	Three Point	1675	Undamaged
B05	B6 – P47/46	Four Point	1656	Undamaged
B06	B6 – Ab/P47	Four Point	1720	Undamaged
B07	B6 – P48/47	Four Point	1445	Damaged (4 strands cut)
B08	B10 – Ab/P47	Four Point	1684	Damaged (2 strands cut)

4 DYNAMIC TEST CAMPAIGN

The description of the test setup is reported in Figure 3. The setup is made of 10 capacitive 1 V/g accelerometers and an instrumented hammer.

Figure 3. Dynamic test setup.

The accelerometers have been placed on the upper slab along the longitudinal axis of the beam, spaced to get an adequate spatial resolution of the vertical flexural modes. The sensors 1X on the rolling support and the couple of accelerometers 4Z and 5Z placed near the midspan on the edges are used to discriminate the longitudinal and torsional dynamic components.

The acceleration signals were acquired at a 512 Hz sampling frequency for both ambient noise and impact hammer excitations. The impact tests were carried out by hitting the beams with an instrumented hammer in vertical direction in the halfway of two consecutive accelerometers. To replicate as close as possible the onsite supporting conditions of the deck, the bench components lying on the upper slab during the static tests are each time removed.

The dynamic test campaigns have been performed before the static test (Phase 0), after the intermediate unloading cycle (Phase 1) and after the application of the ultimate load (Phase 2).

4.1 Experimental modal analysis

The extraction of the principal modal components is performed evaluating the frequency response function (FRF) matrix with respect of the input given by means of the instrumented hammer. When dealing with experimental or operational modal analysis, the FRF is defined for a linear system by the relationship between the forcing function $\{F(\omega)\}$ and the p structural responses $\{Y(\omega)\}$, usually recorded by accelerometers when measured during in-situ testing. In the frequency domain the FRF matrix $[H(\omega)]$ in described by equation (1):

$$\begin{matrix} \{Y(\omega)\} \\ (p \times 1) \end{matrix} = \begin{matrix} [H(\omega)] \\ (p \times q) \end{matrix} \begin{matrix} \{F(\omega)\} \\ (q \times 1) \end{matrix} \quad (1)$$

The element of FRF matrix $H_{k,j}(\omega)$ maps the input $F_k(\omega)$, applied at the k -th degree of freedom (DOF), and the output Y_j measured at the j -th DOF. In case of acceleration as output signals, the FRF matrix is expressed in the accelerance form (Ljung, 1999). The generic element of the accelerance matrix, expressed in terms of modal properties, is given by:

$$H_{j,k}(\omega) = \frac{\ddot{Y}_j(\omega)}{F_k(\omega)} = -\omega^2 \sum_{r=1}^N \frac{1}{m_r} \frac{\psi_j^r \psi_k}{\omega_r^2 - \omega^2 + 2i\omega\omega_r} \quad (2)$$

The FRF can be estimated by classical H_1 or H_2 estimators, given by the ratio between the cross-spectrum $S_{jy}(\omega)$ of the output $Y(\omega)$ and the input $F_k(\omega)$ and the auto-spectrum of the input $S_{ff}(\omega)$ or of the output $S_{yy}(\omega)$ that can be chosen according to whether the major source of noise is for input or output signals. The FRF is a complex function which amplitude has a maximum at the resonant frequency. The magnitude of the modal coefficient is simply taken as the value of the imaginary part at resonance. The sign is either positive or negative, considering the direction of the peak along imaginary axis. This implies that the phase angle is either 0° or 180° .

Figure 4 shows an example of FRF, magnitude and imaginary part, from the excitation and the time history measured at the position from 1Z to 9Z on the beam.

After a preliminary analysis of the spectral content, the signals were pre-treated by filtering out of the bandwidth [0 - 100 Hz], removing the trends. The FRFs have been estimated basing on each singular impulse acceleration data and then averaged for each hitting position. The first three modal components are clearly identified as shown by the example proposed in Figure 4. The mode shapes associated to these components correspond to the three main flexural modes of the beam. The modal coordinates are estimated by the imaginary part of the FRFs.

5 RESULTS OF THE DYNAMIC IDENTIFICATION

In this paragraph the result of the dynamic identification for each of the five beams for each of the three phases are reported. The tests phases are depicted in Figure 5. The Phase 0 aims at investigating the dynamic properties of the structural elements before the execution of static test, describing the condition after 50 years of service life. The results of the dynamic tests campaign performed on the decks from which the beams have been removed are reported in (Quattrone et al., 2021).

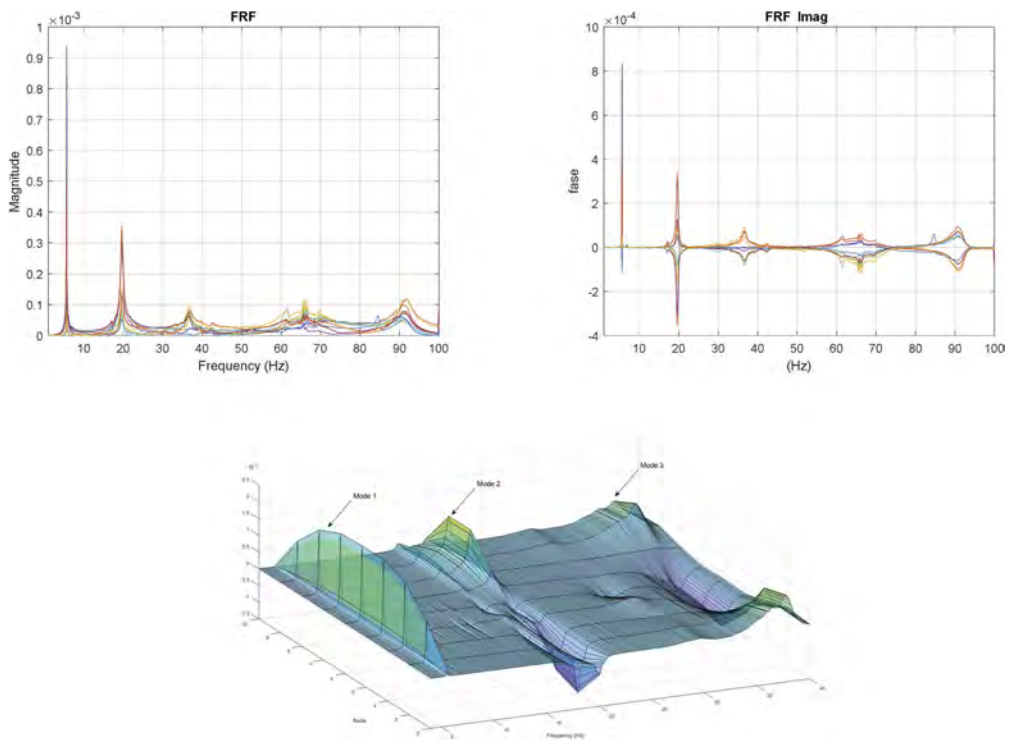

Figure 4. Example of FRF. Left: Magnitude; Right: Imaginary part. Bottom: Mode Shapes.

Figure 5. Force – midspan deflection. The dots indicate the phase test.

The Phase 1 corresponds to the unloading condition, subsequent the reaching of the full cracked condition, identified in Table 2 as a fraction of the ultimate bending moment reached during the static tests. The Phase 2 regards the dynamic test on the beams which experienced their ultimate load condition.

Table 2. Damage levels corresponding to Phase 1 tests.

Specimen	M (kNm)	% M_R
B02	1080.7	68.7%
B05	884.0	55.8%
B06	939.9	57.0%
B07	855.7	62.3%
B08	910.7	56.5%

The Table 3 reports the mean values of frequencies and damping estimated at the three phases for each beam.

Table 3. Mean modal frequencies and damping ratios.

		Phase 0			Phase 1			Phase 2

	ξ (%)	0.29	1.46	1.32	0.31	1.04	1.57	0.43	1.06	1.57

The following figures illustrate, as an example, the comparison between the mode shapes at different damage levels (phases 0, 1 and 2) for girder B08. It worth noting that small but noticeable differences can be observed with the increasing of damages. Similar results have been found for the other girders.

Figure 6. Beam B08 mode shapes at different damage levels.

The Figure 6 shows the distributions of frequencies and damping identified at the different damage levels. It can be noted that at the increase of the damage level correspond the reduction of the modal frequencies and the increasing trend of damping ratios. Moreover, the scattering of both the parameters increase.

The reductions of the frequencies of the first mode vary in range of about 2-4% for Phase 1 tests and about 8-14% for Phase 2. The entities of these reductions are comparable to the findings reported in similar experimental campaign present in literature (Quatrone et al. 2012).

Figure 7. Distribution of frequencies and damping ratios. The colors correspond to the phases as indicated in Figure 4.

6 CONCLUSIONS

This work presents the results of the experimental dynamic campaign performed on a set of bridge girders dismantled after 50 years of service life. The tests are part of the BRIDGE|50 research project.

The girders have been characterized for different damage levels induced by static tests. The variation of the modal parameters have been observed and the results confirm the low sensitivity of modal parameters to the damages for prestressed concrete structures. Albeit the small magnitude, the variations of the structural condition are clearly detectable, confirming the capability of the dynamic structural identification to follow the evolution of damage. The experimental results here presented should be very useful in the field of permanent structural health monitoring. Future works will refine the estimation of damping ratio and the implementation of damage localization and quantification techniques.

Decentralized control-based intervention policies for road networks

Y. Nakazato, D. Mizutani & T. Nagae

Tohoku University, Sendai, Miyagi, Japan

ABSTRACT: In the infrastructure management field, the centralized control-based framework is widely applied to the road network management problem to derive network-level intervention policies. However, the optimal network-level intervention policy by the centralized control-based framework is difficult to derive and apply because there is no efficient solution method. In this study, we propose a new framework for the road network management problem, a decentralized control-based framework, where the network is divided into multiple groups and the sub-manager of each group decides the group-level intervention policy according to the aggregated information of all groups. Particularly, we propose a method to decide the groups of links and the solution method for deriving decentralized control-based intervention policies for road networks. Numerical studies demonstrate that the proposed decentralized control-based intervention policy can reduce the life-cycle costs of the road network compared with existing intervention policies.

1 INTRODUCTION

Facilities on road networks stochastically deteriorate due to continuous loading, weather and other uncertain factors. These deteriorated facilities should be repaired for the safety and reliability of the road networks. The repair work is costly and might disturb the traffic; therefore, the road network manager must carefully decide the repair timing of all facilities. In this study, we propose a new framework for such a road network management problem: a decentralized control-based framework.

When the deterioration of facilities is expressed as a stochastic process, a typical road network intervention policy is described as a state-dependent rule that assigns an intervention alternative for each facility corresponding to the condition state (CS) of all facilities. Mathematically, the rule is a mapping from the set of possible CS patterns to the set of possible intervention alternative patterns. For example, suppose a road network comprises 5 links with link id k ($k = a, b, c, d, e$) as shown in Figure 1. Every link has an identical facility, and the CS of each facility is 1 (good), 2 (slightly deteriorated), or 3 (severely deteriorated), whereas the intervention for each facility is either 0 (no repair) or 1 (repair). Let x_k be the CS of the facility on link k and $\mathbf{x} = (x_k)$ be the corresponding CS pattern. The set of the possible CS patterns is then denoted by $\mathcal{X} = \{1, 2, 3\}^5$, whereas the set of possible intervention patterns is $\mathcal{Y} = \{0, 1\}^5$. Then the network intervention policy is denoted by a mapping from $\delta: \mathcal{X} \rightarrow \mathcal{Y}$, whose typical element, $\delta_k(\mathbf{x})$, is the repair alternative of each facility k corresponding to each CS pattern \mathbf{x} . The network intervention policy can also be summarized by the tables as shown in Figure 2, which assign a repair alternative to each facility on link k corresponding to each of the $3^5 = 243$ possible CS patterns, \mathbf{x} .

This typical network intervention policy belongs to a centralized control-based framework because the only manager of the network decides the intervention for all facilities in the network according to the CS pattern. Previous studies using the centralized control-based framework show that other than corrective repair, which means the repair for the facilities severely deteriorated, preventive repair, which means the repair for the facilities slightly deteriorated, can reduce costs because of the interdependence of facilities. However, the intervention policies derived from the centralized control-based framework (i.e. centralized control-based intervention policies) become implausibly complicated as the number of facilities increases, due to the combinatorial explosion of the possible CS patterns. Such complicated intervention policies should be impractical to derive and, even if they are derived, difficult to apply.

Figure 1. A road network example.

Figure 2. Centralized control-based intervention policy.

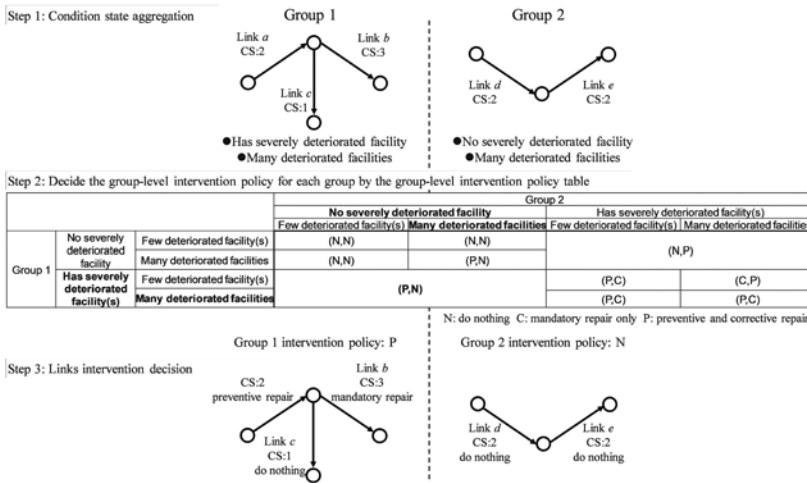

Figure 3. Example of the flow of the intervention decision by the decentralized control-based framework.

In this study, we propose a new framework for the road network intervention policy problem: a decentralized control-based framework. Decentralized control has been employed in many engineering fields other than infrastructure management. Different from the centralized control-based framework, the decentralized control-based framework has multiple sub-managers deciding the intervention policies for part of the network where they are managing. As a result, the intervention policies from the decentralized control framework (i.e. decentralized control-based intervention policies) may have fewer possible CS patterns and hence are relatively easy to derive. Besides, the decentralized control-based framework may be more suitable for real road network management because many road networks are managed by multiple officers.

Figure 3 Shows an example of the flow of the management for the road network shown in Figure 1 by the proposed framework. The road network is divided into 2 groups $G_1 = \{a, b, c\}$ and $G_2 = \{d, e\}$ in advance, and each group is managed by an individual agent (referred to as a “sub-manager”). Each time the decision of intervention is required, there are totally 3 steps to decide the intervention for all links. In Step 1, each sub-manager aggregates the CSs of facilities in each group. Here, the CS of each group is aggregated by 2 criteria: “whether there is severely deteriorated facility(s) in the group” and “whether the network has many deteriorated facility(s)”. This enables the sub-managers to share the least information about CS of each group, while also keeping the complexity of the decision at an considerable level. In Step 2, the group-level intervention policies are decided by the group-level intervention policy table. In this study, we consider 3 types of group-level intervention policies: N, C and P. N means to do nothing, C means to conduct corrective repair to the facilities severely deteriorated (with CS 3) in the network, and P means to conduct preventive repair to the facilities slightly deteriorated (with CS 2) in the network in addition to conduct corrective repair to the facilities severely deteriorated (with CS 3) in the network. In Step 3, each sub-manager decides the intervention for all links managed according to the group-level intervention policies. In the example in Figure 3, to avoid road network

disruptions due to simultaneous repair of links a , d and e , an intervention policy is derived in which the preventive repair is conducted only on link a , not on all links with CS 2.

The centralized control-based intervention policy has exactly $3^5 = 243$ possible CS patterns for the entire network and each CS pattern has $2^5 = 32$ possible intervention alternatives; meanwhile, the decentralized control-based intervention policy have only $4^2 = 16$ possible aggregated CS patterns for the entire network and each aggregated CS pattern has only 3^2 possible intervention alternatives and are hence easier for derivation and application if the group division is given.

In this study, we propose a decentralized control-based framework for road network management. Particularly, we propose (1) a method for deciding the group of links and (2) the solution method for deriving decentralized control-based intervention policy.

2 PREVIOUS STUDIES

To consider the interdependence of facilities managed simultaneously, many centralized control-based studies have targeted network-level management problems. Golabi et al. (1982) proposed an approximate solution method called a randomized policy that assumes that all facilities are homogeneous and decides the facilities to repair stochastically. Smilowitz & Madanat (2000) targeted yearly repair policy problems for road networks considering the yearly budget constraints. However, their solution methods are unsuitable for road networks that have costs highly dependent on the network structure. Lee et al. (2016) considered the repair policy problem by minimizing the LCC of a road network under the green gas emission constraints, using the genetic algorithm (GA). However, the optimal repair policy derived by GA is a large set of network-level situation-dependent rules that contains repair patterns for all combinations of CSs of all links. When the size of the network is large, the result derivation will become extremely difficult and even if the result is derived, it is difficult to interpret and apply. Medury & Madanat (2013) targeted the optimal repair policy by minimizing the LCC of a road network using approximate dynamic programming. They also targeted the derivation of the optimal repair policies for sub-networks. However, they did not consider the interdependence of the multiple sub-networks. Mizutani et al. (2020) considered the optimal repair policy for a road network where economies of scale exist in repair costs, using a heuristic method. But it considers only the repair costs, which is unsuitable for road networks where user costs extremely changes according to the structure. Compared with single-facility-level intervention policies, centralized control-based intervention policies can reduce the costs but have high computational complexity and hence are difficult to derive and apply to real-scale problems. To the best of our knowledge, there is no study considering the decentralized control-based framework for the road network management problem.

In various engineering fields, many studies, such as Bakule (2008), Becker et al. (2004), Chandan et al. (2014), and Sonnenschein et al. (2015), employed the decentralized control-based framework to solve problems. The studies using decentralized control usually target the management problem for a large-scale system, where multiple sub-managers are required to manage the entire system. Each sub-manager makes a decision for the managing group by the simplified information from other sub-manager(s); therefore, the management problem has low computational complexity compared with centralized control.

3 DETERIORATION AND REPAIR PROCESSES OF ROAD NETWORK

In this section, we model the facility deterioration and repair processes of a road network comprising of multiple road links. Each link has only one identical facility. For convenience, the facility of a link is referred to as a link in this study.

Consider a discrete time axis starting at calendar time t_0 , when the road network was constructed. For the road network, the CSs of all links are inspected at the same time interval Δt from t_0 , and based on the inspection results, the manager decides the links to repair. Let z be the positive nature number ($z \in \mathbb{Z}^+$); we define a set \mathcal{T} of inspection and repair times: $\mathcal{T} = \{t_z | \forall z \in \mathbb{Z}^+\}$ where $t_z = t_0 + z\Delta t$.

In this study, the managing network is expressed as a directed graph $\mathcal{G}(\mathcal{N}, \mathcal{A})$. \mathcal{N} is the set of all nodes, whereas \mathcal{A} is the set of all directed links. CS of link $(i, j) \in \mathcal{A}$ is expressed as an M -level discrete variable, $s_{i,j} \in \mathcal{M} = \{1, 2, \dots, M\}$, where $(i, j) \in \mathcal{A}$. \mathcal{M} is the state space of the CS. The larger $s_{i,j}$ is the worse CS is. The CS right after the repair and construction is 1, and the CS M means severely deteriorated. The condition of the entire road network can be expressed as a $|\mathcal{A}|$ -dimensional CS vector: $s \equiv [s_{i,j}] \forall (i, j) \in \mathcal{A}$. The state space of the CS vector is the product of the CSs of all links and can be expressed as $S = \mathcal{M}^{|\mathcal{A}|}$.

We assume that the deterioration process of each link follows the same Markov chain. First, we model the deterioration process of a single link. To identify CS before and after repair, the CS before repair at time $t \in \mathcal{T}$ is expressed as $s^-(t)$, and the CS after repair is expressed as $s^+(t)$. The probability that CS change from $s_{i,j}^a \in \mathcal{M}$ to $s_{i,j}^b \in \mathcal{M}$ from $z(z \in \mathbb{Z}^+)$ th inspection time t_z to t_{z+1} can be expressed as $p_{s_{i,j}^a, s_{i,j}^b} = \text{prob}[s_{i,j}^-(t-1) = a | s_{i,j}^+(t_z) = a]$. In this study, we define the deterioration process of a single link by Markov transition matrix p as $p \equiv [p_{a,b}]$, $\forall a, b \in \mathcal{M}$.

Then we model the deterioration process of the entire road network. In terms of the road network, the probability that the CS vector changes from $s^a \in \mathcal{S}$ at time t_z to $s^b \in \mathcal{S}$ at time t_{z+1} can be expressed as the product of transition probabilities of all links: $P_{s^a, s^b} = \prod_{(i,j) \in \mathcal{A}} p_{s_{i,j}^a, s_{i,j}^b}$.

We only consider reconstruction repair work that changes the CS of the repaired link to 1. At time $t_z \in \mathcal{T}$, the repair for the entire road network can be expressed by an intervention vector consisting of binary variables: $\delta(t_z) \equiv [\delta_{i,j}(t)] \forall (i, j) \in \mathcal{A}$. The change in CS vector s with respect to intervention vector $\delta(t_z)$ can be expressed as $s^+(t_z) = s^-(t_z) - [s^-(t_z) - 1] \circ \delta(t_z)$, where $\delta_{i,j}(t_z) \in \{0, 1\} \forall (i, j) \in \mathcal{A}$. At each time point, the link(s) having CS M (severely deteriorated) must be repaired, i.e.,

$$\delta_{i,j}(t_z) = 1 \quad \text{if} \quad s_{i,j}(t_z) = M \quad (1)$$

4 LIFE-CYCLE COSTS AND INTERVENTION POLICIES FOR THE ROAD NETWORK

4.1 Repair cost, user cost, and life-cycle cost

First, we define the repair costs with the intervention vector $\delta(t_z)$. In this study, we assume that the manager needs to set up a work zone for intervention. Repair costs contain of 2 types of costs: variable and fixed costs. The repair variable cost is proportional to the number of links to repair (i.e. material and labor costs), whereas the fixed repair costs is proportional to the number of continuous work zones (i.e. construction machine and traffic control costs). Assume that the length of link (i, j) is expressed as $l_{i,j}$, the unit price of the repair variable costs is expressed as α , and the unit price of the repair fixed costs is expressed as β , the repair costs $r(\delta(t_z))$ when intervention vector $r(\delta(t_z))$ is implemented can be calculated as follows:

$$r(\delta(t_z)) = \alpha \sum_{(i,j) \in \mathcal{L}} l_{i,j} \delta_{i,j} + \beta \sum_{n \in \mathcal{N}} b_n \quad (2)$$

$$\text{where} \quad b_n = \begin{cases} 0 & \text{if } \delta_{n,j} = 0 \quad \text{and} \quad \delta_{n,i} = 0 \\ 1 & \text{else} \end{cases} \quad \forall (n, j) \in \mathcal{L}, \forall (i, n) \in \mathcal{L} \quad (3)$$

where b_n is the binary variable indicating whether node n is connected to any intervened links.

Then we define the user costs with the intervention vector $\delta(t_z)$. In this study, we consider the traffic demand of the entire road network as constant. K type(s) of traffic demand exists in the network; therefore, the traffic demand $\mathcal{F} \equiv \{(O_k, D_k), f_k\} \forall k \in \mathcal{K}$ $\mathcal{K} \equiv \{1, 2, \dots, K\}$ where O_k denotes the origin node of the k th type of traffic demand, D_k denotes the end node of the k th type of traffic demand, and f_k denotes the amount of the k th traffic demand. The user costs when 1 unit traffic flow passed link $(i, j) \in \mathcal{L}$ for Δt is $c_{i,j}$, max flow in link $(i, j) \in \mathcal{L}$ is $\mu_{i,j}$, k th type of traffic flow in link $(i, j) \in \mathcal{L}$ from time t_z to t_{z+1} is expressed as $y_{i,j,k}(t_{z+1})$.

When a link is intervened at time t_z , the traffic capacity of the link becomes $\gamma(0 < \gamma < 1)$ times until t_{z+1} . If the traffic demand exceeds the network capacity, the excess traffic will use a public

road with a high cost to detour. In this study, we assume that users cannot detour between specific links, and that the public roads have enough capacity for all users to travel. The user costs when 1 unit traffic flow of k th traffic demand passed the public road is C_k , and the traffic cost is $\hat{w}_k(t_z)$.

When intervention vector is $\delta(t_z)$, the user costs $u(\delta(t_z))$ from time point t_z to time point t_{z+1} can be calculated by the following minimum flow problem:

$$u(\delta(t_z)) = \in \left[\min_{\mathbf{w}(t_z), \hat{\mathbf{w}}(t_z)} \sum_{k \in \mathcal{K}} \left(\sum_{(i,j) \in \mathcal{L}} c_{i,j} w_{i,j,k}(t_z) + C_k \hat{w}_k(t_z) \right) \right] \quad (4)$$

$$\text{s.t. } \sum_{(n,j) \in \mathcal{L}} w_{n,j,k}(t_z) - \sum_{(i,n) \in \mathcal{L}} w_{i,n,k}(t_z) = 0 \quad \forall n \in \mathcal{N} \setminus \{\mathcal{O}_k, \mathcal{D}_k\}, \quad \forall k \in \mathcal{K} \quad (5)$$

$$\sum_{(\mathcal{O}_k, j) \in \mathcal{L}} w_{\mathcal{O}_k, j, k}(t_z) + \hat{w}_k(t_z) = f_k, \quad \sum_{(i, \mathcal{D}_k) \in \mathcal{L}} w_{i, \mathcal{D}_k, k}(t_z) + \hat{w}_k(t_z) = f_k, \quad \forall k \in \mathcal{K} \quad (6)$$

$$\sum_{k \in \mathcal{K}} w_{i,j,k}(t_z) \leq \mu_{i,j}(\gamma) \delta_{i,j}(t_z) \quad \forall (i,j) \in \mathcal{L} \quad (7)$$

$$w_{i,j,k}(t_z) \geq 0 \quad \forall (i,j) \in \mathcal{L}, \forall k \in \mathcal{K} \quad \hat{w}_k(t_z) \geq 0 \quad \forall k \in \mathcal{K} \quad (8)$$

\in is the unit cost per time. The objective function of user costs Equation 4 is the sum of the user costs of the road network and the user costs of the public roads. Equation 5 means the total inflow of any node except OD is 0; Equation 6 means the traffic outflow from each O equals each traffic demand, and the traffic inflow to each D equals each traffic demand; Equation 7 means the traffic in each link must not exceed the link capacity; Equation 8 means the non-negative constraint for traffic flow in each link, and the non-negative constraint for traffic flow on each public road.

In this study, the goal of the intervention policy is to reduce LCC Ψ of a newly constructed road network starting from t_0 . The LCC Ψ can be calculated as follows:

$$\Psi(\{\delta(t_z), \forall t_z \in \mathcal{T}\} | s(t_0) = 1) = \sum_{t_z \in \mathcal{T}} \frac{1}{(1+\rho)^{t_z}} E_{s^-(t_z)} [r(\delta(t_z)) + u(\delta(t_z))] \quad (9)$$

ρ is the discount rate, and $E_{s^-(t_z)}[\cdot]$ means the expected value with respect to $s^-(t_z)$.

4.2 Centralized control-based intervention policies

The optimal repair policies can be defined by the following LCC minimizing problem:

$$\min_{\{\delta(t_z), \forall t_z \in \mathcal{T}\}} \Psi(\{\delta(t_z), \forall t_z \in \mathcal{T}\} | s(t_0) = 1) \text{ s.t. (1)} \quad (10)$$

This is an infinite-time Markov decision process, where the optimal intervention vector $\delta(t_z)$ is determined by the CS vector $s(t_z)$ at the time t_z . The optimal intervention policy problem can be defined by the set of the optimal intervention vector Δ , which depends on the CS vector:

$$\min_{\Delta} \Psi(\Delta | s(t_0) = 1) \text{ s.t. (1) where } \Delta \equiv [\delta(s^a)] \quad \forall s^a \in \mathcal{S} \quad (11)$$

The following Bellman equations can be used to calculate the optimal intervention vector $\delta^*(s^a)$ for CS s^a :

$$V(s^a) = r(\delta(s^a)) + u(\delta(s^a)) + \frac{1}{(1+\rho)^{\Delta t}} \sum_{s^c \in \mathcal{S}} P_{s^b, s^c} V(s^c) \quad \text{where } s^b = s^a - [s^a - 1] \circ \delta(s^a) \quad (12)$$

The optimal intervention policy Δ^* is a situation-based pattern of combinations of CSs of all links; therefore, we have to calculate the optimal intervention vector for all patterns of CS vectors simultaneously. To the best of our knowledge, there is no efficient solution method for this problem. One orthodox solution method is full enumeration of all possible intervention policies.

However, in the following numerical study of Sioux Falls, the network has $|\mathcal{A}| = 76$ links and the max CS is $M = 3$, meaning this problem has 76 decision variables, each with 3 possible integer alternatives. As a result, the number of possible intervention policies is 3^{76} , and the optimal intervention policy for such a real-scale road network is impossible to calculate by full enumeration.

4.3 Decentralized control-based intervention policy

The approximate solution method based on the decentralized control in this study does not derive the optimal intervention vectors for all CS vectors but derives the intervention vector at each inspection and repair time. For the observed CS vector s^a , (a) the group of the links $\mathcal{G}_1, \mathcal{G}_2$, (b) the aggregated state for each group $\{\Lambda_1\}, \{\Lambda_2\}$, and (c) repair strategy variables Y_1, Y_2 for each group, are used to derive the group intervention vector $\hat{\delta}(s^a)$.

In this study, we decide the group of links as follows:

$$\min_{\{\delta(t_h), \forall h \in \mathcal{H} = \{1,2\}\}} \sum_{h \in \mathcal{H}} \frac{1}{(1+\rho)^{Mh}} [r(\delta(t_h)) + u(\delta(t_h))] \quad \text{s.t.} \quad \sum_{h \in \mathcal{H}} \delta(t_h) = 1 \quad (13)$$

The group number is 2, and the binary variable $\delta(t_h)$ indicates whether each link belongs to group h . Group $\{\mathcal{G}_h\}$ is decided as follows: $\mathcal{G}_h \equiv \{\mathcal{N}_h, \mathcal{A}_h\}, \forall h \in \mathcal{H}$ where $\mathcal{A}_h \equiv \{(i,j) \in \mathcal{A} | \delta_{i,j}(t_h) = 1\}$, $\mathcal{N}_h \equiv \{\forall n \in \mathcal{N} | \delta_{n,j}(t_h) = 1, \forall (n,j) \in \mathcal{A}\} \cup \{\forall n \in \mathcal{N} | \delta_{i,n}(t_h) = 1, \forall (i,n) \in \mathcal{A}\}$. Equation 15 is a combinatorial optimization problem; in general, it is difficult to obtain an exact solution. In our numerical studies, we find solutions using Gurobi Optimizer (<http://www.gurobi.com/>). However, there is no guarantee that an exact solution to Equation 29 can be easily obtained for any given case. This problem can be interpreted as a “network renewal planning problem within a specific period of time.” This suggests that the Equation 29 may be some approximation to the original intervention policy optimization problem Equation 25 (e.g. a problem that dismisses deterioration), but a rigorous proof is beyond the scope of this study.

The CS of each group is approximated by η_h , a binary variable indicating whether there is any severely deteriorated link in the group, and θ_h , a binary variable indicating whether there are many deteriorated facilities in the group. When the CS vector s^a is observed, the network’s state can be approximated using state aggregation as follows Λ :

$$\Lambda \equiv \{\Lambda_h, \forall h \in \mathcal{H}\} \quad \text{where} \quad \Lambda_h \equiv \{\eta_h, \theta_h\} \quad (14)$$

$$\eta_h = \begin{cases} 1 & \text{if } |\{(i,j) \in \mathcal{A}_h | s_{i,j} = M\}| > 0 \\ 0 & \text{else} \end{cases} \quad \theta_h = \begin{cases} 1 & \text{if } |\{(i,j) \in \mathcal{A}_h | s_{i,j} \geq \bar{M}\}| \geq X_h \\ 0 & \text{else} \end{cases} \quad (15)$$

$\bar{M} = M - 1$ means slightly deteriorated, and links with CS equals to or greater than \bar{M} are assumed to be deteriorated (either slightly or severely). The state space of the solution is $\mathcal{X}_h \equiv \{1, 2, \dots, |\mathcal{N}_h|\}$. When the degradation is progressing in group h (the number of links with CS \bar{M} or higher is equal to or greater than the borderline X_h), $\theta_h = 1$; otherwise, $\theta_h = 0$.

Whether repair is conducted to link (i,j) in group h is decided by the decision variable $Y_h(\Lambda)$ indicating the group-level intervention policy, which is expressed as follows Λ :

$$\hat{\delta}_{i,j}(s^a) = \begin{cases} 1 & \text{if } s_{(i,j)} = M \leq s_{i,j} \\ 1 & \text{if } s_{(i,j)} = M - 1 \text{ and } Y_h(\Lambda) = \text{P} \forall (i,j) \in \mathcal{A}_h \text{ where } Y_h(\Lambda) \in \{\text{N}, \text{C}, \text{P}\} \\ 0 & \text{else} \end{cases} \quad (16)$$

$\hat{\delta}_{i,j}(s^a)$ means whether the link (i,j) is repaired.

$Y_h(\Lambda)$ is a decision variable that indicates the group-level intervention policy for group H . N means to do nothing policy, C means to conduct corrective repair to the facilities severely deteriorated (with CS M) in the network, and P means to conduct preventive repair to the facilities slightly deteriorated (with CS $M-1$) in the network in addition to conduct corrective repair to the facilities severely deteriorated in the network. Because Λ comprises 2 binary variables, there are a total of 16 patterns for the aggregated CS patterns of the network and $Y_h(\Lambda)$ is a 16 - dimensional integer variable; therefore, the state space of the solution is $\mathcal{Y}_h \equiv \mathcal{M} \times \mathcal{M} \times \mathcal{M} \times \mathcal{M}$.

The optimization problem for the decentralized control-based intervention policy $\hat{\Lambda}$ can be written as follows:

$$\min_{\{(X_h, Y_h(\Lambda)), \forall h \in \mathcal{H}\}} \Psi(\hat{\Lambda}(\{(X_h, Y_h(\Lambda)), \forall h \in \mathcal{H}\}) | s(t_0) = 1) \text{ s.t.} \quad (17)$$

where

$$\hat{\Lambda} \equiv [\hat{\delta}(s^a)] \quad \forall s^a \in \mathcal{S} \quad Z \equiv \mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_H \times \mathcal{Y}_1 \times \mathcal{Y}_2 \times \dots \times \mathcal{Y}_H \quad (18)$$

The proposed decentralized control-based intervention policy have 16 decision variables of the group-level intervention policies, each with 3 possible integer alternatives, and 2 decision variables of the borderline, each with $|\mathcal{N}_h|$ possible integer alternatives. Compared with the centralized control-based intervention policy that has 3^{76} possible patterns, the decentralized control-based intervention policy has $3^{16} \times |\mathcal{N}_1| \times |\mathcal{N}_2|$ possible patterns and is possible to calculate by full enumeration.

In this study, the optimal decision variables for the decentralized control-based intervention policy are derived by full enumeration and Monte Carlo simulation. First, all possible combinations of the decision variables for the decentralized control-based intervention policy are listed. Second, the LCCs for decentralized control-based intervention policy with the combinations of decision variables are calculated via Monte Carlo simulation. Finally, the combination of decision variables that has the minimum LCC is chosen as the combination.

5 NUMERICAL STUDY

In the numerical study, we first demonstrate the proposed solution method by applying it to the Sioux Falls network, which is a real-scale road network. Then, we apply an intervention policy by a facility-level solution method, an intervention policy by a centralized control-based solution method, and the derived policy to the Sioux Falls network and compare the costs of the intervention policies by each solution method.

The Sioux Falls network is used in the numerical study, and the parameters of the network are summarized in Table 1. The facility-level intervention policy here does not consider the repair fixed and user costs and hence performs only corrective repair or does nothing to each link. The centralized control-based intervention policy here is from Mizutani et al. (2020), where repair fixed cost are considered but user cost, which changes according to the network capacity, is not considered. To compare these 3 policies, we apply them to the Sioux Falls network from $t = 1$ to $t = 100,000$ and calculate the costs.

All numerical calculations were performed using a machine and a program with the following specifications OS: Windows 10 Pro (64-bit); Processor: Intel(R) Xeon(R) Gold 6258R CPU @ 2.70 GHz; Python version: 3.8.11; Gurobi Optimizer version: 9.1.2 build v9.1.2rc0 (win64).

The grouping result of the proposed solution method is shown in Figure 4, and the optimal decision variables of the proposed intervention policies are listed in Table 2. The optimal borderlines for group 1 and 2 are $X_1^* = 9$ and $X_2^* = 2$, respectively. As an example of Table 2, the (P, C) in the bottom right cell means “If group 1 has severely deteriorated facility(s) (facilities with CS 3) and group 1 has many deteriorated facilities (the number of facilities with CS more than 2 equals to or larger than group1 borderline $X_1^* = 9$); and if group 2 has severely deteriorated facility(s) (facilities with CS 3) and group 2 has many deteriorated facilities (the number of facilities with CS more than 2 equals to or larger than group 2 borderline $X_2^* = 2$), the sub-manager of group 1 should conduct preventive and corrective repair policy (P) and the sub-manager of group 2 should conduct corrective repair policy (C).”

For the sub-manager of group 1, the result of this table can be summarized as follows:

“When group 1 has no severely deteriorated facility and few deteriorated facility(s), implement the do nothing policy (N). When group 1 has no severely deteriorated facility and many deteriorated facilities, if group 2 has no severely deteriorated facility and many deteriorated facilities, implement the preventive and corrective repair policy (P), otherwise, implement the do nothing policy (N). When group 1 has severely deteriorated facility(s) and few deteriorated facility(s), if group 2 has severely deteriorated facility(s) and many deteriorated facilities, implement the corrective repair

policy (C), otherwise, implement the preventive and corrective repair policy (P).” For the sub-manager of group 2, the result of this table can be summarized as follows:

“When group 2 has no severely deteriorated facility, implement the do nothing policy (N). When group 2 has severely deteriorated facility(s) and few deteriorated facility(s), if group 1 has no severely deteriorated facility, implement the preventive and corrective repair policy (P); if group 1 has severely deteriorated facility(s), implement the corrective repair policy (C). When group 2 has severely deteriorated facility(s) and many deteriorated facilities, if group 1 has no severely deteriorated facility, implement the preventive and corrective repair policy (P); if group 1 has severely deteriorated facility(s) and few deteriorated facility(s), implement the preventive and corrective repair policy (P); if group 1 has severely deteriorated facility(s) and many deteriorated facilities, implement the corrective repair policy (C).”

Table 2. Decentralized control-based intervention policy: group-level intervention policy table.

		Group 2				
		No severely deteriorated facility		Has severely deteriorated facility(s)		
		Few deteriorated facility(s)	Many deteriorated facilities	Few deteriorated facility(s)	Many deteriorated facilities	
Group 1	No severely deteriorated facility	Few deteriorated facility(s)	(N,N)	(N,N)	(N,P)	
		Many deteriorated facilities	(N,N)	(P,N)		
	Has severely deteriorated facility(s)	Few deteriorated facility(s)	(P,N)		(P,C)	(C,P)
		Many deteriorated facilities			(P,C)	(P,C)

Figure 5. Ratio of costs by each policy.

The ratio of the cost of each policy to the cost by the facility-level intervention policy is shown in Figure 5. Compared with the facility-level intervention policy, the centralized control-based intervention policy can target minimizing the repair costs and reduce the annual repair costs by 88%. However, the annual user costs increased, increasing the LCC. The decentralized control-based intervention policy do not significantly reduce the annual repair costs but instead reduce the annual repair costs and annual user costs simultaneously, reducing the LCC. The calculation time for each intervention policy is as follows: the facility-level intervention policy without preventive repair does not require any calculation; the centralized control-based intervention policy that only considers the economies of scale in repair costs requires 30 minutes to 1 hour; and the decentralized control-based intervention policy by the proposed solution method require 2 ~ 3 days.

6 CONCLUSION

In this study, we proposed a decentralized control-based framework for road network management including (1) a method to decide the groups of links and (2) the solution method for deriving decentralized control-based intervention policies for road networks. The decision variables of the decentralized control-based intervention policy, i.e. the variable defining the aggregated CS of all groups and the group-level intervention policies that minimize the LCC, are optimized by full enumeration where the expected LCC is estimated by Monte Carlo simulation. In the numerical study, for comparison, we applied a facility-level intervention policy, a centralized control-based intervention policy, and the proposed decentralized control-based intervention policy. The decentralized control-based intervention policy can reduce the LCC compared with other intervention policies.

Efficient early estimates of bridge interventions: Costs, required possession times and associated failure risks

H. Mehranfar, B.T. Adey & S. Chuo

Institute of Construction & Infrastructure Management, ETH Zurich, Switzerland

S. Moghtadernejad

Construction Research Centre, NRC Canada, Ottawa, Canada

ABSTRACT: Due to recent technological advances and the accumulation of historical information related to bridge conditions and bridge maintenance interventions, many managers are in the position to make efficient systematic early estimates of future bridge interventions. If this was possible, it would facilitate communication between different actors within the intervention planning process, e.g., asset managers, production managers, capacity managers, and network developers. Consequently, this paper proposes a methodology to efficiently and systematically make early estimates of bridge interventions, their costs, required possession times and associated risks. The methodology is used in a case study to make early estimates of the possible interventions in different planning periods for a 50m-long masonry bridge located in Switzerland. The results indicate that the methodology has the potential to provide efficient and complete over-views of possible upcoming interventions on all bridges within a bridge portfolio. Once implemented in a digital environment, the methodology is likely to provide bridge managers with an improved way to determine the timing of detailed bridge investigations by engineering offices.

1 INTRODUCTION

Currently, many bridge managers make early estimates of intervention requirements rather qualitatively, meaning that they use inspection reports and discuss with inspectors and engineers as to which interventions may be required on bridges in the future. A downside of the current process is its inability to provide a systematic and efficient overview over all the possible upcoming interventions, and without this systematic estimate it is also difficult to have a good overview of the intervention costs and the required possession times. The lack of a systematic overview may result in interventions being planned earlier or later than they ideally should be, resulting in additional intervention costs and greater than necessary service disruptions. An efficient and systematic approach to estimate the intervention requirements would help bridge managers to reduce costs and service disruptions. The use of digital tools has the potential to support bridge managers in taking advantage of their available data to address this gap in the current intervention planning.

Researchers and asset managers have developed multiple methodologies to improve bridge intervention planning by incorporating different concerns of the bridge managers. For example, (Adey et al., 2015; Adey & Hajdin, 2011) developed methodologies to determine asset-level intervention strategies and estimate financial requirements to execute the interventions. Although such methodologies provide bridge managers with an efficient and systematic overview, they require some improvements before they become useful. The improvements required are more detailed estimates, i.e., no longer focusing on the bridge level but on the component or element level, estimates of risk, and approximations of required track possession times. Examples of methodologies focused on making estimates at the component level include (Kim et al., 2022; Martani et al., 2021; Tserng et al., 2009). Examples of methodologies that have been developed to estimate the risk associated with bridges (Adey et al., 2012).

Examples of studies that make estimates of intervention costs and/or possession times include (Adey & Hajdin, 2011; Burkhalter & Adey, 2022).

This paper fills the identified gaps by proposing an algorithm to estimate the component-level intervention requirements, related costs, and possession times systematically and efficiently for multiple planning periods at the early stages of bridge intervention planning considering:

- the condition evolution over time due to the multiple deterioration processes affecting the components,
- the failure risks as a function of the components being in different condition states,
- the possible preventive interventions on the different components of the bridge, and the associated costs and effects on service through the allocated possession times during their execution.

The methodology enables the use of both qualitative and quantitative information coming from different sources, e.g., results of visual inspections, approximate and detailed estimates of failure risks, and approximate and detailed estimates of the costs and impacts on service of executing interventions on the provided service. The methodology is used to estimate component-level intervention requirements, related costs, and possession times over future planning periods for a masonry arch bridge in Switzerland with a length of 50 m.

2 ALGORITHM

Figure 1 provides an overview of the algorithm for estimating the type, costs, and possession times of interventions that need to be executed over future planning periods.

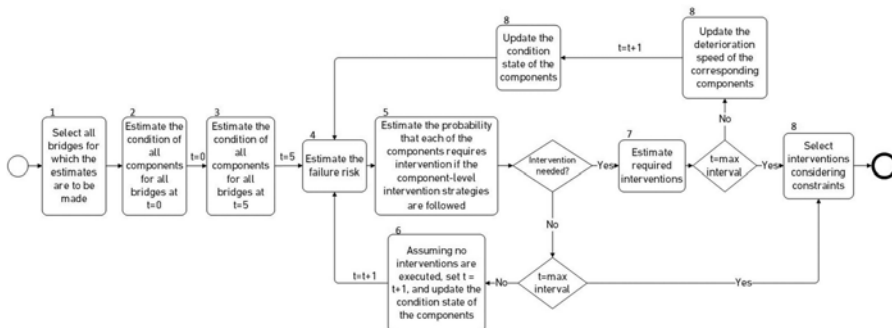

Figure 1. Flowchart for performing the intervention planning process in a digital platform.

Step 1: Select all bridges for which the estimates are to be made. No estimates need to be made for bridges that are already undergoing detailed investigations by engineering offices.

Step 2: Estimate the condition of all components for all bridges at $t=0$.

Step 3: Estimate the condition of all components for all bridges at the start of the planning period to be considered, e.g., $t=5$.

Step 4: Estimate the failure risks at $t=5$.

Step 5: Estimate the probability that each of the components will require intervention if the component-level intervention strategies are followed.

Step 6: Assuming no interventions are executed, set $t = t + 1$ and repeat Steps 3 to 6 until the probabilities of components requiring intervention and the failure risks have been estimated for each of the years in the planning period.

Step 7: Estimate the required interventions: If the probability of requiring an intervention on at least one of the components is higher than a specific threshold value set, or the sum of the failure risks in the planning period is higher than a specific threshold value, it is considered that an intervention is to be executed on the bridge in this period, and indications are given as to which type of interventions are possible and the one that is the most likely, the possessions that are possible and most likely, and the likely intervention costs as a function of the type of intervention and possession times.

Step 8: Propose interventions to postpone if required: If it is known that not all interventions are possible within the planning period, e.g., due to a restricted budget even at this early stage, the indicator of the risk of failure is used to prioritize the bridge interventions, i.e., the bridges exhibiting the highest risk are first on the list. The bridges lowest on the list are postponed until the costs of the interventions included in the list are below the allocated budget.

3 EXAMPLE BRIDGE

The example masonry bridge was constructed in 1926 with a length of 50.8 m. This bridge is located in the canton of Bern, Switzerland and is characterized by three arches made of concrete blocks and resurfaced by rammed concrete (Figure 2).

3.1 Components

The main components of the example masonry bridge are remarked in Figure 2, i.e., foundations, piers, abutments, masonry arches, deck, spandrel walls, and railings and safety walkways.

Figure 2. An overview of different components of the example masonry bridge.

3.2 Condition of components at $t=0$ and $t=5$

Five discrete condition states are defined such that condition state 1 represents a situation with no or insignificant damage, while condition state 5 represents an alarming situation in which safety is at risk. The intermediate states indicate a worsening situation, with an increasing amount of damage. Table 1 shows an example of such definitions for the piers. Similar to the piers such condition states are defined for other bridge components.

Table 1. An example of condition state definition for the piers.

CS	Condition description	Damage description	Damage indicator
1	Good	None/ insignificant	No visible damage; only thin superficial cracks; no sign of corrosion; no or few humid zones.
2	Acceptable	Minor	Visible spot of rust and/or local spalling; thin cracks due to corrosion of the reinforcement; some humid zones; insignificant mechanical damage.
3	Damaged	Significant	Spalling with visible reinforcement; insignificant loss of section, less than 10% than visible reinforcement; cracks and/or humid zones with leaching of the concrete.
4	Poor	Extensive	Spalling of concrete with less than 25% of exposed reinforcement; significant loss of section, more than 10% of visible reinforcement; cracks with significant calcium deposits and/or large humid zones with the leaching of the concrete.
5	Alarming	Safety is endangered	Spalling of concrete with more than 25% of exposed reinforcement; significant loss of section area of the reinforcement; advanced pitting corrosion occurring; large humid zones with the leaching of concrete.

The condition state of all components is then estimated by matching the definition with the physical indicators mentioned in the latest inspection report. According to the records, the

railings and safety walkways are in condition state 1, the foundations and abutments are in condition state 2, and the rest of the components are in condition state 3.

The evolution of the condition states over time is estimated using probabilistic discrete state modelling that approximates the probabilities of the transition of the components from one state to another in each unit of time, similar to the method being used in existing Bridge Management Systems (Mirzaei & Adey, 2015). An example of the transition probabilities for the piers is shown in Table 2. These transition probabilities are for one-year periods, which is the average time between the annual observations. In addition, the deterioration speed is considered as a function of the number of maintenance interventions executed on the component. This assumption is made since the execution of maintenance activities does not necessarily completely improve the physical and chemical properties of the components (Adey & Hajdin, 2011). For example, refilling the cracks in the piers and their rehabilitation can restore the condition state of the piers to condition state 1. There might still be an accumulation of aggregated alkali-silica in the pier, which accelerates the deterioration rate. In this example, it is assumed that following construction and a first maintenance intervention, the deterioration rate increases by 2% after each intervention. The maintenance intervention count resets after the replacement of the components. Similar logic is used to estimate the transition probabilities for other bridge components.

Table 2. An example of the transition probabilities for the piers.

CS	1*					2*				
	1	2	3	4	5	1	2	3	4	5
1	94%	6%	-	-	-	92%	8%	-	-	-
2	-	92%	8%	-	-	-	90%	10%	-	-
3	-	-	83%	17%	-	-	-	81%	19%	-
4	-	-	-	78%	22%	-	-	-	76%	24%
5	-	-	-	-	100%	-	-	-	-	100%

* Maintenance intervention count

An overview of the condition state of all components at $t=5$ is provided in Table 3. These are estimated using the condition states at $t=0$ and multiplying them with the probability of them transitioning from their initial state into the possible future states within 5 years.

Table 3. An overview of the condition state of the components at $t=5$.

Component	CS				
	1	2	3	4	5
Foundations	0%	93%	5%	2%	0%
Piers	0%	0%	48%	35%	17%
Abutments	0%	80%	16%	4%	0%
Masonry arches	0%	0%	46%	36%	18%
Spandrel-walls	0%	0%	50%	34%	16%
Deck	0%	0%	56%	32%	12%
Railing & Safety walkway	35%	56%	8%	1%	0%

3.3 Component-level interventions and intervention strategies

Interventions are executed on components to ensure they continue to function as expected. These interventions are defined individually for each component category in response to the severity of the observed damage. An example of intervention definitions for piers is shown in Table 4, which is defined using two sources (Adey & Hajdin, 2011; VICROADS, 2018). Three generic labels are given, i.e., rehabilitation, renewal, and replacement, to reflect the increasing effort and work required for interventions of each type (Adey & Hajdin, 2011).

Table 4. An example of the intervention definitions for the piers.

Intervention type	Activities
Rehabilitation	Fill out cracks and spalls with mortar or epoxy grouting; concrete protection coating.
Renewal	Renew concrete & reinforcement damaged; strengthen the pier; protection coating.
Replacement	Replacement of part or the whole pier.

The costs associated with these component-level interventions are estimated in terms of the owner and user costs. The owner unit costs are roughly estimated based on the values mentioned in Swiss Construction Price Index (Federal Statistical Office, 2021). The user costs are estimated in terms of the added travel time due to taking alternative connections. It is estimated that the closure of the bridge will increase the travel time by 8 minutes. The unit user cost is estimated based on the average wage, i.e., almost 43 mu/h (Federal Statistics Office, 2020). The total cost associated with an increment in the travel time varies as a function of the number of passengers. The average train occupancy in Switzerland, i.e., 50% occupancy, is considered to estimate the number of affected passengers. The total user costs are estimated as 86'232 mu/day (Equation 1).

$$\text{Daily user costs} = \text{Average number of passengers per day} * \text{average wage}(\mu/h) * \text{added travel time per passenger (h)} \quad (1)$$

An overview of the intervention costs for the piers is shown in Table 5, which indicates, the more advanced and labour-intensive the activity, the more investment is needed. The owner and user costs for other components are estimated as with the pier interventions.

Table 5. An example of intervention costs for piers of the example masonry bridge.

Intervention type	Unit owner cost (mu/m ³)	Volume (m ³)	Duration of the service disturbance (weeks)	Owner cost (mu)	Service disturbance costs (mu)
Rehabilitation	290	11.3	0	3'289	172'465
Renewal	570	11.3	1	6'464	344'929
Replacement	1'100	11.3	2	12'474	603'626

The execution of these interventions does not necessarily restore the condition of the components to a like-new state. The intervention effectiveness for different components is estimated using different sources (Adey & Hajdin, 2011; Martins et al., 2004; VICROADS, 2018).

The intervention strategy selected for the components, along with the effectiveness of the interventions is shown in Table 6. No intervention is needed when the component is in condition state 1 and 2, whereas a replacement is needed when the component is in condition state 5. For condition states 3 and 4, rehabilitation and renewal interventions are carried out respectively, and the values in the table correspond to the effectiveness of these interventions. For example, when a rehabilitation intervention is executed on a component in condition state 3, there is an 85% chance that the component will be in condition state 1 at the beginning of the next year.

Table 6. An example intervention strategy for a bridge component with the effectiveness of interventions.

Condition state	Intervention type	CS1	CS2	CS3	CS4	CS5
1	Do nothing	-	-	-	-	-
2	Do nothing	-	-	-	-	-
3	Rehabilitation	85%	15%	-	-	-
4	Renewal	80%	20%	-	-	-
5	Replacement	100%	-	-	-	-

3.4 Failure risks between $t=6$ and $t=10$ and $t=11$ and $t=15$

As long as the component-level intervention strategies are followed, and there are no changes to the expected loading of the bridge, it can be assumed that failure risks are within the acceptable thresholds that are set by the asset managers, and the consideration of these thresholds can be omitted from the analysis for planning future interventions. If, however, interventions are going to be postponed beyond the time suggested by the component-level intervention strategies the probability and consequences of the bridge not functioning as intended. Two fault trees are developed to approximate the consequences associated with the failure of the bridge to provide the required level of service, while components are in different condition states. The associated top events, i.e., restricted service and interrupted service, are defined based on the severity of the bridge failure which is a function of the severity of component failures. In the former, rehabilitation interventions are executed during night closures, and in the latter, replacement interventions are conducted during a period that includes total closure of the bridge for a certain time. The basic events are defined to include gradual and sudden deterioration events. These events can occur due to a combination of external loads, e.g., traffic loads and excessive loads due to natural hazards.

Figure 3 shows the fault trees developed for the interrupted service.

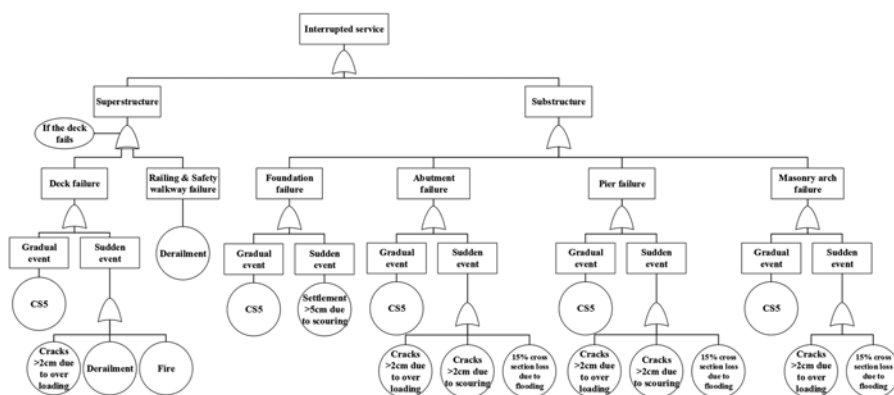

Figure 3. An example fault tree for interrupted service on the masonry bridge.

The probability of failure of each component is estimated as a function of the occurrence probability of each basic event, which in turn is estimated as a function of the probability of imposition of external loads and the resistance of the components. The probability of the imposition of the excessive loads does not depend on the condition state of the components and their annual occurrence probability was estimated using expert opinion. The resistance of the component, however, depends on its geometric and material properties. This resistance changes over time as a function of its condition state. Table 7 shows the considered occurrence probabilities of basic events, where it is less likely that basic events occur when a component is in condition state 1 and it is very likely to occur when the component is in condition state 5. These estimations were used to quantify the probability of failure of each component. The occurrence probability of each top event is estimated using the failure probability of the components.

Table 7. An example of occurrence probabilities of basic events.

Condition state	The annual occurrence probability of each basic event	Assumed probability of occurrence of basic event
1	Very low	0.001%
2	Low	0.01%
3	Medium	0.02%
4	High	0.05%
5	Very high	0.1%

The occurrence of each top event has different consequences. The consequences vary as a function of the amount of work needed to recover the required level of service. The values of required service disruptions and intervention costs are calculated using the information in section 3.3.

The estimates of failure risks as a function of the component behaviour enable the setting of a threshold on the value of additional failure risk that would trigger an intervention, especially in case component-level strategies are for some reason not set. Considering such a threshold also enables obtaining a meaningful overview of the component-level intervention requirements and eliminates the possibility of requiring intervention on different components every year. In this study, the tolerable failure risk threshold was set as the value of failure risks when all components are in CS4. Figure 4 shows the evolution of the failure risks over time for the studied bridge. It is shown how triggering interventions can be dependent on the level of failure risks, given the tolerable failure risk threshold.

Figure 4. The evolution of the failure risks over time considering a failure risk threshold.

4 MOST LIKELY INTERVENTIONS

The intervention requirements are estimated for the initial phases of the intervention planning process, i.e., 6-15 years ahead of the execution time. Therefore, three planning periods are defined, i.e., 1-5, 6-10, and 11-15, where it is assumed that no interventions are planned for years 1-5 since decisions related to this planning period have already been made. The intervention requirements for the future planning periods are predicted using the intervention strategies determined in section 3.3 and the deterioration rate estimated in section 3.2. Interventions are scheduled to be executed on a component when the failure risks approach the defined failure risk threshold. Table 8 represents detailed information associated with the intervention requirements with the highest probability in the second planning period along with the expected costs and impacts on the service. The execution of this intervention on the

Table 8. The most probable intervention in the future planning periods.

Planning period (expected execution year)	Component	Likelihood of requiring inter- vention (%)	Intervention type	Expected duration	Expected effects on service (weeks) if done alone*			Expected intervention costs (×103 mu)
					None	Restrictions on the traffic	Closure	
11-15 (year 11)	Piers	46	Replacement	51	30	14	7	616
	Abutments	25	Rehabilitation	23	14	7	2	293
	Deck	36	Replacement	64	30	14	20	1'861
	Masonry arches	48	Replacement	57	30	7	20	1'939
	Spandrel-walls	44	Replacement	18	14	4	0	433
	Railings + Side walkway	25	Rehabilitation	3	2	1	0	101

* This table is to serve as a starting point for discussions as to what exactly will be required for the bridge.

piers of this bridge will require 51 weeks to be complete such that the traffic needs to be disrupted for a week, followed by two weeks of service restriction during the execution.

5 CONCLUSIONS

This paper proposed a systematic and digital methodology to make early estimates of future bridge interventions their costs, required possession times and associated risks. The methodology was tested in a case study to provide a detailed overview of intervention requirements for a masonry bridge with a length of 50.88 m in Switzerland. The main novelty of the methodology proposed in this study is in focusing on components instead of assets, and the use of fault trees to estimate the condition state dependent failure risks, since the systematic consideration of failure risks associated with the level of service is missing in existing bridge management systems (Mirzaei et al., 2014). The proposed methodology considers the aspects that are important to bridge managers.

To ensure compatibility with existing practice, the current condition state, the condition evolution, and plausible intervention strategies were estimated to be used in a five-state model with probabilities of transitioning between states over time. The failure risks of the bridge were estimated using fault trees considering two top events associated with the severity of the traffic disturbance. The failure probabilities were estimated as a function of the condition state of the components. The consequences of top events were calculated considering the owner cost of interventions and user costs due to service disruption.

Future studies should focus on the implementation of the proposed methodology to plan the component-level interventions for all assets in a network in both simulated and real planning processes to assess the improvements in efficiency and effectiveness of the proposed digital methodology.

Estimation of bridge component condition states with varying data availability

S. Chuo, B.T. Adey & H. Mehranfar

Institute of Construction and Infrastructure Management, ETH Zürich, Zürich, Switzerland

S. Moghtadernejad

Construction Research Centre, NRC Canada, Ottawa, Canada

ABSTRACT: For computer systems to estimate the type and timing of future interventions on a bridge, and more specifically, on its components, it is important for the bridge managers to understand their current condition states. That information, however, is almost never perfectly available. In this paper, a methodology is developed that accounts for the scenarios of having no or partial inspection data on the bridge components. A Bayesian network is used to estimate the probabilistic condition states of an asset, requiring the utilization of information that is external to an inspection campaign, including the component properties and environment. With partial information available on the bridge and/or component condition state, the Bayesian network takes advantage of the inference capability to draw conclusions on the condition state of interest. The methodology is used to estimate the condition of a railway bridge pier located in Switzerland.

1 INTRODUCTION

Detailed bridge inspections in many countries are usually carried out routinely every five to six years by qualified engineers, where the component condition is described in an inspection report if damages are observed, and an overall bridge condition state is recorded and archived in an internal digital bridge management database. There are two main challenges with using this information to estimate when future interventions might be required: (1) lack of consistencies in the assessment and documentation of condition states for all bridges and their components, such as the information recorded (description of damage vs. numerical condition state) and the platform used (paper-based vs. digital database), and (2) sporadic historical data available through various points in time. This makes it difficult for bridge managers to coordinate activities efficiently and effectively with other stakeholders, including network developers for development interventions, capacity managers for rail traffic scheduling, other asset managers for affected infrastructure objects, and project and production managers for intervention execution. This is especially difficult as the planning of many infrastructure interventions occurs at least 15 to 20 years ahead of time. When the condition state is not known for a bridge component of interest, or there is little confidence in the existing record, bridge managers must request detailed inspection to be performed in order to evaluate the current condition state of the bridge component. Before detailed investigations are ordered it would be useful for bridge managers to be able to make the best estimates of the condition state possible considering all information at their disposition.

With this in mind, this paper contains a methodology to be used to make estimates of the condition state of all bridge components at the current time. The methodology enables the use of different levels of data and can be used to make estimates when no data is available on the condition of the components themselves, but on other explanatory variables. The paper demonstrates how the methodology works by using it to estimate the current condition state of a pier component of a railway bridge in Switzerland. It is an essential component in helping to exploit digitalization in the intervention planning process (Adey 2019, Burkhalter and Adey 2022).

2 OVERVIEW OF METHODOLOGY

The spectrum of data availability to be used to estimate the condition state of bridge components ranges from none to knowing the exact current condition state. There are three levels of condition data availability: (1) no inspection data available on the bridge and on the components of the bridge, (2) partial inspection data available on the bridge and/or on the components of the bridge, and (3) all inspection data available on the condition of the bridge components.

In level 1 where no condition data is available, information that can be used to approximate the condition state needs to be extracted from sources external to those included in an inspection campaign. This information is then used in a Bayesian network to estimate the probable condition states the asset. The Bayesian network makes use of engineering judgment considering design concerns, such that the design variables (e.g., construction year, location, geometry, loading, etc.) serve as explanatory variables (Chang *et al.* 2017). When there is a lack of available inspection data, evident explanatory variables are used as influencing factors to infer the condition state of the component directly. This is different from the use of deterministic physics-based models, which require considerable computation power and simplifying assumptions, and uncertainties are generally not accounted for (Prakash *et al.* 2020). In level 2 where partial data is available, there are several sub-levels which depend on the exact information available. The Bayesian network takes advantage of the updating and inference capability to draw conclusions on the current condition state.

The proposed methodology is demonstrated using an example railway bridge as shown in Figure 1, which consists of the following components: trusses, girders, bearings, abutments, foundations, and the pier. Five condition states are used to describe the different levels of damage of the components, as well as indicators to reflect the specific details that each condition state entails. A condition state of 1 indicates the component is as good as new, with no measurable and observable defects, while condition state 5 suggests that the component has a high probability of requiring an emergency intervention. Structural failure (e.g., collapse) is not considered, as the focus is on serviceability and it is assumed that management teams will detect any problems and request emergency interventions as soon as something alarming is detected, making the probability of structural failure negligible. The methodology is demonstrated in detail using the pier of the example railway bridge.

Figure 1. Illustration of the example railway bridge.

3 ESTIMATION OF CURRENT CONDITION STATE WITH NO CONDITION DATA

3.1 General

In the absence of condition data, estimates have to be made using data that is not normally in an asset management database. This requires the estimation to be based on information coming from either other internal sources (e.g., construction blueprints) or external sources (e.g., traffic frequency). The identification of influencing factors establishes factors and their proxies as indicators to the condition state of the component. These factors may be estimated through regression analysis to model the relationship between dependent and independent variables, to predict based on said relationship, and to infer causality. With lack of sufficient data to support the analysis, expert opinions could be used to provide initial estimation.

For the example bridge pier, the following four influencing factors are identified: pier age, traffic dynamic force, river discharge, and pier geometry. The values of these factors, either

alone or in combination with one another, are likely to be correlated with the condition state of the pier. Together they can be included in a Bayesian network that represent their conditional dependencies as a probabilistic graphical model, as shown in Figure 2.

Figure 2. Bayesian network of pier condition state.

The pier age factor represents the length of time the pier has been in operation since construction. It is correlated with condition because gradual deterioration of the pier materials overtime would lead to worsening condition state. That is to say that without any sudden impact (e.g., boat collision, scour from an extreme flood) in the past and no maintenance interventions throughout its life, the gradual deterioration would ensure that a pier that has been in operation for 60 years would be in a worse condition state than the same pier in an identical environment that has been in operation for only 10 years. This factor does not, however, consider the maintenance history. If maintenance history is known this would be handled in the partial inspection information scenario.

The traffic dynamic force factor represents the repeated axial loading on the pier itself, as trains operate over the bridge carrying passengers and cargo across the river. The effect of cyclic loading on the pier is transferred from the kinetic movement of the trains onto the railway tracks and to the girders beneath, through the bearings, and finally to the substructure including the pier. The stronger and more frequent the loading, the greater damage it would cause to the pier, thus reducing the carrying capacity of the component and the bridge overtime.

The pier in this example is located in the middle of the Aare river in the canton of Bern, Switzerland. In a study that examined over 500 bridge failures between 1989 and 2000, it was found that over 50% of the failures can be attributed to hydraulic factors, which include flood and scour (Wardhana and Hadipriono 2003). As such, scour is identified as a dominant factor that could influence the pier condition state. Scour is a complex process, but can be examined from the perspective of hydraulic, geotechnical, and structural aspects (Wang *et al.* 2017). While the soil bed materials can vary between different parts of a river stream (i.e., upstream and downstream), the bed composition may not be uniform across the cross-sectional depth. Therefore, the geotechnical aspect is not considered, and the hydraulic and structural factors are represented by river discharge and pier geometry, respectively.

In a Bayesian network as shown in Figure 2, the size of the conditional probability table for the child node grows exponentially with increasing number of parent nodes (Diez 1993). For example, in a Bayesian network of five nodes each having three discrete states, with four parent nodes and one child node, a total of 3^5 (i.e., 243) conditional probabilities would need to be defined for the child node. This results in an unrealistic implementation in practice as it requires tremendous cognitive capacity from subject matter experts to provide consistent and dependable results across all possible combinations (Werner *et al.* 2017, Barons *et al.* 2022).

This is a significant challenge given the current structure of the Bayesian network, as the estimation of condition state needs reliable conditional probabilities to infer the component condition state. A comparable problem has been addressed in a methodology that developed a Bayesian network to represent masonry railway bridge condition using bridge components, where the substructure (supports) includes abutments and wing walls, and the bridge deck includes the barrel arch, face rings, parapets, and spandrel walls (Rafiq *et al.* 2015). Their research determined a set of weights to quantify the relative strengths of the influences of the parent nodes (condition states of the bridge components) on the child node (condition state of the bridge), based on the Structures Condition Marking Index (SCMI) developed by Network Rail, the owner and operator of rail infrastructure network across Great Britain. A set of probability

distributions are subsequently assigned to the parent and child nodes to derive the conditional probability table for the child node. While there are similarities between the application of their methodology and this work, their research focused on the estimation of condition state for the bridge while having complete data on the parent nodes, and this work is focused on the estimation of bridge component condition states without complete data on the parent nodes.

The following sections present an objective and efficient process to elicit child node conditional probabilities through an improved methodology for the context of this research, focusing on capturing the expert opinions while maintaining their coherence, as well as generating possible combinations of values using the Monte Carlo simulation. Figure 3 outlines the steps required to develop the final conditional probability table in a Bayesian network.

The first step, which is already complete, is where the Bayesian network is developed for pier condition state based on the four identified influencing factors as explanatory variables, as shown in Figure 2. The description of the remaining steps in the process will use the developed Bayesian network to provide detailed description and direction on the implementation.

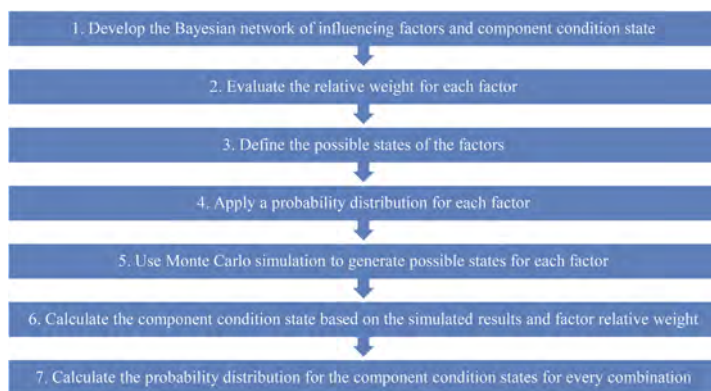

Figure 3. Process to develop the conditional probability table for a Bayesian network child node.

3.2 Relative weights of influencing factors

While the four influencing factors as shown in Figure 2 affect the condition state of the pier either individually or in combination with each other, their scale of impact may be different. This means that certain factors could be more strongly correlated with component condition state than others. To capture the potential difference in influencing factor impact, instead of assuming equal weights for each of the factors, their relative weights are evaluated. Without sufficient data to support regression analysis, which is assumed here the case for illustrative purposes, expert opinion is relied on to facilitate the initial estimation, where the analytic hierarchy process (AHP) is used to quantify the relative weights of the factors through pair-wise comparisons (Saaty 1990). With this approach, two factors are compared with each other at a time, until all possible pairs have been analysed. Table 1 shows the results from the comparisons using the AHP and summarises the final calculated relative weight for each influencing factor. The consistency ratio is 0.0107 (Alonso and Lamata 2006), confirming that the subjective evaluation of the pair-wise comparison is consistent and therefore statistically rational.

Table 1. Pier factor relative weight using the AHP.

Criteria	Pier age	Traffic force	River discharge	Pier geometry	Relative weight
Pier age	1	5	3	7	0.579
Traffic force	1/5	1	1/2	2	0.121
River discharge	1/3	2	1	4	0.233
Pier geometry	1/7	1/2	1/4	1	0.067

3.3 Factor states

The factor states are proxies that describe the different possible input variables that could affect the component condition state. This addresses the problems when (1) there is no quantified value associated with the condition state (e.g., pier geometry), and (2) when there is uncertainty associated with the quantified value of the influencing factor (e.g., traffic force). Similar to how the component condition is classified under five categories of increasingly worse state from 1 to 5, the factors are also classified on an ordinal scale according to their contribution to increasingly worse component condition states. The level of detail for each of the factor is low enough where the differences between each state would not be significant, but high enough where the states can be distinguished from one another.

3.4 Factor probability distribution

In order to simulate different combinations for the possible states of the pier influencing factors (e.g., the pier in the second quartile life, low traffic force, medium discharge level, and bad pier geometry), a probability distribution is assigned to each factor. It is assumed that all four factors are represented by a uniform distribution, meaning all states have an equal likelihood of occurrence. The choice of distribution can be updated when there is supporting data available (Molnar *et al.* 2006, Sobanjo *et al.* 2010). When a random number is generated between 0 and 1, this allows for the classification of the factor state according to the definition of the state itself and the range of values associated with it. Table 2 lists the possible states for each of the influencing factors for the pier, as well as the range for each possible state of the factors on an ordinal scale.

Table 2. Possible states of the pier factors and the ranges of factor states.

Pier life		Traffic force / River discharge		Pier geometry		Pier condition	
States	Range	States	Range	States	Range	States	Range
1 st quart.	0 – 0.25	Low	0 – 0.33	Good	0 – 0.5	1	0 – 0.2
2 nd quart.	0.25 – 0.5	Medium	0.33 – 0.67	Bad	0.5 – 1	2	0.2 – 0.4
3 rd quart.	0.5 – 0.75	High	0.67 – 1			3	0.4 – 0.6
4 th quart.	0.75 – 1					4	0.6 – 0.8
						5	0.8 – 1

3.5 Monte Carlo simulation

In principle, the determination of the component condition state based on various combinations of factor states could be deterministic. However, given the complexity of the model, the Monte Carlo simulation can easily generate random numbers based on the assumed statistical distributions for the component influencing factors, and then compute the resultant condition state without much difficulty. It is important to note that the random numbers are independent for every simulation across the different influencing factors.

3.6 Component condition state

The component condition state is computed based on the pier factor relative weight as determined previously in Table 1. Applying the relative weights from Table 1 where the AHP method was used, Equation 1 is used to determine the final condition state:

$$CS_P = 0.579(S_A) + 0.121(S_T) + 0.233(S_R) + 0.067(S_G) \quad (1)$$

where CS_P is the pier condition state, S_A , S_T , S_R , and S_G represent the state for the pier age, traffic force, river discharge, and pier geometry, respectively. The states from the four influencing factors are the simulated results from the Monte Carlo simulation, where a number between 0 and 1 is randomly and independently generated.

When the pier condition state is computed, its value is transformed to a scale of 1 to 5, where condition state 1 means the component can perform its intended function at full capacity with no structural or cosmetic damage, while condition state 5 means it is no longer safe to continue using the component, thus disrupting the required level of service. A uniform distribution is considered in the conversion of calculated condition state into the linear scale of 1 to 5, as shown in Table 2.

3.7 Component conditional probability table

After running 50,000 simulations, the probability distribution for the component condition state can be evaluated for every possible combination considering the effect of all the influencing factors. This allows for the elicitation of the conditional probability table given that all the combinations are generated through the Monte Carlo simulation. For example, with the combination of having a bad geometry, medium discharge, second quartile life, and low traffic, the probability for the pier condition state from 1 to 5 can be calculated, as summarised in Table 3.

Table 3. Probability distribution of an example pier factor combination.

Combination	Number of results	Probability
B-M-S-L-1	0	0
B-M-S-L -2	22,761	0.455224
B-M-S-L -3	27,239	0.544776
B-M-S-L -4	0	0
B-M-S-L -5	0	0

4 ESTIMATION OF CONDITION STATE WITH PARTIAL INSPECTION DATA

In the database that manages the example bridge, the bridge condition states are recorded as an overall discrete value on a scale from 1 to 5. Despite the inspection reports describing the damages that are observed on the component level, they are not converted into the same numerical scale. This means that when there are partial data available, specifically the availability of the bridge condition state, it can be used in the estimation of the component condition state. This is done by developing another Bayesian network, such that the bridge condition state is a function of the condition state for each of the six components. The structure of the relationship is shown in Figure 4, where the bridge condition state is the child node in the Bayesian network, and the six bridge components are the contributing parent nodes.

Figure 4. Bayesian network of bridge condition state.

In this network, each node contains five discrete states, as such the conditional probability table for the bridge condition state requires a total of 5^7 (i.e., 78,125) conditional probabilities. This Bayesian network is different from the one developed for the component condition state as shown in Figure 2 such that the process to elicit probabilities could be simplified, therefore the methodology is not the same between these two networks. In this case, a policy is put in place to determine the bridge condition state given the combination of the component condition state, where the bridge condition state is the worst condition state out of any of the component condition states. For example, if all the components are in condition state 2 except for the girders which are in condition state 4, then the overall bridge would be in condition state 4 as well. This rationale is in line with the assumption that the failure of any one of the components to provide service would inevitably result in the failure of the bridge to provide service (Faber *et al.* 2000).

In terms of having partial information, there are several possible scenarios that could be evaluated, where they make use of: (1) known condition state of the bridge, (2) known condition state of other bridge components, and (3) external information as described in Section 3. This means the Bayesian network for estimating the current condition state with no inspection data (i.e., Figure 2) would be incorporated into the Bayesian network for estimating the current condition with partial inspection data (i.e., Figure 4). The known information in combination with each other creates a more detailed estimation of the current pier condition state compared to relying only on the known bridge condition state or external information, and this allows for a better planning of future maintenance interventions. For example, five scenarios are considered as outlined in Table 4, and their comparisons are summarised in Table 5, where the pier condition state probabilities are shown given different levels of granularity of known information.

Table 4. Levels of available information.

Scenario	Available information		
	Bridge condition = 3	Abutment condition = 2 Bearing condition = 1	Pier life = 2 nd quartile Traffic = low Geometry = bad Discharge = medium
1	✓		
2	✓	✓	
3			✓
4	✓		✓
5	✓	✓	✓

Table 5. Probability distributions of the pier condition state given known information.

Pier condition state	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5
1	0.317	0.292	0	0	0
2	0.317	0.292	0.455	0.42	0.37
3	0.365	0.415	0.545	0.58	0.63
4	0	0	0	0	0
5	0	0	0	0	0

With the fifth scenario using the largest amount of available information out of all the options, its estimation would provide the highest level of confidence given the input data is accurate. This is naturally contingent on the Bayesian network adopting a structure (i.e., relationship between the nodes) and parameters (i.e., weights between the nodes) that adequately reflect the behaviour of the bridge component in estimating its condition state. Nevertheless, the methodology presented heretofore is able to adapt and manifest the level of granularity desired, as well as revise according to the latest understanding of bridge performance and deterioration.

5 CONCLUSIONS

The results of this work help better estimate the current condition states of bridge components based on different levels of inspection data availability, which is essential in using computer software to predict future deterioration and estimate when likely interventions are required on bridges. A Bayesian network is developed that uses information external to an inspection campaign to estimate the probabilistic condition states, where four influencing factors are identified for the example bridge pier. Different combinations of available partial information are also demonstrated, where the condition state of the bridge, condition states of other components of the bridge, and the four influencing factors allow the example bridge pier to be evaluated with

a higher level of confidence compared to the results from any one of the three known available information acting alone. The methodology in this paper supports the existing intervention planning process, where the results would contribute towards the initial estimation of interventions required, which is done 15 to 20 years before planned execution.

There is a couple of limitations in this work that will be addressed in the future. Firstly, given more information could be made available regarding the most likely state for each factor, other probability distributions may be more suitable to reflect the inherent properties of the factors. This would essentially affect the probability that each state would be generated through simulation, and ultimately affect the calculation of the component condition state towards developing the final conditional probability table, as shown through the proposed methodology in Figure 3. Secondly, in this work the bridge condition uses the worst element model, however, risk-based methodology could be implemented for the assessment of bridge condition as a function of the elements that make up the bridge. This means that the structure of the Bayesian network as shown in Figure 4 would remain the same, but the parameters of the component-bridge relationship would need to be updated according to the determined risk class of the bridge element.

Antoine G. Faddoul, Sneha Suvarna & Venkata K.T. Gunturu

School of Construction Management Technology, Purdue University, West Lafayette, USA

ABSTRACT: The built environment consists of construction and infrastructure that are called to provide the required services for a long stretch of time, often decades. If they fail to do so, the consequences for society can be very severe. Over this time horizon, assets are exposed to variable conditions that influence their performance, e.g. roads are confronted with a volume of traffic that is largely variable both on the short-term, i.e. hourly variation between pick and off-pick times and in the long-term, i.e. trend of demand over decades. Under such variable operation conditions, static construction and infrastructure cannot guarantee an acceptable level of service all the time, e.g., a road with a fixed capacity cannot guarantee to be adequate in peak hours and efficient in off-peak hours. Variable operating conditions require a responsive built environment able to adapt accordingly to provide an effective and efficient response. Recent developments in sensing technologies, actuating systems, and the IoT have explored the potential for the use of responsive systems to optimize the service provided by built environments operating under variable conditions. Some examples include automatically controlled buildings' lighting and fencing, as a function of the outdoor sun exposure, and road line capacities, as a function of the traffic demand. Despite some examples of responsive systems, there is still a lack of systematic analysis of their use in infrastructure and construction. This lack prevents a full understanding of the current capabilities of a responsive built environment is presented. In this work a systematic analysis of the most cutting-edge use of responsive systems for the built environment - in terms of sensing technologies, actuating systems, and triggering logics - and possible future developments are outlined.

1 INTRODUCTION

Infrastructures are built to operate over a long-life span, often decades, under variable conditions. As such it is difficult that assets designed to deliver constant performances are able to provide a satisfactory level of service in the long term. This is due to the fact that assets that deliver constant performances are prone to two types of falls: either they have been designed for a standard operational demand, in which case they are undersized for a non-negligible amount of the time they operate (i.e. they are ineffective), or they have been designed for the maximum demand, in which case they are oversized most of the time they operate (i.e. they are inefficient).

To overcome these limitations and maximize both the effectiveness and the efficiency of the built environment, infrastructure should be made responsive. Responsive infrastructures are those that are able to adjust their performance in real-time to adapt to changing environmental conditions, e.g., buildings with a heating and cooling system that adapt their functioning automatically based on the internal temperature sensed. Responsive infrastructures are equipped with systems characterized by three main components: (i) a sensing technology that monitors the environmental conditions that can influence one or some of the services provided by infrastructure (e.g. temperature, lighting,

number of people in an indoor environment, speed of a vehicle on the highway); (ii) an actuator, or response system, that modifies the characteristic or the performance of the infrastructure according to the condition sensed (e.g. a window that automatically opens and closes according to the indoor air quality and outdoor weather conditions); and (iii) an interface that connects the sensing and the actuators through a triggering logic. These components work together to collect, process, and use a large wealth of information to optimize infrastructure performance.

The recent developments in sensing technology (Kumar et al. 2015), the Internet of Things (IoT) (Tang et al. 2019), machine-to-machine (M2M) communications, artificial intelligence (AI) (Seyedzadeh et al. 2018; Ullah et al. 2020), and robotics (Pan et al. 2018), have created the conditions for the development of several applications of responsive systems. Despite the notorious resistance of the construction industry to the adoption of new technologies (Setaki and van Timmeren 2022), these systems have been recently tested and also used on infrastructure of different kinds (Dong et al. 2019; Valena et al. 2021).

Notwithstanding the numerous recent attempts to use sensing and responding systems to optimize the operation of the built environment, to the best of the authors' knowledge, a systematic analysis of these works has not yet been conducted. The lack of a systematic literature review on the subject prevents the scientific community from gaining a full understanding of the current capabilities, gaps, and future perspectives of responsive systems for the built environment. To address this lack, in this paper a systematic literature review is presented on the current development of responsive infrastructure to chart out a roadmap for how sensing technologies, actuating systems, and triggering logic can be used to improve the effectiveness and efficiency of the built environment.

2 ANALYSIS OF THE STATE-OF-THE-ART IN THE USE OF RESPONSIVE SYSTEMS FOR THE BUILT ENVIRONMENT

In this section, the most cutting-edge works on the use of sensing and responding systems in the built environment are analyzed using a systematic method. In sub-section 2.1, the method used to conduct the analysis is first explained, and then, in section 2.2, the results are presented.

2.1 *Method of the analysis*

To analyze systematically the state of the art of research on responsive infrastructure, the relevant scientific publications on the field have been first selected, then classified, and finally analyzed, according to the following logic. Publications were selected based on three criteria. Works: (1) written within the last ten years; (2) that focused on the use of sensing and responding systems; and (3) applied to the operation and management of the built environment. Each publication selected has then been classified according to: (1) the type of responsive system, classified in: artificial, i.e. where changes on the infrastructure are triggered through a predefined logic based on data sensed, or natural, i.e. where changes on the infrastructure are automatically triggered by environmental variations; the (2) sensing technology, classified in: motion, imaging, light, temperature, humidity, distance, moisture, pressure and other sensors, and Wi-Fi connections; (3) response systems, classified in: information (i.e. where no change in the infrastructure is triggered and the only reaction planned is a data recording on critical situations, alert response, i.e. where only an alert signal is triggered in critical situations, an automatic response, i.e. where only a physical change in the infrastructure is triggered in critical situations, and an alert and automatic response, i.e. where both an alert signal and a physical change in the infrastructure are triggered in critical situations); (4) the triggering logic used, classified in: no triggering (i.e. where the systems work without the need for triggering, explicit triggering, i.e. where the triggering logic is reported, and implicit triggering, where the triggering logic exists but is not explained in the paper); along with (5) the maturity of the technology used (i.e. TRL¹); and (6) the specific infrastructure in object, classified in: buildings,

1. Source: <https://esto.nasa.gov/trl/>

dams and irrigation, transportation, and others (e.g. energy distribution infrastructure). Finally, the classified works have been analyzed to identify frequencies, trends, and gaps in the development of responsive infrastructure. This has been done on two levels. Level 1: the frequency distribution of results for each of the 6 classification characteristics has been investigated, e.g. how many works on responsive infrastructure have been published with a TRL7, 8 and 9. The implementation of the frequency distribution of results has required clustering the results of each classification characteristic into categories. See Table 1. Level 2: an interpolation of the most significant level 1 analysis was made to generate a frequency distribution of results for one classification characteristic versus the others, e.g. how many works on responsive buildings specifically have been published with an automatic responding system and a TRL7, 8, and 9.

2.2 Results

The 51 publications selected for the analysis are reported in Table 1 along with their classification characteristics. The results of the 2 levels analysis are further shown in Figures 1 and 2 and discussed.

From the level 1 analysis (Figure 1), it is possible to appreciate, in terms of technical characteristics, that: most of the works analyzed are based on types of sensing and responding systems; the deployment of these solutions has affected mainly buildings and transport infrastructure; the sensors used are pressure, motion, and temperature sensors in more than half of cases, while the response systems are largely automatic; and that most of the works reported an explicit triggering logic to control the response. Moreover, it is of interest to notice that in about 70% of the cases, the sensing and responding systems are TRL 7 to 9, which means that the vast majority of the works use technologies that are in an advanced stage of development, if not already commercialized.

Figure 1. Level 1 analysis of the six classification characteristics.

The level 2 analysis (Figure 2), allows investigating these data deeper, revealing that: (i) in terms of the state of advancement of research, on top of the consolidated technologies, some experimental work, i.e. TRL 1-5 are undergoing mainly to develop alert response and automatic responses on building and transport infrastructure; while (ii) in terms of the type of technology used, the lighting, motion, and temperature sensors, as well as Wi-Fi connections, are largely used mostly in alert and automatic response systems for buildings and transport infrastructure.

Figure 2. Level 2 analysis of the interpolation between response systems, TRL and infrastructure (left), and response systems, sensing and infrastructure (right).

3 CONCLUSION

A substantial literature exists on the use of sensing and responding systems to optimize the operation of the built environment. The systematic analysis presented in this work shows how the state-of-the-art research in the field has mostly focused on the development of automatic alert response and automatic response systems for buildings and transport infrastructure, although prominent works exist also with respect to dams and irrigation, and other type of infrastructure. This seems to be motivated by the wealth and maturity of the sensing technologies required for optimizing interventions on these assets (i.e. the lighting, motion, and temperature sensors, as well as Wi-Fi connections). Nonetheless, despite the prominent role of the consolidated technologies in the development of a large part of the current applications, some experimental works (i.e. TRL 1-5) are undergoing that use motion, imaging, and distance sensing to develop alert response and automatic response systems, particularly for buildings and transport infrastructure. In the near future, advancements in the use of these environmental and motion sensors are expected to have a high potential for the development of new types of sensing and responding solutions.

ABSTRACT: Digital Twins are a key concept for the industry 4.0 and they are also becoming increasingly important in the construction industry. For the application in construction practice, the paper gives a short introduction of the Digital Twin theory, describes the different elements of a Digital Twin, and discusses the different tasks, which have to be addressed within the life cycle. Based on this, an approach to structure, harmonize, and integrate heterogeneous data is presented. The key element is the definition and exhaustive implementation of a project data structure which is applied to all elements within a 3D-model and all other data sources. This approach allows to “glue” data from multiple sources and to access filtered results. Finally, the paper presents the realization of a Digital Twin. For this purpose a German highway project operated in a public private partnership with a length of 47 km is introduced. The Digital Twin integrates data from different sources like roadway inspections, mobile status monitoring, traffic data, weather data, and 3D model data. All of them are processed for the application in different use cases. A dashboard generated with a Business Intelligence solution provides visually prepared information for the decision making process.

1 INTRODUCTION

Digital Twins (DT) gain more and more attention in the construction industry, both in scientific analyses and practical implementations. The basic concept was created 20 years ago by Michael Grieves and the ongoing digitalization facilitates to bring the concept to life (Grieves 2016). The topic can be classified as a young discipline as shown in Figure 1. Since the year 2016 the number of publications increased significantly and at the same time the internet based search interest rose up.

In Germany, for the implementation of various digitization components in the infrastructure sector the Master Plan BIM Federal Trunk Roads was created, which contains an overarching digitalization strategy (BMVI 2022). The primary focus is on the phased introduction of the BIM method for the planning and erection phase of constructions. This procedure corresponds with the international implementation process of the method Building Information Modeling (BIM), which is currently still accelerating and represents the fundamental basis for an increasing digitalization of the sector (EU BIM 2017).

At the same time, in the masterplan introduces the term “Digital Twin” as a vision for the future, which is primarily aimed at the maintenance and operation of constructions and thus performs its main task in the use phase. This vision provides an important basis for determining which tasks will be assigned to the digital twin in the future. Within the conceptualization of the term Digital Twin a set of various, project-stage depending components that can even exist individually is often associated (Sacks et al. 2020). The components shall be integrated in a holistic information system. However, such holistic information systems are not trivial to build, as the constituting Digital Twin components are often only available fragmented and

Figure 1. Results for number of scientific publications (left in blue) and relative search interest based on the search engine Google (right in green) for the named topics/terms for the period 2010 to 2022.

semantically disconnected. Addressing these problem statements, this paper suggests practical recommendations for integrating different Digital Twin components as well as the data that they carry, which is usually generated in numerous different data sources. Moreover, this concept is validated by an actual built Digital Twin realization allowing for the implementation of several Digital Twin use cases in practice. The type of use cases from a case study implementation in a German highway operation project are presented in this paper as well.

2 RESEARCH STRATEGY AND IMPLEMENTATION APPROACH

The research strategy presented in this paper is based on a Design Science Research (DSR) approach, which – according to Peffers et al. (2014) – is comprised by the steps of (1) finding a practically relevant problem and describing the motivation, (2) defining the objectives for a solution, (3) designing and developing a potential solution, (4) showing the demonstration, (5) evaluating of the practical applicability of the solution and (6) communication of the results.

While the problem in step (1) has been introduced in the previous section as an increasing importance of Digital Twins and simultaneously existing gap of practically applicable implementations, the next section on related works covers the state-of-the-art of the investigated domain (2). It focusses in particular on the components for theoretical conceptualization of Digital Twins as a main starting point for practical implementation. DSR steps (3) and (4) are addressed in section 4, where it is outlined how different DT components can be semantically connected and how the application of auxiliary artifacts for traceability throughout all data sources can be used. Secondly, section 4 describes how this concept can be transmitted to a practical application. At the example of a case study utilizing an infrastructure project, a short project description and an overview of the implemented use cases is given. Next, in DSR step (5), the practical application is connected to existing DT theory, evaluated and assessed concerning further development activities, also addressing DSR step (6).

3 FRAMEWORK AND OBJECTIVES

Building on the various theoretical considerations of the last 20 years, different definitions can be identified that place different emphases depending on the application domain, target group, or focus on different life cycle phases. However, all definitions have fundamental components in common, which are used in the following as the basic definition of digital twins (Boje et al. 2020):

- a physical component (real asset, asses under construction or actually existing asset),
- a virtual component (digital representation of the real asset or parts of it) and
- a data exchange between the components, which is takes places bidirectional.

As a first objective, a solution for a Digital Twin must be able to address all of the named *three components*. In addition to the physical-virtual components of a digital twin, the differentiation between *construction products and processes* is of particular importance. Leaning on and partly reproducing the fundamental work by Sacks et al. (2020), Table 1 provides examples of components for the product-process dimension representing both the digital and physical twin. It is also indicated what type of information these components can provide when used separately and what type of knowledge this information could lead to when linked (e.g. by means of comparison).

Table 1. Examples for the relation between products and processes in different life cycle phases based on Sacks et al. (2020).

Product	Process	Physical/virtual	Provided information type	Lead to knowledge type
Prototype or mock-up	First run study	physical	Small scale realistic design appearance and constructability facts	Ex-ante knowledge for finding best design alternatives and assessing constructability by considering small scale facts and mapping product to process intent information
3D-Model and documents	4D-Simulation or energy simulation	virtual	Design/process intent information	
Building under construction	Construction process	physical	Construction status perception	Ex-post knowledge gained during construction by comparison of status facts with perception and with ex-ante knowledge (can be used for decision making in current project both for design and construction stage, provided that part of design is still ongoing)
Current As-built model	Progress monitoring data	virtual	Construction status facts	
Finished building	Building in operation	physical	Operation status perception	Ex-post knowledge gained during operation by comparison of facts with perception (can be used for decision making within facility management processes in current operation project, and for design of upcoming projects)
Asset information model	Operational data coming from sensor or forms	virtual	Operation status facts	

It must be emphasized that a purely digital representation of an actually existing structure is not yet a digital twin. A Digital Twin requires a data exchange that both transfers data from the real structure to the digital representation (e.g., inventory of the actual condition of a bridge) and uses the digital representation to perform measures on the real structure, e.g. evaluation of the recorded data and derivation of maintenance measures that are performed manually or automatically (Bittencourt et al. 2021). It must be emphasized that the data combined in the digital representation consist of a *variety of different data types*. These can be, for example, the following data types:

- Measurement data from sensors (traffic load, strain gauges, weather sensors, etc.)
- Data from construction documentation (construction files, construction books, inspection reports, etc.)
- Condition data of structures, components and elements (database)
- Model data (BIM model, GIS model)

As described above, Digital twins can be used for a variety of tasks. Therefore, it is recommended to differentiate between different scopes of application. This is done by defining *Digital Twin use cases* based on existing business processes. These business processes can then be further subdivided if necessary. The advantage of thinking in terms of use cases is that an

overall context can be broken down into individual delimited parts. These can be formulated in detail, for example by writing down the process to be executed with all process steps. Each process step requires data for processing, which in turn can be collected, stored or processed with various software tools. Only when the data required for each use case is known, the implementation of the respective use case can be started.

According to Nieborowski et al. (2023), Digital Twin use cases for traffic infrastructures can be divided into three different subject areas:

- Operational processes, which have to be performed regularly and are necessary for maintenance.
- Maintenance and rehabilitation planning and conduction, which takes place in longer intervals, requires larger measures and is usually carried out by a different groups of people than the operational processes.
- Strategic tasks of life cycle management, through which measures to be carried out in the future, costs, building conditions, etc. are calculated or forecasted.

Based on all aspects described above, a concept for the practical implementation of a Digital Twin can be defined. The developed solutions for a highway project in Germany are presented in the following section.

4 DIGITAL TWIN CONCEPTUALIZATION AND IMPLEMENTATION

4.1 Implementation concept

The definition of a Digital Twin presented above can be combined with the idea of applicability throughout the entire life cycle of structures. A visualization of this concept is given in Figure 2. The first data of a Digital Twin are already generated in the design phase and form the basis for the later application. This can be geometric data, materials, qualities or product descriptions.

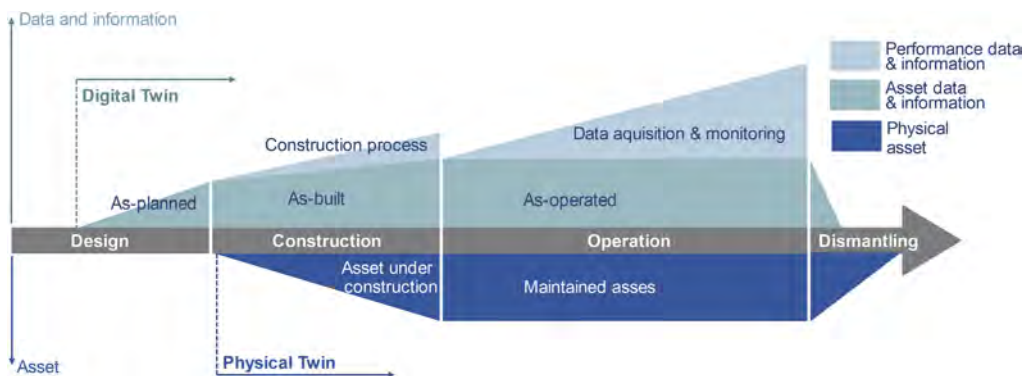

Figure 2. Applied concept of the Digital Twin within its life cycle.

In the manufacturing and construction phase, the component of the physical asset is created for the first time. Especially in the area of construction processes, the exchange of data between the two twins can generate added value. If, for example, the positions of construction equipment on the construction site are known in real time, the deployment planning can be optimized. With regard to the transport routes of materials, such as excavated material, it is possible to minimize transport distances by calculating on a daily basis where sources and sinks exist and to what extent.

Especially in the utilization phase, a large number of possible use cases for digital twins can be identified. The successive recording, storage and processing of data generated during the entire life cycle can support all business processes to be carried out. The most important applications are discussed at the example of the case study in section 4.4.

4.2 Project data structure and data integration

Within software engineering, the term “traceability” refers to the capability of relating data within different artifacts to each other (Unterkalmsteiner & Abdeen 2023). Knowledge of trace links between artifacts allows for semantic reasoning and insights as these artifacts can refer actually to the same “things” in the real world. They may exist on a variety of different abstraction levels, with different appearances as well as with different tools of origination in the virtual world. Insights that are based on these relationships would be more costly to obtain when artifacts are decoupled and no trace links exist.

An example within the domain of software engineering is the connection between requirements and the implemented software features that are supposed to fulfill the requirements. Only when trace links between both artifacts are known, one could decide whether a requirement is fulfilled or not. Unterkalmsteiner & Abdeen (2022) propose to make use of an auxiliary artifact in the form of a domain-specific taxonomy to create this trace links as indirect links instead of associating artifacts directly with each other. In more detail, they propose to apply this concept in the domain of civil infrastructure design and establish trace links between technical project requirements and objects within BIM models by means of a consistent taxonomy, which is comprised of an existing and industry-wide accepted classification system to reduce barriers for adoption. A simplified example of this approach is shown in Figure 3.

Figure 3. Enabling traceability by means of auxiliary artifacts.

For practical application a multi-hierarchical custom taxonomy is created on a project-specific basis combining location breakdown structures as well as breakdown structures for objects and work activities in a project data structure (PDS). Applying the PDS approach during the project construction and utilization phases allows for data integration, which can be defined as “the problem of combining data residing at different sources, and providing the user with a unified view of these data” (Lenzerini 2002). Data integrated following this approach enables the creation of highly customizable views on that data. Combined views based on both a data-centric representation (table and chart based) and a 3D model representation that are leveraging the PDS concept as data backbone of Digital Twins, see Figure 4.

Figure 4. Applied project data structure (PDS) and key functionalities of the implemented Digital Twin A6.

4.3 Project description

The German highway A6 is one of the most important east-west connections between France and central Europe. A particular section of the A6 in the southwest of Germany, comprising approximately 47 km, is currently highly charged with a traffic load up to 110,000 vehicles per day. With the expansion from four to six lanes, sections of the A6 will be adapted to the growing traffic volumes. For the expansion and the operation of the 47 km long section the HOCHTIEF PPP Solutions GmbH is, inter alia, accountable within a public private partnership project running until the year 2046.

For operation and maintenance, the created Project Information Model (PIM) in line with the terminology in ISO 19650 will continuously be used as part of the Digital Twin of the highway. A wide range of external data is linked to the developed data model leveraging the introduced PDS concept to support numerous Digital Twin use cases comprising the case study in this paper. Key facts of this case study are summarized in the following:

- Length of the route 47,2 km route, thereof 25,4 km expanded and renewed,
- 12 rest areas and parking lots, 7 interchanges,
- 45 rainwater retention or clarification basins,
- 70 bridges, 50 traffic sign bridges, 100 noise barriers and 16 retaining walls.

The A6 operating organization “ViA6West” manages all services and assessments with the help of the digital Twin system developed by HOCHTIEF ViCon and HOCHTIEF PPP Solutions in its day-to-day business. Defined use cases ensure efficient project management and digital, process-supported collaboration between the operating organization, the construction joint venture, construction supervision, the client, and other partners.

4.4 Implemented Digital Twin use cases

The use cases implemented within the scope of this project are mainly related to operational processes, but also to maintenance and rehabilitation planning and execution. The implementation of the use cases in the A6 Digital Twin can be characterized as a first stage of development, which is geared towards the feasibility of the processes set up and not towards the fullest possible integration of all possible use cases. This means that the Digital Twin A6 will be successively developed further by continuously improving processes, integrating additional data sources and implementing new use cases. In addition, data exchange (execution of measures) from the digital twin to the real asset is mainly carried out via manual processes. In the future, the aim is to automate these processes to a greater extent.

The currently implemented use cases are summarized in Figure 5. Depending on the required data, the conversion is carried out on the route, structure or component level.

Figure 5. Implemented use cases of the Digital Twin A6 (buildingSMART award 2022).

4.5 Exemplary presentation of the solution

An example of the implemented frontend for the Digital Twin A6 is shown in Figure 6. Here, different key elements can be used to work with the information provided. The information in the right area are linked to a digital asset model (left) for better orientation. Both a selection of model elements in the building model and the filtering of the results based on this selection can be done, as well as the reverse way of data selection and display of the corresponding building model elements. This is only possible if the project data structure is consistently applied to all data fed into the digital twin.

All data sets required for the underlying knowledge base of the digital twin are captured via mobile apps, external databases and live sensor data (such as weather data, SIB structures, and operating sensor data) or online forms. The digital workflows used for data capturing and processing ensure the high quality and reliability of the information entered. Thus, integrating all information with data from other use cases via the PDS is consistently possible.

Figure 6. Explanation of the key elements in the frontend of the Digital Twin A6.

5 DISCUSSION

The case study A6 introduces a Digital Twin that mainly contains use cases for operational processes, typically carried out by persons of the highway maintenance departments. In addition, various use cases for maintenance planning and execution are integrated. The connection of a 3D asset model is an aid for users to gain better orientation through visualization.

The greatest added value of the A6 Digital Twin lies in the structured storage of data and the resulting processing options. Different data sources are linked with each other and thus made centrally analyzable. In this way, knowledge can be generated that could not be obtained from data stored in data silos. Knowledge is generated by processing data with a Business Intelligence solution and thus generating information that can be used by people for decision support. Harmonizing the PDS across projects, for example by using always a standard classification system for the aspect of system breakdown, would even allow for conducting portfolio analyses on the mid-term and derivation of valuable insights for upcoming projects that have comparable characteristics.

The presented solution is developed for a stand-alone project of a single asset operator. For an application of Digital Twins for a large portfolio of infrastructures possibly operated by different stakeholders, generally accepted and standardized regulations must be generated. They need to cover the description of all data for example by applying taxonomies or ontologies. Based on

this, different technical approaches can be utilized. These are, for example, the usage of a linked data approach and the application of information containers (Hagedorn et al., 2023).

6 CONCLUSIONS

Digital Twins – especially for use in the utilization phase of transport infrastructures – are currently being discussed in many different forms. Due to the comparatively recent history of development, no uniform understanding has yet emerged. However, existing frameworks and first practical examples show that powerful Digital Twins can be built up and a continuous digital information chain can be created with a structured implementation taking into account basic relationships for data linking.

In the future, Digital Twins will gain importance in all areas. A central challenge in the development will be the integration of different existing data sources. In addition, it is desirable for the area of transport infrastructures to develop open linking standards based on ontologies, for example. In this way, different software providers can build on the existing data bases and it will be possible to switch between software solutions.

Numerical analysis of weld throat crack of rib-to-deck reinforced by bonding angle steel

Z.L. Lv, X. Jiang & X.H. Qiang
Tongji University, Shanghai, China

H.L. Wu & J.M. Ding
Tongji Architectural Design, Shanghai, China

ABSTRACT: It is well known that rib-to-deck welded joints are one of the typical fatigue details in the steel bridge decks. The existence of cracks will pose a threat to the safe operation of the bridges. Hence, it is necessary to adopt retrofitting techniques to retard the crack growth. This paper focuses on the failure mode of weld throat cracking of rib-to-deck welds and fatigue improvement of weld throats strengthened by angle steel. Finite element models with repaired and unrepaired specimens were established to investigate the fatigue properties based on linear elastic fracture mechanics. The stress intensity factor (SIF) at the crack front was calculated and the crack propagation trend was predicted. It was demonstrated that out-of-plane bending deformation between the top plate and the U-rib is the main reason for the cracking of the weld throats. The numerical results showed that the fatigue cracks belonged to type I-dominated mixed-mode cracks, and the stress intensity factor increases with the increase of crack depth. However, bonding angle steel can reduce the effective stress intensity factor range to prolong the fatigue life of the cracked weld throats. The stress intensity factor could be reduced by 80% to 97% after repairing. And fatigue crack propagation can be further arrested when strengthening in the early stage of crack initiation. The predicted crack propagation behavior was almost consistent with the experimental results, and the angle between the propagation path and the top plate was between 30° and 45°.

1 INTRODUCTION

Orthotropic steel bridge decks have been universally applied for large-span bridges due to its light weight, high bearing capacity and fast construction speed. However, due to the large number of welds, complex details and the increase of heavy trucks, fatigue damage has become the main problem of orthotropic steel bridge decks. In the previous study (Li et al., 2018, Luo et al., 2020), it was found that the rib-to-deck weld throats of the steel bridge decks built in the early stage are prone to produce fatigue cracks because of the out-of-plane deformation and the influence of welding defects. Therefore, it is urgent to carry out research on fatigue repair of rib-to-deck welds in steel bridge decks.

Several repair methods for damaged steel structures include stop hole method (Fang et al., 2023), welding (Park et al., 2012) and bolting plates (Liu et al., 2022), etc, and these methods are applicable to certain occasions. For the weld throat cracks of rib-to-deck welds, it is difficult to drill a hole at cross weld joints. Welding may introduce residual stress and welding defects. Bolting needs to drill holes and the section strength will be weakened. The use of adhesively bonded steel plates, on the other hand, seems to become a promising strengthening option compared to common repair methods, as the existing structures will not be damaged when repairing by bonding (Abeln et al., 2021, Wang et al., 2018, Teixeira de Freitas et al., 2017). In this paper, the weld throat cracks repaired by

bonding angle steel are investigated by experiments and numerical simulation. At the same time, fatigue failure modes and fatigue assessment of strengthening will be presented.

2 STRENGTHENING TEST

2.1 Specimen fabrication

The notch local specimen was designed to simulate the structure details of a roof and U rib weld, as shown in Figure 1. The deck plate thickness is 14 mm and the rib thickness is 8 mm. Q345qB steel plate was adopted for the fabrication of these specimens. The top plate was connected to the rib by a single-sided groove weld, and the depth of penetration is not less than 0.8 times the plate thickness. Besides, the 4 mm pre-crack was set at the weld root. For strengthened specimens, the angle steel was pasted on the structures after polishing the steel surface. The angle steel was 400 mm in length, 140 mm in width, and 10 mm in thickness. And the thickness of the adhesive was controlled at 5 mm. The strengthened specimens were obtained after curing for seven days, as illustrated in Figure 2.

Figure 1. Un-strengthened test specimen (Unit: mm).

Figure 2. Strengthened test specimen (Unit: mm).

2.2 Experimental test

The fatigue machine was used to test all specimens with repairing or not. The deck plate was fixed to the testing fixture with high-strength bolts. Then the load was directly applied to the rib plate to simulate the relative deformation between the top plate and rib plate. The test set-up is shown in Figure 3, and the loading conditions are listed in Table 1. The fatigue load amplitude was set according to the equivalent stress amplitude of Eurocode. Furthermore, the

deflection of the loading end was measured by deformation gauge during the static test. And the stress distribution along the weld of all specimens was obtained by strain gauges until the cracks were clearly observed.

Figure 3. Test set-up.

Table 1. Loading case.

Specimens	Fatigue load/kN	Load amplitude/kN	Loading cycles/ 10^4 times	Cumulative loading cycles/ 10^4 times
RL-1	1-3	2	114.8	114.8
RL-2	1-4	3	68	68
SRL-1	1-3	2	200	200
	1-3	2	100	
	1-4	3	600	
SRL-2	1-6	5	60	953
	2-20	18	150	
	4-40	36	43	

* RL and SRL denote unreinforced specimens and reinforced specimens respectively.

2.3 Test results

Before the fatigue test, the static test was conducted to verify the effectiveness of strengthening angle steel. As shown in Figure 4, the displacement of the rib was significantly reduced after reinforcement, with an average reduction of about 66.8%, and the reinforced angle was very effective in limiting the relative deformation of the rib and top plate. The stress at the weld root of the rib under a static load of 3 kN showed an overall trend of being large in the middle and small at both ends. The average stress at the weld root side of the un-strengthened rib was 177 MPa, while the overall average tensile stress level at the weld root side of the strengthened rib was about 15 MPa, with a reduction of 91.5%, indicating that the angle reinforcement could effectively reduce the tensile stress at the rib weld, thus improving the fatigue resistance of the weld throat. In terms of fatigue failure, as shown in Figure 5, the fatigue crack initiated from the weld root and extended along the weld throat for un-strengthened specimens. For specimens strengthened by angle steel, it was observed that the crack extension to the deck appeared as well as the adhesive layer.

3 FINITE ELEMENT ANALYSIS

3.1 Establishment of FE model

A local model described in the previous experiments was established through ABAQUS software, as depicted in Figure 6. The plane strain CPE8R element was used and collapsed

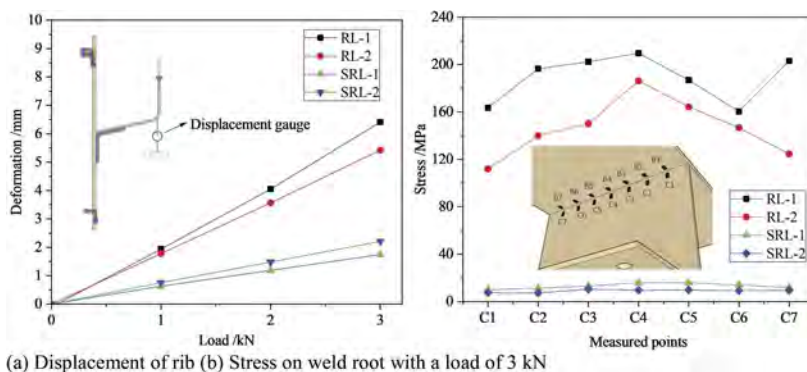

Figure 4. Displacement and stress of specimens under the static load.

Figure 5. Failure modes of specimens.

triangular singular element was adopted for the crack tip. The global size of the specimen was set at 2 mm, and a refined mesh of 0.1 mm was set around the crack tip. The elastic modulus of steel and the Poisson's ratio were set at 2.06×10^5 MPa and 0.3, respectively. The elastic modulus of structural adhesive was 3500 MPa and the Poisson's ratio was 0.35. "Tie" constraint was set between the steel plate and the adhesive layer. The load was 2 kN.

Figure 6. FE model of specimen.

3.2 Crack propagation of un-strengthened weld throat

The amplitudes of the stress intensity factor (SIF) are calculated separately for different crack depths and initial inclined angles, as shown in Figure 7(a). The stress intensity factor amplitude increases with the increase of crack depth. The value of type I is much larger than that of type II, which indicates that the fatigue crack belonged to the type I-dominated composite crack. For planar composite cracking mode cracks, the equivalent stress intensity factor amplitude can be safely calculated according to the following equation (Kuna, 2013)

$$\Delta K_e = \frac{\Delta K_I}{2} + \frac{1}{2} \sqrt{\Delta K_I^2 + 5.336 \Delta K_{II}^2} \quad (1)$$

Where ΔK_I , ΔK_{II} , ΔK_e refer to type I SIF, type II SIF and equivalent SIF respectively.

In linear elastic fracture mechanics, when ΔK_e exceeds the threshold value ΔK_{th} , cracks begin to spread and an unstable forced fracture occurs when the ΔK_e exceeds $(1-R)$ times fracture toughness K_c . And the ΔK_{th} and K_c were set at $63 \text{ MPa}\cdot\text{mm}^{0.5}$ and $110 \text{ MPa}\cdot\text{m}^{0.5}$ according to BS7910 code (BSI, 2019). According to the test, the stress ratio R is equal to 0.3.

Figure 7(b) depicts the variation curve of ΔK_e with crack depth for various initial α . With the increase of crack depth, the equivalent SIF increases, indicating an increase in crack expansion rate. At the same crack depth, the equivalent strength factor increases with the initial inclined angle in the range of 0 to 45° but decreases when greater than 45° . All calculated ΔK_e is greater than the threshold value of $63 \text{ MPa}\cdot\text{mm}^{0.5}$, indicating that the unreinforced specimens will expand under different damage conditions, and crack instability expansion will occur when the crack depth exceeds 9 mm.

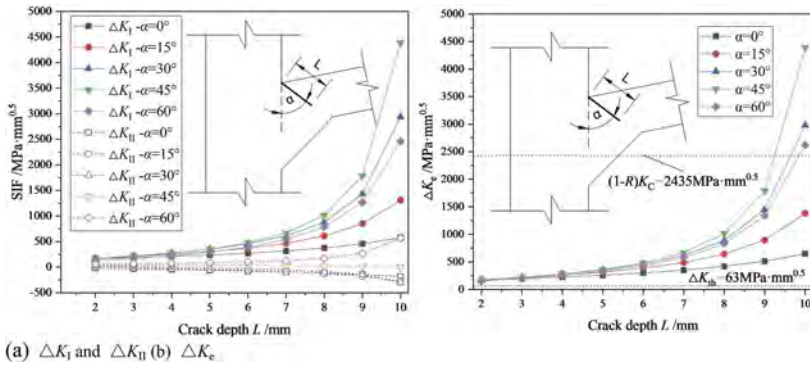

Figure 7. Variation curve of stress intensity factors at different initial angles with crack depths.

The direction of crack initiation can be calculated using the maximum tangential stress criterion. And the crack propagation angle θ can be obtained from the following equation:

$$\theta = \cos^{-1} \left(\frac{3K_{II}^2 + \sqrt{K_I^4 + 8K_I^2 K_{II}^2}}{K_I^2 + 9K_{II}^2} \right) \quad (2)$$

Where K_I and K_{II} refer to type I stress intensity factor and type II stress intensity factor, respectively.

Figure 8 presents the calculated crack propagation angles with different initial angles and crack depths. For the crack at the same depth, with the increase of the initial inclination angle α , the crack extension angle θ gradually changes from positive to negative values, and the absolute values all decrease before increasing. After accounting for the superimposed initial inclination, the angle range $(\theta + \alpha)$ is approximately 30° to 45° , which corresponds to the test results shown in Figure 9.

3.3 Fatigue evaluation of strengthening effectiveness

Take $L=4 \text{ mm}$ as an example, the influence of various angle thicknesses and adhesive thicknesses was investigated. From Figure 10, the equivalent stress intensity factor gradually declines with the increase of thickness, but the amplitude decreases. In contrast, the thickness

Figure 8. Calculated values of crack propagation angles.

Figure 9. Crack propagation path of test.

of the adhesive layer has few effects on the change of equivalent stress intensity factor. Figure 11 shows the equivalent stress intensity factor of specimens with a 10 mm thick angle steel and a 5 mm thick adhesive. Compared with Figure 7, the equivalent stress intensity factor could be reduced by 80%-97%. And the SIF could be controlled under the extension threshold when the crack depth is less than 7 mm. Therefore, the adoption of bonded angle steel can effectively reduce the stress intensity factor at the crack tip and thus extend the fatigue life of weld details.

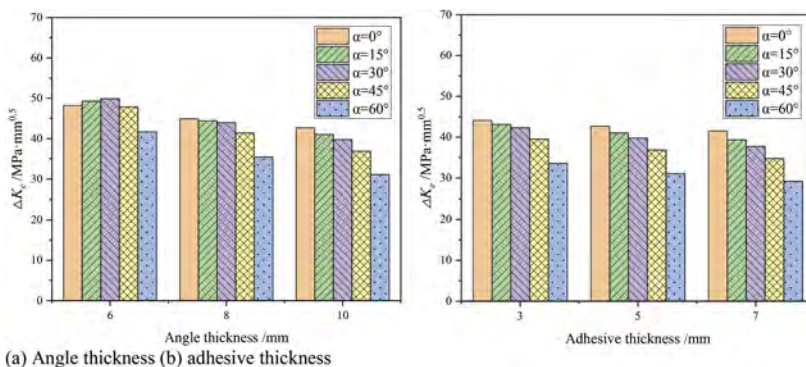

Figure 10. Equivalent stress intensity factors with different strengthening parameters.

Figure 11. ΔK_c with crack depths after repairing.

4 CONCLUSIONS

- (1) Out-of-plane deformation is the main cause of U-rib weld throat cracking in the top plate. Both experimental and numerical analyses have proved that the reinforced angles can effectively limit the relative deformation and eliminate the risk of fatigue cracking of the weld throat.
- (2) The stress response of weld detail can be reduced by 91.5% in the static test. The strengthened specimens exhibit excellent anti-fatigue performance.
- (3) Weld throat cracks are type I-dominated mixed-mode cracks. The stress intensity factor can be reduced by 80%-97%. The crack propagation angle between the propagation path and the top plate is about 30°-45°.

Flexural behavior of prestressed concrete beams strengthened with external CFRP tendons

L.L. Chen, X.H. Qiang & X. Jiang

College of Civil Engineering, Tongji University, Shanghai, China

P. Liu

Tongji Architectural Design, Shanghai, China

ABSTRACT: The considerable age of many prestressed concrete (PC) bridges conjointly with a steadily increasing amount of traffic and changes in design concepts have made maintenance and retrofitting more and more important over the years. The prestressed carbon fiber reinforced polymer (CFRP) strengthening is an effective reinforcement method for deteriorative bridges. A total of four PC beams with a length of 4300 mm were tested via four-point bending test. One beam was not strengthened and served as the reference beam, and three beams were strengthened by prestressed CFRP tendons with different diameters (7 mm and 10 mm) and initial prestress levels (15%, 30% and 50%). The promising results showed that the self-designed mechanical devices and end anchorage of CFRP tendons worked well. The ultimate load of strengthened beams was increased by 31%, 39% and 54%, respectively, compared with that of reference beam.

1 INTRODUCTION

Prestressed concrete (PC) beam has been extensively used in bridge (Sun et al., 2022). With elongation of service time, increasing traffic load and deterioration of material properties, numerous bridges in service are faced with a variety of problems, such as stiffness degradation, deflection increment and ultimate bearing capacity reduction, which increase collapse risk (Askar et al., 2022). Compared to demolition and reconstruction, strengthening of bridge in service greatly reduces adverse impact on society, environment, and economy (Qiang et al., 2022). Thus, structurally efficient and cost-effective means of reinforcement need to be employed to improve load bearing capacity and prolong service life of bridge (Siwowski et al., 2020).

In recent decades, carbon fiber reinforced polymer (CFRP) materials, including sheet, plate and tendon, have been used in bridge reinforcement due to their high strength, low density, high durability, good corrosion and fatigue resistance (Li et al., 2022; Wu et al., 2022; Hosseini et al., 2019; Michels et al., 2016). Previous research led to the development of the externally bonded (EB) technique (Yang et al., 2022) that non-prestressed CFRP sheets or plates are generally bonded to the tension side of bridge by resin. Debonding, caused by intermediate crack, is the most common failure mode, however, the CFRP sheet is always at a low-level strain and the advantage of the material cannot be fully utilized (Teng et al., 2003).

External prestressing reinforcement is an effective reinforcement system, without the use of structural adhesive bonding. Therefore, it is very convenient to supplement prestress loss and replacement, which are utilized to reinforce existing bridge structures. CFRP tendons are very suitable for external prestressing tendons, because benefits of durability and lightweight.

However, flexural behavior of PC beam strengthened with prestressed CFRP tendons remains unclear. Herein, four PC beams are designed based on a railway prestressed concrete beam in service. One un-strengthened beam plays the role of the reference beam and three beams are strengthened by prestressed CFRP tendons with different diameters and initial prestress levels. The flexural behavior of beams is investigated via four-point bending test.

2 EXPERIMENTAL PROGRAM

2.1 Specimen preparation and material properties

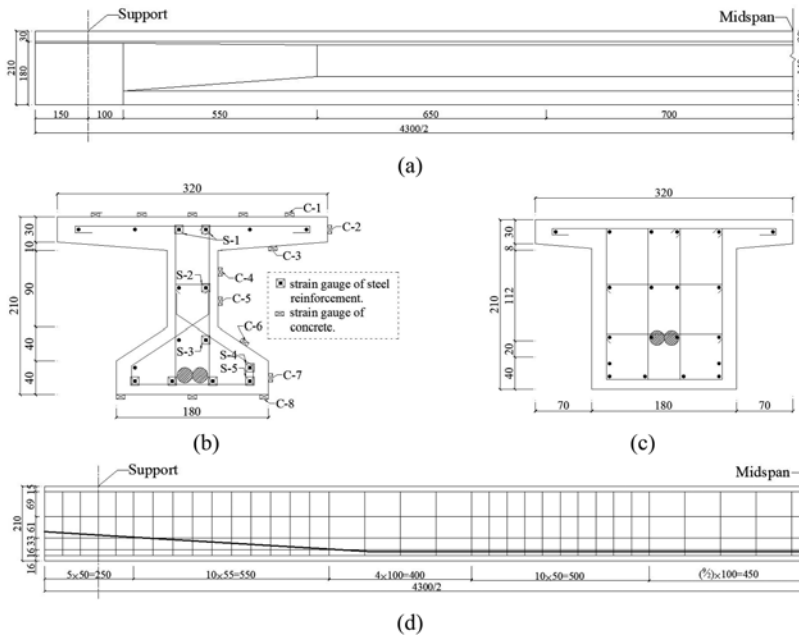

Figure 1. Details of precast concrete beam (unit: mm).

Table 1. Properties of all materials.

Materials	Compressive strength	Yielding strength	Elastic modulus	Ultimate strength
	MPa	MPa	GPa	MPa
Concrete	72.1	-	36.8	-
Steel bar	-	601.4	195.6	751.8
Steel strand	-	-	201	1860
CFRP tendon	-	-	170	2300

Four simply supported PC beams with variable cross-section, designed based on a railway prestressed concrete beam in service, were fabricated. The total length of the beam was 4300 mm, of which calculated span was 4000 mm, and two end supports were 150 mm, as shown in Figure 1a. The dimension and steel reinforcement arrangement of cross-sections at mid-span and support were displayed in Figure 1b and 1c. The mid-span was a π -shaped section. Height of section was 210 mm, and widths of the upper flange, lower flange and web were 320 mm, 180 mm and 60 mm, respectively.

Concrete of beam was Grade C60, and steel reinforcements including longitudinal and transverse reinforcements were HRB335 bars with diameter of 4 mm. The transverse reinforcements of beam were arranged along the full length at a spacing of 100 mm, as presented in Figure 1d. Two unbonded prestressed steel strands with diameter of 15.2 mm were arranged in concrete beam with a folded line shape. Two steel strands were tensioned by 30 T hydraulic jack, and controlled stretching stress of strands were 624 MPa. CFRP tendons with diameters of 7 mm and 10 mm were employed to strengthen PC beam by external prestressing reinforcement. The properties of all material were displayed in Table 1.

2.2 Reinforcement scheme

Four PC beams were tested in this test, including one unreinforced reference beam and three externally reinforced beams with prestressed CFRP tendons. The reinforcement details of specimens were displayed in Table 2. For each reinforced beam, two CFRP tendons were symmetrically arranged on two sides of the beam.

A set of mechanical anchorage was designed independently, including deviation blocks, anchor-roots, and wedge pads, as shown in Figure 2. Each beam was equipped with two anchor-roots and four deviation blocks that were divided into two types according to their installation positions. The wedge pads were used to adjust the angle between CFRP tendon and anchor-roots.

The circular self-locking anchorages were employed to tension and anchor CFRP tendon. Anchorage consisted of external shell, internal clip, nut and gasket, as shown in Figure 3a. The length and diameter of anchorage were 150 mm and 26 mm, respectively. CFRP tendons were stretched by a 30 T hydraulic jacks and pull rods, as shown in Figure 3b.

Table 2. Reinforcement parameters of tested beams.

NO.	Diameter mm	Prestress level %	Prestress MPa	Tension force kN
PCB-U-0	-	-	-	-
PCB-S-1	7	15	345	26.5
PCB-S-2	7	50	1150	88.5
PCB-S-3	10	30	690	108.3

Figure 2. Mechanical anchorage.

Figure 3. Anchorage and tension of CFRP tendon.

2.3 Test setup and measurement scheme

Four-point bending test was used to investigate the flexural behavior of concrete beams. The external load is applied by a 200 T hydraulic jack and dispersed by distribution beams. The pure bending section between loading points was 1400 mm, and two bending-shear sections on both sides were 1300 mm. The concrete beams were simply supported on the counterforce frame as shown in Figure 4. The loading was controlled by force with rate of 0.1~0.2 kN/s. Every load stage increased 10 kN before cracking and maintained 5 min to check crack. After cracking, the load stage was set to 5kN and maintained 10 min to observe and record the development of crack by black marker pan. All specimens were loaded to failure.

The applied load of hydraulic jack was record by a load cell. The displacements of concrete beam were measured by five displacement meters. The strain development of longitudinal

Figure 4. Test setup for four-point bending test.

reinforcement and concrete at mid-span section were measured by 9 BX120-3AA strain gauges (2 mm×3 mm) and 14 BX120-100AA strain gauges (120 mm×3 mm). The strain gauge distribution was shown in Figure 1b. Each CFRP tendon was divided into five segments by four deviation blocks, and a total of ten BX120-3AA strain gauge (2 mm × 3 mm) were arranged in the middle of each segment.

3 RESULTS AND DISCUSSION

3.1 Failure modes

3.1.1 Reference beam (PCB-U-0)

The deflection of the specimen increased slowly with the increasing of loading, and no crack was observed on the concrete surface in the initial stage of loading. When the load increased to 40 kN, some fine cracks were observed on the low flange of the concrete beam. A main crack with a length of approximately 40 mm appeared near the mid-span section. With the further increase of load, more cracks gradually appeared on the concrete beam.

A sudden drop of external load (about 10 kN) was observed, due to the break of longitudinal reinforcements in low flange. The prestressed steel strand was still work that bears the all the tensile force of beam section, and the deflection at mid-span increased little. The deflection of the beam basically increased linearly with the applied load. The longitudinal reinforcements in upper flange were buckled and deflection suddenly increases. The concrete beam was completely damaged.

3.1.2 Strengthened beams (PCB-S-1, PCB-S-2 and PCB-S-3)

The deformations of strengthened beams linearly increased with the increase of the external load in the initial stage. Cracking loads of three strengthened beams were delayed to 50 kN, 70 kN and 80 kN, respectively. Some small cracks appeared near the mid-span section when the applied load exceeded crack load (P_{crack}). There were a few cracks appear at deviation blocks, which might be due to the limitation of deviation blocks (Sturm et al., 2020). The main crack suddenly increased when width of crack reaches approximately 1 mm. The longitudinal reinforcements in low flange of concrete beam were fractured, which showed plastic characteristics of necking.

The tensile force was borne by prestressed steel strands and CFRP tendons at the cracked section. Therefore, strengthened beams still retained part of load bearing capacity. Finally, the upper flange concrete was crushed and strengthened beams were failure with a loud noise.

CFRP tendons of the three strengthened beams remained intact during loading. It was not observed that fracture or pull-out of CFRP tendons appeared, which indicated that the designed mechanical devices and anchorages were well suited for PC beam reinforcement.

3.2 Load-deflection behavior

The load-deflection relationship of four test beams is illustrated in Figure 5. Each of deflection curve can be divided into three stages: elastic stage, crack stage and fracture stage. Table 3 shows the main experimental results of all beams.

Table 3. Summary of test results of all beams.

NO.	$\frac{P_{crack}}{kN}$	$\frac{P_{fracture}}{kN}$	$\frac{P_{max}}{kN}$	$\frac{\Delta_{crack}^*}{mm}$	$\frac{\Delta_{fracture}^{**}}{mm}$	$\frac{\Delta_{max}}{mm}$
PCB-U-0	40	100	106	6.68	60.17	90.47
PCB-S-1	50	130	139	7.72	67.17	95.38
PCB-S-2	70	140	148	12.33	68.98	97.99
PCB-S-3	80	155	163	13.43	68.92	94.03

* Δ_{crack} is mid-span deflections corresponding to P_{crack} .

** $\Delta_{fracture}$ is mid-span deflections corresponding to $P_{fracture}$.

Figure 5. Load and mid-span deflection relation.

Before cracks appearing, the deflection of concrete beam increases linearly with the increase of load. The prestressed CFRP tendons can significantly improve the cracking load of concrete beams. The P_{crack} of three strengthened beams are increased by 25%, 75% and 100%, respectively. When the load reaches P_{crack} , the load-deflection curve begins to deviate from linear.

When the load reaches fracture load ($P_{fracture}$) that longitudinal reinforcements fractured, applied loads are suddenly decreased about 10 kN. The $P_{fracture}$ of strengthened beams are increased by 30kN, 40 kN and 55 kN compared with the unreinforced beam. As the load continues to increase, the deflection of the concrete beam linearly increases. The maximum loads (P_{max}) that corresponds to concrete crush were 106 kN, 139 kN, 148 kN, 163 kN. When beams are completely damaged, the maximum mid-span deflection (Δ_{max}) of strengthened beams increases by 5.38 mm, 7.99 mm and 4.03 mm, respectively.

3.3 Development of concrete strain

Figure 6 shows the development of concrete at the mid-span section during loading. The strain gauges from top to bottom of concrete beam are numbered C-1~C-8, as shown in Figure 1b.

The concrete strain of the upper flange is in compressive state during the whole loading process, as displayed in Figure 6a~6c. The compressive strain of top surface concrete increases linearly with the increase of the external load. The compressive strain of the lower surface of the upper flange increases with the increase of the load. When the load reaches about 0.7 P_{max} , the compressive strain decreases gradually. Figure 6d~6f show the strain development of concrete web. It can be seen from figures that the concrete web is in compression first and then in tension, which is related to the movement of the neutral axis. The lower flange concrete is subjected to tensile stress throughout the loading process, as shown in Figure 6g~6h. When the load reaches 0.50 ~ 0.55 P_{max} , the concrete at the C-7 position is damaged, which indicates that the concrete in C-7 cracked.

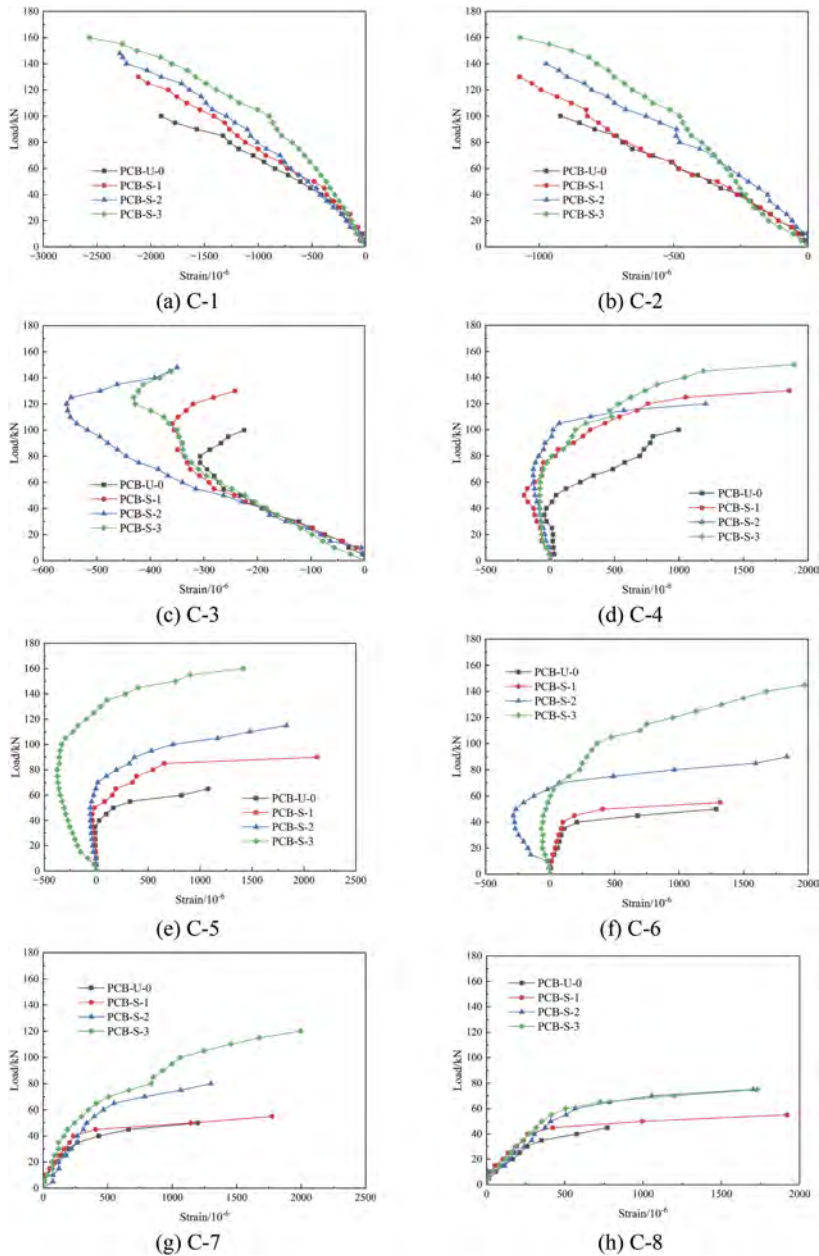

Figure 6. Strain development of concrete.

3.4 Development of steel reinforcement strain

The strain development of longitudinal reinforcements in the mid-span section during loading is shown in Figure 7. The reinforcement in the upper flange is in compressive state and increases linearly with the increase of the load as displayed in Figure 7a. When concrete crushed, the compressive strain of reinforcement is 750~900 ue. Figure 7b shows the development of reinforcement strain in the web. The strain of reinforcement is in compressive state in the initial stage, but change to tensile state when load reaches P_{crack} . The strain development law of reinforcements in lower flange is shown in Figure 9c~9e. Before the cracking load, the reinforcement strain increases linearly with the load. The reinforcements in lower flange are fractured and strain gauges are damaged when load reaches $P_{fracture}$.

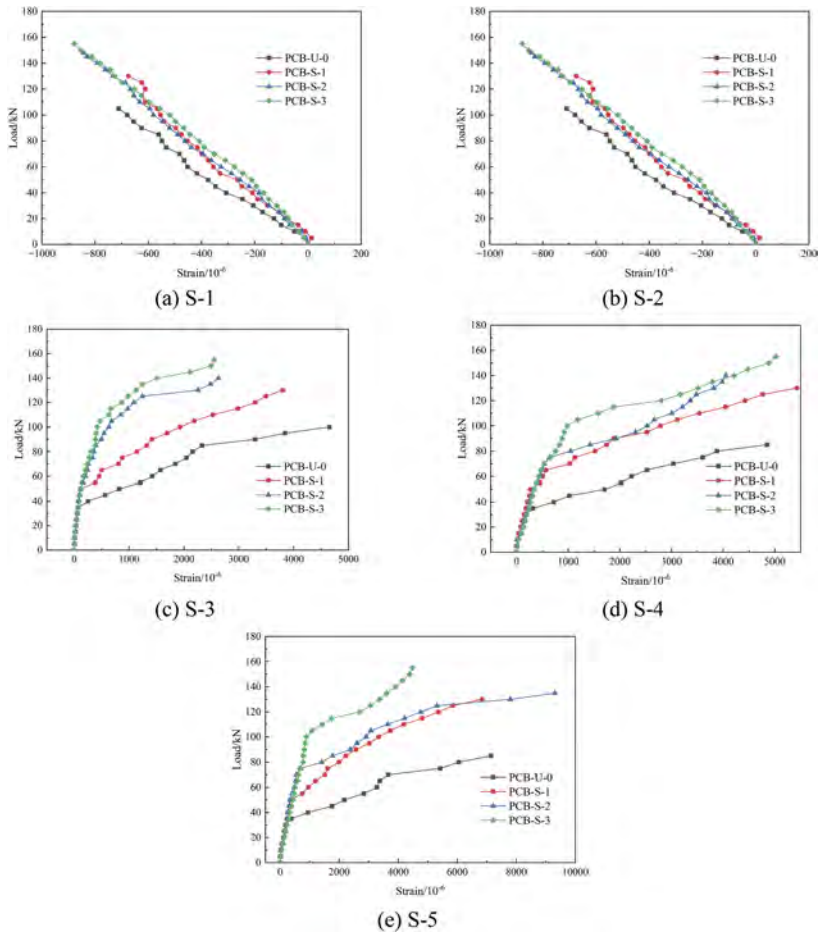

Figure 7. Strain development of reinforcements.

3.5 Development of CFRP tendons strain

Figure 8. Strain development of CFRP tendons.

Figure 8 shows the relationship between mid-span deflection of beam and strain increment of CFRP tendon. The strain increment of CFRP tendon is basically line with the mid-span deflection during the entire stress process, which is similar to the strain increment low of unbonded prestressed steel strand (Xu et al., 2013). Moreover, curves of the three strengthened specimens are coincident, which indicates that the CFRP tendon strain development is only related to the deflection development of the prestressed beam rather than to the initial prestress level or diameter of CFRP tendon.

4 CONCLUSION

In this study, the flexural behavior of prestressed concrete (PC) beams strengthened by prestressed CFRP tendons with different diameters (7mm and 10mm) and initial prestress levels (15%, 30% and 50%) are investigated. Four beams, including one un-strengthened reference beam and three strengthened beams, are tested via four-point bending test. The following conclusions are drawn:

- 1) The failure mode of strengthened beam is concrete crushing and CFRP tendons remain intact, which is an ideal failure mode. The concrete beams show good plastic performance, and damaged beams does not collapse due to prestressed steel strands and CFRP tendons.
- 2) The concrete beam is in the elastic stage before cracking. Compared with the reference beam, the cracking load of strengthened beams is increased by 25%, 75% and 100% respectively, and ultimate loads is increased by 31%, 39% and 54% respectively.
- 3) The upper flange of the mid-span section including steel and concrete is in compression during loading, while the lower flange is in tension. The strain of steel and concrete at the web shifted from compression to tension, which is related to the upward movement of the neutral axis.
- 4) There is no obvious damage on CFRP tendons, i.e. no fracture or slip, in the whole loading process. The self-designed mechanical devices and end anchorage work well. The strain increment of CFRP tendons has a good correlation with the deflection development of the beam and increases uniformly along the full length during the tension and loading process.

Rehabilitation of cracked diaphragm cutouts in steel bridge using Fe-SMA

Y.P. Wu, X.H. Qiang & X. Jiang

College of Civil Engineering, Tongji University, Shanghai, China

H.L. Wu & J.M. Ding

Tongji Architectural Design, Shanghai, China

ABSTRACT: The Fe-SMA plates covering crack-stop holes method is presented to repair cracks of the diaphragm cutouts in orthotropic steel bridge decks. The activated Fe-SMA plate can increase the local stiffness and introduce precompression in the cracked region of steel plates. The recovery stresses of Fe-SMA with the pretension strain of 4% and activation temperatures of 150, 200, and 250 °C are 192.3, 226.4, and 270.8 MPa respectively, which can meet the requirement of cracking steel plates. The temperature of the non-activated region is maintained below the glass transition temperature of the adhesive during activating, indicating that the activation operation has little effect on the bonding performance between the Fe-SMA plate and the diaphragm. With activating Fe-SMA, compression stresses of 44.2 MPa–63.9 MPa are introduced at the hole edge. The stress at the hole edge is reduced by 66.65% through bonding the Fe-SMA plate.

1 GENERAL INSTRUCTIONS

Orthotropic steel bridge decks are a landmark innovation of modern bridge engineering and have been widely used in long-span bridges (Pfeil & Battista 2005, Freitas et al. 2013). Numerous structural details are prone to fatigue cracking under vehicle-induced vibration and repeated wheel load. Referring to the investigation of cracks distribution in several steel bridges, most fatigue cracks in orthotropic steel bridge decks occur at the arc-shape cutouts of the diaphragm, the connection between the roof plate and the U-rib, and the joint of the U-rib, accounting for about 90% in total (Editorial Department of China Journal of Highway and Transport 2014).

Carbon fiber reinforced polymer (CFRP) has superior mechanical properties, scholars have applied CFRP to strengthen cracked metallic members and studied the repair effect (Jones & Civjan 2003, Colombi & Fava 2015, Lepretre et al. 2018). Many scholars combined NiTi-based shape memory alloys (NiTi-SMA) and CFRP into composite patches to repair cracks in steel plates; specifically, CFRP sheets can increase local stiffness, and activated SMA can introduce precompression (El-Tahan et al. 2015, Abdy et al. 2018, Li et al. 2020).

The crack-stop hole can reduce the stress concentration at the crack tip and noticeably improve the fatigue performance of structures. Moreover, it is convenient in operation and fast in construction, making it especially suitable for the crack repair of orthotropic steel bridge decks involving narrow internal spaces and complex structures (Makabe et al. 2014, Fu et al. 2017). However, the crack-stop hole weakens the cross-section and is prone to secondary cracking (Razavi et al. 2017). Given this, Reddy et al. combined CFRP and crack-stop holes to repair bridge cracks and analyzed the repair mechanism and reinforcement performance (Reddy et al. 2016).

Drawing on the above repair concepts, this study proposes the Fe-SMA plates on the basis of crack-stop holes to repair cracks of the diaphragm cutouts. The stress level of the cracking

region can be effectively reduced by increasing the local stiffness and introducing precompression using the shape memory effect of Fe-SMA. Izadi et al. fixed the Fe-SMA strip on the steel plate using the bolt anchorage and introduced compressive stress of 74 MPa on the steel plate after activating Fe-SMA (Izadi et al. 2018). Wang et al. strengthened the cracked steel plate with the activated Fe-SMA strip, and the fatigue life of the repaired steel plate is 3.51 times higher than that of the unreinforced plate (Wang et al. 2021).

Therefore, this study presents the method of the Fe-SMA plates covering crack-stop holes to repair the cracked diaphragm cutouts in orthotropic steel bridge decks. The material properties of Fe-SMA, strengthening principle, repair scheme, and reinforcement effect are studied.

2 MECHANICAL PERFORMANCE OF FE-SMA

2.1 Mechanical properties

In order to obtain the mechanical properties of Fe-SMA, material specimens were prepared for static tensile tests according to the code of *Metallic materials-Tensile testing-Part 1: Method of test at room temperature* (GB/T228.1-2010, 2010), as shown in Figures 1a, b. In the first loading stage, the strain rate was $3.0 \times 10^{-4} \text{ s}^{-1}$. After the strain reached 0.05, the displacement rate was kept at $2.0 \text{ mm} \cdot \text{min}^{-1}$ until the specimens fractured.

Figure 1. Static tensile test of Fe-SMA: (a) specimens design, (b) test device.

The engineering stress–strain curves of Fe-SMA plates under static tension are shown in Figure 2. The detailed mechanical properties are listed in Table 1. The stress of $\sigma_{y,0.2}$, corresponding to its residual strain of 0.2%, is used to describe the yield strength. The elastic modulus of Fe-SMA plates is determined by the tangent slope of the stress-strain curves in the initial stage, and the calculated average value is 172 GPa, which is close to that of the ordinary

Figure 2. Engineering stress–strain curves of Fe-SMA.

steel. The ultimate strain of the Fe-SMA plates is 38.31%, while the yield strength and ultimate strength are 494 MPa and 960 MPa, respectively.

Table 1. Mechanical properties of Fe-SMA.

Number	Elastic modulus (GPa)	$\sigma_{y,0.2}$ (MPa)	Ultimate strength (MPa)	Ultimate elongation (%)
Static-1	176	519	1000	40.09
Static-2	168	477	940	34.39
Static-3	172	485	939	40.45
Average	172	494	960	38.31

2.2 Activation properties

The Fe-SMA specimens, as shown in Figure 3, are designed to test the activation recovery performance. The total length of the specimens is 326 mm, consisting of 220 mm in the high temperature furnace, and 50 mm for clamping at both ends. Following the pretension strain of 4%, the heating activation was performed at 150°C, 200°C, and 250°C, respectively.

Figure 3. Specimens for activation recovery performance.

Three pairs of thermocouples were arranged on the Fe-SMA specimens’ surface to track the heating temperature, as shown in Figure 4a. An initial tensile stress of 50 MPa was applied to the specimens before activation to prevent buckling in the heating process. the temperature–stress curves in the activation process are depicted in Figure 4b. The internal stress of Fe-SMA specimens decreased initially due to thermal expansion. With the temperature grew, the shrinkage caused by the shape memory effect was dominant, and the internal stress of Fe-SMA specimens gradually increased. After ceasing to heat, the recovery stress of Fe-SMA

Figure 4. Activation test of Fe-SMA: (a) test device, (b) temperature-stress curves.

continued to increase under the cooling shrinkage effect. The recovery stress of Fe-SMA obtained with the pretension strain of 4% and activation temperatures of 150°C, 200°C, and 250°C are 192.3 MPa, 226.4 MPa, and 270.8 MPa, respectively.

3 REPAIR SCHEME AND TEST SYSTEM

3.1 The diaphragm model

This study intercepts the local model of the diaphragm in orthotropic steel bridge decks to conduct the repair research. The diaphragm cutouts use the Haibach hole type and the interception position of the local diaphragm model is denoted in Figure 5.

Figure 5. Model selection of the diaphragm specimens.

Figure 6 illustrates the parameters of the diaphragm model: the length of 1000 mm, the center width of 300 mm, and the thickness of 12 mm. An idealized horizontal crack is designed at the minimum section of the diaphragm, with a length of 60 mm. The crack-stop hole schemes with a diameter of 16 mm, whose center is located at the tip of the prefabricated crack. The effective width of the diaphragm section is 175.3 mm.

Figure 6. Geometry of diaphragm specimens (Unit: mm).

3.2 Repair scheme of the diaphragm

As shown in Figure 7, five cracked diaphragm specimens were designed, one of which was repaired with the crack-stop hole, and the other four were repaired with the Fe-SMA plates covering crack-stop holes. The fundamental parameters of different reinforcement schemes are listed in Table 2. The cracks and crack-stop holes in steel plates were prefabricated by wire cutting during specimen processing. In the S-FH group, the crack in the diaphragm is adopted as the center, and a 75 mm × 400 mm Fe-SMA plate is bonded on each side of the steel plate.

The thickness of the Fe-SMA plates includes 1.75 mm and 2 mm, and the activation conditions include no-activation, activation at 150°C, and activation at 200°C.

Figure 7. Physical picture of the diaphragm specimens.

Table 2. Specimens design and reinforcement parameters.

Repair method	Name	Stop hole size	Activation temperature	Thickness of Fe-SMA plate
Crack-stop holes	S-H-1	Φ16 mm	None	None
Fe-SMA plates covering	S-FH-1	Φ16 mm	200°C	1.75 mm
	S-FH-2	Φ16 mm	200°C	2 mm
crack-stop holes	S-FH-3	Φ16 mm	150°C	2 mm
	S-FH-4	Φ16 mm	None	1.75 mm

3.3 Test system and measuring points

The specimens were subjected to a static loading process of 0–128.6 kN using the MTS 311.31 S test system, and the load gradient was 20 kN for each grade (as shown in Figure 8a). Six thermocouples were arranged on each side of the diaphragm numbered as denoted in Figure 8b to monitor the temperature on the surface of Fe-SMA and steel plates in the activation. Strain gauges were symmetrically arranged on both sides of the diaphragm along the direction of the prefabricated crack (as shown in Figure 8b). In specimen S-H-1, the center of the strain gauges is 2 mm, 15 mm, 30 mm, 60 mm, and 90 mm away from the hole edge. In the S-FH group, the center of strain gauges is 2 mm, 12 mm, 18 mm, 24 mm, 30 mm, 60 mm, and 90 mm away from the hole edge. The stresses at measuring points with different distances away from the hole edge are denoted from σ_{2mm} to σ_{90mm} , respectively.

Figure 8. Testing and measuring arrangement: (a) testing device, (b) thermocouples and strain gauges.

3.4 Material properties

The mechanical properties of the steel used in the diaphragms were evaluated in accordance with the Chinese code (GB/T 228.1-2010, 2010). The structural adhesive was provided by Shanghai Horse Construction Co., LTD, and its mechanical properties were tested according

to the code of *Test methods for properties of resin casting epoxy* (GB/T 2567-2008, 2008). The measured mechanical properties of steel and structural adhesive are summarized in Table 3.

Table 3. Specimens design and reinforcement parameters.

Material	Elastic modulus (GPa)	$\sigma_{y,0.2}$ (MPa)	Ultimate strength (MPa)	Ultimate elongation (%)
Steel	208.2	406.39	504.04	16.17
Adhesive	5.892		31.16	0.66

4 RESULT ANALYSIS

4.1 Temperature during activation

The temperature of the repaired diaphragm activated at 200°C is illustrated in Figures 9a, b. Although the instantaneous temperature at the activation boundary (points 2 and 4) exceeded 85°C during the heating procedure of maintaining the Fe-SMA plate center (point 3) at 200°C, it mostly stayed below the glass transition temperature of the structural adhesive (85°C). The temperature farther away from the activation region (points 1 and 5) was maintained under 50°C in the heating process. The temperature at Point 6 on the diaphragm was between 100°C and 120°C, which had no significant effect on the mechanical properties of the steel plate. The temperature on the non-activated surface of the Fe-SMA plate and the diaphragm was maintained at a low level and the maximum value was 60.7°C. Therefore, the temperature in the non-activated region remained at a low level during heating, indicating that the activating operation has little effect on the secure bonding between the Fe-SMA plate and the diaphragm.

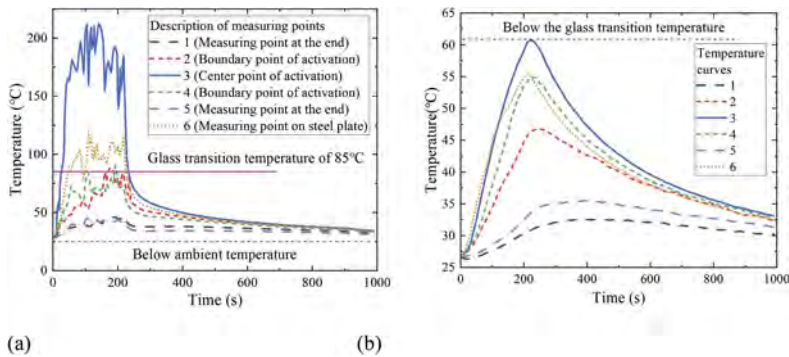

Figure 9. Temperature distribution during activation: (a) activated surface, (b) Non-activated surface.

4.2 Stress comparison

The compressive stresses introduced in the diaphragm after activating the Fe-SMA plates are depicted in Figure 10a. After activating the Fe-SMA plates, compressive stresses of 44.2 MPa–63.9 MPa could be introduced at the edge of crack-stop holes, which could considerably reduce the stress amplitude and stress concentration of the cracking part, and greatly improve the mechanical performance of the diaphragms. At the same activation temperature, the compression stress introduced by the 2 mm Fe-SMA plate at the hole edge was about 9 MPa (16.48%) higher than that of the 1.75 mm Fe-SMA plate. With the same thickness, the compression stress introduced by the Fe-SMA plate activated at 200°C was about 20 MPa (44.59%) higher than that of the Fe-SMA plate activated at 150°C.

As depicted in Figure 10b, the σ_{2mm} of all reinforced specimens increased linearly with the increasing load. For specimen S-FH-4, bonding the Fe-SMA plate significantly reduced stress

concentration and decreased stress at the hole edge from 390.09 MPa to 128.94 MPa, representing a reduction of 66.95%. For specimens S-FH-1, S-FH-2, and S-FH-3, the activation of Fe-SMA makes the stresses of measuring points remain at a low level, and the stresses at the hole edge are reduced by 84.74% in average. The Fe-SMA plate improved the section stiffness of the diaphragm, and the slope of load–stress curves of the S-FH group are obviously reduced compared with specimen S-H-1. Inside the S-FH group, the slope of load–stress curves of specimens S-FH-1 and S-FH-4 is smaller than those of specimens S-FH-2 and S-FH-3 since the thinner thickness of the Fe-SMA plates. Compared with specimen S-FH-4, specimens S-FH-1, S-FH-2, and S-FH-3 achieved considerable results by activating Fe-SMA, which could introduce precompression in the cracking position based on increasing stiffness.

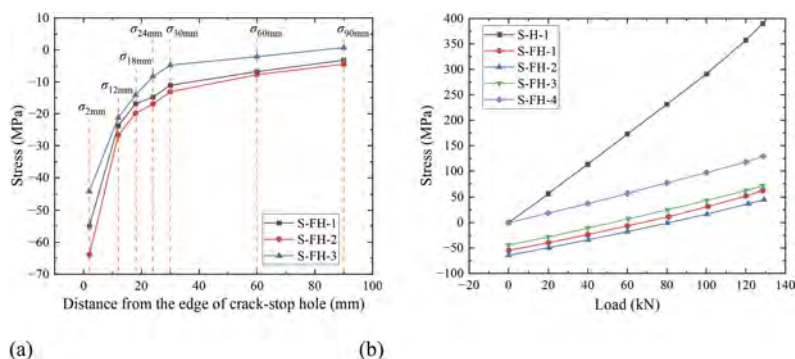

Figure 10. Stress results of repaired diaphragms: (a) compression stress, (b) σ_{2mm} under load.

5 CONCLUSIONS

Based on the crack-stop hole method, the Fe-SMA plate is used to repair cracks of the diaphragm cutouts in orthotropic steel bridge decks. The material properties of Fe-SMA and the reinforcement effect of the proposed method are studied. The operation procedure is introduced and the feasibility is confirmed. The main conclusions are as follows:

- (1) The elastic modulus of Fe-SMA plates is 172 GPa, which is comparable to that of ordinary steels. The yield strength, ultimate strength, and ultimate strain are 494 MPa, 960 MPa, and 38.31%, respectively, indicating its high strength and exceptional ductility. The recovery stresses of Fe-SMA using the pretension strain of 4% and activation temperatures of 150°C, 200°C, and 250°C are 192.3 MPa, 226.4 MPa, and 270.8 MPa respectively, which can meet the repair needs of cracking steel plates.
- (2) During the activation process, the temperature decreases sharply from the activation center to the non-activated region, showing that the activation has little effect on the bonding performance between the Fe-SMA plate and the diaphragm. When Fe-SMA is activated at 200°C, the temperature of the non-activated region is kept below the glass transition temperature of the structural adhesive.
- (3) Activating the Fe-SMA plates can introduce compressive stresses of 44.2 MPa–63.9 MPa at the edge of crack-stop holes, which could considerably reduce the stress amplitude and stress concentration of the cracking diaphragms. The compression stress introduced by the 2 mm Fe-SMA plate is about 9MPa (16.48%) higher than that of the 1.75 mm Fe-SMA plate. In comparison to 150°C, the activation of Fe-SMA at 200°C can raise the compression stress by nearly 20 MPa (44.59%). By bonding the Fe-SMA plate, the stress at the hole edge can be significantly reduced by 66.95%, and the activation of Fe-SMA can further reduce the stresses of measuring points by over 15%.

ABSTRACT: This paper aims to investigate the mechanical behavior of the Fe-SMA/steel hybrid joints. Based on the cohesive zone modeling of software ABAQUS, the numerical model of Fe-SMA/steel hybrid joints is developed, and the parametric analysis on overlap length is carried out. Besides, the damage evolution, failure modes and failure load of hybrid joints under tensile load are evaluated. The proposed model can reasonably simulate the performance of Fe-SMA/steel hybrid joints under tensile load. The results show that the failure load of Fe-SMA/steel hybrid joints increases with the improving overlap length. The existence of the optimal overlap length can ensure good mechanical behavior of Fe-SMA/steel hybrid joints and can reduce the consumption of engineering materials. Furthermore, the failure process of Fe-SMA/steel hybrid joints is firstly the failure of adhesive layers, and finally the bearing failure of the Fe-SMA plates leads to the failure of the whole joint.

1 GENERAL INSTRUCTIONS

Shape memory alloys (SMAs) have both the shape memory effect (SME) and super-elasticity (SE), and there is growing interest in SMAs from almost every industry (Pan et al., 2019). Iron-based shape memory alloy (Fe-SMA) is more and more used in the reinforcement field of civil engineering because of its excellent SME and low price (Hosseini, Michels, et al., 2019; Fritsch et al., 2019). The research has proved the effectiveness of Fe-SMA plates in strengthening steel structures (Fritsch et al., 2019; Izadi et al., 2019; Izadi, Ghafoori, Shahverdi, et al., 2018). In civil engineering, different materials are usually connected by adhesive, welding and bolted joints to repair steel structures. The stress concentration in the bolted joints causes damage and reduces the bearing capacity of structures (Jiang et al., 2013). Although the adhesive joints have a more uniform stress distribution (Jiang et al., 2014), in practical applications, adhesive layers have considerable defects such as bubbles and cracks, and there is peeling stress and stress concentration at the ends. Bolts can prevent sudden fracture of joints, and adhesive layers make the force transfer effective. In order to improve the mechanical performance of joints, hybrid joints are formed by combining the advantages of bolted joints and adhesive joints. Compared with simple bolted joints or adhesive joints, hybrid joints can obtain better static strength and fatigue life (Zhang et al., 2021). Hybrid joints with flexible adhesives can improve the bearing capacity and fatigue life of joints (Kelly, 2006). There are few studies on the mechanical behavior of hybrid joints composed of Fe-SMA plates. Therefore, it is necessary to study the failure load and failure modes of Fe-SMA/steel hybrid joints to optimize the reinforcement design using Fe-SMA plates.

Many studies have investigated the mechanical performance of hybrid joints made of composite materials. A simplified analysis model based on the experimental results of aluminum/aluminum hybrid joints was developed by Paoissien et al. (2017). The model could well capture the mechanical performance of hybrid joints and be adopted to select the optimal adhesive materials. The performance of CFRP/aluminum hybrid joints was evaluated by Chen et al. (2019) through tensile

tests. The results showed that the energy absorption capacity of the hybrid joints was superior. A tensile test of adhesive joints and hybrid joints using digital image correlation was carried out by Sun et al. (2021) to investigate the performance and failure mechanisms of joints. The results demonstrated that CFRP/aluminum hybrid joints had the best mechanical behavior and adhesive layers could reduce the stress concentration around the bolt holes. The stiffness, failure modes and failure progress of CFRP/CFRP hybrid joints were investigated by Jiang et al. (2022) through tensile tests. The results proved that the stiffness of hybrid joints increased considerably. The mechanical performance of FRP/FRP hybrid joints was explored by Mehrabian & Boukhili (2022) using the digital image correlation method. The results indicated that the shear and peeling strains were critical factors influencing the failure of hybrid joints. The influence of temperature on the performance of FRP/FRP hybrid joints was evaluated by Ulus (2022). The failure load of hybrid joints in the temperature range of 20–150°C was better than bolted joints and adhesive joints. However, experimental research is generally costly and time-consuming. In contrast, using the finite element (FE) method to predict the strength and failure modes of hybrid joints is more efficient and conducive to parametric analysis. The FE analysis can also obtain the stress distribution which is difficult to acquire in the experiments, such as the stress distribution and damage evolution process of adhesive layers, to make up for the defects of the experimental results.

The mechanical performance of Fe-SMA/steel hybrid joints requires to be well understood to fulfill the goal of using Fe-SMA plates for strengthening steel structures. In this work, a numerical study is conducted to reveal the damage process and failure mechanisms of Fe-SMA/steel hybrid joints. Based on the previous experimental research, this paper proposes a FE model of Fe-SMA/steel hybrid joints considering the progressive damage model of adhesive layers. Furthermore, the failure load and failure modes of Fe-SMA/steel hybrid joints are investigated based on the B-K energy criterion determining the failure of adhesive layers. A parametric analysis is conducted to reveal overlap length on the performance of Fe-SMA/steel hybrid joints. The optimal design suggestions for Fe-SMA/steel hybrid joints are given.

2 MATERIALS AND DIMENSIONS

2.1 Materials

The adherends employed the Q355 mild steel and Fe-SMA plates were employed in the adherends of hybrid joints. According to the tensile test results of Qiang et al. (2023b) and Qiang et al. (2023a), the material properties of Fe-SMA and Q355 mild steel were implemented, see Table 1. The performance of high strength bolts is listed in Table 1 which obtaining from the Li et al. (2020) and Lyu et al (2021). The preload of high strength bolts is specified in GB50017-2017 (2017), see Equation 1.

$$F_{p,b} = 0.61f_{u,b}A_e \quad (1)$$

Where $F_{p,b}$, $f_{u,b}$ and A_e are preload, ultimate strength and effective area of bolts, respectively, and $A_e = 84.3$ for M12 bolts (GB50017-2017, 2017). In order to describe the change of cross-sectional area during large deformation of Fe-SMA/steel hybrid joints, true strain ε_{true} and true stress σ_{true} are used. ε_{true} and σ_{true} are expressed as:

$$\varepsilon_{true} = \ln(1 + \varepsilon_{nom}) \quad (2)$$

$$\sigma_{true} = \sigma_{nom}(1 + \varepsilon_{nom}) \quad (3)$$

Where ε_{nom} and σ_{nom} are nominal strain and stress, respectively.

For steel plates and bolts, a bi-linear model was implemented in the FE modeling of the hybrid joints.

The adhesive layers are made of Araldite® 2015 structural adhesive, and the mechanical performance of structural adhesive is obtained by Rocha & Campilho (2018) shown in Table 2, which is adopted to develop cohesive zone law in the FE modeling.

Table 1. Mechanical performance of steel (Qiang et al., 2023a; Li et al., 2020; Lyu et al., 2021; Qiang et al., 2023b).

Materials	Elastic modulus E (GPa)	Yielding strength f_y (MPa)	Ultimate strength f_u (MPa)
Q355 steel	211	458	587
Fe-SMA	186	490	894
12.9s bolts	194	1120	1220

Table 2. Mechanical performance of structural adhesive (Rocha & Campilho, 2018).

Property	Araldite® 2015
Elastic modulus, E (GPa)	1.85
Shear modulus, G (GPa)	0.56
Poisson ratio, ν	0.33
Tensile strength, σ_f (MPa)	21.63
Shear strength, τ_f (MPa)	17.9
Tensile fracture toughness, G_{IC} (N/mm)	0.43
Shear fracture toughness, G_{IIC} (N/mm)	4.70

2.2 Dimensions

The dimensions of hybrid joints are presented in Figure 1. $l_0 = 48$ mm, $l_s = 200$ mm and $l_f = 200$ mm are overlap lengths of overlap zone, steel plates and Fe-SMA plates, respectively. $t_f = 1.8$ mm, $t_a = 1$ mm and $t_s = 10$ mm are thicknesses of Fe-SMA plates, adhesive layers and steel plates, respectively. The width of hybrid joints is b , and the diameter of bolts is d_0 . e_1 and e_2 are end and edge distances, respectively. The values of e_1 and e_2 are equal to $2d_0$, which satisfy the requirements of Eurocode 3 Part 1–8 (2005).

Figure 1. Dimensions of Fe-SMA/steel hybrid joints.

3 NUMERICAL WORK

3.1 FE modeling

Software ABAQUS was employed to investigate the mechanical performance of Fe-SMA/steel hybrid joints. The mixed-mode triangular CZM was employed to simulate the damage behavior of adhesive layers, and COH3D8 elements were adopted to reveal the initial damage, damage evolution and stiffness degradation of adhesive layers.

The diameter of nuts equal to the diameter of washers to improve the efficiency of numerical modeling, and the effects of screw thread were ignored. The simplified method can obtain

the same interaction area when the preload of bolts is applied, and the error caused by simplification can be ignored (Chaudhuri & Xie, 2015). The simplified method considerably reduced the element number in FE models and simulation time.

3.1.1 Boundary and loading conditions

A fixed constraint was applied to one end of hybrid joints and a load was applied to the other end.

3.1.2 Mesh generation

According to the ABAQUS manual (Karlsson & Sorensen, 2021), the $T - \Delta$ relationship to determine the interface failure is based on the relative displacement of the top and bottom of the COH3D8 elements. When the thickness direction of the adhesive layers is divided into two or more layers, the calculation results would be unreliable. Therefore, the thickness direction of adhesive layers was divided into one layer of COH3D8 element, see Figure 2b. C3D8R element was adopted by Fe-SMA plates, steel plates and bolts. The mesh at the overlap zone of the FE model was refined, and the mesh around the holes and the bolts were refined. The mesh generation of Fe-SMA plates, steel plates and bolts is presented in Figure 2.

Figure 2. Mesh generation: (a) Bolts, (b) Adhesive layers, (c) Steel plates, (d) Fe-SMA plates.

3.1.3 Interactions and analysis steps

Tie interactions in FE modeling comprise adhesive layers to Fe-SMA plates and adhesive layers to steel plates due to the discretization level of adhesive layers being different from Fe-SMA and steel plates. Surface-to-surface contacts consisted of Fe-SMA plates to bolts and steel plates to bolts, the normal behavior was “hard contact”, and a friction coefficient of 0.3 (Fritsch et al., 2019) was adopted in the tangential direction.

There were five analysis steps in the numerical modeling to reveal the performance of Fe-SMA/steel hybrid joints. First, a temporary fixed boundary was applied to the ends of Fe-SMA plates and adhesive layers, and a 10N force was applied to bolts to establish a stable contact interaction. Second, the temporarily fixed boundary was removed. Third, the corresponding preload was applied to the screw. Fourth, the current length of the bolts was fixed. Fifth, a load was employed at the end of Fe-SMA plates.

3.2 Results

3.2.1 Failure modes

Understanding the failure modes of adhesive and bolted joints is the basis of exploring the failure modes of Fe-SMA/steel hybrid joints. There are four typical failure modes of adhesive joints (Zhao & Zhang, 2007): (i) cohesive failure, (ii) adherend failure, (iii) interface failure and (iv) mixed failure. The adherends of metal adhesive joints generally do not occur yielding, and the adherend failure of composite adhesive joints is generally due to the delamination and rupture of composite materials. The adhesive joints with critical adhesive layers and low adhesive interface strength are prone to cohesive failure and interface failure, respectively.

Net cross-section, shear-out, splitting, bearing, end pull-out and screw shear failure will occur in bolted joints when applying tensile load (Ulus, 2022; He & Wang, 2011). For bolted joints with composite materials, splitting failure will occur when the composite adherend interacts with bolts until cannot bear the load. The zone of adherends tightly contacts with the screw of bolts, when it cannot

bear the shear force, shear-out failure forms in composite adhesive joints. Both shear-out and splitting belong to brittle failure modes, and the bearing capacity of composite bolted joints under brittle failure modes is low. Net cross-section failure occurs when bolted joints with a small edge distance e_2 . For metal bolted joints with thin-walled plates and an appropriate edge distance e_2 , end pull-out failure will occur (Obeydi et al., 2020). Compressive and frictional forces around holes lead to bearing failure of bolted joints. Screw shear failure often occurs in the case of the high load-bearing capacity of adherends, especially if the adherend is a high strength and thick metal material.

The damage distribution and progress of adhesive layers based on the secondary nominal stress criterion (QUADSCRT) in different stages are shown in Figure 3. The Mises stress of Fe-SMA plates, bolts and steel plates are given in Figure 4. After the preload is applied, part of the adhesive layers in contact with the nuts has begun to damage, and as the load is applied until the whole section begins to damage, see Figures 3a, b. At the initial stage of loading, the mechanical behavior of Fe-SMA/steel hybrid joints was the failure of adhesive layers, and the failure propagates from one loading end of Fe-SMA plates in the overlap zone to the inside, see Figure 3. When the adhesive layers failed, the applied load mainly was bore by bolts and Fe-SMA plates of hybrid joints, and the load began to increase. Finally, the bearing failure of Fe-SMA plates around the hole led to a decrease in the bearing capacity of the joints, and the final failure of joints occurred. After the failure of hybrid joints, the overlap zone of Fe-SMA plates generated obvious curling deformation. Curling deformation was also observed in Ref. (Mahmood et al., 2020) when the plates were thin, and curling deformation might lead to bearing failure of hybrid joints due to prevent the shear deformation. When joints failed, the steel plates and bolts almost did not yield and occurred obvious deformation due to the critical parts being the Fe-SMA plates (see Figure 4).

Figure 3. Damage distribution and progress of adhesive layers: (a) Completion of applying preload, (b) Initial stage of applying load, (c) Whole section reached initial damage, (d) Adhesive layer near the loading end began to fail, (e) Adhesive layer away from the loading end began to fail, (f) Adhesive layer completely failed.

Figure 4. Mises stress of components: (a) Fe-SMA plates, (b) Steel plates, (c) Bolts.

3.2.2 Destruction process of hybrid joints

The tensile load-displacement curve of hybrid joints calculated by FE is given in Figure 5. The first load drop of hybrid joints corresponds to the failure of the adhesive layer, and the load is

46.37 kN. The second load drop corresponds to the bearing failure of Fe-SMA plates, and the failure load of hybrid Fe-SMA/steel joints was 46.85 kN. After the adhesive layer failed, Fe-SMA plates and bolts continued to bear the load, but the ultimate bearing capacity of hybrid Fe-SMA/steel joints did not improve. Three stages of load-displacement curves can be divided. At the first stage of loading, the Fe-SMA plates, the bolts and the adhesive layers bore the load together, and the load-displacement curve was linear. There was no relative sliding between the components and no gap between the bolts and the bolt holes. With the development of adhesive layer damage, the load gradually transferred to the bolts and Fe-SMA plates. The first load drop indicated the failure of adhesive layers. Finally, the bearing failure occurred, the bearing capacity of hybrid joints decreased, and hybrid joints failed.

Figure 5. Tensile load-displacement curve of Fe-SMA/steel hybrid joints.

4 PARAMETRIC ANALYSIS

4.1 *Overlap length*

OL series is employed to explore the influence of overlap length on the performance of Fe-SMA/steel hybrid joints, see Table 3. The tensile load-displacement curves of Fe-SMA/steel hybrid joints obtained by the FE modeling are presented in Figure 6. The FE results and failure modes are listed in Table 4.

Table 3. Details of OL series.

ID	Fe-SMA thickness (mm)	Steel thickness (mm)	Adhesive thickness (mm)	Overlap length (mm)
OL1	1.8	10	1	48
OL2	1.8	10	1	60
OL3	1.8	10	1	80
OL4	1.8	10	1	100

It can be seen from Figure 6 that when adhesive layers fail, Fe-SMA/steel hybrid joints can continue to bear the load, and the load-displacement curves of all joints with different overlap lengths are similar. As the overlap length increased, the failure load F_f of hybrid joints improved, but the increasing amplitude gradually decreased. There was an optimal overlap length for Fe-SMA/steel hybrid joints. When hybrid joints reached the optimal length, F_f of Fe-SMA/steel hybrid joints was no longer significantly increased. In practical engineering, the optimal overlap length can be used to save the consumption of materials. Interestingly, when the overlap length was 100 mm, failure modes of hybrid joints changed from bearing failure to net cross-section failure. This might be because adhesive layers could reduce the curling deformation of Fe-SMA plates, with the increase of overlap length. The section along bolts was weakened by openings and became a critical section, resulting in net cross-section failure of Fe-SMA/steel hybrid joints.

Figure 6. Tensile load-displacement curve of OL series.

Table 4. Mechanical behavior of OL series.

ID	Overlap length (mm)	Failure modes	F_f (kN)
OL1	48	Bearing failure	46.85
OL2	60	Bearing failure	51.14
OL3	80	Bearing failure	53.24
OL4	100	Net cross-section failure	54.06

5 CONCLUSIONS

This paper aims to evaluate the failure modes, failure load and damage process of Fe-SMA/steel hybrid joints based on cohesive zone modeling. The effects of overlap length and overlap width on the mechanical behavior of Fe-SMA/steel hybrid joints are studied. The conclusions are as follows:

- (1) The numerical model can predict the mechanical performance of adhesive layers based on cohesive zone modeling, which provides suggestions for the finite element analysis of Fe-SMA/steel hybrid joints.
- (2) The numerical model of Fe-SMA/steel hybrid joints can reveal the damage mechanism and damage evolution. The numerical model can predict the failure load and failure modes, hence it has good calculation accuracy. At the first stage of loading, the Fe-SMA plates, the bolts and the adhesive layers bear the applied load together. With the development of adhesive layer damage, the load is gradually transferred to the bolts and Fe-SMA plates until the final failure occurs.
- (3) The failure modes of Fe-SMA/steel hybrid joints are related to the overlap length. When the overlap length is 100 mm, Fe-SMA/steel hybrid joints change from bearing failure to net cross-section failure. The adhesive layers could reduce the curling deformation of Fe-SMA plates, with the increase of overlap length.
- (4) The failure load of Fe-SMA/steel hybrid joints improves with the increase of overlap length. The existence of the optimal overlap length can ensure good mechanical behavior of Fe-SMA/steel hybrid joints and can save the use of engineering materials.

L. Chen & C. Zhang

Shanghai Municipal Engineering Design Research Institute (Group) Co., Ltd, Shanghai, China

ABSTRACT: Songpu Bridge, a riveted steel truss bridge, was transformed for more traffic, and therefore, the truss members and riveted gusset joints required strengthening. Here, a typical truss joint connecting chords, verticals, and diagonals was focused. The strengthening of the joint included the truss members, gusset plates, and rivets. The tension and compression diagonals were strengthened by bolting additional steel plates and angles to the members, respectively. The gusset plates were strengthened by adding new cover plates, which had a large central opening such that they could be attached to the existing gusset plates without removing the existing rivets. Additional rivets were installed to connect the strengthened members and gusset plates. After strengthening, the riveted gusset joint had a complicated configuration. To evaluate the performance of the joint, a full-scale specimen that simulated one quarter part of the joint was experimentally tested. Failure modes including yielding of gusset plates and diagonal member and shear failure of rivets were observed. An ultimate bearing capacity of 11868 kN was obtained. The experiment aided the designing of the strengthening solution of the riveted gusset joint.

1 INTRODUCTION

Numerous steel structures require strengthening because of aging, corrosion, fatigue, impact damage, or an increase in service loads. Compared with demolition and reconstruction, strengthening is typically a more economical and sustainable solution. For instance, Songpu Bridge, a historical riveted steel truss bridge in Shanghai, was strengthened and transformed (Shao et al., 2019, Su et al., 2019a, Su et al., 2019b).

1.1 Project overview

The superstructure of Songpu Bridge consists of 96 m+112 m two-span continuous riveted steel trusses. Figure 1a shows the diagram of the truss. Songpu Bridge was initially built in 1976 as a highway–railway bridge, of which the upper layer was a two-lane highway and the lower layer was a single-track railway, as shown in Figure 1b.

In recent years, with the road traffic increasing, the highway capacity has been oversaturated; meanwhile, the railway has been disused. In order to improve the transportation capacity across the river, the existing Songpu Bridge is strengthened and transformed. The upper deck is widened from 12m to 24.5m for six vehicle lanes, whereas the lower deck is transformed into bicycle lanes and sidewalks, as shown in Figure 1b. As a result, the truss also requires to be strengthened to undertake the increased service load. The truss members and joints that require strengthening are indicated as red in Figure 1a. For truss members in compression, steel angles are bolted to improve the stability, whereas for truss members in tension, steel plates are bolted (Wang et al., 2022b, Wang et al., 2022a, Wang et al., 2023). For joints, cover plates are attached to the existing joints and more rivets are installed (see more details in Section 1.2).

Figure 1. Overview of the strengthening and transformation project of Songpu Bridge (Unit: m).

1.2 Strengthening of truss joints

Taking A17 joint as an example to explain the strengthening solution for joints. The original A17 joint has insufficient horizontal shear resistance and needs to be strengthened. Moreover, the diagonal members connected with A17 joint (i.e., E16A17 and A17E18, in compression and tension, respectively) are strengthened by adding steel angles and steel plates, respectively. The designed strengthening solution of A17 joint is shown in Figure 2, where the strengthening parts are indicated as red. Two cover plates with a big opening are attached to the outside of the original gusset plate, without removing the existing rivets (the opening of the cover plates is for the space of the existing rivets). In addition, splice plates are attached to enhance the connection between the joint and truss members. New rivet groups are added to connect the plates.

Figure 2. Designed strengthening solution for A17 joint.

1.3 Research significance

After strengthening in-situ, the joint has a complicated configuration, and the load transfer paths and failure modes become unclear. To evaluate the strengthening solution, a full-scale experimental study was conducted.

2 EXPERIMENTAL STUDY

2.1 Specimen

Some researchers conducted full-size tests on gusset joints (Bjorhovde and Chakrabarti, 1985, Turan et al., 2013) and riveted connections (D’Aniello et al., 2011, Collette et al., 2015). To test an entire full-size joint is very costly, which requires a huge reaction frame and multipoint loading devices; on the other hand, it is also difficult to have scaled specimens because of the riveted structure (the manufacturer can only provide a limited range for rivet size). Therefore, a full-scale specimen simulating one quarter structure of the prototype joint was designed, as shown in Figure 3.

The half part connecting with the tension diagonal member A17E18 and the half structure in the z direction was selected. The specimen consisted of 6 plates: original diagonal member ($t=30$ mm, which is equivalent to the area of a flange plate and half web of the H-shaped truss member), cover plate for diagonal ($t=16$ mm), original gusset plate ($t=16$ mm), cover plate for gusset ($t=16$ mm), and two splice plates ($t=16$ mm). The cover plate for diagonal was in the same plane with the original gusset plate, and the cover plate for gusset and the splice plates were on the top surface and bottom surface of these two plates, respectively. The photo of the specimen is shown in Figure 4.

Figure 3. Full-scale joint specimen: one quarter of the prototype joint.

2.2 Test set-up and instrumentations

Figure 5 shows the test set-up that worked as a self-balancing system. The specimen was welded to the two bases. The two bases were customized such that they simulated the boundary

Figure 4. Photo of joint specimen (top and bottom sides).

conditions. Base-1 simulated the chord, vertical member, and the unselected parts of the prototype joint, whereas base-2 simulated the force transfer from the far-end of the tension diagonal A17E18. Two jacks were employed above and under the specimen, respectively. When the upper and lower jacks exerted pressure, the specimen in the middle was pulled. In order to ensure the free deformation of the specimen, rollers were arranged above and below the two bases.

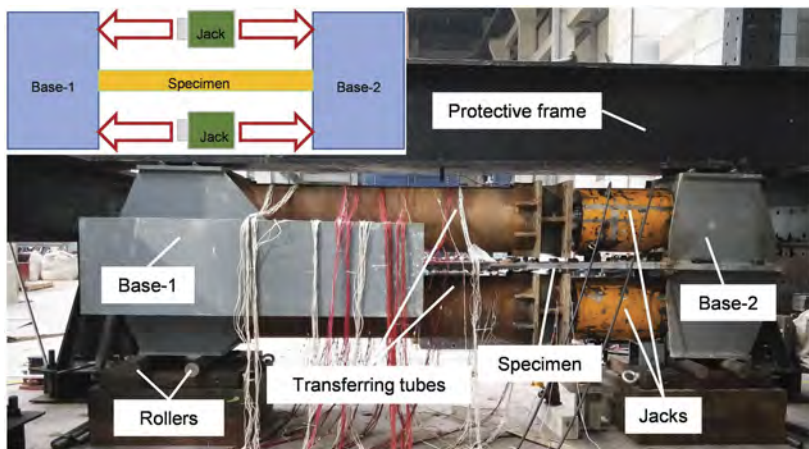

Figure 5. Photo of test set-up.

Eight linear variable differential transducers (LVDTs) were arranged as shown in Figure 6. LVDTs 1~4 were arranged in the plane of the specimen. LVDTs 1~4 measured the deformations in the load direction, of which LVDTs 1~2 and 3~4 measured the deformations of the entire specimen and the joint only, respectively; LVDTs 5~8 were arranged in the direction perpendicular to the plane of the specimen to measure the out-of-plane deformation.

Figure 6. Layout of LVDTs.

3 EXPERIMENTAL RESULTS

3.1 Failure modes

Figure 7 shows the failure modes of the specimen, which included yielding of diagonal member, yielding of gusset plates, and shear failure of rivets.

- (1) Yielding of diagonal member. The original diagonal member and cover plate for the diagonal both yielded, and the bolt holes were elongated whereas bolts were undamaged (Circle A in Figure 7).
- (2) Yielding of gusset plates. Obvious residual deformations were observed at the locations where the cover plate for gusset was connected to the cover plate for diagonal (Circle B in Figure 7) and where the gusset plates were connected to the vertical member (Circle C in Figure 7).
- (3) Shear failure of rivets. The rivet connecting the original gusset plate and the cover plate for gusset, located near the vertical member was sheared to fracture.

3.2 Load–deformation curves

Figure 8a shows the tensile deformation of the entire specimen measured by LVDTs 1–2 and the tensile deformation of the joint measured by LVDTs 3–4, respectively. Both the gusset plates and the diagonal member yielded, resulting in large tensile deformations.

3.3 Ultimate tensile bearing capacity

According to the working conditions of the prototype joint, the required minimum capacity of the specimen is 3500 kN. The test was stopped when the maximum load reached 11868 kN, given that obvious plastic deformation of the specimen was observed, despite that the load could be still increased. The ultimate tensile bearing capacity was therefore taken as 11868 kN, which is 3.39 times of the required one.

4 CONCLUSIONS

An experimental study was conducted on a full-scale joint specimen that simulated one quarter part of a strengthened riveted joint to evaluate the strengthening solution. A novel test set-up was designed and customized to realize the test. Main conclusions are as follows:

Figure 7. Failure modes.

- (1) The ultimate tensile bearing capacity of the specimen in the test reached 11868 kN, which is 3.39 times of the required minimum capacity, indicating that the strengthening solution of the riveted joint is safe and satisfactory.
- (2) The main failure mode was the yielding of the diagonal member and gusset plates. When the diagonal member yielded, the gusset plates also had obvious yielding deformation.
- (3) Shear failure of a rivet near the vertical member, connecting the original gusset plate and the cover plate for gusset, was observed. Although the failure of one rivet did not cause chain reaction to destroy other rivets around, such rivet failure is undesired. The rivets near the vertical member should be further strengthened.

As a follow-up, the design company optimized the strengthening solution according to the experimental results. An additional cover plate was attached to further strengthen the area near the vertical member.

Figure 8. Load–deformation curves of test specimen.

Weather condition effect on the road surface friction: A preliminary assessment based on sensor data

M. Rasol, F. Schmidt & S. Ientile

Université Gustave Eiffel, Champs sur Marne, France

ABSTRACT: Changes in weather condition have a significant influence on the road surface friction. Extreme weather conditions are considered during heavy rains, and ice accumulation or snow-fall for the study of road surface. This could modify the road surface friction, a decrease of the road surface friction due to extreme wet condition, and increase car accident rates. Weather condition related factors usually are water film thickness due to the rain, ice accumulation and major temperatures (pavement, ambient and freezing). Better understanding of the weather condition changes on the road surface friction coefficient considering real-scale data monitoring system is essential to acclaim a reliable maintenance solution for road transport infrastructures. Long term data collection is a key factor for assess the relation between weather conditions, road surface friction coefficient. In the current re-search study, a preliminary assessment of weather condition influence on the road surface friction is elaborated for eighteen months considering data-driven from a novel intelligent road-based passive sensor. Results show that the most extreme weather conditions could impact road surface friction coefficient over time in road transportation system; mostly due to an increase of water film thickness and possibility of ice accumulation on the road surface. In conclusion different friction thresholds are elaborated for traffic management procedures, mainly 0.80 friction coefficient is considered the most stable and standard conditions, 0.60 acceptable, and 0.30 is an urgent condition.

1 INTRODUCTION

1.1 *Main background knowledge*

Road crashes are a major concern and significant problem for highway owners and operators.

There are numerous factors involved in a road accident rate. Friction between tires and pavements is considered one of the factors that could have a partial role in increasing accident rates. Poor friction on the pavement surfaces leads to uncontrolled condition of the driving task, partially this could have an impact on the driver behaviour during the riding. In particular this could be even more dangerous in wet conditions. Friction coefficient is subjected to numerous influential factors, which can be commonly classified into five categories First, tire-related factors (rubber compound, tire properties, rubber tread design and condition, inflation pressure, and tire operation temperature) (Kogbara 2016). Second, the road pavement surface - interrelated factors (pavement type, mix design materials, microtexture and macrotexture, surface temperature and construction age of the pavement) (Srirangam 2015). Third, intervening-substance-related factors (quantity particulate matter, and oil contaminants). Fourth, driver behavior related factors (stopping sight distance, driver health condition, speed control and knowledge of the surface pavement friction) (Plati, 2020). and, the fifth category is weather conditions factors which can influence the friction between vehicle tires and road surface pavement (van Bijsterveld, 2016).

The study of weather conditions influences on the friction force generated between tires and road surface pavement is a key to advance knowledge on the road surface in order to provide an appropriate solution for traffic management procedures. On the other hand, an appropriate traffic management procedure depends on the relation between the road surface friction and weather condition. Weather conditions have significant influence on the driving task considering both on the road surface pavement which directly affect the driving operation and the climate weather which is an important factor being able to modify the driving task in the road network system (van Bijsterveld, 2016) . Combination of both cases could make an impact to the roadway system and in extreme cases, temporary closing roads is recommended. Weather conditions affects can be from various weather changes factors such as ambient temperature, pavement temperature, ice temperature on the road surface during extreme winter condition (Rasol, 2021). On the other hand, under specific conditions, changes in weather condition can produce ice layer, water film. This could need an action which is commonly considered to decrease ice possibility (%) on road surface by means of a de-icing salt procedure. However, de-icing salt action could also affect the road surface when the deterioration is already on the pavement, independently of pavement materials (cement concrete or asphalt). These factors are essential to advance the knowledge on road surface friction coefficient which can partially (directly or indirectly) be involved in the increase of the accident crashes.

A complete traffic management procedure requires an adequate friction coefficient of the road surface pavement based on a specific minimum friction coefficient in a specific region considering changes in weather conditions. A steady minimum required friction of the roadway surface is mandatory. For this reason, an advanced understanding of the weather conditions which can affect the steady level of the friction is crucial to avoid obstacles in driving task operation on roadway. Weather condition data collection is a challenging task for infrastructure assessors specifically in real-time monitoring, and continues data acquisition. Different studies on the influence of the weather condition on road surface and friction has been conducted. Mainly water film thickness and air temperature are considered. In several studies a significant influence of the pavement temperature on friction is identified. In addition, mentioned research studies are based on data-driven from models or/and commonly used techniques such as Finite Element based models. Although, some researches present insignificant or low influence of temperature on road surface friction. Current methodologies are still in use for the purpose of the weather daily data collection on road pavements, a challenge is how accurate and efficient data are taken in term of daily data acquisition. In this study a novel weather sensor is applied to automatically monitoring big data in the daily form or monthly form related to weather changes and factors influencing road pavement surfaces.

In recent works, the use of intelligent road-based passive sensor is highly recommended due to the advantages of ability of big dataset storage, invasive technique, contactless, environmentally approachable and the real time automated data acquisition considering similar interval-time of adverse parameters.

1.2 Objectives and contribution

During the last decades various researches have been conducted by considering diverse techniques in order to define the effect of the weather conditions related parameters on road surface friction. This work focuses on a real case study of the eighteen months data-driven based on a commercially developed intelligent road-based passive sensor. Thus, weather data are collected considering time-interval and location of data acquisition station for current research case study.

The **main objective** of this research study is to present preliminary findings and results of a medium-size number of monitoring data on a real-case roadway system, and link to the followings highlighted points:

- Main objective: To monitor the road surface related data including weather condition and Friction coefficient of road surface on the real scale site based on the data driven from ice sensor in long term database,

- Sub-objective: Decision making tool to support road owners for the purpose of the traffic management procedures. To check with the minimum thresholds,
- The main link between weather condition factors influence on the traffic management procedures and friction coefficient thresholds.

The contribution of this work to the current knowledge is to understand how the consideration of the weather-related parameters can influence the friction stability. In order to provide a safe and reliable traffic management system it is crucial that the future friction measurement models take into account weather parameters.

2 CASE STUDY AND DATA COLLECTION

Intelligent road-based passive sensor is one of the innovative technologies to monitor the meteorological factors in the traffic road pavements. This sensor is installed towards the vehicle moving direction.

Data acquired for this research work is conducted for the purpose of the enhancing the resilience of the road transport infrastructure in the framework of the European project called PANOPTIS; aimed at increasing the resilience of the road transport infrastructures and remaining in safer and robust conditions during unfavorable conditions (Panoptis 2021). Data are acquired for eighteen months (starting December 2019 until June 2021) using intelligent road-based passive sensor.

This case study is conducted in the Spanish on-site highway located in Guadalajara province which connects Madrid city to Barcelona city. The length of the highway is about 77.5 kms (See Figure 1) with four lanes (two each traffic direction). Weather condition in mentioned zone can be severe and long winter session (temperature is commonly decreasing by $\sim 3^{\circ}\text{C}$) and hot and dry summer session (temperature is commonly increase to $\sim 50^{\circ}\text{C}$). The selection of this case study is based on three main reasons:

- The importance of the A2 Highway between two main and largest Spanish cities (Madrid and Barcelona).
- Diverse weather conditions.
- Road transport infrastructure age, and current health condition concern to public.

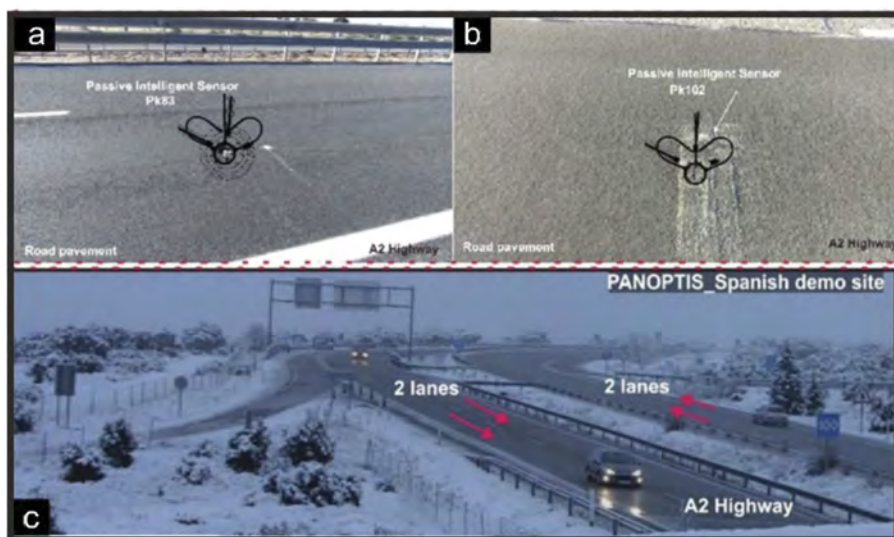

Figure 1. View of the case study in Spain; (a) Intelligent road-based passive sensor at station PK83, (b) Intelligent road-based passive sensor at station PK102, and (c) Spanish case study (adapted from previous work of authors [30]).

3 INFLUENCE OF WEATHER CONDITIONS ON ROAD SURFACE FRICTION

3.1 The relation between road surface friction and weather-related parameters

Safe highway pavement to serve a reliable transportation of humans and goods is crucial for further economy growth. Understanding the pavement friction and factors affecting the operation of surface pavement texture is key in order to provide a safe, comfortable path for transportation operations. In this section, weather conditions factors are investigated by means of weather intelligent road-based passive sensor.

Weather data are collected during eighteen months in a selected A2 highway case study in Spain (see Section 2) for better understanding the influence of weather factors (e.g., ambient temperature, pavement temperature, ice temperature, ice possibility, water film thickness and road conditions) on pavement friction functionality and to further explore influence of each parameter individually on pavement friction. Various minimum thresholds are considered in the literature for a safe friction coefficient operation in road pavements. Generally, a safe and optimal standard friction coefficient is considered in a range of 0.80 in normal conditions (Rasol 2020), and these range is also considered by Spanish authorities in this case study. Figure 3 presents the influence of (ambient or (in another meaning is air temperature and pavement temperature) on the pavement friction. Ambient temperature alone could have slight influence on the friction of the road surface as shown a group of measurements in the square, which friction keeps in a normal range. In addition, during winter season with a decrease in ambient temperature in-between (0 - 10 °C), pavement friction decreases up to 0.58 according to the data collected in this case study this could be not only because of the ambient temperature but interaction with other weather condition for example the presence of temperature of ice layer/ice temperature or water on the road surface (see Figures 2a and 3a, b). On the other hand, Figure 3. b presents a similar reduction in pavement friction during winter season when pavement temperature reaches a low range of (0 - 10 °C) This could be also partially related to the possibility of ice and rainfalls due to the accumulation of water on road surface.

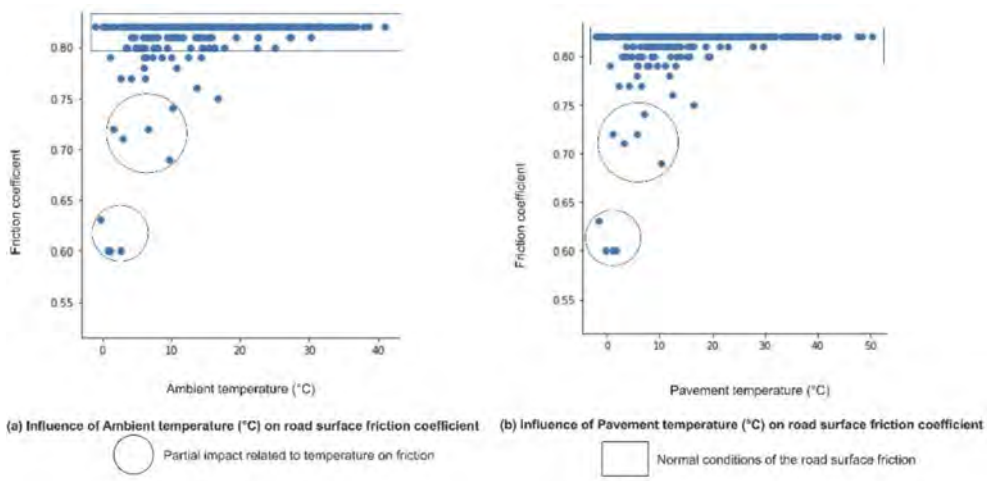

Figure 2. Influence of temperature on road surface friction: (a) Ambient temperature (°C), and (b) Pavement temperature (°C).

Figure 2 presents the data collecting related to two other main weather factors, namely ice temperature and possibility of ice on the surface pavement. In respect of the low ice temperature the friction coefficient decreases up to 0.6. (see Figure 3a). However, the existence of ice possibility (ice layer distribution percentage) on the surface pavement lead to a significant dropping of the friction. For instance, in the winter when ice possibility reaches

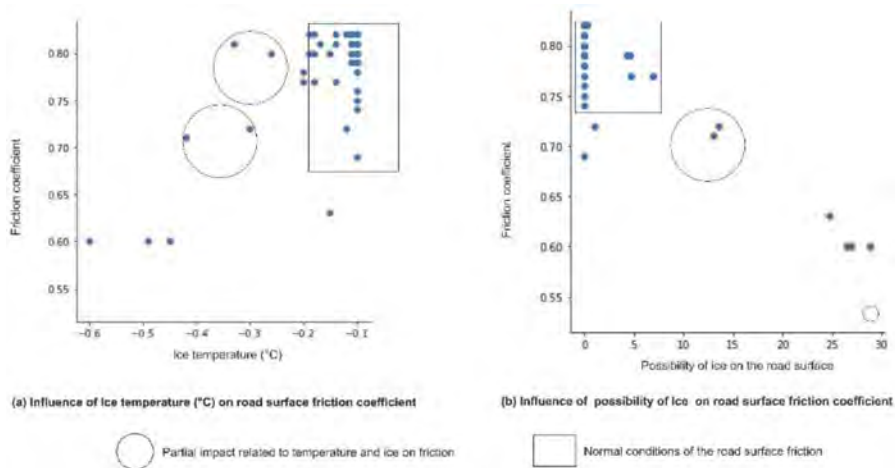

Figure 3. Influence of (a) Ice temperature (°C), and (b) Ice possibility on road surface (%) on road surface friction.

to 30% the friction decreases to 0.24, which is unacceptable threshold according to different standards. For this reason, in similar cases usually de-icing and de-salting plans (Trenouth 2015) are employed in order to guarantee road user's safety (see Figure 4b, small circle in the right).

Water film thickness is one of the main weather conditions factors occurring after a rainfall, which can significantly influence the reliable functionality of the road pavement friction. An increase of water film thickness could cause a decrease in the road surface friction. Figure 3a show the increase in water film thickness would cause decrease in pavement friction coefficient: when water film thickness reaches 1250 (μm) surface pavement friction decrease up to 0.55. Additionally, road conditions (e.g., dry, moist, damp, ice covered, snow and chemically wet) can influence the reliable transportation of goods and people in road pavements. Figure 3b shows during damp (moist) and wet road condition (coding represents in-between 20-255, which is a mix of water and conditions of ice, which is considered wet condition), this is the most frequent condition when friction decreases. In a case of chemically wet or contaminated road pavement surface (see Figure 4b, horizontal axis 35) friction dramatically reaches unsafe value which is 0.24, this could be also partially related to the existence of possibility of ice (Figure 2b).

Figure 4. Influence of (a) Water Film Thickness (μm), and (b) Road conditions on road surface friction.

Table 1 shows some critical condition in the different periods of the year including winter and summer season, the relevant and partial influence or more precisely the interaction between two parameters can be observed. For instance, in the point 4 (P4) during winter ice possibility is around 24.76 and water film thickness is 88.49 μm which decreases friction coefficient to 0.63. Here, probably the interaction between ice and water influences the road surface friction. More researches are needed in order to find the interaction between parameters and their influence on the friction.

Table 1. Critical weather conditions for some specific points (not all data) on the Spanish case study.

No.	Time	Season	Friction coefficient	Water Film thickness (μm)	Possibility of ice on road surface	Road condition (see Table 3)
P1	2019/12/20 00:00 - 2019/12/20 23:59	Winter	0.69	559.45	0.00	17.36
P2	2020/03/31 00:00 - 2020/03/31 23:59	Winter-Spring	0.72	403.39	1.00	22.90
P3	2020/05/31 00:00 - 2020/05/31 23:59	Spring-Summer	0.53	1275.32	0.00	20.00
P4	2021/01/08 00:00 - 2021/01/08 23:59	Winter	0.63	88.49	24.76	19.70

3.2 Pre-assessment thresholds and possible action of road surface friction

According to the current procedure, the friction coefficient is monitored in a non-steady basis to ensure the good state of the road surface for drivers, but it does not consider the effect of climatic conditions. This study introduces the effect of the climatic condition on friction coefficient.

Even though the road surface should remain in a good state according to the squid resistance standards, but it is useful to be aware about the effect of climatic conditions in instantaneous friction coefficient. In order to use this valuable information as input when making decisions on instantaneous traffic management (e.g., control of maximum velocity).

For this reason, defining possible thresholds of road surface friction value with potential actions based on different condition is essential. As a consequence of this study and considering local authorities' thresholds for traffic management system, three main thresholds are defined for this specific case study taking into account the global standards of the most stable friction coefficient.

Table 2 presents thresholds of the friction with possible actions of monitoring of road pavement associated to thresholds of friction coefficient.

Table 2. Thresholds of the friction with possible actions of monitoring of road pavement associated to thresholds of friction coefficient.

No.	Thresholds (Friction coefficient)	Conditions	Possible actions	Monitoring level
1	0.30	Critical	An urgent action is needed (e.g., maintenance)	Intervention level [20]
2	0.60	Acceptable low	Frequent monitoring and traffic management plan (TMP) e.g. control of maximum velocity	Intervention level [20]
3	0.80	Optimal	Normal TMP	Investigatory level [20]

Table 3. Summary results of the influence of the critical weather conditions on road surface friction.

No.	Road surface	Weather conditions	Critical values	Surface friction	Friction Reduction Percentage (%)	Figure
1	Temperature	Ambient (°C)	-3	0.59	26.25	3.a
		Pavement (°C)	-2	0.58	27.5	3.b
		Ice (°C)	-0.5	0.58	27.5	4.a
2	Conditions	Possibility of ice on surface	80	0.24	70.00	4.b
		Water film thickness (µm)	1250	0.55	31.25	5.a
		Road conditions	35	0.24	70.00	5.b

4 CONCLUSIONS AND FUTURE WORKS

Reliable road pavement is dominant infrastructure for both human safe transportation and economy growth, specifically with a vast growth in the traffic management system in Europe and worldwide. In order to provide a comprehensive knowledge on road system network various factors should be taking into account (e.g., weather conditions, pavement texture, human behavior, lighting and visibility, signals and road marking, safety instructions). In this research paper, the influence of weather conditions on road surface friction is investigated by means intelligent road-based passive sensor. This work concludes that the relation between several weather condition related factors on the road surface friction in real scale case study. The final remarks for this preliminary study are:

- The use of intelligent road-based passive sensor for 18 months weather condition data related recorded in a real scale case study in Spain. The relation between weather condition, road surface friction is presented in this work. Results show that the most reliable friction coefficient thresholds alarms are considered by Spanish authority, and previous knowledge is 0.80 optimal friction coefficient, which is considered standard condition. On the other hand, a frequent monitoring of the road surface is essential when the friction coefficient decrease to less than 0.60, and less than 0.30 could be considered an urgent condition (see Table 2), and in this case an urgent maintenance of the road surface is needed, specifically in case of extreme weather condition such as ice or snow.
- The most extreme weather condition factors (the weather factors which can influence the road surface friction stability) have significant impact on road surface friction are the increase of ice-percentage and water film thickness on the road surface (see Table 3).
- Ambient (air) and pavement temperatures have slightly similar influence on road surface friction. Which can be considered as an in-direct factors or partially influence the road surface friction and accident rates.
- Beside other intervention factors can also affect the friction stability, which are age, texture depth, abrasion and other macro texture properties. This study has considered a preliminary finding of the main relation between road surface friction and weather condition related factors.
- This study provides a decision-making support tool for end-users, and owners/operators in charge of the operation of the road network. This model has been integrated to the holistic novel platform of the PANOPTIS project funded by European Union in order to increase resilience of road transport infrastructure.
- This work will be extended for future/and on-going project by using machine learning approaches. In the context of machine learning application for forecasting prediction of friction coefficient and use of real-time monitoring of friction coefficient.

Prediction of recovery time of infrastructure functionalities after an earthquake using machine learning

B. Derras

University of Tlemcen and University of Saida, Tlemcen, Algeria

N. Makhoul

Politecnico di Milano, Milan, Italy

ABSTRACT: The recovery time (RT) is one of the essential components of infrastructure seismic resilience analysis. This seismic infrastructure resilience is crucial to keep the functionality of critical infrastructure and recover them quickly during strong earthquakes. It is necessary to ensure that the RT is estimated beforehand. This RT depends on some factors (Derras & Makhoul 2022). We develop machine-learning empirical models for estimating the RT based on earthquake damage data to achieve that goal. Firstly, a dataset of earthquake damage was established. This dataset contains the metadata (explanatory factors), such as earthquake magnitude (M), Ground-Motion Intensity Measures (IM), as well as the recovery time (target). Using the more famous machine learning algorithms, we establish empirical models to predict the RT of a given system (gas, power, water, and Telecommunications). The best model must represent well the resilience curve with an optimal aleatory variability. The estimate early of the recovery time (here by machine learning approach) is essential information for authorities and a primary step in the infrastructure seismic resilience assessment.

1 INTRODUCTION

Prediction of recovery time of infrastructure functionality refers to the process of estimating how long it will take for infrastructure, such as roads, bridges, buildings, and utilities, to be repaired and restored to full functionality after an earthquake or other disaster (Cao et al. 2022). The recovery time prediction is based on various factors, including the earthquake severity, the infrastructure condition before the earthquake, and the availability of resources for the recovery effort.

There are several reasons why predicting the recovery time of infrastructure after an earthquake is essential: 1) It helps emergency responders and decision-makers allocate resources and plan for the response and recovery efforts more effectively. 2) It allows affected communities and individuals to better prepare for the disruption and plan accordingly. 3) It informs the prioritization of repair efforts, ensuring that essential services, such as electricity and water, are restored as quickly as possible. 4) It helps identify potential bottlenecks or challenges in the recovery process, allowing for proactive planning to address these issues. 5) It can aid in the development of contingency plans in case the recovery takes longer than expected.

Several methods (Cremen et al. 2020) can be utilized to predict the recovery time of infrastructure after an earthquake, including: a) Statistical models: Statistical models can be used to analyze data on past earthquakes and the recovery time of infrastructure in order to identify trends and patterns that can be utilized to make predictions about future recovery times. b) Expert judgment: Experts in earthquake engineering and infrastructure recovery can use their knowledge and experience to make informed estimates about the recovery time of different types of infrastructure. c) Machine learning algorithms: Machine learning algorithms can analyze a range of data, including data on the severity of the earthquake, the condition of the infrastructure before the earthquake, and the availability of resources for the recovery effort (Derras & Makhoul 2022) and (Durante & Rathje 2021). By training a model on data from past earthquakes, it may be possible to make more accurate predictions about the recovery time for future earthquakes.

Statistical models present several potential disadvantages to predicting the recovery time of infrastructure after an earthquake: i) Limited data: Statistical models rely on data to make predictions. However, there may be a limited amount of data available on past earthquakes and the recovery time of infrastructure. This can make it difficult to predict recovery times for future earthquakes accurately. ii) Assumptions: Statistical models often rely on certain assumptions about the data and the underlying relationships between variables. If these assumptions are not met, the predictions made by the model may not be accurate. iii) Limited flexibility: Statistical models are designed to identify patterns and trends in data and may not be able to accurately capture more complex relationships or unusual events. This can limit the accuracy of the predictions made by the model. iv) Black box approach: Statistical models can be difficult to interpret, making it difficult to understand why a particular prediction was made. This can make it challenging to identify any potential biases or errors in the model.

On the other side, there are several potential disadvantages to using expert judgment to predict the recovery time of infrastructure after an earthquake: α) Limited knowledge: Experts can only provide predictions based on their knowledge and experience. They may not be aware of all relevant factors that could impact the recovery time. β) Limited objectivity: Expert judgment is subject to personal biases and opinions, which can impact the accuracy of the predictions. γ) Limited scalability: Relying on the expert judgment can be time-consuming and may not be practical in situations where a large number of infrastructure systems need to be evaluated. δ) Dependence on a single source: Relying on a single expert for predictions can be risky, as the expert may not be available or may make an error in their evaluation.

Considering these inconveniences, we are choosing, in this study, machine learning algorithms as a powerful tool for predicting the recovery time of infrastructure after an earthquake, and they can provide a range of benefits in certain situations. There are numerous advantages to using machine learning algorithms to predict the recovery time of infrastructure after an earthquake: 1) Ability to handle large amounts of data: Machine learning algorithms can analyze a large amount of data, including data on the severity of the earthquake, the condition of the infrastructure before the earthquake, and the availability of resources for the recovery effort. This can help to identify patterns and trends which may not be visible to the human eye and can improve the accuracy of the predictions. 2) Ability to make accurate predictions: When trained on sufficient data, machine learning algorithms can make highly accurate predictions. This can be particularly helpful in situations where the recovery time of infrastructure is critical, as it can help to ensure that the necessary resources are allocated, and the recovery process is planned effectively. 3) Ability to continuously improve: Machine learning algorithms can be trained on new data as it becomes available, which can help to improve the accuracy of the predictions over time. 4) Automation: Machine learning algorithms can automate the prediction process, saving time and reducing the potential for human error. Overall, machine learning algorithms can be a powerful tool for predicting the recovery time of infrastructure after an earthquake and can provide a range of benefits in certain situations.

For example, researchers at the University of Texas at Austin and the Texas Advanced Computing Center used machine learning to assess the effectiveness of four common algorithms in predicting earthquake-induced damage grade and rehabilitation intervention in residential buildings (Sajan et al. 2023). The researchers used a dataset of 549251 buildings collected after the 2015 Nepal earthquake (Sajan et al. 2023). In addition, machine learning has been used to predict earthquakes in four different seismic zones (Japan, Turkey, Greece, and Indian Subcontinent) (Hoque et al. 2020). Researchers have also published data, models, and methods related to their research on natural hazards (Dubrow 2021), which can be used to refine machine learning models for predicting the recovery time of infrastructure functionalities after an earthquake.

The roadmap used in this study that allows estimating the downtime caused by an earthquake is summarized in the following: 1) Determine the scope of the analysis: First, you should determine the specific systems or infrastructure that you are interested in analyzing, as well as the time frame over which you want to estimate the downtime. 2) Collect data: Next, you will need to collect data on the location and magnitude of earthquakes, as well as information about the types and conditions of the systems or infrastructure that you are analyzing. This may include data on the material, design, and construction of the systems or infrastructure, as well as any past damage

or repairs. 3) Analyze the earthquake's impact: Using the data you have collected, you should assess the earthquake's potential impact on the systems or infrastructure that is of interest to you.

This may involve analyzing the damage that the systems or infrastructure are likely to sustain, as well as the time needed for repair or replacement. 4) Estimate the downtime: Based on the earthquake's impact on the systems or infrastructure, you should estimate the downtime the earthquake will cause. This may involve calculating the time needed for repair or replacement and any additional time required to implement contingency plans or bring the systems or infrastructure back to full capacity. 5) Validate your results: To ensure the accuracy and reliability of your estimates, it is essential to validate them by comparing them to real-world data or by using other methods to estimate the expected downtime due to an earthquake. This will help you confirm your analysis validity and identify areas for improvement.

2 DATA

2.1 *Initial dataset and basic evaluation model*

The dataset used herein is based on (Kammouh et al. 2018) dataset from 32 earthquakes all over the world (around 28% in USA, 31% in Japan, 3% in Africa, 6% in Oceania, 18% in South America, and 12% in Southern and Eastern Asia). The selected earthquakes occurred between 1960 and 2014 and has a magnitude ranging between 6 and 9. The affected lifelines are the power, water, gas, and telecom, and the downtime (DT) is reported for those infrastructures. The dataset detailed in (Kammouh et al. 2018), is an empirical dataset, and it was completed using (AI methods) and will be developed further for article (Derras & Makhoul 2024). In this article we consider the downtime DT in number of days similarly as the T_{AB} time needed for the infrastructure or here the lifeline to recover (Cimellaro et al. 2006) and (Bruneau et al. 2003). The Downtime DT is similar to the recovery time RT. The evaluation model with the initial dataset is very simplistic one and it rows with sophistications as we add additional input factors.

2.2 *Adding additional factors to improve data quality.*

Adding estimation factors as inputs to the machine learning model can help improve its performance by providing the additional information from which the model can learn. This process is called feature engineering, and it's an iterative process where different features are tested, and the most informative ones are selected for the final model. Before adding the estimation factors to the inputs, it is essential to understand how they relate to the output variable and if they can add value to the model. It's also important to preprocess the data and handle any missing or outliers' values. Once the estimation factors are added to the inputs, the model can be re-trained using the new data. The model's performance can be evaluated using metrics such as square correlation coefficient R^2 (in the cross-validation phase) and Root Mean Square Error (RMSE). If the performance improves, the new features are considered beneficial and kept in the final model.

The initial dataset has three factors system, magnitude, and PGA. Here we add and test four strong factors: Joyner-Boore distance (RJB), cumulative absolute velocity (CAV), EMS-98 (European Macro-seismic Scale), and global recovery time by country from the GEM platform. We use the neural networks technic as a reference model (B. Derras et al. 2012). As discussed in (Derras & Makhoul 2022), many other variables need to be considered such as the region wealth, man-power, season of the earthquake occurrence, the localization within a country etc. The first model here is a simplification and the full assessment is considered in (Derras & Makhoul 2024).

2.2.1 *Joyner-Boore distance (RJB)*

The relationship between Joyner-Boore distance and downtime after an earthquake is generally inversely proportional. The greater the Joyner-Boore distance, the less intense the ground motion is likely to be, and the less severe the damage to the structure or building is expected to be. This means that structures or buildings farther away from the earthquake's epicenter will have a shorter downtime after the event. Conversely, structures or buildings closer to the epicenter will experience stronger ground motion and are more likely to sustain severe damage, leading to a longer downtime.

2.2.2 Cumulative Absolute Velocity (CAV)

Cumulative Absolute Velocity (CAV) is a metric (that accounts for the amplitude, frequency, and time) used in seismic engineering to measure the total amount of ground shaking that occurs during an earthquake. CAV is a good indicator of an earthquake's damage potential, so that it might add and test in the current study.

There is a relationship between CAV and downtime after an earthquake, as a higher CAV value generally corresponds to more significant damage and longer downtime. The more damage an infrastructure sustains, the more repairs will be needed and the longer the downtime will be. Infrastructure exposed to higher levels of ground shaking will typically sustain more damage than those exposed to lower levels, which can result in a longer downtime (Figure 1).

Figure 1. The RJB function of peak ground acceleration (PGA) for an RSME equals 0.23.

2.2.3 EMS-98 (European macro-seismic scale)

The European Macro-Seismic Scale (EMS-98) is a scale used to measure the intensity of ground shaking during an earthquake. It denotes how strongly an earthquake is felt and the associated damage it causes. It is used to evaluate seismic intensity in European countries. It ranges from 1 to 10, with 10 being the highest level of intensity. There is a correlation between EMS-98 and ground-motion parameters such as peak ground acceleration (PGA, CAV). Still, there is no direct relation between EMS-98 and downtime after an earthquake: This is what we show next.

However, theoretically, there is a relationship between the EMS-98 and downtime after an earthquake, as a higher EMS-98 value generally corresponds to greater damage and longer downtime. Buildings and infrastructure that experience a higher level of intensity of ground shaking will typically sustain more damage than those exposed to lower levels, which can result in a longer downtime. The more damage an infrastructure sustains, the more repairs will be needed and the longer the downtime will be. It is worth noting that the EMS-98, potentially, is a good indicator of the damage potential of an earthquake with other factors, such as the ground intensities measured (PGA, CAV). (Zanini et al., 2019) suggested the following expression:

$$ESM_{98} = 2.03 + 2.28 * \log_{10}(PGA); \% \text{ PGA in gal} \quad (1)$$

2.2.4 Global recovery level

The Recovery/Reconstruction Potential Map is closely aligned with the concept of disaster resilience. Enhancing a country's resilience to earthquakes is to improve its capacity to anticipate threats, reduce its overall vulnerability, and allow its communities to recover from adverse impacts from earthquakes when they occur. The measurement of recovery and reconstruction potential includes capturing inherent conditions that will enable communities within a country to absorb the impacts and cope with a damaging earthquake event, such as the density of the built environment,

education levels, and political participation. It also encompasses post-event processes that facilitate a population’s ability to reorganize, change, and learn in response to a damaging earthquake.

3 METHODOLOGY

The correct prediction of downtime T_{AB} is crucial for evaluating the resilience of a system (The parameter systems are the considered lifelines (i.e., power, water, gas, and telecom)). that has been disturbed by an external force. T_{AB} is closely related to functionality Q , which is, in turn, dependent on various social, economic, and intensity measures of the earthquake and structural factors. A supervised machine learning model ((Derras et al. 2012), (Derras & Makhoul 2022)) can be used to establish a correlation between these factors and the T_{AB} . This can be done by using the factors as inputs and training the model to output predictions for T_{AB} . However, it is essential to state that the accuracy of this model will depend on the quality of data and the complexity of the model used. Preprocessing the data and adequately selecting the model architecture will help to improve the predictions. It is also essential to consider the factors that influence T_{AB} and to take them into account when building the model.

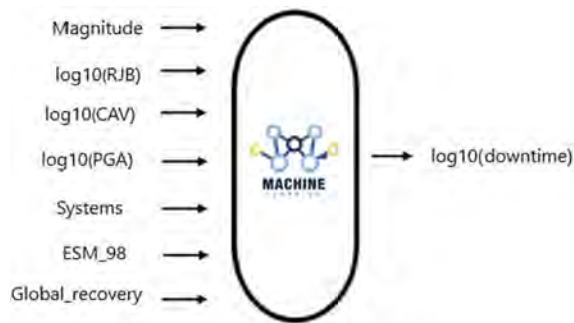

Figure 2. The Input and output factors of the machine learning final model.

3.1 Machine learning algorithms

The concept of Machine Learning (ML) was first introduced in 1959 by IBM scientist Arthur Samuel. ML is considered a subset of the broader field of Artificial Intelligence (AI), and it allows computers to learn and improve their performance without being explicitly programmed. ML algorithms can be divided into different categories based on their purpose. One category of particular interest is supervised learning, which involves training a model to map inputs to outputs based on example input-output pairs. In earthquake engineering, various ML algorithms are commonly used to extend classical regression techniques and eliminate the need for pre-defined functional forms. The following section presents some of this field’s most widely used ML algorithms.

4 COMPARISON BETWEEN SEVERAL MACHINE LEARNING APPROACHES

The correlation coefficient and Root Mean Squared Error (RMSE) are commonly used metrics to evaluate the performance of different machine learning algorithms. We can use these metrics to compare the performance of different machine learning algorithms like Tree Decision, SVM, Boosted tree, Gaussian-Process Regression, and Neural Networks. A higher correlation coefficient and lower RMSE indicate a better model fit to the data and better algorithm performance.

- **Linear Regression:** Linear regression is a supervised machine learning algorithm for predicting a continuous target variable based on one or more input features. It finds the line of best fit through the data points and uses it to make predictions. It’s a simple algorithm that can be useful when the relationship between the input and output is linear.

- **Decision Tree (DT):** A decision tree is a supervised machine learning algorithm that creates a tree-like model of decisions and their possible consequences. It's commonly used for classification and regression problems. It's simple to understand, interpret and visualize.
- **Support Vector Machines (SVM):** The SVM is a supervised machine learning algorithm. SVM can be utilized for classification and regression problems. It's effective in high-dimensional spaces and can be used with a non-linear boundary using the kernel trick. It finds the best boundary between different classes by maximizing the margin, i.e., the distance between the closest data points of each class and the boundary.
- **Boosted Tree:** Boosted tree is a supervised machine learning algorithm combining multiple decision trees to improve the model's overall performance. It iteratively adds decision trees to the model and adjusts the weights of the trees to minimize the overall error. It's a powerful algorithm that can handle large datasets and complex relationships between inputs and outputs.
- **Gaussian-Process Regression:** Gaussian Process Regression (GPR) is a supervised machine learning algorithm based on the theory of Gaussian processes. It's a non-parametric approach that can model any continuous function and makes predictions by computing the probability distribution of the function's values at any point. GPR is useful for problems with small datasets or complex relationships between inputs and outputs.
- **Neural Network:** Neural network is a supervised machine learning algorithm that is inspired by the human brain structure and function. It's composed of layers of interconnected nodes, called neurons, that process information. Neural networks can be used for various tasks, natural language processing, including image and speech recognition, and time series forecasting. They are particularly useful for handling large and complex datasets.

4.1 *Boosted tree ensemble method.*

The Boosted Regression Trees (BRT) is a combination of two techniques: decision tree algorithms and boosting methods (Sajan et al. 2023). Boosting is an ensemble meta-algorithm used in machine learning to reduce errors in predictive data analysis (Sajan et al. 2023) and (Dubrow 2021). It generates multiple weak learners and combines their predictions to form one strong classifier (Hoque et al. 2020) and (BCCVL 2021). In the case of BRT, each tree is dependent on prior trees (Dubrow 2021). The Boosted Trees Model makes predictions by combining decisions from a sequence of base models (BCCVL 2021). When to use a boosted trees model? It is useful when you have a large number of variables concerning the number of observations (Sajan et al. 2023) and (BCCVL 2021). Whereas decision tree algorithms are supervised learning approaches used in statistics, machine learning and data mining (Sajan et al. 2023). They use multiple algorithms to decide to split a node into two or more sub-nodes, increasing the homogeneity of each node (Dubrow 2021). Decision trees are an easy way to understand and interpret, require little data preparation, and have a low cost of predicting data (Hoque et al. 2020). Example of decision tree is where each leaf node corresponds to a class label, and branches to attributes (BCCVL 2021).

4.2 *Hyperparameter optimization*

Hyperparameter optimization for boosted trees involves tuning parameters such as the learning rate, the minimum number of leaves, and the number of learners to improve the model's performance. This is done here by (popular method) using Bayesian optimization techniques (BOT), which uses a probabilistic model to guide the search for the optimal set of hyperparameters. By using this technique, a probabilistic model guides the search for the optimal set of hyperparameters. We have obtained the following values: Minimum leaf size = 1, Number of learners = 1000, and Learning rate = 0.1. Moreover, we keep 20 % of all data for the validation phase to avoid an overfitting problem.

5 RESULTS

The results are presented briefly in Section 5.1 for the predictor importance and the final improved estimation using a machine-learning techniques (Section 5.2).

5.1 Predictor importance

The predictor importance (PI) chart aims to indicate the relative importance of every predictor in the model estimation. The sum of all the predictors relative values is 1.0 (or 100%). The PI does not express the model accuracy but reflects the importance of the predictors in prediction making. For the DT Machine Learning model we suggested, we obtained as show in Figure 3 that the systems (i.e., lifelines) are the most important predictors (around 60%), followed by CAV (15%), and the least important is EMS₉₈ with 0% relative value.

Figure 3. The predictor importance for the DT machine learning model.

Figure 4. The residual downtime in days for: a) initial model and b) improved model.

5.2 Improve estimation by using a machine-learning technique.

To show how the machine-learning technique improved the DT estimation model, in Figure 4 the residual downtime in days is computed and compared for the initial model and the improved model. The residual downtime varied between -1.5 and 1.5 for the initial model and between -1 and 1 for the improved model, which is a noticeable improvement.

We also report in Table 1 the values of the simple metrics RSME and R². Namely, for the original model ((Kammouh et al. 2018) data and the improvement model ((Kammouh et al.

Table 1. Values of the simple metrics RSME and R².

Metrics (validation phase)	Initial model	improved model	improvement (%)
RMSE in log10	0.59	0.29	51
R ² in log10	0.07	0.53	757

2018) data + boosted data for this study). We can clearly see that it is a significant improvement of 51% (RMSE) and 757% when we consider R^2 .

6 CONCLUSIONS

The recovery time (RT) or its counterpart the downtime DT is an essential components of seismic resilience analysis of infrastructure. Thus, it is crucial to keep the functionality of critical infrastructure and recover them quickly during strong earthquakes.

In this article, we developed machine-learning empirical models for estimating the DT based on an earthquake damage dataset to predict the DT of the gas, power, water, and telecommunications lifelines. The machine-learning models used the most renowned machine learning algorithms. The model was increasingly, improved by adding additional factors such as RJB, CAV, etc. It was deduced that those factors can improve the DT model and that that the lifelines systems are the most important predictors followed by the CAV.

Condition assessment and management protocols for concrete infrastructure affected by internal swelling reactions: Challenge and research needs

R. Medeiros, A. Bergmann & L.F.M. Sanchez
University of Ottawa, Ottawa, Canada

ABSTRACT: Internal swelling reactions (ISR) are amongst the most harmful deterioration mechanisms affecting the durability, serviceability, and overall performance of critical concrete infrastructure around the globe. Over the years, several approaches have been developed worldwide to assess the condition and manage ISR-affected structures. However, several challenges have still been faced in the proper selection and efficiency of laboratory and field tools to assess the condition, along with rehabilitation strategies and management protocols to mitigate effects and extend the service life of affected infrastructure assets. This paper aims to conduct a thorough literature review on the topic, showing the recent developments and current challenges faced by engineers, infrastructure owners and researchers dealing with ISR-affected structures. In addition, it will highlight current research needs and future opportunities.

1 INTRODUCTION

Despite its limitations, concrete durability has been highlighted as one of the main reasons for being the world's most widely used construction material. Yet, a combination of factors such as design and severe exposure conditions may trigger deterioration, resulting in aesthetic, functional, and structural issues. Billions of dollars have been invested in maintaining and replacing critical concrete infrastructure worldwide. For instance, in North America, Canadian, US infrastructure requires a minimum investment of \$50 and \$70.9 billion, respectively (Hajjalizadeh et al. 2017; Omar & Nehdi, 2018). Thus, concrete infrastructure maintenance has been a topic of interest in many research investigations from both civil engineering material and structural perspectives; for example, the Robert-Bourassa/Charest overpass (Fournier et al. 2015) and Champlain bridge (Cartier Bridge, 2019).

Different distress mechanisms may affect critical concrete infrastructure; these mechanisms may be generated by external sources (e.g., fire, static overload, impact, chloride ingress, and carbonation) and internal sources (e.g., free and thaw, internal sulfate attack, alkali-aggregate reaction) (Blight & Alexander 2011). Although both sources may develop extremely aggressive damage in concrete and require expertise to be dealt with, it is agreed in the scientific community that deterioration caused by external sources is easier to manage since a) one may rapidly identify the occurrence of deterioration, b) there are several past literature works on the topic and, c) one may reproduce the deterioration process (and forecast future behavior) through accelerated tests in the laboratory that display quite acceptable outcomes. Nevertheless, the external sources may be considered well understood since they have been further investigated due to the possibility of rapidly identifying the damage mechanism, reproducing it in laboratories and advancing in numerical models to forecast the behavior.

On the other hand, internal sources of distresses are more complicated to assess since the first signs (i.e., surface cracking) may be influenced by several factors, such as the type and abundance of reactive aggregate present in the reaction (i.e., alkali-aggregate reaction - AAR) or the amount of sulfate and water available (i.e., delayed ettringite formation - DEF). Alkali content of the concrete, geometry of members, presence and arrangement of reinforcement, exposure condition, load and stress applied, and presence of other distressing mechanisms are also parameters that

may corroborate on initiating or maintaining internal damaging mechanisms. In addition, ISR mechanisms have been identified as distressing structures worldwide (Sims & Poole, 2017). Since its cause is intrinsic to concrete, there is no specific affected region that can be cleaned and protected or strengthened as per the protocols of corrosion and overloading. Hence, the management of ISR-affected critical infrastructures is vital for the structure owners in order to maintain the serviceability of pavements, dams, bridges, overpasses, and railroads. In this sense, to enhance the safety of the structure once distressed by ISR, at least two questions must be addressed: a) Which mechanism(s) is the main cause(s) of deterioration? b) what is the extension of the current deterioration? c) Is it possible to foresee the future of the structure?

In this context, a significant amount of work has been dedicated to diagnosing and prognosing ISR-affected structures, and few management protocols have been proposed. This paper focuses primarily on the management protocols proposed for critical concrete infrastructure in general purpose, with the aim of synthesizing current knowledge, demonstrating the current perspective of the topic, and then drawing attention to infrastructure management once distressed by ISR. Finally, the gaps in the state-of-the-art of ISR management infrastructures protocols are explored.

2 MANAGEMENT OF CRITICAL CONCRETE INFRASTRUCTURE

Several evaluation and management protocols are used worldwide for critical infrastructure, including bridges, culverts, tunnels, ferry berths, retaining walls, highways, pavements, and quays. Although each country has its management system adjusted to particular conditions, the protocols are based on fundamental concepts and follow a general framework.

Figure 1. General framework of a management system of critical infrastructure.

As seen in Figure 1, the management system structured into ten streams enhances the oversight of the information for each structure by gathering design drawings, calculations, material data, delivery protocols, former inspection protocols and reports, special investigations, repairing, strengthening measures, and available photographic documentation throughout the lifetime of the structure. In addition, this management system structure supports the planning and schedule of condition and structural assessment, deterioration prediction, lifecycle cost, and effectiveness of maintenance optimization. However, Helmerich et al. (2008) discuss the need for improvements in current management protocols, particularly early assessment of deterioration progress so that the cause can be appropriately identified. Accordingly, Sanchez (2014) establishes that diagnosis must consider the cause of the deterioration process (i.e., what has triggered the damage) and its extent (i.e., the point where the damage has escalated).

Figure 2 presents the management system, rating scale, and inspection frequency for distinct countries. One can notice that inspections are usually performed in fixed intervals. Moreover, Helmerich et al. (2008) comment that performing regular inspections of the most critical concrete infrastructure is sufficient.

Country	Canada	Denmark	United Kingdom	Japan	Germany	South Africa	USA	Norway	France
Rating scale	1 - 9	0 - 5	3 categories	4 categories	1 - 4	4 categories	0 - 9	1 - 4	1 - 3
Inspections frequency	1 - 2 years	5 years	6 years	5 years	6 years	3 - 5 years	2 years	5 years	3 years

Figure 2. Critical concrete infrastructure management systems for different countries (modified from (FHWA, 2005).

Generally, critical infrastructures are rated into three categories, which might be further split into nine subcategories: poor, adequate (fair), and good, based on the structure components' condition and functionality. The structure assessment is usually based on inspection results performed in

a specific frequency, ranging from 1 to 6 years. The inspections currently commence performing a visual routine inspection and depending on the results obtained, the frequency and approaches may change. The countries suppressed in this paper usually appraise critical infrastructure following a few approaches, such as visual inspection, non-destructive testing (NDT), structural health monitoring (SHM), and numerical modelling (Finite element - FEM).

Visual inspection: Visual inspection is the primary step of all existing critical infrastructure management protocols regarding assessment. Visual inspection relies solely on the inspector's experience, and this approach usually provides qualitative results and external structure characteristics (Hsien-Ke et al., 2017). Even though it is only the first step in managing critical infrastructure, visual inspection results have been the input parameters in deterioration models, such as damage description, photography, dimension of the elements under evaluation, and cracking pattern. Additionally, ISR signs, such as cracking propagation and orientation, discoloration, and presence or not of secondary products, shall be easily noticed at moderate damage degree.

Non-destructive testing (NDT): In the early stages of deterioration, non-destructive techniques may be used to correlate concrete properties with possible deterioration mechanisms. Also, stiffness and strength may be assessed, the moisture content may be examined, and hidden defects may be detected. Some management protocols recommend NDT during periodic surveys or when visual inspections indicate irregularities. The most used NDT tools to assess concrete infrastructure are chain drag and hammer sounding. Despite their convenience to be performed, they are not entirely reliable due to inherent subjectivity (Kot et al. 2021). Advanced NDT techniques can provide improved reliability, such as acoustic techniques (i.e., impact echo, ultrasound pulse velocity, surface wave), electro-magnetic techniques (i.e., ground penetration radar), electro-chemical techniques (i.e., half-cell potential, electrical resistivity, polarization resistance), thermal techniques (i.e., infrared thermography), and digital imaging (i.e., 3D optical evaluation, remote viewer camera, digital image correlation). However, these techniques have been questioned regarding their accuracy in evaluating ISR-distressed structures.

Structural health monitoring (SHM): Embedded sensors have been used to monitor structural response and detect anomalous behavior. Critical infrastructure maintenance systems may be assisted by these devices, which capture a variety of physical measurements related to loads, environmental conditions, and structural responses. Further, laser scanning may help monitor infrastructures' health and damage, and laser point clouds may be used to develop a condition rating system. Structural health monitoring systems can rate structural capacity or assess specific structural performance aspects (e.g., corrosion) over long periods (Güemes et al., 2020). Regarding ISR distressed structures, it is expected to monitor at least the internal temperature and humidity of the concrete, the deformations and cracking propagation.

Numerical modelling (Finite element - FEM): FEM may provide a more accurate structural response and condition representation than traditional methods of assessing structure health. In developing robust FEM models, the construction method, material properties, geometric accuracy, cracking, and creep in concrete are crucial factors (Gorga et al., 2020). In addition, by calibrating FEM with digital image correlation, critical infrastructures that display unusual behavior, such as defects caused by ISR, can be assessed long-term. The ISR FEM models are expected to provide the future behavior of the swelling process, along with, the displacement, and mechanical properties reduction.

3 MANAGEMENT OF CRITICAL CONCRETE INFRASTRUCTURE AFFECTED BY INTERNAL SWELLING REACTIONS

In North America, there are a few guidelines for managing critical infrastructure when affected by internal swelling reactions; due to the frequency of occurrence, these guidelines are more specific for alkali-silica reactions. In addition, the US department of transportation – Federal Highway Administration (FHWA) issued the Alkali-silica reactivity field identification handbook in 2011. This handbook refers to the CSA A864 (2000).

Although it has been applied to manage critical infrastructures in North America, this approach is solely a general descriptive step-by-step procedure to evaluate a structure distressed by ASR. Yet, it neither presents any threshold concrete properties or structural performance to determine

whether the structure is safe nor takes into consideration past experiences of affected structures to propose future recommendations.

3.1 Bérubé et al. (2005) management protocol

Bérubé et al. (2005) developed an extensive experimental campaign involving parallel field and laboratory investigations. As a result, they proposed a protocol for assessing and managing structures affected by ASR in Quebec (Canada). This protocol emphasizes that concrete expansion is the main criterion for determining whether action should be taken in a structure affected by ASR. Additionally, they established that the elastic limit of the reinforcement is reached when the concrete expands by 0.20%. Thus, the decision-making in this protocol lies in the expansion achieved, the current rate of expansion, and the number of years remaining before the reinforcing steels are yielded. The investigation strategy includes the following steps.

Visual inspection of ASR-affected critical infrastructure (Step 1): The first inspection must determine if the ASR is present in the studied structure. It may be determined based on the visible defects generally associated with this reaction.

Once ASR is probably the mechanism distressing the critical infrastructure, the investigation must move to step 2.

Crack readings and estimating the expansion attained (Step 2): For each component, surveys should be conducted on the most exposed areas since they are the spots where surface cracking will provide the closest estimates of volumetric expansion. For instance, barriers located under overpasses expanded more slowly than those directly exposed to the weather in the Quebec City region. It is recommended that the first crack readings be performed in the middle of summer and preceded by at least two days of sunshine. The crack measurements shall be separated by structural member type (e.g., column, slabs, and beam). Further, the direction of the surface accessed may reveal appreciable comparisons on the expansion development throughout the structure. The main criterion of whether an intervention is required lies in the expansion already achieved by the concrete, estimated either from the surface cracking (i.e., the sum of the crack opening per unit of length) or from the mechanical test, such as Stiffness damage test (SDT) carried out on specimens cored under the reinforcement.

Calculation of current expansion rate - %/year (Step 2): The calculation of the current expansion rate (i.e., expansion (%)/year) is based on the expansion achieved to date (i.e., in %/age - in years) and the ratio between the measured expansion rate (studs) and the estimated expansion rate from surface cracking.

Calculation of the number of years before yielding (Step 2): The present step consists of estimating the years the structure expansion may take to reach 0.20% at the current expansion rate estimated before, which may follow Equation 1. This expansion level (i.e., 0.20%) can be considered as the steel reinforcements have reached their elastic limit.

$$\text{years before 0.20\%} = \frac{0.20\% - \text{expansion achieved (\%)}}{\text{expansion rate} \left(\frac{\%}{\text{year}} \right)} \quad (1)$$

Analysis of the results and follow-up: In order to continue the evaluation, it is necessary to evaluate the results obtained in the previous step. Three possibilities are considered based on the age of the structure and the number of years that can elapse before there is yielding: (a) 15 years → Monitoring program I. (b) 5 to 15 years → Stage 3A and follow-up monitoring program II. (c) <5 years → Stage 3B and follow-up monitoring program II.

When the crack opening exceeds 0.3 mm, and corrosion is still limited, the following intervention is required: sand blasting the element surface and applying silane based penetrant sealants. Under these conditions, corrosion and degradation of the reinforcements will be prevented while the progression of ASR will be reduced. Additionally, if there is an imminent risk to the safety of the users of a structure, action must be taken.

Monitoring program I: When an expansion of 0.20% is not expected to be reached before 15 years, the follow-up program I shall be applied. It includes regular visual inspections every 5 years and cracking readings at the same spots.

Plot and minimum coring (Step 3A): Stage 3A consists of installation of studs, reading distances between plots, and minimum coring with petrographic examination and specific mechanical tests.

Metallic studs should be installed on the same sections as those used for the crack surveys (see step 2) but also on less exposed sections. In this stage, the concrete volumetric expansion is also of interest beyond the deterioration of the surface, leading to coring demands. Therefore, at least three specimens of 100 mm diameter and 300 mm length in the components showing signs of ASR must be cored from the most exposed places. Samples must be used for detailed petrographic examination and mechanical evaluation involving the stiffness damage test (SDT).

Following step 3A, monitoring includes an annual visual inspection, along with cracking and expansion surveys, at least three times a year. If necessary, other cores may be taken for physical (i.e., porosity) and chemical (i.e., alkalis, chlorides) analyses, as well as for specific mechanical tests (including pure tensile test) and expansion residual.

Plot and greater coring (Step 3B): Step 3B applies when an expansion of 0.2% is expected within five years. This step, which can be started immediately after steps 1 and 2, requires the coring of specimens to perform SDT, pure tensile strength, and residual expansion (i.e., at least one specimen kept at 38°C, >95% RH, soaked in 1N NaOH and two specimens kept at 38°C, >95% RH only in at humid air) for a minimum of 1 year. The monitoring, the petrographic evaluation, and the mechanical tests support the re-adjustment of the expansion rate; likewise, the residual expansion test estimates the expansion's plateau.

3.2 *Saouma et al. (2014) management protocol*

Saouma & Hariri-Ardebili (2014) extensively reviewed available public documents from the Seabrook nuclear power plant (NPP) located in the US once the structure has been reported to be suffering from ASR. Based on the available data and the knowledge of the essence of ASR (i.e., the behavioral monitoring records of existing structures affected ISR, and the laboratory testing experience up-to-date), the authors addressed the following management protocol.

Structural tests: Because of the differences between laboratory tests conducted on small samples and field tests and monitoring, structural tests are highly recommended. For instance, the Seabrook NPP was assessed by laboratory tests on structural elements designed to represent the real members affected by ASR. Along these tests, the affected elements were evaluated regarding their mechanical behavior and reaction development. In addition, laboratory testing was used to validate the numerical model.

Field measurements: In the authors' view, surface cracking measurements are of minimal significance since member confinement and reinforcement greatly influence ISR cracking. Hence, it is suggested that long-term monitoring of the dynamic elastic properties through an appropriate technique (i.e., pulse velocity, frequency resonant, and impact echo), the strains in the rebars (i.e., by simply scraping the concrete surface to install strain gauges), and surface deformation (i.e., using laser measurements) shall be performed. Further, the internal relative humidity and temperature measurements may support the accuracy of reaction propagation modelling.

Material testing: Regarding the material testing, it is suggested to conduct residual expansion according to Saouma (2013) to obtain the magnitude (i.e., plateau of the reaction) and the kinetics (i.e., the time required to reach a certain expansion level). The mechanical tests suggested are the tensile strength, modulus of elasticity, and fracture energy GF. If the mechanism identified is ASR, it is recommended that the compressive strength may be disregarded since it is the less affected concrete mechanical property.

Nonlinear finite element: The serviceability and safety of the structure shall be of the primary interest. Thus, the structural modelling must consider the deformation and crack, giving proper attention to the members' mechanical solicitation and correctly identifying if the member is under shear, tensile, or compressive. Moreover, the code must be validated before evaluating serviceability and safety. It is crucial to gain a holistic understanding of permanent deterioration displayed by the ISR mechanism, which may be obtained by correlating materials testing, structural testing, field measurements, and nonlinear finite element simulations. It is considered a dynamic process and, as such, must be updated every few years up until the lifespan of the structure is achieved.

The authors highlighted the complexity of evaluating ASR-affected structures and the demand for further understanding and managing critical infrastructure affected by ISR. Therefore, they suggested consulting available literature before conducting an affected structure assessment.

Furthermore, the authors emphasized that a proper structural evaluation must be carefully performed, considering the particularity of each type of structure. Finally, it was stated that ISR mechanisms present particular kinetics and just considering the worst-case scenario without modelling the affected structure behavior is no longer satisfactory. Hence, proper modelling and testing must be performed so that the safety and serviceability of the investigated structure may be estimated.

4 DISCUSSION

4.1 *Comparison of the management protocols*

Helmerich et al. (2008) and Omar & Nehdi (2018) noted that non-destructive testing (NDT) is not incorporated into most routine inspection procedures proposed for general evaluations. Even though these tools are very effective for monitoring deformation and differential displacement, there is no NDT technique available to diagnose ISR in the field, although some researchers suggest that they have proven to be reliable indicators for ISR progression (Swamy & Al-Asali, 1988; Saint-Pierre et al., 2007; Sargolzahi et al., 2009). However, most management protocols recommend that the structure evaluation starts with a visual inspection. It is suggested that the structural members be inspected closely, but the tools recommended first involve tapping the structural members with a hammer or making measurements by hand (MTO, 2008; CSA, 2019).

Aside from that, no consideration is given to diagnosing the mechanisms causing the damage to critical concrete infrastructure in any protocol of general purposes management. It is solely recommended to perform a visual inspection routine where critical concrete infrastructures are classified into three categories, purely qualitative and heavily subjected to the inspector's experience and point of view. Additionally, inspection frequency is insufficient in some countries to detect mechanisms, such as ISR (in some conditions), that can rapidly escalate and significantly distress structures. The recommendation, in the case of a structure deemed substandard or unsafe, is a local repair or strengthening.

On the other hand, the management protocols proposed for internal swelling reactions begin with a field investigation; however, there is no agreement about approaching the structure. Bérubé et al. (2005) recommend that the crack opening must be taken as one of the primary references to estimate the damage extent. In contrast, Saouma & Hariri-Ardebili (2014) suggest that the cracking measurement is doubtful since reinforcement and member confinement geometry heavily influence cracking from ISR. While Bérubé (2005) does not recommend any NDT test, Saouma & Hariri-Ardebili (2014) suggest using pulse velocity, frequency resonant, and impact echo. Moreover, the use of NDT is recommended by a few researchers (Swamy & Al-Asali, 1988; Saint-Pierre et al., 2007; Sargolzahi & Rivard, 2009), whereas their accuracy in appraising ISR-distressed structures is questioned (Sanchez, 2014; Sanchez et al., 2016). The first protocol (item 3.1) specific for ISR suggested that 0.20% concrete expansion is the safe threshold of the structure since the reinforcement yields at this deformation point. The second protocol (item 3.2) argued that ISR-induced tension might damage the reinforcement. Nevertheless, it is essential to highlight that a proper bond loss must be assessed since the ISR swelling takes place on a tridimensional scale, which is yielded by the reinforcement. Therefore, a bond loss is supposed to occur, releasing the rebars rather than over-stressing them.

Both ISR protocols suggest that residual expansion must be conducted, and the mechanism propagation rate shall be reassessed and updated over time. The first protocol suggests that the expansion rate may be estimated through the overtime surface cracking measurements. However, this rate is just a fragment of the real swelling since ISR mechanisms behave as explained by a sigmoid curve divided into four phases (Sanchez et al., 2014; De Grazia et al., 2021). It means that the expansion rate may increase or decrease depending on where the structure is on the expansion curve.

Apart from that, it is essential to mention that the approaches presented by the protocols used worldwide are descriptive and, at best, deterministic. However, it is well known that the structure behavior must be assessed and foreseen by robust deterministic or stochastic approaches, which is still not the case. With a deterministic model, future events can be calculated precisely without the involvement of randomness. However, to be precise, it requires a heavy amount of data, and different scenarios must be simulated and validated prior to implementation into the model. Further data

must be collected in order to be able to predict the outcome with certainty. However, stochastic models are capable of handling uncertainties in the inputs that are to be applied. In addition, stochastic models have the inherent property that their output will fluctuate based on the parameter values and the initial conditions. For example, the same initial conditions will produce a range of different outcomes depending on the parameter values and the initial conditions. This range of outcomes may enhance more timely decision-making compared to weak deterministic models.

4.2 *Research needs and opportunities*

Based on an overview of existing literature, it is clear that some research findings related to critical concrete infrastructure management protocols still require research and further development. For instance, there remains a significant gap between recent research and the protocols currently used to assess structures, as well as a lack of comprehensive investigations of applying the recently developed tools to appraise concrete structures distressed by internal swelling reactions. However, some of them have already been validated in the field. In addition, the relationship between the laboratory test used to assess ISR-affected concrete in the scale of laboratory and the behavior observed in the field has still needed to be adequately investigated to date. These highlighted gaps might be addressed by stochastic approaches, using the current data obtained in the inspections already carried out in critical concrete structures worldwide.

Stochastic approaches to managing critical concrete infrastructure involve using probabilistic methods to assess and mitigate risks associated with the structural integrity of the infrastructure. These approaches can be used to evaluate the likelihood of different types of failures or degradation, such as ISR mechanism, and to identify the most effective maintenance and repair strategies based on the likelihood and consequences of different failure scenarios. They can help decision-makers understand the likelihood of different outcomes and make informed choices about how to manage best and maintain the infrastructure. Some common stochastic techniques used in critical concrete infrastructure management may include:

- Monte Carlo simulation: This involves generating many random samples based on the factors that could affect the performance of the infrastructure, such as its age, design, environmental conditions, and presence of a distressing mechanism. The simulation helps to estimate the probability of different outcomes and can be used to evaluate the risks and benefits of different courses of action.
- Fault tree analysis: This uses logical reasoning to identify the various ways in which a system could fail and can be used to evaluate the risks associated with different courses of action.
- Reliability analysis: This involves estimating the probability of failure for different components of the infrastructure and can be used to identify vulnerabilities and prioritize maintenance and repair efforts.
- Risk assessment: This involves identifying, analyzing, and evaluating the potential risks associated with the infrastructure and developing strategies for mitigating or managing those risks.

With these and other stochastic techniques, decision-makers can make more informed choices about managing critical concrete infrastructure.

5 CONCLUSIONS

The main objective of the literature review investigation carried out in this study was to review the current protocols available to assess critical concrete infrastructure worldwide from a general perspective and those focused on internal swelling reaction distressed structures. The main conclusions of the above investigations are:

- Most general-purpose management protocols rely on unaided visual inspections based on qualitative rating classification of the structural condition;
- The general-purpose management protocols consulted do not address the diagnosis of the mechanism distressing critical concrete infrastructure;
- The ISR protocols do not agree on whether the cracking measuring supports the ISR field assessment;

- Modern NDT techniques may address the purpose of measuring the cracks to understand the swelling process. The embedded sensors and the laser scanning may replace the studs installed on the distressed structure surface. It would ensure the reliability of the results and strengthen structural health monitoring. Furthermore, using these techniques would enable the evaluation of the influence of the reinforcement on the tridimensional swelling, accurately identifying the yielding phenomena. In addition, valuable data for the modeling of ISR propagation, such as internal concrete humidity and temperature, may be monitored over time by embedded sensors;
- The lab tests and field tests must be combined to provide more correlatable results, which would increase the reliability of the monitoring process, and the results would converge in the same direction;
- Mathematical modeling must be on top of any management protocol since it is a powerful tool able to evaluate the structure's condition and foresee future behavior quickly. However, the models still need to be further enhanced;
- The descriptive qualitative rating systems and weak deterministic approaches must be improved by some stochastic approaches to strengthen the reliability of critical infrastructure management.

The efficiency of laboratory test procedures for assessing field performance of concrete against Alkali-Aggregate Reaction (AAR)

A. Bergmann, R. Medeiros & L.F.M. Sanchez
University of Ottawa, Ottawa, Canada

ABSTRACT: Alkali-aggregate reaction (AAR) is among the most harmful deterioration mechanisms affecting concrete infrastructure worldwide, impacting more than 50 countries. Over the last decades, numerous laboratory tests have been developed to evaluate the reactivity of aggregates and the effectiveness of supplementary cementitious materials (SCMs) to mitigate AAR. Among them, the accelerated mortar bar test (AMBT) and the concrete prism test (CPT) stand out and are used around the globe nowadays. However, in recent years, some discrepancies have been found between laboratory results (i.e., AMBT or CPT, especially AMBT) and concrete mixture performance in the field. Yet, these discrepancies have never been quantified. This work aims to critically review current laboratory methods for assessing AAR-induced development, followed by a comparison of performance (i.e., laboratory versus field) at distinct scales (i.e., laboratory specimens vs. field blocks and structures) and quantification of the risk associated with these tests to forecast AAR in the field.

1 INTRODUCTION

As one of the more harmful deterioration mechanisms affecting concrete infrastructures worldwide, the alkali-aggregate reaction (AAR) has been reported in over 50 countries. In hardened concrete, both types of AAR, alkali-silica reactions (ASR) and alkali-carbonate reactions (ACR), occur when dissolved alkali hydroxides react with unstable mineral phases (Fournier & Bérubé, 2000; Nixon & Sims, 2016). In order to evaluate the potential and avoid AAR in the field, several approaches and recommendations have been developed based on the three main reasons for its development: reactive aggregates, high alkali hydroxide, and moisture (Borchers et al., 2022; Fournier et al., 2018; Kawabata & Yamada, 2017; Oberholster & Davies, 1986).

Among the several testing methods developed in laboratories to assess aggregate reactivity and the effectiveness of supplementary cementitious materials (SCMs) in mitigating AAR, the accelerated mortar bar test (AMBT) and the concrete prism test (CPT) are among the most used around the globe (Fournier & Bérubé, 2000; Sims & Nixon, 2003). Based on these results, aggregates are then classified as non-, moderately, highly, and very highly reactive (ASTM C1778, 2022; CSA A23.2-27A, 2019). Nevertheless, a number of discrepancies have been documented in the past few years between the laboratory results (i.e., AMBT or CPT) and the actual performance of concrete mixtures in the field (Borchers et al., 2022; Custódio et al., 2022). Although the magnitude of these discrepancies has not been quantified, the amount of data regarding outdoor exposure sites has significantly increased (Borchers et al., 2022; Custódio et al., 2022; Fournier et al., 2016; MacDonald et al., 2012, 2012).

By studying parameters that have been identified in the literature as influencing the testing performance, it is possible to investigate several factors in depth, such as type of aggregates and binders, mix design aspects, pre-storage circumstances, and sample exposure conditions (Lindgård et al., 2012). In spite of this, current descriptive and, at best, basic deterministic approaches (ASTM C1260, 2022; CSA A23.2-27A, 2019) are not sufficient to predict the potential behavior of alkali-reactive aggregates since the field outcomes are influenced by several factors. Using stochastics and artificial intelligence methods may therefore lead to a faster diagnosis and

prognosis of AAR-affected structures. Further, it can accelerate the understanding of the risks associated when incorporating specific aggregates into new structures.

In this scenario, this work aims to critically review current laboratory methods for assessing AAR-induced development, followed by a comparison of performance between laboratory specimens and field blocks and quantification of the risk associated with current tests to forecast AAR in the field.

2 ALKALI AGGREGATE REACTION (AAR) AND TEST PROCEDURES

AAR is a destructive process in concrete, causing premature distress and resulting in serviceability reduction of concrete-affected structures. To initiate and sustain AAR in concrete, three conditions are required: reactive aggregate, high concentration of alkali hydroxides in the concrete pore solution, and sufficient moisture. It is recommended, however, to avoid AAR deterioration when designing new concrete, especially in critical infrastructure, by (a) establishing an adequate alkaline pore solution in the concrete; (b) acquiring the critical amount of reactive silica; and (c) defining the sufficient supply of water (Fournier & Bérubé, 2000; Nixon & Sims, 2016). Alkali-silica reaction (ASR) and alkali-carbonate reaction (ACR) are two types of AAR.

According to Fournier & Bérubé (2000), ASR occurs in poorly crystalline or metastable silica minerals and quartz-bearing rocks incorporating fine-grained quartz. In which alkali hydroxides attack the microcrystalline particles within the fine and/or coarse aggregates, transforming them into a viscous reaction product: ASR gel. By causing localized differences in free energy, water and ionic species diffuse into the gel. Internal tensile stresses increase with gel expansion, and cracking is displayed when localized pressure exceeds the tensile strength of concrete components. The result is extensive microcracking, allowing the gel to spread freely and gradually lose its expansive properties due to ion exchange with the paste's hydrates. Thus, concrete tensile strength and modulus of elasticity are significantly reduced by ASR, whereas compressive strength remains relatively unaffected until high expansion occurs (Sanchez et al., 2018).

There is an entirely different and still not fully understood damage pattern for ACR (Scaglione & Piercey, 2016), which produces cracks most frequently at cement paste and adjacent aggregate locations without the presence of secondary products (Alexander, 2011; Sanchez et al., 2015). As per some researchers, ACR expansion is a consequence of the dedolomitization process, more specifically due to the brucite ($Mg(OH)_2$) crystallization (Alexander, 2011; Fournier & Bérubé, 2000). In contrast, it has also been suggested that swelling may be caused by water adsorbing from intergranular clay materials in the matrix and new clay released in the dedolomitization (Beyene et al., 2013; Grattan-Bellew & Katayama, 2017). Nevertheless, ACR-susceptible aggregates are more concentrated in the southern edge of the Canadian Shield in the southern Ontario (Alexander, 2011; Fournier & Bérubé, 2000). Thus, ASR has been studied more among AARs.

In such context, the addition of supplementing cementitious materials (SCM) (e.g., fly ash, slag) has proven to mitigate ASR concrete expansion (De Souza et al., 2022; Lindgård et al., 2012; Thomas, 2011) since they reduce the pore solution alkali concentration to safe levels (Duchesne & Bérubé, 1994). Besides rate and amount (Swamy, 1991), the effectiveness of SCMs depends on their composition, aggregate reactivity, Portland cement alkalis, exposure conditions, and criticality of the structures (Thomas, 2011). Contrary to ASR, SCM is ineffective at mitigating ACR (Grattan-Bellew & Katayama, 2017; Scaglione & Piercey, 2016).

Nevertheless, new and existing aggregate sources must often be assessed for their suitability prior to use in concrete. In the past, it was believed that petrographic examination was enough to assess the alkali-reactivity potential when conducted by an experienced petrographer (Fournier & Bérubé, 2000). However, it has been explored that petrography examination may be used only as a first step to determine whether an aggregate presents AAR potential and further testing is required (CSA A23.2-27A, 2019; Nixon & Sims, 2016). In cases where silica and/or carbonate are identified, rapid screening tests (e.g., AMBT and Concrete Microbar Tests (CMBT)) are recommended to determine whether the aggregate is non-reactive, reactive, or potentially reactive. In addition, concrete expansion through Concrete Cylinder Test (CPT) is necessary if an aggregate is potentially reactive. While there are a few different test methods to assess AAR potential in aggregates, only the most used ones (Nixon & Sims, 2016) are summarized in Table 1.

Other tests have also been conducted, which usually are modifications of the methodologies presented in Table 1. Danish mortar bar tests, or TI-B51, are variants of the AMBT in which samples are stored at 50°C, and expansions are monitored for 52 weeks. Another variant is the Danish Chatterji method, which measures the degree of reaction between silica and KCl by checking the alkalinity with a non-reactive standard. Moreover, for concrete tests, the Norwegian concrete prism method (NCPM), which is similar to RILEM AAR-3, varies the concrete prisms' sample size (e.g., 100×100×450 mm³). AAR-4 Alt is a variation of RILEM AAR-4, with wrapped samples. German concrete method (GCM) suggests the evaluation of concrete prisms (e.g., 100x100x450 mm³) and cubes (300x300x300 mm³) stored at 40°C in a fog chamber for nine months. Finally, the Texas DOT CCT considers cylinder samples, typically used for compressive strength (e.g., 100x200 mm). The test can be conducted under different temperatures, 38°C, 50°C, and 60°C, and measurements are taken until 730 days. This method has shown that final expansion values in the 15th week are comparable to those in the 1-year CPT (Stacey et al., 2016).

Table 1. Laboratory test procedures for evaluating AAR development in concrete.

Procedure	Description
Petrographic examination (RILEM AAR-1)	Petrographic examinations can be conducted in fine-grained rock types and fine and coarse aggregate particles with the following objectives: (a) determine physical and chemical characteristics of the sample, (b) determine and classify sample constituents, (c) quantify sample constituents, and (d) compare aggregate samples from new sources with aggregate samples from other databases (ASTM C295/C295M, 2019). In general, the test depends on the nature of the aggregate and can be conducted by hand, under microscope, or by preparing thin sections.
Accelerated Mortar Bar Test – AMBT (RILEM AAR-2)	The purpose of AMBT is to quickly determine (e.g., 14 days) if aggregates are alkali-reactive through the expansion of mortar bars (i.e., AAR-2.1: 25x25x285 mm ³ or AAR-2.2: 40x40x160 mm ³) immersed in NaOH solution at 80° C. First, mortar prisms using 1:2.25:0.47 proportions of cement, aggregate, and water by mass are cast. After 24 ± 2 hours, the prisms are demolded, stored in moist rooms (20 ± 1 °C and RH≥90%) and initial length is measured. The specimens are placed in a sealed container coated with a 1M NaOH solution for 14 days at 80°C. Regular measurement of the specimens' length reveals information regarding the reaction's kinetics (Nixon & Sims, 2016).
Concrete Prism Test – CPT (RILEM AAR-3)	This method aims to assess the potential for alkali-aggregate reaction by regularly measuring concrete prism (e.g., 75x75x250 mm ³) expansion stored in warm (38°C) and high humid conditions (RH>95%) for 12 months. The method may be performed for two purposes: AAR-3.1 to assess the potential for alkali-aggregate reactive and AAR-3.2 to appraise the alkali threshold of a combination of aggregates. For AAR-3.1, prisms are made with high content of cement and the alkali content must be adjusted to 5.5kg/m ³ in order to promote further any potential for reaction. Further, pessimum effects should be assessed by either combining reactive fine and coarse aggregates or by combining the aggregate of interest with a non-reactive aggregate. For AAR-3.2 the alkali content may be adjusted between 2-5 kg/m ³ (Sims & Nixon, 2003).
Accelerated Concrete Prism Test – ACPT (RILEM AAR-4)	This method is a shorter version (e.g., 20 weeks) of conventional CPT, in which concrete prism (e.g., 75x75x250 mm ³) specimens are stored in a harsh environment to rapidly trigger the development of the ASR. To promote the potential for ASR development, the alkali content of the concrete also must be adjusted to 5.5kg/m ³ . Now the storage conditions must be 60°C of temperature and high humid condition (RH>95%). The swelling of the specimens must be monitored periodically for 20 weeks (Sims & Nixon, 2003).
Concrete Microbar Test – CMBT (RILEM AAR-5)	The ACR potential test method was proposed based on the AAR-2 method, for concrete bars (e.g., 40x40x160 mm ³) immersed in 1M of NaOH solutions at 80°C. Then, the kinetics of the reaction is monitored by regular measurements of the specimens' lengths over 14 days.
Field measurements	Cubes of concrete (e.g., usually 300x300x300 mm ³) are exposed to the outside environment. It is possible to measure the sample expansion by placing studs into the surface over a period. A crack width analysis is also performed on field samples.

3 CORRELATION BETWEEN LABORATORY METHODS AND FIELD RESULTS

In the last few decades, outdoor exposure sites have clarified the correlation between laboratory test methods and the performance of AAR-affected field concrete. Researchers have mainly evaluated the alkali-reactivity of concrete aggregates (Borchers et al., 2022; MacDonald et al., 2012) and investigated SCMs and lithium-based admixtures and supplementary cementing materials as mitigation approach for AAR (Custódio et al., 2022; Fournier et al., 2016; MacDonald et al., 2012).

Borchers et al. (2022) have conducted an extensive study evaluating the alkali-reactivity potential of thirteen aggregates, covering most types of reactive aggregates found in Europe. Field specimens (e.g., concrete cubes) were exposed for 15 years to eight different field sites; their expansions and maximum cracks were compared with laboratory specimen expansions tested according to currently used methods (AMBT RILEM AAR-2.1, AMBT RILEM AAR-2.2, CPT RILEM AAR-3, CPT RILEM AAR-4.1, GCM, NCPT, Danish mortar bar test TI-B51, Danish Chatterji).

In general, highly reactive aggregates expanded within the first six years, while moderately reactive aggregates expanded considerably slower. No cracking or expansion was observed in cubes containing non-reactive aggregate. When compared with the laboratory results, both AMBT versions (RILEM AAR-2.1 and AAR-2.2) reliably differentiated between non- and highly reactive aggregates and could identify moderately reactive aggregates in most cases. Conversely, CPT (RILEM AAR-3 and AAR-4.1) effectively distinguished between non-reactive and highly reactive aggregates. Yet, the RILEM test method AAR-4.1 was found to be more accurate than AAR-3 in detecting moderately reactive aggregates. Yet, the authors suggested assessing the samples after 20 instead of 15 weeks and agreed with RILEM's proposal to change the acceptance limit to 0.03%.

Moreover, in the study, the GCM did not identify moderately reactive aggregates properly, probably because of the fog chamber's higher alkali leaching rate. Compared with AAR-3 and GCM, NCPT showed the strongest correlation with cube performance. The effectiveness of NCPT would be related to the samples' size, which is slightly larger than the adopted by AAR-3, consequently due to less alkali-leaching. Lastly, the Danish mortar bar test TI-B51 proved to be successful for non-reactive and highly reactive aggregates but underestimated moderately reactive aggregates. Yet, the Danish Chatterji method produced equivocate results regarding the reactivity of aggregates.

Additionally, for over 30 years, Canadian researchers have implemented a very relevant comparative field and laboratory research program (Fournier et al., 2016). In 1991, it was initiated at CANMET to evaluate the efficacy of laboratory tests for reliably evaluating the potential alkali-reactivity of concrete aggregates and the efficacy of SCMs in preventing ASR. This study found that the CPT and AMBT reliably identified alkali-reactive aggregates. In the performance evaluation of concrete incorporating SCMs, it was found that the correlation between CPT and expansion of exposure blocks decreases over time, possibly due to alkali leaching and local environmental conditions at the exposure site. It was also found that by exposing the laboratory test prisms to alkalis and/or storing them at higher temperatures, correlations improved in some cases.

Another relevant project, a combination of the Norwegian R&D project and the RILEM TC 258-AAA activities, was launched in 2015 to correlate the results of field and laboratory investigations against ASR in concrete (Custódio et al., 2022). A total of 85 concrete cubes were manufactured and placed at ten different outdoor exposure sites situated in Europe and North America for the purpose of monitoring long-term expansion and cracking.

A high-alkali cement and a normal cement were used in this project, along with three coarse aggregates: an extremely alkali-reactive polymictic gravel from the USA, a highly alkali-reactive crushed aggregate from Norway, and a non-reactive crushed limestone from Portugal. Furthermore, selected concrete mixtures incorporated Fly ash Type F and Category A to evaluate SCMs' effectiveness in preventing ASR development. In addition to the concrete blocks, prism specimens were tested and evaluated with RILEM AAR-3.1 and AAR-4.1 over 205 and 28 weeks, respectively.

Regarding the study conducted by Custódio et al. (2022), current approaches graphically correlate the laboratory test results (Expansion 38°C CPT, in %) and field performance (Expansion field site cube, in %). One can notice different clusters and behavior among the different aggregates when performed in two different environments: laboratory and field. The three methods (NCPT, CCT, RILEM AAR 3.1) show similar behavior despite a few discrepancies between them. In the AAR-3.1 test method, expansion was higher than in CCT and

NCPT. However, it should be noted that the AAR-3.1 testing was conducted at a different laboratory than NCPT and CCT. Furthermore, air-entraining admixtures were not added to the concrete mixes performed at SINTEF. Overall, both laboratories obtained almost identical classification results using the same test procedure, RILEM AAR-4.1, despite using concrete mixtures with (LNEC) and without (SINTEF) air entrainment. This project is still in progress, and further results should be available soon.

4 CURRENT PROTOCOLS FOR ASSESSING THE POTENTIAL ALKALI-REACTIVITY OF AGGREGATES

Current approaches to determine the potential alkali-aggregate reactivity are proposed by CSA A23.2-27A (2019), ASTM C1778 (2022), and RILEM AAR-0 (Sims & Nixon, 2003). For all protocols, descriptive flowchart procedures are used either to validate the use of aggregates or suggest preventative measures. CSA A23.2-27A (2019) decision-making process starts with a geological examination of the aggregate, including rock type, formation, quarry name, and petrographic composition. Additionally, the first acceptance process relies on the aggregate meeting the CSA A23.1 (2019) specifications, specifically aggregate grading limits, uniformity, color, and particle shapes. Upon failure to meet these requirements, the aggregate must be rejected for use, further investigation must be conducted, or corrective measures must be adopted.

The following step in the Canadian standard, corresponding to ASTM C1778's (2022) starting point, involves evaluating the field history of the desired aggregate. The aggregate may be accepted if its performance in the field is satisfactory within the imposed parameters. To be more specific, the following items need to be considered: the cement and alkali contents in the field concrete must be the same or higher than the proposed new structure, exposed concrete must be at least ten years old, exposure conditions of the evaluated concrete must be as severe as defined for the proposed structure, the petrographic analysis must reveal that aggregates are identical in the existing and new structures, SCM implementation must be considered, and water to cementitious material ratio must be noted. When the desired aggregate lacks a history of field use or previous satisfactory performance but has differences between existing and new structures, a petrographic examination should be conducted in accordance with all the mentioned protocols.

A petrographic examination, the first step of RILEM AAR-0 (Sims & Nixon, 2003), can identify silica and/or carbonates in aggregates and classify them as follows: (a) Class I: very unlikely to be alkali-reactive, meaning the sample does not contain known alkali-reactive minerals or rock types, (b) Class II: alkali-reactivity uncertain, meaning neither Class I nor III is applicable, and (c) Class III: very likely to be reactive, meaning the sample contains alkali-reactive minerals or rock types in sufficient quantities to cause damage. Although RILEM AAR-0 (Sims & Nixon, 2003) indicated no further tests for Class I aggregates, it has been suggested that using solely petrographic results may be insufficient (CSA A23.2-27A, 2019; Nixon & Sims, 2016).

For both CSA A23.2-27A (2019) and ASTM C1778 (2022), the presence of carbonate rocks indicates that chemical analysis (e.g., CaO, MgO, and Al₂O₃ contents) are required. After comparing the limits with CSA 23.2-26A (2019) and confirming the possible expansion due to alkali-carbonate reaction, it is recommended to perform CPT. If the CPT expansion is within the established limits (e.g., 0.04% for CSA and ASTM after one year), aggregate can be used without preventative measures. The ASTM C1778 (2022) recommends avoiding aggregates when their alkali-silica reactivity exceeds standard limits, while CSA A23.2-27A (2019) states that aggregates should be classified as moderately (0.04% to 0.12%) or highly (>0.12%) reactive. For CSA A23.2-27A (2019), if ACR has not contributed to the expansion, the aggregate can be accepted; however, if the contribution has been confirmed, its extent should be determined by someone with experience in this type of reaction and further testing must be conducted, such as the CMBT.

If petrographic examinations do not reveal carbonated rocks, but ARS-potential exists, two options must be considered: (a) the aggregate may be accepted without further testing, but preventative measures should be taken considering an extremely reactive aggregate, or (b) further test, such as AMBT, must be performed. The aggregate can be accepted without AAR preventative measures if AMBT results in lower expansion than the established limits (e.g., 0.15% and 0.10% for CSA and ASTM, respectively). If AMBT is not satisfactory, CPT must be conducted.

In cases where standard limits are not exceeded, the aggregate can be directly used; otherwise, preventative measures are required.

5 RESEARCH NEEDS AND OPPORTUNITIES

Extensive experience has been gained using CPT in various forms, which has established it as a reference test nowadays (Sims & Nixon, 2003). For reliable results, CPT needs a longer evaluation period, up to 1 year, so other tests have been used, like AMBT, to provide results earlier, in 14 days. However, it has been observed that AMBT and CPT can show contradictory results when compared to each other (De Souza, 2022). Figure 1a illustrates the uncertainty when defining aggregates as reactive or not, based on ASTM C1778 (2022) limits of 0.04% and 0.1%, for CPT and AMBT, respectively. Since the proposed approaches may provide doubtful interpretations in this scenario, the reliability of test outcomes is questionable.

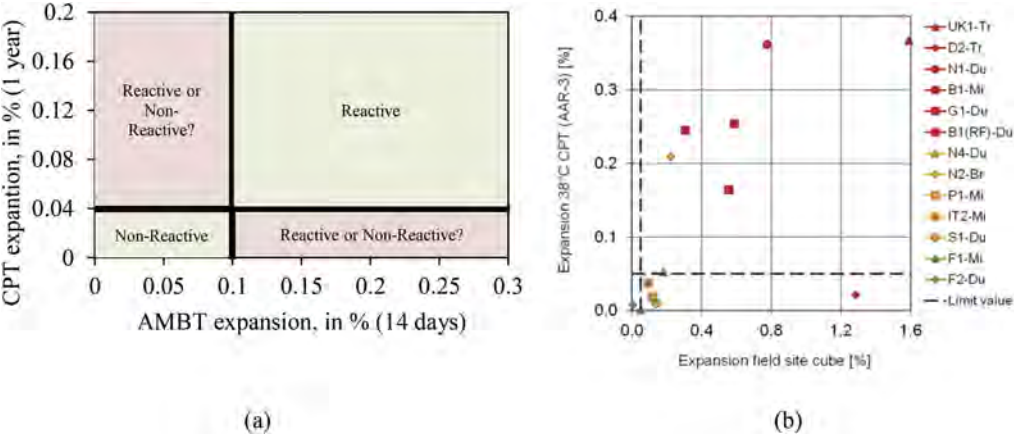

Figure 1. (a) Comparison between CPT and AMBT results (Authors, 2023). (b) Preliminary results from the Norwegian R&D project and the RILEM TC 258-AAA activities: correlation between field and laboratory investigations against ASR in the concrete (Custódio et al., 2022).

As seen in Figure 1b, field and laboratory results are presented comparing both observed expansions. Again, a proper correlation between short-term results (i.e., laboratory) and long-term field performance has not yet been demonstrated. Nevertheless, current approaches interpreting the extensive amount of data generated by outdoor fields are still descriptive and are not explored to predict future behavior nor explored to understand particular contributions of each variable in the final expansion.

As such, implementing anything other than a descriptive approach requires a large research effort with the aim of elaborating accurate predictions based on currently established methodologies. In this sense, the representation of laboratory tests may become more reliable in representing field conditions even though many variables interfere the outcomes. As a final improvement consideration, stochastic and artificial intelligence approaches can be used to enhance prediction and reduce the risk of false non-reactive results.

6 STOCHASTIC AND ARTIFICIAL INTELLIGENCE AS PROPOSED APPROACHES

Stochastic methodologies and artificial intelligence (AI) are being implemented in various fields, including civil engineering. Yet, lacking information technology (IT) human resources with a civil engineering background is related to a slow process of implementing such powerful tools to interpret data inputs (Pregolato et al., 2022).

In this sense, a few solutions can be explored to incorporate stochastic and AI approaches to enhance prediction and reduce the risk of false non-reactive results, such as using probabilistic

modeling, implementing Monte Carlo simulations, developing machine learning (ML) algorithms, and utilizing active learning tools such as Artificial Neural Networks (ANN).

By implementing probabilistic modeling, the outcomes would explore the probability of the occurrence of aggregate reactivity. It would better capture uncertainties regarding the risk of field AAR development that is dependent on the above-mentioned variables. Moreover, Monte Carlo simulations would be a useful tool for generating random samples in the probabilistic distribution, which would allow analyzing more variable combinations to better predict the AAR development on the field. Next, using current laboratory and field data would be sufficient to train machine learning algorithms and evaluate the risk of occurrence of AAR; this process would lead to better predictions and accurate decision-making. It could be implemented by decision analysis, such as decision trees or sensitivity analysis, by evaluating the variable's impacts. Moreover, active learning models, as the case of ANN, can be extremely suitable for pattern recognition and prediction. In this way ANN can be trained to identify a common pattern in data collected from laboratory methods and field measurements regarding AAR.

7 CONCLUSION

The main objective of the literature review investigation carried out in this study was to critically review current laboratory methods for assessing AAR-induced development and understand the context in which laboratory specimens and field blocks are being evaluated to quantify the risk associated with current tests to forecast AAR. The main conclusions of the above investigations are:

- It has been stated that it is necessary to consider not only the potential of an aggregate for AAR but also an assessment of the conditions under which the aggregate might still be used in an actual structure. Therefore, an outdoor exposure site is necessary to validate the effectiveness of performance laboratory tests used to select long-term prevention measures against ASR in concrete infrastructure in different environments.
- It has been observed that AMBT and CPT can show contradictory results when compared to each other. Therefore, complementary methods can be implemented to evaluate the data and propose accurate limits when correlating both tests.
- A proper correlation between laboratory methods and long-term field performance has not yet been demonstrated. Nevertheless, current extensive data on outdoor exposure sites are valid for implementing stochastic and AI to better understand and predict the future behavior of AAR development.

Digital twins for civil infrastructure: A case study on the Clifton suspension bridge (Bristol, UK)

M. Pregnotato, S. Gunner, E. Voyagaki, R. De Risi, G. Gavriel, P. Tully, N. Carhart, T. Tryfonas & C. Taylor

Department of Civil Engineering, University of Bristol, Bristol, UK

ABSTRACT: Validated digital Twins support the optimisation of the performance, life-extension, maintenance, design and full-life costs of infrastructural assets; however, in the Civil Engineering sector their actual application and technology is still largely at the development stage. This study advanced a framework for using Digital Twins for civil infrastructure, which could be applied to various assets. This paper applied the framework to the historic Clifton Suspension Bridge in Bristol (UK). This aim was achieved through the following objectives: (i) proposing a working framework applicable to various assets; (ii) applying the framework and developing the physical-virtual architecture for the case study of the Clifton Suspension Bridge (Bristol); (iii) reflecting and drawing lessons from the application. The novelty of this work consists in illustrating the step-by-step framework of twinning, which is not limited to a methodological perspective nor to a particular asset of civil infrastructure. In addition to the theoretical contribution, this work's importance also includes the case study itself, which ultimately offers a needed demonstration of the concept of digital twinning.

1 INTRODUCTION

The smooth running of modern cities is hugely dependent on our national and local infrastructure. Buildings, roads and bridges are key elements of communities and economies, affecting immediate through to very long-term performance and investment. However, climate change, aging and societal changes (e.g. urbanization) are threatening the functionality and integrity of these structures (Pregnotato, 2019). The risks involved are also exacerbated by disjointed infrastructure data and ad-hoc maintenance that often does not address a problem until it becomes a very costly fix, or a structural failure. As part of the UKCRIC (UK Collaboratorium for Research in Infrastructure and Cities) programme (<https://www.ukcric.com/>), this study explores how to ensure the resilience of infrastructure in the face of increasingly severe hazards, proposing an entirely new way of managing all kinds of infrastructure around the world: Digital Twins (DTs).

Digital twinning is the process of digitally replicating all the facets and features of a real-world object in a 3D computational model, whilst integrating real-world data such that it has an effect on that object (CDBB, 2020; Jones et al., 2020). This technique supports the forecasting of outcomes over broad timescales and the exploration of different performance improvement scenarios safely on a computer, rather than navigating the risks that would come with doing so in real life (Figure 1). Digital twinning has already seen widespread application in the manufacturing sector in the creation and design of new products, but it has been limitedly applied to civil infrastructure (Lamb, 2019; Pregnotato et al., 2022; Voyagaki et al. 2022).

Dang et al. (2018) suggested a 3D DT model for improving the maintenance of typical bridge structures, combining 3D, FE and damage models. Similarly, Ye et al. (2019) studies two railway bridges and the relative capabilities required for developing

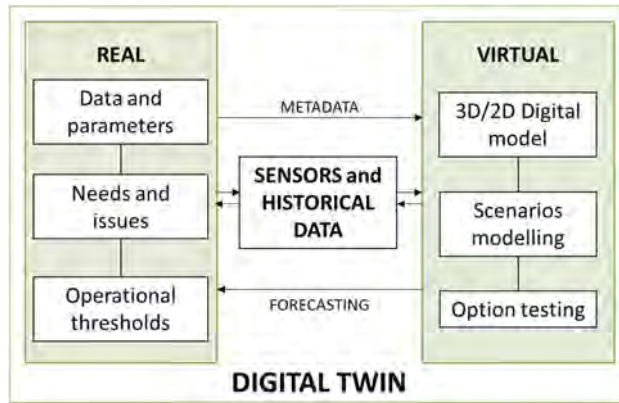

Figure 1. Digital Twin diagram.

a DT for structural health monitoring purposes. Also, Shim et al. (2019a) presented a DT-based model concept for bridge maintenance and more reliable decision-making; this work progressed into Shim et al. (2019b), who offered a DT model for a suspension bridge and stiffening girders, applied to a pilot for maintenance and automatic damage detection in Korea. Lu and Brilakis (2019) adopted cloud-to-cloud distance-based metrics to advance the automation of digital twinning for existing reinforced concrete bridges, using ten highway bridges around Cambridgeshire (UK). In the same geographical area, Lu et al. (2019, 2020a) developed a DT-enabled anomaly detection system for built asset monitoring to support operation and maintenance. They developed a process flow and a pilot for circulating pumps in a building's HVAC (heating, ventilation, and air conditioning) system, which was further extended by Lu et al. (2020b). Others have investigated the incorporation of real-time sensor data into BIM-like bridge models, such as Davila Delgado et al. (2017 and 2018).

This paper re-proposed the methodology of Pregnotato et al. (2022) (which is under a Creative Commons license), using the Clifton Suspension Bridge in Bristol (UK) as proof-of-concept (Figure 2). This work was developed in collaboration with the Clifton Suspension Bridge Trust and the engineering firm COWI.

Figure 2. The Clifton Suspension Bridge in Bristol (UK).

2 METHODOLOGY

The proposed methodology combines the DT “maturity spectrum” presented in Evans et al. (2020) and the five layers of Lu et al. (2020b). A framework of five actionable steps is advanced (Figure 3) and outlined below (Pregnotato et al., 2022).

(1) *Data and need acquisition.* This step consists of an enquiry into the ‘real’ structure, that elicits the information required for building and calibrating the virtual model. This step generates information about the operational processes used to manage a structure, clearly identifying the objectives and decisions that the DT will support, as well as the actions that provide the feedback between the DT and structure.

(2) *Digital modelling.* This step involves the creation of a ‘virtual’ ‘physics-based model that simulates, visualises, controls and models the behaviour of the structure (either in 2D or 3D). Depending on the purpose of the DT, multiple compatible models may be required. Open and well-documented interfaces must be created if the model is to become part of a federated ecosystem of connected DTs, and these should be considered during the design stage. The DT must be able to combine models and data (e.g. for calibration, validation, updating, etc.), requiring suitable model interfaces.

(3) *Sensor data transmission.* The collection of sensor data is the other element of the ‘real’ component of a DT. Suitable sensors (or observations) enable model validation and updating, while the data management elements facilitate automatic retrieval and processing. The sensing and transmission system must collect, transfer and store data, presenting it and its metadata through open interfaces for use by the integration framework. The necessary data quality (e.g. resolution and sample rate) depends on the requirements of the application and have an impact on the sensing and communications technology that can be used. The adoption of industry standards, both in technology and process, is also strongly advised as this will reduce design time and improve functionality.

(4) *Data/model integration.* A DT’s peculiarity is the link between the real and virtual. An interoperability architecture guarantees this connection, which should be flexible and agile (through open platforms and a modular design) to accommodate advances in technology and society. At a systems-of-systems level (where outputs from one DT become inputs to another), a scalable federation requires the adoption of yet-to-be-created standards, as well as governance frameworks that clarify issues of data ownership and service level agreements.

(5) *Operation.* To inform and enable effective and efficient asset management, actions should drive the purpose of a DT. A DT informs operational decisions when its outputs flow into the decision-making process, i.e. essentially by allowing comparison between the potential outcomes of a set of available actions, based upon available information.

The detailed five-step framework provides a process to create a DT by considering each of its components. The framework is applied to the case study of the Clifton Suspension Bridge (monitoring of the tower saddles) in Section 3.

3 RESULTS

The Grade I listed Clifton Suspension Bridge (Figure 2) in Bristol (UK) spans the river Avon and was completed in 1864, based on a design by I. K. Brunel. It constitutes an excellent example of legacy infrastructure, with obvious ageing and maintenance issues (Mitchell-Baker and Cullimore, 1988; Anderson, 2013) and no BIM data. The Clifton Suspension Bridge Trust (CSBT) is responsible for managing and maintaining the bridge; one of their concerns is the operation of the tower saddles, seizure of which may impair the bridge’s safety. Currently, sensor information about the saddles is presented to the bridgemanter in the form of periodic reports, whereas a system able to detect real-time changes in the friction of these saddles would allow managers to better quantify risk factors and select appropriate, safety and cost effective, actions. This demonstration focuses on this operational need.

(1) *Data and need acquisition.* Without BIM data to rely on, enquiry into the current state of the structure has included examining historical drawings and operational records from archives and site visits to inspect specific details in person. For this study, the Trust and the bridge consultant COWI facilitated data, the definition of needs, and the model validation. The tower rollers minimise the horizontal forces on the towers and land saddles from the chains, which would otherwise result from changes due to changes in loads and temperature, but this is only possible while the rollers move freely. If they seized, large forces could be

Figure 3. The five-step framework to develop a Digital Twin (e.g. for a bridge) (from Pregnolato et al., 2022).

transferred to the towers, which could significantly increase the stresses in the rock abutment. This abutment is a natural structure, so exact operational stress thresholds are not easy to identify. There is, therefore, an operational imperative to ensure that the frictional coefficient of the saddles is kept low. Understanding the change in the friction coefficient over time allows bridge management to schedule preventive maintenance and actions, e.g. lubricant application, or even bridge closure. The expansion and contraction of the chains due to changes in temperature were identified as providing the cause of the largest contribution to impact on the force applied to the saddles; thus, the bridge was instrumented with appropriate sensors (Figure 4). Temperature sensors measure the temperature of chain links while displacement transducers (located on each saddle, two in each tower) measure the saddle displacements. The strain on the chain links of one saddle in the East tower is measured by a single strain gauge. Finally, two weather stations and two weigh-in-motion machines, for measuring vehicle weights, are also in place.

(2) *Digital modelling.* A 3D FEM (Finite Element Model) of the bridge has been developed by the authors to numerically simulate the response of the structure under the loading conditions of interest (Figure 4). The software Midas Gen (Midas, 2020) was selected for initial FE modelling. The model has been calibrated and validated against two previous numerical models: the NODLE model (COWI, 2010); and 3D FEM model developed in ANSYS (Yeung and Smith, 2005). Comparisons against experimental results of some selected symmetric load cases presented by Flint and Pugsley (1955) generally show reasonable agreement. Modal analysis results show good agreement when comparing the vibration modes to available experimental data (Macdonald, 2008; BEELAB, 2003) using the Modal Assurance Criterion (MAC) (Allemang, 2003; mean MAC=0.973). Modelling and validation details are available in Pregnolato et al. (2022) and Voyagaki et al. (2022).

(3) *Sensor data transmission.* For this case study, the deployment is limited to the tower tops, where wired communications are provisioned. Regarding the strain gauges fitted to each

of the bridge side chain links, analogue to digital converters encapsulate the sensor measurements and publish them via IP to a server located at ground level in one of the nearby toll houses. The displacement transducers are functional to calculate the friction coefficient; the strain gauge provides the data necessary to calculate the friction estimation. A WSN (Wireless Sensor Network) deployment removes the need for provisioning wired power and communications on-site by relying on battery power and wireless communications technologies. The WSN gateway will receive the temperature readings and publish them to the local server hosting an InfluxDB time-series database instance. There are two layers at which the model and data interface: (1) the software layer, i.e. the model software's interface through which parameters can be modified, and the model invoked; and (2) the application layer, i.e. the interface at which the link "understands" the received input measurement (e.g. a temperature reading) and send back information about how to adjust the model eventually. Layer 1 enables the functionality of Layer 2. At a software layer, real-time integration between the model and sensors requires each functional block to have a set of computing interface (APIs) through which it can be interacted with. Technical details include that the sensors' API is provided by an MQTT message broker (MQ Telemetry Transport protocol), to which the ADCs and WSN gateway will publish their data. The DT software will subscribe to this data stream and so be passed any measurements received by the broker. The specific software package used for this purpose was the Lord MicroStrain MSCL Python API.

(4) *Data/model integration.* Different types of sensor data are present and need to be integrated. To enable this range of functionality, the model requires a sophisticated set of APIs. The DT software must be able to update the FEM by modifying the parameters of interest. For example, data from the chain strain measurements due to temperature change will inform the friction coefficient at the saddles. Features of interest are returned as software variables that the DT software can access. This study is currently at the exploratory stage and uses a simple software (Midas GEN); however, a more sophisticated software package, such as the OpenSeesPy library, allows models to be build and run in a Python environment. Before producing any output, the DT compares the modelled strain values with the recorded value to help provide confidence that the model parameters are correct. This comparison allows the system to generate an uncertainty value for the modelled output. Consistent or systematic discrepancy between the modelled and verified and validated measured values require the model to be updated. This updating is based on all the available information since any measurement (or set of similar measurements) could give huge uncertainty, especially for short records. The DT then combines the strain values with the relevant recorded displacement values to calculate the coefficient of friction for each saddle, which is the feature of interest. These coefficients are recorded in an InfluxDB time-series database so that historical trends can be created and values be presented to the infrastructure management.

(5) *Operation.* Historical records could enable the definition of operational thresholds, i.e. in this case the operational limit of the saddles friction of coefficient. Thus, engineering judgement is used to estimate what is a maximum safe strain on the back-span chains, and so at what value of friction a particular course of action must be taken. The DT can then report real-time and historic friction values and present rates of change, presenting the data through a dashboard. When the operational threshold is reached, a set of pre-defined actions or alerts are triggered, e.g. for maintenance or inspection of the rollers. For example, if the friction coefficient increases linearly over time, the validated DT information would prompt the infrastructure managers and operators to adjust maintenance schedule accordingly. On the other hand, more complicated scenarios can arise. For example, cold weather could increase the value of the friction coefficient since low temperatures affect the performance of the lubricant. In this scenario, weather forecasting data would allow the DT to predict what value of friction might be expected for those temperatures and allow maintenance when temperatures are mild and access is straightforward.

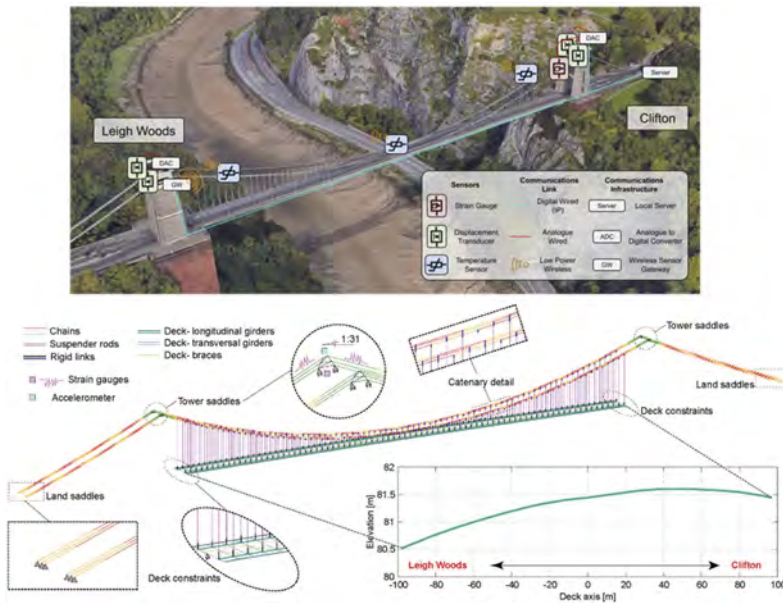

Figure 4. Top: an illustration of sensor deployment required for a DT which would serve for saddle monitoring (base photograph from Google Earth) for the Clifton Suspension Bridge. Bottom: the 3D FEM developed using Midas Gen platform.

4 DISCUSSION AND FUTURE RESEARCH

Digitalisation, and digital twinning in particular, will play a fundamental role in future infrastructure management, by driving the business case for investment and ultimately making structures safer and cost effective. However, DTs are heavily reliant on data. Data management and sharing is a delicate process due to privacy issues, and policies are needed to set standards and share data confidently. As owner and manager of the bridge, the Trust must sign a Data Transfer Agreement (DTA) which defines data and DT ownership, exchange and governance, e.g. stating explicitly which sorts of data belong to which organisation. This agreement relates to the contingency of academic research and, thus, also underpins any wider dissemination of data (e.g. via publication, presentation). In other contexts (e.g. industry), a DT would be run for and by (or under a contract for) the owner or operator, who decides on any agreements they make with any other organisations. Although infrastructure data is unlikely to contain any personal data (so not under the remit of regulations such as the EU's GDPR), it can still be extremely sensitive and not liable to open access. However, if the data are structured on *open standards* frameworks (which does *not* imply *open access*), they can be more readily integrated with other similarly structured data sets and be processed by tools that can ingest these structures, thereby opening up new, controllable, value creation pathways for the data owners and the data processors.

This study started to explore how valuable digital twinning can be in the built environment by developing a DT framework for civil infrastructure and applying it to the Clifton Suspension Bridge. More case studies are needed to demonstrate the viability of digital twinning, and the potential benefits. Future works could look into applying the framework to other structures, such as buildings or wind turbines. In the medium-term, there is also a clear scope for the integration of artificial intelligence and machine learning into the platform, which could help researchers identify novel threats or those forecast within a timeframe outside the usual monitoring period. In the longer-term, it is evident that no single DT will be sufficient for modern complex cities: in a smart city

scenario, independent validated DTs of various assets will need to communicate and cooperate, providing feedback to a central decision making “hub” or city-level decision makers. For example, the DT of a particular asset (e.g. a bridge) could be federated with the DTs of other related assets (e.g. roads). Finally, the fundamentals of the proposed workflow could be combined with other elements related to human health, safety and well-being, environmental sustainability and disaster/climate resilience. For example, a DT of an asset of interest (e.g. a building) could be used in relation to users’ health and wellbeing, by means of immersive reality and other tools.

5 CONCLUSIONS

The concept of Digital Twins (DTs) could potentially change the design, production, maintenance, and life-extension of civil infrastructural assets; however, more research is needed in order to accelerate this digital transformation. This paper has advanced a five-step framework for developing DTs for existing structures, which comprised: data and need acquisition (1), digital modelling (2), dynamic data transmission (3), data/model integration (4) and operation (5). The framework was applied to the Clifton Suspension Bridge (Bristol, UK), which was adopted as a case study. In the future, machine learning and AI could provide the DT with autonomous decision-making; in the longer-term, this bridge DT could be federated with the DTs of other bridges or related assets (e.g. roads). Some challenges were identified in the development and adoption of DTs, such as its transferability to other structures (e.g. wind turbines), data management and the business proposition (cost vs benefits) behind it. This paper’s importance resides in the knowledge challenge, value proposition and operation dictated by developing a DT framework for civil infrastructure, as well as the demonstration for an exemplary bridge which ultimately represents a relevant use case.

ACKNOWLEDGEMENTS

SHM analysis for damage detection using time series analysis methods

F. Schmidt & F. Chabi

Université Gustave Eiffel, MAST-EMGCU, France

J.-F. Bercher

Université Gustave Eiffel, LIGM, France

ABSTRACT: SHM is generally performed using continuous vibration or deformation monitoring. These signals correspond then to time series, whose evolution can be predicted based on their past history. This paper presents such a study on the Austerlitz bridge in Paris: it is a steel bridge, built during the 19th century, and carries the Parisian metro since then. The monitoring is therefore important to detect anomalies in its behavior. For that, it has been instrumented by 24 strains sensors (optic strands) and 4 temperature sensors, which record the corresponding signals during train passages at a 100Hz frequency. The individual passage signals have been extracted, the corresponding data has been gathered (data fusion) and cleaned. Finally, the evolution of the monitoring signals has been predicted based on their evolution with time and temperature. Machine Learning algorithms of type VARMAX have been used to realize the time prediction. The anomalies, defined as differences between the prediction and measured signals, have been identified. This paper will explain the context and the research questions, the work that has been realized and to finish the still-open points.

1 INTRODUCTION

1.1 Background

In France, 10% of the value of the road heritage comes from the engineering structures that are existing in the country (estimated at 200,000 to 250,000 bridges) (Patrick, 2019). This road network is used a lot since it ensures 88% of all trips for freights and people travels, which is why it plays an essential role in the communication and the economy of the country. However, a survey by the IPSOS institute has highlighted an increase in the rate of dissatisfaction of the French people, which has risen from 17% to 22% in two years (Patrick & Michel 2019). This follows the collapse of the Morandi bridge in Genoa in 2018, which revived the debate on the safety of engineering structures and the memory of the Mont Blanc tunnel disaster in 1999. This feeling may be justified when we know that a third of the bridges managed by the French State require repair, according to the Ministry of Ecological Transition and Solidarity in 2018, and that all metal bridges are in non optimal health condition. This leads to traffic restrictions or closures, which is detrimental to economic activity, the environment and the mobility.

This ageing of the French road network is perfectly normal and expected, since the theoretical lifespan of a bridge structure is estimated at 100 years. However, many bridges were built before the year 2000 and the introduction of European standards (Eurocodes, Eurocodes 1992), which means that their lifespan is less than the expected 100 years and tends to be around 70 years. Indeed, a large proportion of the structures were built in the post-war period, in the 1950s and 1960s, and should therefore reach the end of their life very soon and at the same time. This lifespan varies according to several factors such as the type of bridge but also global warming and environmental conditions which can lead, for example, to corrosion (see for example Île de Ré bridge), conditions of use (with the increase in road traffic, some advice of GPS to use the secondary network to avoid slowing down while it has been not designed to receive such loads), or the quality and regularity of maintenance.

The last point tends to be lacking as the inventory of bridges in France is complicated since the managers of some of them are not always known. Moreover, the monitoring of deterioration is only visual, which is far from sufficient to identify certain types of pathologies, such as corrosion, which develops inside the materials. There is therefore a need to address the problem further upstream. However, under-investment and lack of technical skills are a problem as small municipalities do not always have the means and skills to check the condition of their structures and maintain them. It is therefore necessary that the tools used are adapted to all, including local managers, since this emergency management of assets is not good maintenance practice and is neither sustainable nor economically viable in the long term.

A solution which is nowadays widely proposed is the intensive monitoring of structures, also called Structural Health Monitoring. Nevertheless, this monitoring may sometimes lead to (big) amount of data, which may therefore be difficult to be treated. More precisely, it might be difficult to extract pertinent information which would help the infrastructure manager to take decisions related to maintenance, repair, or strengthening actions (Tripura, 2000), (Salawu, 1997), (Seo, 2015).

1.2 *State-of-the-art*

Damage detection is traditionally done through vibration analysis, see (Burgos, 2020), (Lakhdar, 2013) for some examples in the civil engineering domain. Nevertheless, these methods are of various natures, depending on the focus they make, namely on eigenvalues (Belmokhtar, 2022) or eigenmodes, or the mathematical/algorithmic procedures for dealing with the fact that the actions on the structure are unknown (Sadhu, 2017), (Bandara, 2014). Nevertheless, it may be quite difficult to propose or use some criteria to decide if changes/damage in the structure have occurred (Jayasundara, 2019).

Therefore, with the development of bigger data volumes, new ways of detecting damages have been proposed (Rasol, 2023) (Wang, 2022): while some works use supervised learning methods (Zhou, 2013), some others propose unsupervised methods (Entezami, 2020). In particular, neural networks are used to predict future time series, and assess the deviation between this predicted data with the “real”, measured one (Manzini, 2021) (Xu, 2015). Changes can then be detected, also via pattern recognition (Yeung & Smith 2005).

It should be noted that other Machine Learning methods are sometimes proposed, like random forests (Zhou, 2013) and XG-Boost (Wang, 2022).

This paper proposes to predict the time series of strain sensors, using the theory of ARMA processes and comparing the predicted values with the measured ones.

2 THE AUSTERLITZ VIADUCT AND ITS MONITORING SYSTEM

The Austerlitz viaduct allows metro line 5 to cross the Seine between the Austerlitz station and the quai de la Rapée (Figure 1).

Figure 1. Photo of Austerlitz bridge.

The viaduct consists of two arches of 20 metres in span with three joints, one at the top of the arch and two at the abutments. This system creates an underpinning at the supports, the span of the arch is thus reduced from CC' to RR' , which is equivalent to going from 140

metres to only 107 metres. In addition, the ball-and-socket joint at the top allows the height of the arches to be reduced considerably.

Two masonry abutments are placed at the end of the arches, which are then cantilevered by 16.4 metres. The two ends of the half-arches are joined by a lattice brace on each side of the keystone.

Figure 2. Drawings of the Austerlitz bridge.

Today the Austerlitz viaduct is facing three major pathologies whose origins are still unknown. The first was reported in November 1998: a central hanger oscillated abnormally, by 7 or 8 cm laterally, while all the other lines had remained completely inert. This phenomenon was observed by technicians working on the track. The second pathology would impair the proper behavior of the bridge. Indeed, the male-female connections and the central connecting rod seem to be blocked. Finally, inspections of the bridge revealed the presence of numerous cracks at the attachment nodes of various lines.

2.2 Monitoring based on optical strands

The structure is inspected every five years with a gondola mounted on a train and visited by foot every year to prevent pathologies.

Since 2010, several types of structural elements are monitored using fiber strands sensors: these sensors and the corresponding data are denoted by S1, S2, S3, S4, S5, S6, S7, S8, S9, S10, S11, S12, S13, and S14 (in Figure 3) and listed in Table 1. In all, 14 strain sensors and 3 temperature probes have been installed. It is noted that among these 14 strain sensors, 8 sensors are installed at the level of the bridge deck, 2 sensors are at the level of the hanger, and 6 sensors are fixed at the level of the arch of the bridge.

Also, for any two nearby structures, stain sensor have been duplicated: This aims to see if these nearby structures have the same strain behavior as a function of time, when the metro passes.

The general conclusions while studying this data are:

- The support beams become longer because they are located under the deck, so they tend to bend.

Figure 3. Scheme of Austerlitz bridge, and the installed sensors.

- The anchor beam on the Austerlitz side lengthens because it tends to sag, whereas the anchor beam on the Rapée side shortens because it tends to lift.

Table 1. Name of sensors and corresponding structural elements.

Name of sensor	Monitored structural element
S1	Anchoring beam Austerlitz
S2	Braking tie-rod Austerlitz
S3	Upstream side beam
S4	Downstream side beam
S5	Braking tie-rod Rapée
S6	Inside bottom hanger
S7	Outside bottom hanger
S8	Lower arch
S9	Upper arch
S10	Low diagonal brace
S11	Transverse brace
S12	Diagonal brace Austerlitz
S13	Diagonal brace Rapée
S13	Anchoring beam Rapée

- The tie rods behave in the opposite way to the opposite to the anchor beams. The tie rod on la Rapée side becomes longer while the tie beam on the Austerlitz side undergoes a shortening.

The characteristics of these sensors in term of period and frequency of acquisition and number of the total data that are recorded by each sensor are various:

- For the strain sensors that are installed on structures S1, S2, S3, S4, S5, S6, S7, S8, S9, S10, S11, S12, and S13, the acquisition period starts from 01/09/2020 and ends 23/09/2021, which means that a whole year of measurement is available. For the sensor installed at S14, the acquisition started on 25/01/2021, which has as consequence that we will not be consider this sensor in the analysis. The acquisition of these sensors is triggered when the subway passes, and the acquisition frequency is 100 Hz. During the acquisition period, each of the 13 strain sensors recorded around 500 million points of data. It is noted that as the acquisition is done at the subway crossings, the recording is not continuous, therefore there exists missing data.
- For the 3 temperature probes, the acquisition started on the 01/09/2020 and ended on 23/09/2021, with one acquisition for 10 minutes. Each temperature probe recorded 56285 pints of data. They are installed on structures S8, S1 and S7, and denoted T1, T2 and T3 respectively.

Data processing has been performed with Python language, in Jupyter notebook, using libraries Numpy, Pandas, Scipy, Sklearn, seaborn and matplotlib. In this article, the study is focused initially on the analysis of data from different types of sensors (strain, and temperature) in order to understand how the different structures of the bridges behave in terms of strain when the subway passes.

3 DATA ANALYSIS AND TIME SERIES PREDICTION

3.1 Data analysis

Looking now at the evolution of the strain within the structures that are close (in space), we see that the trend is the same. The correlation matrix (Figure 4) shows that the strain correlation between:

- S1 and S2 is 0.88,
- S3 and S4 is 0.98,
- S6 and S7 is 0.91,
- S8 and S9 is 0.62,
- S10, S11, S12 is between 0.88 and 0.93. However, S13 is less correlated with S10, S11, and S12 with a correlation between 0.57 and 0.64.

Figure 4. Correlation matrix between all sensors (strain and temperature).

As the evolution of the deformation is the same when the structures are close, we have therefore selected to use only the data from the sensors S1, S3, S5, S6, S9, and S10 for the rest of the analysis.

3.2 Time effect removal

The strain within the majority of bridge structures is temperature dependent. It is therefore necessary to correct this effect of temperature, to see the other factors which can influence the deformation of the structures. To eliminate the effect of temperature, the proposed method is as follows:

- Calculate the correlation between strain and temperature values. If the correlation coefficient between the two parameters is close to 1, this means that there is a linear relationship between the two parameters (see Equation (1)):

$$\tilde{\epsilon} = A \times T + B \quad (1)$$

- Apply the Linear Regression prediction model to find the values of A and B of Equation (1) which gives the prediction line, i.e. the predicted strain values $\tilde{\epsilon}$.
- Calculate the difference between the real values of strain ϵ and the predicted one $\tilde{\epsilon}$ to obtain the time evolution of the strain values corrected ϵ_{corr} with no temperature effect.

Figure 5 shows the relation between the real values of the strain of structure S1 and the temperature at the same time: the relationship is linear, which confirms the value of the coefficient of correlation of 0.96 found by the correlation matrix (see Figure 4). The red line in Figure 1 is the predicted strain values $\tilde{\epsilon} = 0.077 \times T - 0.29$. Figure 6 shows the strain time evolution with temperature effect (right graph) and with no temperature effect (left graph): the measured strains are more stable (in amplitude) along time.

3.3 Time series prediction

For temporal signals, we can use ARMA, or ARIMA type models when the signal has to be derived as input. In our case, we have multivariate data for which we wish to use and explore the inter-sensor dependencies. We can then consider multivariate VARMA (Vector Autoregressive Moving Average) extensions. We propose here a variation around these models. We note $x(t)$ the vector of dimension d collecting all the measurements of the d sensors at time t . The model takes the form:

$$x(t) = A_0 x(t) + \sum_{k=1}^p A_k x(t-k) + c + \epsilon(t), \quad (2)$$

Figure 5. Relationship between strain at S1 and temperature values.

Figure 6. Time strain evolution at structure S1: measured value of strain (right), and corrected strain values with no temperature effect (left).

where matrices have dimension $d \times d$, c is a vector of offsets, and where matrix A_0 is constrained to have zeros on its diagonal. The role of A_0 is to take into account dependencies between signals (sensors) at the same time t . A LASSO regularization is used to stabilize the method and has the interesting property of forcing the coefficients of non-active variables to zero.

A prediction of $x(t)$ can be done according to:

$$\hat{x}(t) = A_0 x(t) + \sum_{k=1}^p A_k x(t-k) + c, \quad (3)$$

where $\epsilon(t)$ is the error or prediction residual. This means that a component j is computed as:

$$\begin{aligned} \hat{x}_i(t) &= \sum_{i=0, i \neq j}^d [A_0]_{i,j} x_i(t) \\ &+ \sum_{i=0}^d \sum_k k = 1^p [A_k]_{i,j} x_i(t-k) + c_j. \end{aligned} \quad (4)$$

A value at time t will be estimated as a function of the outputs of other sensors at the same time, and of all sensors outputs at previous timestamps.

For our experiment, we learn the model, i.e. we determine the coefficients, on a part of the data and compute the residuals on the whole data, which allows us to test the predictive capacity on data that have not been used for learning. The data are thus split into a learning part (from September 2 to May 17: two thirds of the data) and a test part (the last third, from May 18 to September 23, 2021). In order to test the capacity of the model to detect anomalies, we have introduced:

- An attenuation of 0.97 on AMPL-AS between the first and 14 of July,
- A factor of 1.05 on AMPL-TFR between 12 and 20 August.

For $p = 0$, the model only explores the interactions between sensors at the same time. In other words, the output of a sensor is only computed from the outputs of the other sensors at the same time. The coefficients of the sensors, and thus the dependencies they reveal, are given in Figure 7.

The residuals are computed, and we note that the introduced anomalies are correctly detected (the “boundaries”, related to the derivation, appear clearly between July 1 and 14 for AMPL-AS and on several other sensors, and from August 12 to 20 for AMPL-TFR). Other points are detected around February 10, when an exceptional freezing period is known to have occurred.

Figure 7. Coefficients of sensors for $p = 0$.

Figure 8. Residuals of prediction for $p = 6$.

For $p > 0$, the results are very similar. The coefficients associated with the time lags are small, and the improvement in the residuals remains tenuous (Figure 8). This indicates that there is in fact little temporal dependence between the samples; or at least that it has been removed by the initial derivation operation.

The predictions obtained show that the model allows to correct the effect of the artificially introduced defects (see Figure 9).

Figure 9. Prediction obtained for a defect on TFR and AS, for $p = 0$.

4 CONCLUSIONS

This work has shown a simple and yet effective method, using time series prediction, to detect changes in behaviour of structures. For that, the time series are analysed and simplified, first by considering only data which is non- (or less) correlated with other, then by removing the effect of temperature which is a big issue in civil engineering.

By experimenting on these data and introducing artificially anomalies into the measurements – which would simulate either a true structural anomaly or a sensor anomaly; we show that the regularised VAR statistical model learned on a portion of the data, is able to (a) detect anomalies on the unseen portion of the data, (b) correct the effect of these anomalies on the data; thus being able to compensate for a deficient sensor.

Future work are on the possibility to introduce physical/mechanical calculations in the analysis, especially for structures like Austerlitz bridge which are quite easy to model.

Effect of size on the shear strength between old to new concrete interface

S. Cattaneo & M. Scamardo

Department of Architecture, Built Environment and Construction Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The retrofitting of the existing RC structures with added concrete layer crossed by post installed rebars is strongly related to the behavior of the interface between the new and the old concretes. The overall strength of the connection depends on several mechanisms such as friction and dowel action between the two concrete layers as well as the type of loading. In the past, attention was given to understand these mechanisms considering several types of specimens, usually characterized by small dimensions. Nevertheless, it is well known that size effect is often crucial in concrete elements. In this paper, with reference to a specimen geometry already employed for assessing the shear strength between old to new concrete interface, the influence of the size effect on the overall response is analyzed. Based on the results of an experimental campaign, a numerical model is adopted and validated. Therefore, specimens with three different dimensions were numerically analyzed to define the suitable specimen size.

1 INTRODUCTION

Connections between concrete layers with different ages are very common in both existing buildings (i.e. repairing or strengthening) and in new buildings (e.g. connecting pre-cast elements) (Júlio et al. 2005). To ensure a reliable functioning of these connections, a quantifiable amount of shear strength at the interface must be mobilized.

The shear transfer mechanism between two concrete layers is a very complex phenomenon influenced by several interacting parameters (Mattock et al. 1975, Bass et al. 1989, Júlio et al. 2005, 2010, Santos & Júlio 2012, Cattaneo et al. 2021, Palieraki et al. 2021): (1) the quality, the strengths and also the thickness of the two layers (new and old); (2) the surface of the old concrete that could be smooth or artificially roughened; (3) the diameter of the reinforcement crossing the interface; (4) the reinforcement ratio crossing the interface; (5) the embedment length into old/new concrete; (6) external actions on the structure; (7) type of actions (monotonic/cyclic and the amplitude of the displacement); (8) the size of the shear interface. For these reasons, several research campaigns have been carried out in the past (Mattock et al. 1975, Bass et al. 1989, Júlio et al. 2005, 2010, Santos & Júlio 2012, Cattaneo et al. 2021, Palieraki et al. 2021) to evaluate the effect of each parameter and their interactions. Most of the studies were based on monotonic loading experimental tests, while in actual cases (i.e. bridge decks, jacketed columns) structures undergo reversal cyclic loading, e.g., due to fatigue or seismic actions.

For this reason, recently the European Organization for Technical Assessment (EOTA) introduced a new European Assessment Document (EAD) (EOTA 2021) that allows to evaluate the shear strength both under monotonic and cyclic actions. The EAD defines an experimental set-up to assess the shear strength (considering also reversal cyclic loads) that was designed to reduce the perturbative effects of the boundary conditions and of parasitic bending moments. Although the proposed set-up seems to be the most reliable (Cattaneo et al. 2021), the parasitic effects are not eliminated, and the specimen dimensions are relatively of large size with respect to the most common dimensions which usually range between 50 and 100 cm (with length from 30 cm) (Wieneke 2019), and require a significant experimental

effort. Nevertheless, it is well known that concrete is a quasi-brittle material, because the size effect could play a crucial effect in assessing the real shear strength (Biolzi et al. 2000).

The aim of this paper is to investigate the influence of the specimen size on the overall behavior. A numerical model of the specimen defined in the EAD (EOTA 2021) was developed and validated on the basis of experimental result. Two additional models were made considering reduced length of the specimen with respect to the length of the reference specimen (ratio between interface area/reference area 1:0.5:0.25).

2 EXPERIMENTAL RESEARCH

2.1 Test specimen and test set-up

An experimental campaign aimed at assessing the shear strength according to EAD (EOTA 2021) was carried out (Cattaneo et al. 2021), considering the geometry shown in Figure 1. The specimens were realized in two phases: the green block, casted first, simulates the existing concrete, while the grey block, casted at a second stage, represents the added concrete. The concrete strengths were evaluated at the time of testing on cubes (side 150 mm). The average compressive strength of the old concrete was about 28.4 MPa and of the new concrete was 32.1 MPa. The interface (area 200 mm x 500 mm) was crossed by three concrete screws (diameter 14 mm, length 150 mm, $f_{yk} = 690$ MPa). After three months from the first casting, the interface surface (500 x 200 mm) was artificially roughened with the use of an electric chisel by employing different bits. The average roughness of the interface was 2.98 mm, measured with the sand-patch method according to (EN 13036-1:2010 2010). In the roughened area three concrete screws (Figure 1, in red) were installed with a spacing of 170 mm, and with an embedment depth in the old concrete of 85 mm (65 mm in the new concrete). Overall, 4 specimens were tested.

Figure 1. Specimen geometry.

Figure 2 shows the test set-ups. The specimen was set on the strong floor and restrained on both sides (front and back) with two stiff supports connected to the strong floor. The load was applied at the interface level with two plates and four rods that connected the specimen to the hydraulic jack (with capability of 500 kN equipped with a load cell of 500 kN).

Two additional orthogonal restraints were added to allow the sliding of the “old concrete block”, preventing rotations. Four steel cylinders (two on both side of the specimen) were added at the bottom to support the specimen. Similarly, on the top of the specimen, four steel cylinders support two steel plates that were connected to the strong floor to prevent the rotation of the specimen. A Teflon sheet was placed between steel cylinders and concrete surface to reduce friction. The slip between the old and the new concrete block was measured with four LVDTs (gage length 10 mm) placed close to the interface. All measurements were acquired with the MOOG system. The tests were displacement controlled with monotonic loading.

Figure 2. Experimental test set-up.

2.2 Test results

The average shear strength was 3.7 MPa with a coefficient of variation of about 9.5%. A typical load-displacement curve is shown in Figure 3, in which distinct phases are clearly identifiable: the elastic branch (up to point A), the cracking of the interface between the two concrete castings (between points A and B), the friction and dowel action effect (associated to the plateau starting from point B). This curve was used to calibrate the parameters of the numerical model.

Figure 3. Load-displacement curve.

3 NUMERICAL ANALYSES

Three different specimens were modeled with the software ABAQUS (Dassault Systèmes 2017) to assess the influence of the size effect on the overall mechanical response. The reference specimen size was assumed according to EAD (EOTA 2021) as in Figure 1, with a shear interface area of 500 mm x 200. The scaled specimens (Figure 4) had the same thickness and reduced length and height (1:0.5:0.25), resulting in shear interface areas of 250 mm x 200 mm and 125 mm x 200 mm. A higher reinforcement percentage has been adopted in the scaled specimens with respect to the reference one (0.61% vs. 0.46%) in order to have an integer number of connectors.

The mesh was created using an automatic tool with some manual refinement (Figure 5, left). The interface between the concrete parts was modelled as a concrete layer with a thickness of 10 mm (Cattaneo et al. 2021). The top and bottom concrete blocks, the interface layer and the anchors were modeled with linear hexahedral elements (type C3D8). The element size ranges from approximately 1.5 mm in regions that require more refinement, such as near the anchors, to around 20 mm in regions that allow a rougher mesh (far from stress concentration). The reinforcement used for the cage of the specimen according to (EOTA 2022) (diameters 8 mm

and 12 mm) was modeled as 1D elements (linear line elements of type B31). As these elements do not require much refinement, their meshes reach element sizes up to 50 mm.

The boundary conditions were defined with the aim to reproduce the experimental settings (Figure 5, right). The new concrete block was fixed on the lateral surfaces of the specimen. Orthogonal constraints were considered at the top of the old concrete, to prevent the rotations and to allow the sliding of the old/new concrete blocks. The top and bottom surfaces of the interface layer were tied to the old and new concrete, respectively (no relative motion allowed). A perfect bond was considered between the anchors and the surrounding concrete, defined as surface-to-surface contact with tangential behavior (friction coefficient $\mu=0.8$) and normal behavior (hard contact). The horizontal displacement was applied on the side of the old concrete block.

Figure 4. Scaled specimens geometry: (a) size II and (b) size III.

Figure 5. FEM mesh (left) and boundary conditions (right).

3.1 Model validation

The validation of the numerical model was performed by comparing the numerical results of the reference specimen with the experimental results (Cattaneo et al. 2021). The nonlinear behavior of the concrete was taken into account by assuming the Concrete Damaged Plasticity (CDP) model (Lubliner et al. 1989, Dassault Systèmes 2017) as constitutive law. The elastic modulus E_c was assumed equal to 31 GPa (C20/25) and 32 GPa (C28/35) for the old and the new concrete, respectively. The adopted Poisson’s ratio had a value of 0.18 for both materials. A lower value of elastic modulus was chosen for the interface ($E_c = 1$ GPa), as proposed in other researches (Cattaneo et al. 2021).

The parameters adopted for the CDP are summarized in Table 1 where Ψ is the dilation angle, e is the eccentricity, f_{b0}/f_{c0} represents the ratio between strengths in biaxial compression and in uniaxial compression, K represents the ratio between deviatoric stresses in uniaxial tension and compression (in absolute values) and μ represents the viscosity. The values were calibrated on the experimental results and according to typical values proposed in the scientific literature (Lubliner et al. 1989). Figure 6 shows the good agreement between the experimental and the numerical load-displacement curves comparison.

Table 1. CDP Parameters.

$\Psi(^{\circ})$	e	f_{b0}/f_{c0}	K	μ	
				C25/30	C28/35
15	0.1	1.16	0.667	0.006	0.00205

Figure 6. Numerical and experimental load-displacement curves.

3.2 Numerical results

The load-displacement curves for the three considered sizes are shown in Figure 7a together with the experimental outcome. Figure 7b shows the variation of the average shear strength for the different contact area of the three specimens.

Figure 7. (a) Load-slip curves of different sizes and (b) variation of the average shear strength.

Table 2 summarizes the peak load and the associated displacement, together with the shear strength evaluated assuming a uniform stress distribution over the interface surface. As expected, the nominal shear strength decreases with increasing size, and a softer post-peak branch is observed in small specimen. These two observations confirm that this type of test is strongly size dependent (Biolzi et al. 2000).

Table 2. Size effect: main results.

	Contact Area [mm x mm]	Peak Load [kN]	Displacement associated to Peak Load [mm]	Average Shear Strength [MPa]
Size I	500 x 200	394.81	0.878	3.95
Size II	250 x 200	256.77	0.617	5.14
Size III	125 x 200	140.96	0.438	5.64

It should be observed that to consider feasible specimens, 3 2 and 1 anchor were used respectively for the different sizes. This implies that the larger specimen has a lower geometric reinforcement ratio than the other two specimens in which the ratio is constant. Nevertheless, the higher reinforcement ratio affects mainly the dowel action (i.e. post peak behavior). Indeed, the size effect is noted also for the two specimens (II and III) with the same reinforcement ratio (Figure 7b).

4 DISCUSSION

The numerical results make possible to add further considerations to the experimental issues. By considering the distribution of the tensile damage at the peak load in a section at a quarter of the width (Figure 8), it is possible to observe that the reference specimen (a) and the medium specimen (b) show non-uniform damage distribution, while the smaller specimen (c) shows a more uniform damage distribution. This is probably due to the fact that, in the bigger specimens, the eccentricity between the applied load (that acts at the interface level) and the respective horizontal reaction force (that is located on the new concrete part at a distance of about 25 cm) is higher than in the smaller specimen. Indeed, on the side of the reaction (Figure 8a) a certain damage appears close to the support reaction.

Figure 8. Distribution of tensile damage for (a) size I, (b) size II and (c) size III models.

Looking at the shear stress distribution (Figure 9), it is interesting to observe that all sizes exhibit similar distribution with a concentration of stresses close to the loaded edge, high stresses close to the anchor position which drop in the anchor section. Although the trend is similar, in the reference specimen there is a high stress concentration close to the edge of the specimen and then, in the intermediate section, there is a nearly uniform stress distribution. The smaller specimen shows the higher stress close to the edge, while the intermediate size has the lower stress close to edge. Overall, the stress distribution of the intermediate specimen does not show steep changes, although there is not an area with constant stress (as shown in the central portion of the reference specimen).

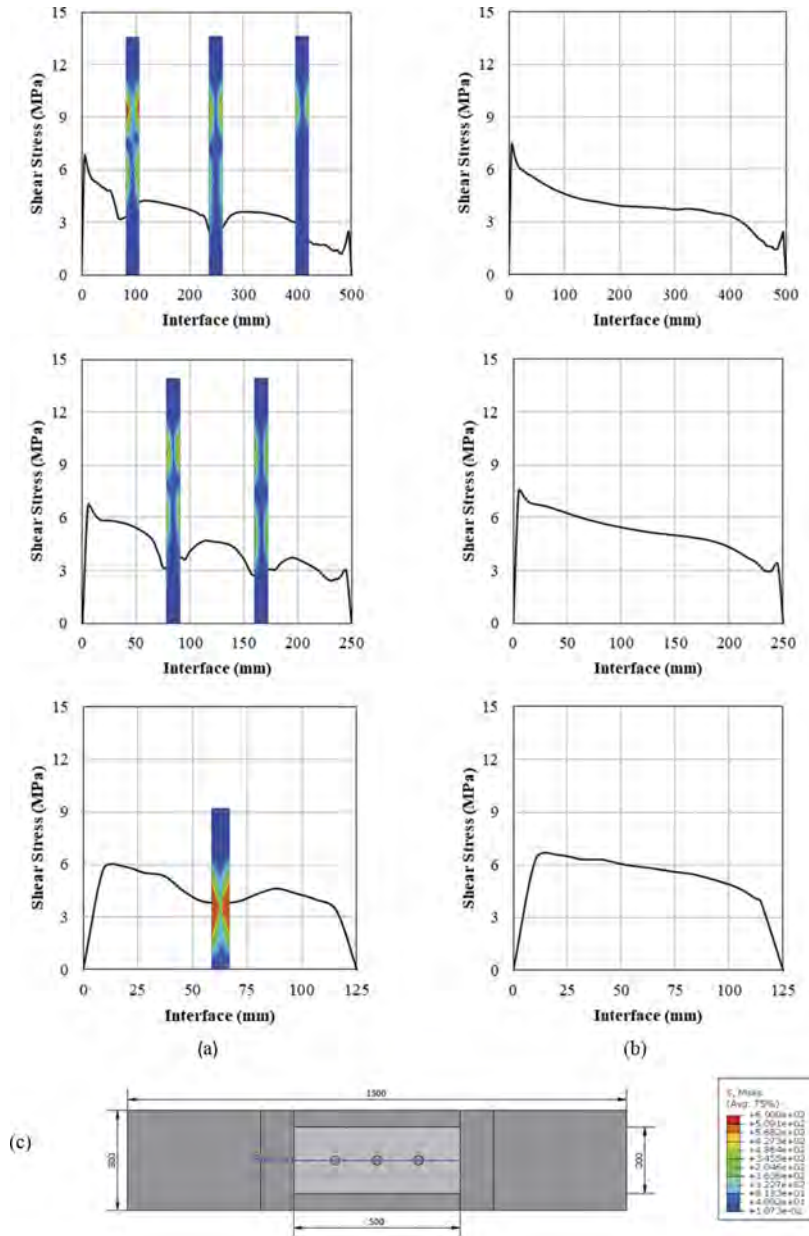

Figure 9. Shear stress distribution in path a (a) and in path b (b) for the three different sizes, with Von Mises Stresses in the anchor. In (c) section scheme with anchor stresses legend.

Based on the obtained results, it is evident how stress and damage distributions are strongly influenced by the size of the specimen and higher stress gradients are found when the size effect is more pronounced. In any case, at the interface, a non-uniform stress distribution is manifest with a mixed-mode stress field which affects the damage evolution and the experimental results (Biolzi 1990). Although the smaller specimen leads to the highest strength and thus it is not on the safe side, it shows a more uniform stress distribution. The intermediate specimen leads to higher strength with respect to the reference specimen, and, although the stress distribution is not uniform, it does not present steep changes. The reference specimen allows to evaluate the shear strength on the safe side.

5 CONCLUSIONS

The numerical analyses conducted highlight that the assessment of the shear strength is strongly affected by the size effect both in terms of shear stress distribution, strength and ductility.

The reference specimen seems a suitable specimen size for a safer evaluation of the shear strength. The intermediate specimen could be considered to assess the shear strength, since the stress distribution along the interface does not show steep changes. In this case, a suitable reduction coefficient should be applied to account for the size effect and a proper experimental validation is needed. The smaller specimen does not seem suitable to assess the shear strength, since it is strongly affected by the size effect. Moreover, the fact that the new cast part resulted strongly damaged suggests that secondary effects could be involved in the strength evaluation.

Hilti AG, Liechtenstein

ABSTRACT: The behavior of interfaces created between existing and added concrete when applying intervention techniques, strongly affects the efficiency of the intervention in terms of stiffness, bearing and deformation capacity. To contribute to the investigation of key parameters related to those interfaces, the current work focuses on cases where the available thickness of the concrete members is limited, thus allowing for small embedment depths for the dowels. Previously performed tests on interfaces reinforced with reinforcing bars or industrial steel screws have shown that a very short embedment depth in the added concrete may ensure substantial interface resistance, thus suggesting that they might offer a solution in case of thin concrete overlays added to existing members. The results of tests performed with the purpose of exploring the behavior of interfaces with limited thickness of the added concrete, where the anchorage conditions of the connectors are unfavorable, are presented herein.

1 INTRODUCTION

Interventions to existing reinforced concrete (RC) structures are a field of growing significance worldwide. In most of the frequently applied techniques (e.g. flexural and shear strengthening of beams, column jacketing, filling of RC frame spans with RC shear walls, etc.), reinforced interfaces occur between the existing and the added concrete layer or element. The efficiency of the intervention techniques, in terms of stiffness, bearing and deformation capacity strongly depend on the behavior of interfaces.

The experimental evidence on the cyclic behavior of RC interfaces is rather limited compared to the significance of the topic. To contribute to the investigation of key parameters related to interfaces between concretes cast at different times and subjected to seismic actions, series of experimental programs were carried out at the Laboratory of Reinforced Concrete, National Technical University of Athens (Palieraki et al., 2021, Vintzileou et al., 2020a, Vintzileou et al., 2020b). The current work focuses on cases where the available thickness of the concrete members is limited, thus allowing for small embedment depths for the interface reinforcement. The behavior of beams or slabs reinforced with an overlay of limited thickness has been investigated by many researchers (indicatively, Seible & Latham 1990, López-Carreño et al. 2020). The test results on specimens with an interface between concretes cast at different times, subjected to direct shear, is very limited. Choi et al. 1999 have tested specimens with an overlay of 145mm, and Randl 1997 has investigated specimens with overlay thickness equal to 200mm. The failure of the overlay is not commented, as in both cases the focus is oriented towards the pullout of the reinforcement from the old concrete part. Millard & Johnson 1984, Papanicolaou & Triantafillou 2002, Dimitriadou et al. 2005 and Costa et al. 2018, have investigated the behavior of specimens with thickness of both the old and the new concrete equal to 125mm, 100mm, 150mm and 100mm respectively. Given that the thickness of both parts was the same, the authors do not comment on the influence of the limited thickness

of the overlay. Finally, Waweru et al. 2018, have performed tests on typical push-off specimens, 254mm thick in total (127mm thick on each side). The anchorage of the reinforcement in the new concrete varied between 50.8mm and 101.6mm. In the case of very short anchorage, the specimens experienced an explosive pullout failure from the new concrete, whereas this failure was not so pronounced in the case of longer anchorage.

Previously performed tests on interfaces reinforced with reinforcing bars or industrial steel screws (Vintzileou et al., 2020a) have shown that a very short embedment depth in the added concrete may ensure substantial interface resistance, thus suggesting that they might offer a solution in case of thin concrete overlays added to existing RC members. To further investigate this possibility, specimens with geometry identical to that of specimens used in previous tests (Vintzileou et al., 2020a) were prepared. The only difference is the limited thickness (50mm) of the RC block simulating the added concrete. In the current paper, the results of the tests performed with the purpose of exploring the behavior of such interfaces (with limited thickness of the added concrete), where the anchorage conditions of the interface reinforcement are unfavorable, are presented and commented upon.

2 EXPERIMENTAL PROGRAM

2.1 The experimental program incentive

In most of the cyclic tests performed up to now by the authors, the main interest of the research was focused on the old part of the specimen, where the (post-installed) connectors were provided with a limited embedment length. Nevertheless, a small number of previously conducted experiments (Figure 1) have shown that alternative connectors (steel screws) provided with a very short embedment depth (2.5d) in the added concrete may ensure substantial interface resistance, thus suggesting that they might offer a solution in case of thin concrete overlays added to existing RC members (e.g. slabs in residential buildings). One of the frequently used solutions in such cases is that of reinforcing bars with a bent at their end into the added thin layer. This paper presents the results of a preliminary investigation performed with the purpose of exploring the behavior of such interfaces, where the anchorage conditions of the interface reinforcement in the new layer of concrete are very unfavorable.

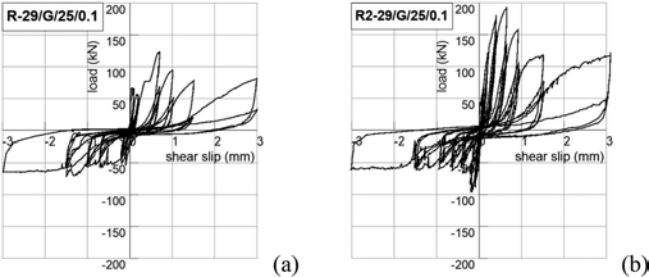

Figure 1. Hysteresis loops of previously conducted tests on specimens with thick overlays, with very short embedment depth (2.5d) in the added concrete part.

2.2 Characteristics of specimens

Figure 2 shows the specimens tested in the context of this experimental program. Their overall geometry was identical to that of specimens used in the previously presented tests (Vintzileou et al., 2020a). The only difference was that, before casting the added concrete, a 50mm thick layer of polyethylene was placed in the molds to limit the thickness of the added layer to the desired value of 50mm.

The type of interface reinforcement was the only investigated parameter within this experimental program. Each specimen (Table 1) was reinforced using either three 12mm reinforcing bars

with a 90° hook (two specimens) or three 10mm concrete screws (two specimens). The embedment length in the old concrete was either 10d (for the reinforcing bars – which is considered adequate for their anchorage) or 6.7d (for the screws - as defined by the Manufacturer), d being the connector diameter. Finally, one specimen was reinforced with three 12mm reinforcing bars embedded 10d into the old concrete block, with a shaped head into the new concrete block. Comparisons between the behavior of interfaces reinforced with the described screws and rebars can be drawn, as the reinforcement parameter, namely ρf_{sy} (ρ being the geometrical reinforcement ratio and f_{sy} denoting the yield strength of steel) is similar for those cases (~163 MPa and ~178MPa respectively).

All 12mm rebars were embedded into the old concrete block using injectable epoxy mortar and the anchorage into the new concrete block was achieved by means of concrete bond. For the interfaces crossed by screws, the anchorage in the old part was mechanical interlock, whereas in the new part both mechanical interlock anchorage (due to the screw’s head) and anchorage provided by concrete bond along the shaft was present as well.

After casting the portion of the specimen simulating the existing concrete, the interface was artificially roughened (chipped with pickaxe). In order to make possible the comparison among the specimens, the same value of medium (~2.00mm) roughness was reached in all five tested interfaces. The standardized “Sand Patch” Test (ASTM E965-96) was applied to measure the interface roughness.

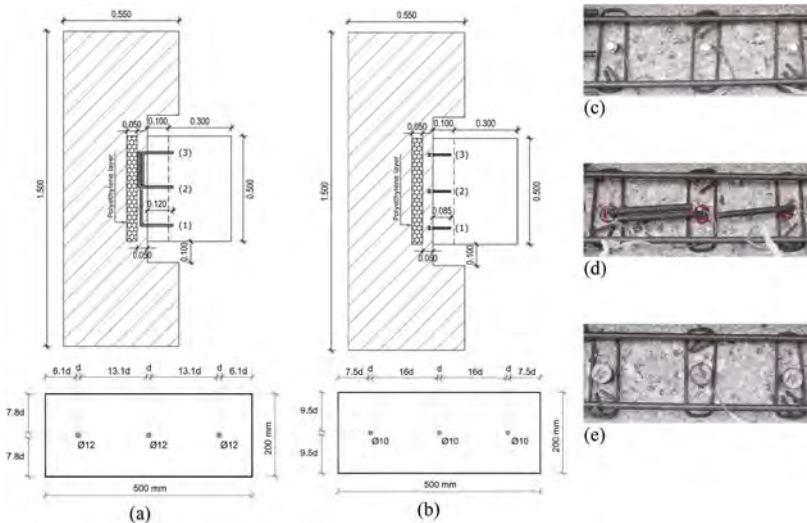

Figure 2. Geometry of specimens simulating thin overlays reinforced with: (a) diameter 12mm rebars with a hook, (b) diameter 10mm screws. The diagonally hatched parts depict the new concrete block. Photos of interfaces reinforced with: (c) diameter 10mm screws, (d) diameter 12mm rebars with a hook, (e) diameter 12mm rebars with a head.

Ready-mixed limestone coarse aggregate concrete was used for the construction of all specimens. For each batch of concrete, conventional cylindrical specimens (diameter 150mm, height 300 mm) were cast. The cylinders were tested (Table 1) to failure the day of testing the respective specimens. The C16/20 concrete of the old part contained aggregates of conventional maximum dimension (32mm), whereas for the new part, C25/30 quality was used, with aggregates of smaller maximum dimension (16mm).

2.3 Test setup and instrumentation

The setup used for testing is illustrated in Vintzileou et al., 2020a. In all tests, there was no external compressive normal stress acting on the interface. Tests were performed under cyclically

imposed shear slip at low speed (i.e., quasi-static conditions); three cycles were carried out at each displacement value with increasing amplitude.

Shear slip along the interface was measured by means of four displacement transducers (two per face of the specimen), placed in close proximity of the interface, whereas in total six displacement transducers placed perpendicular to the interface measure the width of the crack at the interface. In addition, two electrical strain gauges glued on each connector are used to measure the strains developed in the dowels during the test. The strain gauges are positioned close to the interface, at a distance of approximately 1.5 diameters, oriented along the direction of loading.

Table 1. Characteristics of thin-overlay specimens and main test results.

	Thin-R- 33/G/25/0.1	Thin-R- 35/G/25/0.1	Thin-Re- 38/E/10/0.1	Thin-Re- 35/E/10/0.1	Thin-Re- 38/H/10/0.1
f_{sy} (MPa)	690	690	524	524	524
ρ (%)	0.236	0.236	0.339	0.339	0.339
$L_{emb,old}/d$	6.7d	6.7d	10d	10d	10d
$L_{emb,new}/d$	2.5d	2.5d	3d	3d	3d
R (mm)	1.98	2.29	2.04	2.30	1.95
$f_{c,old}$ (MPa)	33	35	38	35	38
$f_{c,new}$ (MPa)	47	50	50	50	50
τ_u (MPa)	0.65	0.76	0.71	1.11	0.88
s_u (mm)	0.40	0.40	0.40	0.80	0.80
τ_{u1+}/τ_{u1-}	5.99	4.30	1.23	6.15	4.57

Notation:

R: mechanical anchorage at rough interface, Re: anchorage by means of epoxy resins at rough interface.

The first number indicates the compressive strength of the weaker concrete block (in MPa).

E: specimens with three bars 12 mm in diameter, G: specimens with three screw anchors 10 mm in diameter, H: specimens with three bars 12 mm in diameter, with shaped head. All dowels are post-installed.

The second number indicates (a) the embedment depth in the old part for the rebars normalized to the bar diameter (b) the embedment length in the new part for the screws, in mm.

The third number indicates the magnitude of the cyclic shear slip imposed during the first set of cycles in mm.

Characteristics of specimens:

The yield stress of the connectors (f_{sy}), the geometrical reinforcement ratio of the interfaces (ρ), the embedment length into the old ($L_{emb,old}$) and the new concrete part ($L_{emb,new}$), the roughness (R) and the concrete strength of the old ($f_{c,old}$) and the new concrete part ($f_{c,new}$) are given.

Test results:

τ_u (MPa) is the maximum shear resistance of the interface, given as the average value between the two loading directions for the first cycle.

s_u (mm) is the shear slip value corresponding to the mobilization of the maximum capacity of the interface, given as the average value between the two loading directions for the first cycle.

τ_{u1+}/τ_{u1-} is the absolute value of the ratio between the maximum resistance at the first loading direction and the second loading direction, at s_u shear slip.

3 TEST RESULTS

3.1 Failure mode and hysteretic behavior

As shown in Figure 3a-c, typical of all thin overlay specimens, the interfaces exhibited a concrete breakout failure: a crack parallel to the interface has occurred, at a distance from the interface approximately equal to the embedment length of the connectors into the new block (25mm-40mm). After the termination of the test, the two concrete parts were easily separated, and the dowels remained into the old concrete block.

The hysteresis loops for all specimens are presented in Figure 4. In addition to the typical characteristics of shear-sensitive behavior, the specimens exhibited extremely pronounced asymmetry in the two loading directions, as depicted in the hysteresis loop envelopes for the first and the third cycle (Figure 5a, b). Moreover, an intense response degradation (of 30% up to 70%) due to cycling is illustrated in Figure 5c. This is attributed to the pullout of joint reinforcement in the first loading direction, confirmed by the shear slip – dilatancy curves

shown in Figure 6, where at first semi-cycle of 0.40mm shear slip there is an abrupt increase of crack opening. Pullout damage cannot be reversed during unloading, thus, not allowing for substantial interface resistance to be mobilized in the second loading direction.

Figure 3. Specimens with thin overlays after the termination of the test: (a) Before the separation of the two blocks. (b) New concrete block: imprints of the two screws near the edges (see arrows), (c) Old concrete block: heads of the two screws near the edges (see arrows). Specimens with thick overlays after failure, reinforced with: (d) screws, (e) reinforcing bars.

In the diagrams presented in Figure 4, it is noted that the interfaces could not withstand shear slips larger than 0.8mm. From then on, the tests were either terminated or were continued monotonically. Specimens reinforced with screws reached their maximum resistance at a slip value of 0.40mm, whereas specimens reinforced with bars reached a slightly higher load, and at a slip value of 0.40mm or 0.80mm. No significant difference in the behavior could be identified between the specimens reinforced with screws and those reinforced with rebars (with hook or shaped head). However, although the number of specimens is limited and may not allow for final conclusions, a more similar behavior is noticed for duplicate interfaces reinforced with screws, compared to those with rebars.

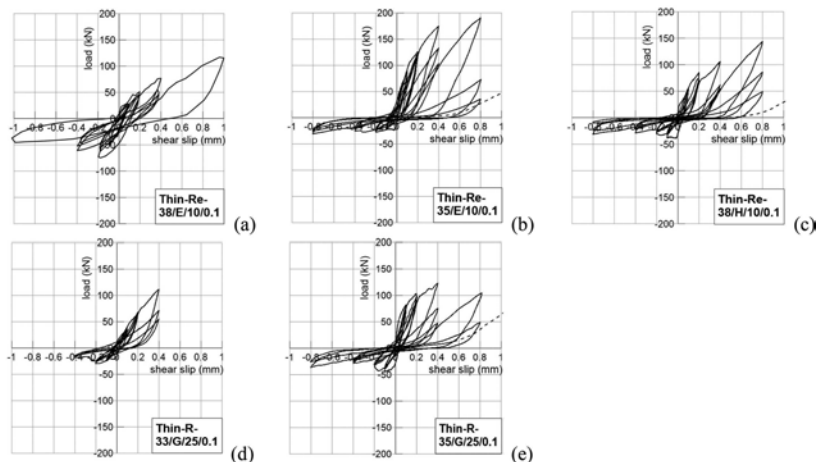

Figure 4. Hysteresis loops for all specimens.

Regarding the steel strain measurements, as observed in Figure 7, the maximum measured tensile strains did not reach the connector yield strain. This is due to the premature brittle concrete failure of the specimens, which occurred at small shear slip and, in turn, at a small interface crack opening, limiting the maximum steel strains to values lower than 1‰, for

specimens reinforced with rebars and screws. When larger embedment length is provided, the reinforcement is more efficiently exploited as steel strains much higher than the strain corresponding to yielding (as high as 4‰) are recorded, so the interfaces can take profit from the yield strength of the reinforcement (Vintzileou et al., 2020b).

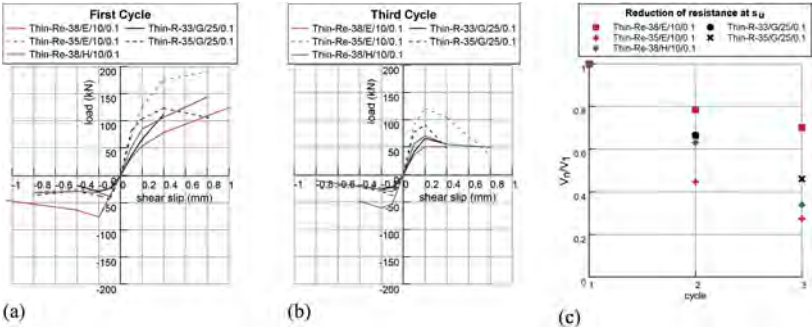

Figure 5. (a) Hysteresis loop envelopes for first cycle and (b) third cycle. (c) Reduction of the resistance during cycling at s_u shear slip for all specimens.

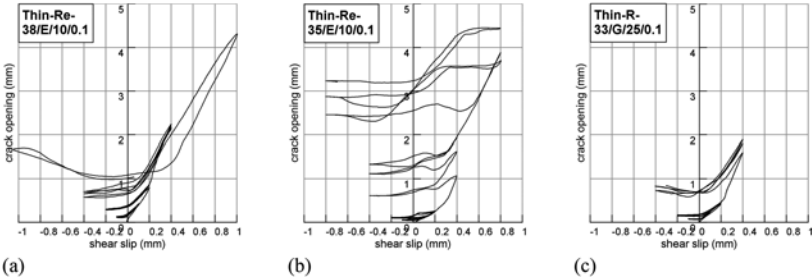

Figure 6. Typical shear slip versus crack opening (lateral dilatancy) curves.

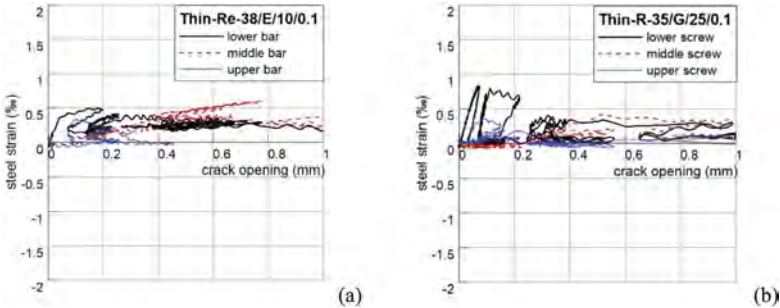

Figure 7. Steel strains versus crack opening (lateral dilatancy) curves. The vertical axis maximum value (2‰) corresponds to the yield strain of the reinforcing bars.

3.2 Comparison with specimens with thick overlays

Table 2 presents the characteristics and the main test results for specimens with similar features, but with thick (400mm) overlay, whereas in Figure 8 the hysteresis loop envelopes for the first cycle for comparable specimens reinforced with bars and screws are provided.

At first, a significant difference of the failure mode could be observed for interfaces with thick overlays, compared to those with thin overlays. The specimens with thick overlays and rough interfaces crossed by screws (Figure 3d) exhibited failure along the interface. After the tests, the two parts of the specimens could be easily separated, due to the wide crack along the

interface, and the imprint of the screwhead could be observed in the new part. The specimens with thick overlays and rough interfaces crossed by reinforcing bars (Figure 3e) exhibited failure along the interface with diagonal crack in the new part or with the formation of a crack at the end of the embedment of the bars into the old block, but without concrete cone failure.

Table 2. Characteristics of thick-overlay specimens and main test results.

	R-29/G/25/0.1	R2-29/G/25/0.1	Re-24/E/10/0.1	Re-31/E/10/0.1	Re2-31/E/10/0.1
f_{sy} (MPa)	690	690	524	524	524
ρ (%)	0.236	0.236	0.339	0.339	0.339
$L_{emb,old}/d$	6.7d	6.7d	10d	10d	10d
$L_{emb,new}/d$	2.5d	2.5d	29d	29d	29d
R (mm)	6.23	5.46	2.50	1.80	1.70
$f_{c,old}$ (MPa)	29	29	24	33	33
$f_{c,new}$ (MPa)	40	40	31	31	31
τ_u (MPa)	0.91	1.28	2.10	2.60	2.04
s_u (mm)	0.70	0.65	0.40	0.40	1.20
τ_{u1+}/τ_{u1-}	2.13	3.08	0.83	1.52	2.94

Thin-overlay interfaces crossed by screws have slightly lower maximum resistance compared to thick-overlay interfaces, a fact that could be attributed also to the significantly larger roughness of the latter. Nevertheless, the difference is obvious for specimens reinforced with bars. In this case, thick-overlay interfaces undertake significantly larger load compared to thin-overlay interfaces, a result imputed to the sufficient protruding length of the bars into the thick overlay.

In general, thick-overlay specimens, in contrast to the thin-overlay ones, do not fail prematurely, so they can withstand larger shear slip values. It is underlined that they are characterized by a more symmetric behavior along the two loading directions, as appears both in the shape of the loop envelopes (Figure 8) and the τ_{u1+}/τ_{u1-} ratio (Table 1 compared to Table 2 values), which acquires values up to 3, approximately.

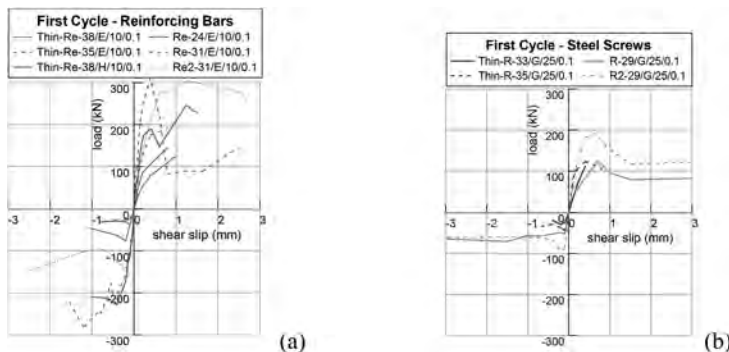

Figure 8. Hysteresis loop envelopes for first cycle for comparable interfaces reinforced with: (a) bars, (b) screws.

4 CONCLUSIONS

On the basis of this preliminary investigation on interfaces crossed by very short dowels, the following conclusions can be drawn:

- All three types of alternative anchors embedded to thin concrete overlays were able to activate interface resistance, which may be sufficient for some applications where very limited deformations are expected (e.g. diaphragm slabs). No remarkable difference could be

identified for interfaces reinforced with conventional bars and the interface crossed by bars with shaped head.

- Compared to the behavior of thick-overlay specimens, thin-overlay interfaces fail at an earlier stage, without reaching large shear slip values, and have typically lower maximum resistance at both loading directions.
- Additionally, the pronounced asymmetry of the hysteresis loops and the degradation of the resistance to minimal values suggest that this small protruding length for either type of reinforcement (bars and screws) is not adequate for applications where cycling of loads is to be addressed.
- Therefore, the use of any type of anchor in seismic conditions needs to be supported by adequate experimental evidence in application tests.

Calculation of the interface resistance in RC construction using different codes

V. Palieraki & E. Vintzileou

National Technical University of Athens, Athens, Greece

S. Cattaneo

Politecnico di Milano, Milan, Italy

ABSTRACT: The need for the assessment of interface shear strength in reinforced concrete construction arises in conjunction with a wide variety of structural details. Several design codes (e.g., EC2, ACI 318, MC 2010) provide guidance on the design of interfaces, assuming full anchorage of the interface dowels. As dowels, cast-in reinforcing bars, are typically assumed. Nevertheless, in case of repair and strengthening of structures, the interface dowels are usually post-installed in the existing concrete member, while their embedment length may be limited. The European Organization for Technical Assessment has issued a design Guideline (EOTA TR 066 2019), allowing to design interfaces with connectors of limited anchorage. To cover the cyclic behavior of interfaces, an extension of the guidelines, amended in 2020, was introduced. In the current paper, the equations for the prediction of interface resistance, included in the codes and guidelines are compared with experimental results, are evaluated, and commented upon.

1 INTRODUCTION

Interfaces being loaded in shear, occur along crack surfaces that develop at points of maximum shear, in cold joints resulting from construction sequencing and between precast elements. The calculation of the interface resistance is particularly relevant for repair and strengthening of structures, where, because of geometrical limitations of existing elements and added overlays, the embedment of the interface reinforcement may be limited. For example, the thickness of an existing slab is limited, in most cases not exceeding 10-12cm, while also the thickness of the added overlay is limited, in order to avoid the excessive increase of the self-weight of the structure.

Several design codes (e.g., EC2 2004, ACI 318 2019, MC 2010 and various National Codes) provide guidance on the design of interfaces. The codes provide equations for the calculation of shear resistance, for interfaces that are smooth, rough or very rough. No guidance is offered regarding the way in which the interface roughness should be measured, except than in MC 2010, which proposes the sand patch method (Kaufmann 1971). It is though noted that this method cannot be used in case of non-horizontal interfaces. Additionally, these design provisions typically assume full anchorage of the dowels crossing the interface, i.e., their anchorage length is sufficient to allow the interface reinforcement to develop its yield strength. As dowels, cast-in reinforcing bars, perpendicular or inclined to the interface, are typically assumed. Nevertheless, strengthening measures in most cases require installation of the dowels in the existing reinforced concrete member, thus making a cast-in solution unfeasible. Last but not least, the codes do not cover the case of cyclic loading of the interfaces. Experimental investigations (Bass et al. 1989, Valluvan et al. 1999, Cattaneo et al. 2021, Palieraki et al. 2023) have shown that the interface resistance is reduced due to cyclic loading, while the amount of the reduction depends on various parameters, such as the concrete strength, the roughness of the interface, the type of the interface reinforcement, the embedment depth and the amplitude of the applied shear slip.

The European Organization for Technical Assessment has issued a design Guideline (EOTA TR 066 2019), which allows to design interfaces with shear connectors provided with an anchorage length smaller than the one required for full anchorage and considering the properties of engineered connectors in terms of material ductility, cross section geometry and pullout resistance. In order to cover the cyclic behavior of interfaces crossed by different types of connectors, an extension of the EOTA guidelines was recently introduced (EOTA TR 066 2019, amended 2020).

In the current paper, the equations for the prediction of the interface resistance, included in codes, and technical documents are compared with experimental results, they are evaluated and commented upon.

2 CODE PROVISIONS

The equations included in some of the current design codes, are presented in Table 1. In those equations the interface resistance is expressed in terms of interface shear stress (MPa).

Table 1. Design codes equations for the calculation of interface resistance.

Code	Equation
EC2 (2004)	$\tau_{calc} = c \cdot f_{ctd} + \mu \cdot \sigma_n + \rho \cdot f_{yd} (\mu \cdot \sin \alpha + \cos \alpha) \leq 0.5 \cdot v \cdot f_{cd}$
ACI 318 (2019)*	$\tau_{calc} = \rho \cdot f_y (\mu \cdot \sin \alpha + \cos \alpha)$
MC 2010 (2010)	$\tau_{calc} = c_r \cdot f_{ck}^{1/3} + \mu \cdot \sigma_n + \kappa_1 \cdot \rho \cdot f_{yd} (\mu \cdot \sin \alpha + \cos \alpha) + \kappa_2 \cdot \rho \cdot (f_{yd} \cdot f_{cd})^{1/2} \leq \beta_c \cdot v \cdot f_{cd}$

*Upper limits are proposed for the ACI 318 equation, depending on the roughness of the interface

where,

τ_{calc} = interface resistance, calculated using the equations proposed in the codes or guidelines

f_{ctd} = design tensile strength of concrete

f_{ck}, f_{cd} = characteristic and design compressive strength of concrete, correspondingly

f_y, f_{yd} = nominal and design yield strength of steel, crossing the interface, correspondingly

α = angle of the reinforcement with the perpendicular to the interface

σ_n = stress caused by the minimum external normal force across the interface (positive for compression)

ρ = percentage of the interface reinforcement

v, β_c = coefficients related to the concrete strength, described in EC2 (2004), MC2010 (2010)

$c, c_r, \mu, \kappa_1, \kappa_2$ = factors which depend on the roughness of the interface

In the equations of Table 1, there are common terms, corresponding to the mechanism of shear friction, namely, the friction coefficient, μ , the percentage of the interface reinforcement, ρ , and the yield strength of steel, f_{yd} . The remaining terms are met in one or more equations and they refer to the adhesion along the interface and/or to the dowel action of the interface reinforcement. It is noted that in almost all equations, an upper limit is set for the interface resistance, equal to a percentage of the compressive strength of concrete. In ACI 318 (2019), this upper limit depends on the roughness of the interface, while there is an additional upper limit, a fixed value of the interface resistance, which depends again on the interface roughness.

The provisions of equations included in the codes and the guidelines, were compared to the experimental results included in a database (Palieraki et al. 2021). The data were obtained from testing interfaces within monolithic specimens, as well as cold joints, i.e., interfaces between concretes cast at different times. In the current paper, the data on cold joints, in total 868 test results, are analyzed.

The database covers a wide range of parameters. The compressive strength of the weaker concrete varies between 6MPa and 120MPa, while the most common values are between 12MPa and 60MPa. The yield strength of the reinforcement ranges between 300MPa and 700MPa, with the higher value being exceeded in a very small number of tests. The reinforcing bars are anchored in the concrete by means of bond, or by means of adhesive material. In a limited number of tests,

special reinforcement is used (screws or bolts). The reinforcement may be in the form of closed hoops, thus, allowing for the assumption of full anchorage to be made, it may be straight and fully anchored, or it may be of limited length, which does not allow yielding of the reinforcement. In most of cases, rough or very rough interfaces are tested, while the specimens with smooth or very smooth interface, as defined in the fib Model Code (MC 2010), do not exceed the 15% of the total number of specimens.

As already mentioned, the design provisions included in the codes, typically assume full anchorage of the reinforcement crossing the interface. Nonetheless, in the fib Model Code (MC 2010), it is stated that the tensile force to be anchored may be assumed equal to a percentage, κ , of the force required for the tensile stress to be fully developed (Paragraph 6.3.5, Equ. 6.3-8).

For the assessment of the various equations, the database is divided into two parts: (a) Tests in which the reinforcement is anchored to a length that allows the development of its yield strength (605 tests). This category includes specimens reinforced with closed hoops, cast-in reinforcing bars with a bonded length larger than $20d_b$ in either side of the interface, and post-installed reinforcement, with a bonded length (in epoxy material) greater than $10d_b$, and (b) Tests on interfaces (189 specimens), where the reinforcement does not fall into one of the cases of category (a).

The plots of Figure 1 prove that even in case of interfaces reinforced with fully anchored bars, the predictions of the equations included in Table 1 are not always conservative. It is noted that the equations were applied without any safety factor on the properties of the materials. Nonetheless, even when safety factors relevant to each code are used (Figure 2), there is still a small percentage of cases, for which the equations remain unconservative. The most significant statistical values resulting from the application of the code equations are reported in Table 2.

In case of interfaces crossed by short reinforcement, which cannot reach yielding, the comparison between experimental and predicted interface resistances is expected to yield unconservative results in a significant number of cases. This is confirmed by Figure 3, where in the calculated interface resistances safety factors are accounted for.

The codes that are assessed in this work are not meant for use in seismic design. Nonetheless, they are evaluated for this case as well, because ACI 318 (2019) is used in practice for seismic design of interfaces as well, while EC8 (2005) (its Part 3 included) refers to the EC2 (2004) equation for the design of interfaces. Finally, in the fib Model Code (MC 2010), there is a provision exclusively for unreinforced interfaces, penalized with a reduction factor of 0.50. In Figure 4, the code provisions are plotted against experimental values obtained from cyclic tests on interfaces. It is noted that in those plots, the reduction due to cycling interface resistance is accounted for. Both the plots of Figure 4 and the statistical data of Table 2 prove that the current code provisions cannot cover in a conservative way the design of interfaces subjected to seismic actions.

3 CHANGES TO THE TR 066 FOR CYCLIC LOADING

As analyzed in the previous section, the evaluated code provisions are not adequate, especially for interfaces with reinforcement of limited anchorage, as well as for the design of interfaces subjected to cyclic loading. Thus, in the framework of EOTA, the equation of the fib Model Code (MC 2010) was modified as per TR 066 (2019) (Table 3). The main difference between the two equations, lies in their third term: The compressive stress, σ_c , used for the calculation of the friction coefficient, μ , i.e. the stress due to clamping effect, is calculated as $\sigma_c = \rho \sigma_s$, σ_s being the tensile stress of the reinforcement crossing the interface and calculated using the following equation: $\sigma_s = l_{emb} * f_{yd} / l_b$, where $l_b = f_{yd} * d_b / (4 * f_{bd})$.

Therefore, the tensile stress of the reinforcement is not assumed to be equal to the yield strength of steel, but it is calculated on the basis of the available anchorage length of the interface reinforcement, and it is associated to the relevant failure mode. In case of post-installed reinforcing bars or industrial connectors, the value of τ_{Rd} (bond strength) provided by the respective manufacturer (based on evaluation tests) is used in the abovementioned Equation in lieu of f_{bd} . When interfaces are crossed by short post-installed bars (embedment length between $6d_b$ and $10d_b$), to predict their reduced bearing capacity, the verification for concrete cone breakout capacity is also required. The results of the application are presented in

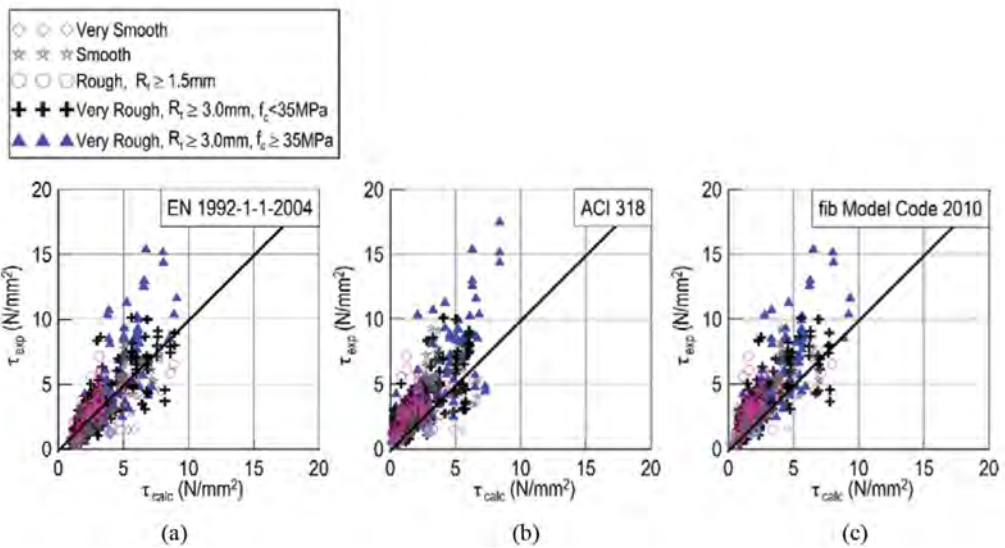

Figure 1. Specimens crossed by sufficiently anchored reinforcement: Comparison between experimental interface resistances and (a) Eurocode 2 (EN 1992-1-1-2004), (b) ACI 318 (2019) code, (c) fib Model Code (MC 2010). No safety factors are used.

Figure 2. As Figure 1, with the use of relevant safety factors, namely, 1.15 and 1.50 for steel and concrete, respectively, for (a) and (c), and global safety factor $\phi=0.75$ in (b).

Figure 3. Specimens crossed by reinforcement with limited anchorage length: Comparison between experimental interface resistances and (a) Eurocode 2 (EN 1992-1-1-2004), (b) ACI 318 (2019), (c) fib Model Code (MC 2010). For the calculations relevant safety factors are used.

Uncos. Values stands for Unconservative Values

τ_c (τ_{calc}) is the value of the interface resistance calculated without the use of relevant safety factors

$\tau_{c,des}$ is the value of the interface resistance calculated with the use of relevant safety factors

Figure 4. Interfaces subjected to cyclic actions. Comparison between experimental interface resistance measured during the third cycle, and values calculated according to (a) Eurocode 2 (EN 1992-1-1-2004), (b) ACI 318 (2019), (c) fib Model Code (MC 2010). For the calculations, relevant safety factors are used.

Figure 5 a, b. It is noted that the information regarding the exact values of f_{bd} or τ_{Rd} are not available for the reinforcement of all tested specimens, therefore the value of σ_s is calculated as: $\sigma_s = l_{emb} \cdot f_{yd} / 20d_b$, in case of cast-in reinforcement and $\sigma_s = l_{emb} \cdot f_{yd} / 10d_b$, in case of post-installed reinforcement. The prediction is more conservative, and a limited number of data points is unconservative.

Table 3. The equations included in TR 066 (2019), and version amended in 2020.

Technical Report	Equation
TR 066, 2019	$\tau_{calc} = c_r \cdot f_{ck}^{1/3} + \mu \cdot \sigma_n + \mu \cdot \kappa_1 \cdot \alpha_{\kappa 1} \cdot \rho \cdot \sigma_s + \kappa_2 \cdot \alpha_{\kappa 2} \cdot \rho \cdot (f_{yd} \cdot f_{cd})^{1/2} \leq \beta_c \cdot v \cdot f_{cd}$
TR 066, amended 2020	$\tau_{calc} = a_{seis} \cdot [c_r \cdot f_{ck}^{1/3} + \mu \cdot \sigma_n + \mu \cdot \kappa_1 \cdot \alpha_{\kappa 1} \cdot \rho \cdot \sigma_s + \kappa_2 \cdot \alpha_{\kappa 2} \cdot \rho \cdot (f_{yd} \cdot f_{cd})^{1/2}] \leq \beta_c \cdot v \cdot f_{cd}$

In the equations of Table 3, c_r , κ_1 , $\alpha_{\kappa 1}$, κ_2 , $\alpha_{\kappa 2}$ and a_{seis} , are factors depending on the roughness of the interface, on the type of the product used as interface reinforcement, as well as on the type of loading, namely monotonic or cyclic.

The equation of TR 066 (2019) does not account for reduced interface resistance due to cyclic loading. This was made possible by the additional provisions of the amended version of TR 066 (2020). It is noted that the method described in the Technical Report TR 066, both versions, deals with the design of connections realized using products covered by an ETA based on EAD 332347-00-0601 (2019) or EAD 332347-00-0601-v01 (2020).

Figure 5. Specimens crossed by reinforcement with limited anchorage length: Comparison between experimental interface resistances and TR 066, for monotonic loading. For the calculations relevant safety factors (a) are not used, (b) are used, (c) Prediction for cyclic loading, using TR 066, in combination with α_{seis} , as proposed in Palieraki et al., 2022.

The equations included in the two versions of the Technical Report TR 066, are similar, in the sense that they account for both mechanisms of shear transfer along reinforced interfaces, namely, friction (due to external normal stress and due to clamping effect of the connectors) and dowel action. Both equations set the same limiting value for the resistance of the interface (the failure of concrete strut). It is noted that the equation in the amended version, is based upon the model presented in Palieraki et al. (2022). The main modifications of the amended version of TR 066 (2020), applicable to interfaces subjected to seismic actions, are the following:

- (a) Interfaces characterized as “very smooth” are excluded, given that their resistance is very small even under monotonic loading, and, thus, they are inadequate for use under seismic conditions.
- (b) The term of adhesive bond resistance/aggregate interlock, added to the resistance due to friction and to dowel action in the current equation is neglected in the new version of the equation. Indeed, in case of seismic actions, under the application of cyclic shear slips at values that exceed those (extremely small) needed for the mobilization of the adhesive bond resistance/aggregate interlock, this mechanism is not any more active. Additionally, another major change is needed, as explained herein:
- (c) In the equation included in the TR 066 (2019), for static loading, conservative (safe for the design) friction coefficient values are adopted. Those values depend exclusively on the roughness of the interface. Although it is well known that the friction coefficient is not constant, as it depends on the normal stress acting on the interface, it is understood that the need for a simple and safe calculation of the shear resistance of interfaces led to the adoption of friction coefficients independent of the value of the normal stress.

On the contrary, and due to the fact that the embedment length of the post-installed anchors is, in most cases, smaller than the one required for full development of the yield strength of the steel, the normal (compressive) stress on the interface is expected to be in several cases rather limited in value. For this frequent case, constant friction coefficient values (depending on the roughness of the interface), in combination with the reduction factors that account for the cyclic behavior, would lead to overconservative (unrealistically small) design values for the resistance of interfaces. Thus, on the basis of the available experimental data (taken from the international literature), a simple equation is proposed for the calculation of the friction coefficient, depending on the normal stress acting on the interface normalized to the compressive strength of the concrete. The friction coefficient is calculated using the following equation:

$$\mu = c \cdot \sqrt[3]{\left(\frac{f_{cd}}{\sigma_c + \sigma_n}\right)^2} \quad (1)$$

where the factor c , depends on the roughness and the concrete strength.

- (d) Last but not least, when the interface is under the adverse condition of cyclic actions, there are four phenomena that lead to the reduction of the maximum shear resistance (taken into account through the coefficient $\alpha_{seis} = \alpha_{seis,1} \cdot \alpha_{seis,2} \cdot \alpha_{seis,3} \cdot \beta_{seis}$, Figure 6), namely: (i) the maximum shear resistance under cyclic actions is smaller than the one corresponding to monotonic action ($\alpha_{seis,1}$), (ii) there is an asymmetry of behavior in the two loading directions, and in most cases, the load along the second loading direction is smaller ($\alpha_{seis,2}$), (iii) the shear resistance is decreased due to cycling ($\alpha_{seis,3}$), while (iv) larger scatter is associated with the seismic behavior of interfaces (β_{seis}). Thus, compared to the static resistance of an interface, its cyclic resistance is decreased by a significant percentage (depending, of course, on the specific anchor, on the roughness of interface, etc.).

For the equation included in the amended version of the TR 066, the coefficient α_{seis} should be calculated, according to tests, as described in the EAD 332347-00-0601-v01 (2020). Nevertheless, such tests are not available for the results reported in the literature, the calculations are performed based on Palieraki et al. (2022), using a reduction factor equal to 50%. The results are presented in Figure 5c and Table 2. The equation is quite conservative, while also the coefficient of variation is high, but this is expected to be corrected, when the values of α_{seis} calculated according to the test results are used.

Figure 6. Typical curves reported for monotonic and cyclic loading, for the first, second and third cycle. The reduction factors due to cyclic loading, $\alpha_{seis,1}$, $\alpha_{seis,2}$, $\alpha_{seis,3}$ are shown in the relative curves.

4 CONCLUSIONS

The current paper provides a comparison of interface shear experimental results on cold joints, with shear resistance values calculated according to the EC2 (2004), ACI 318 (2019) and fib Model Code (MC 2010) provisions, as well as to the two versions of the design Guideline (EOTA TR 066 2019 and amended version, 2020).

The comparison shows that the calculations according to the equations of the assessed current codes, are in most cases conservative, leading at the same time to the overestimation of the results of part of the tests. This conclusion is valid for interfaces provided with reinforcement anchored to allow yielding. In case of interfaces provided with reinforcement of limited embedment length, or interfaces subjected to cyclic loading, the calculated resistance values are in average larger than the experimental resistances. Furthermore, in all cases, the scatter of the ratio between predicted and calculated values of interface resistances, expressed by the coefficient of variation, is very high.

An alternative equation is proposed as an improvement over the current interface shear provisions of fib Model Code (MC 2010) and is included in the Technical Report TR 066 (2019), for the calculation of the shear resistance of interfaces reinforced with post-installed reinforcement of limited length. This formulation accounts for the shear friction and the dowel action, while the tensile stress of the reinforcement, which is taken into account for the calculation of the friction term, is considered reduced, corresponding to the available embedment length. The alternative equation is more conservative and leads to a reduced number of points on the unconservative side.

In addition to the inaccuracy of the code equations in case of bars of limited length, the reduced shear resistance due to cyclic loading is not accounted for. Nonetheless, the provisions used in practice for seismic conditions as well, lead to unconservative results. The amended in 2020 version of the TR 066, provides a modified equation for the calculation of this reduced resistance. The application of the modified equation has proven its satisfactory performance in predicting the shear resistance of cold joint interfaces, subjected to cyclic loading.

Performance-based design of new concrete walls for building seismic rehabilitation

S.M. Alcocer & B. Moctezuma

Institute of Engineering, UNAM, Mexico City, Mexico

ABSTRACT: In the aftermath of the September 19, 2017 earthquake, several hundred buildings were rehabilitated in Mexico City. Based on a research project jointly developed by UNAM and The University of Texas at Austin, addition of new reinforced concrete walls was found to be the most widely used rehabilitation technique. Different configurations were recorded. In cases where building sides were readily accessible, walls were built eccentric to the existing frame structure. Most walls were concentric with the frame axes. Some concentric walls were infilled so that the vertical and horizontal wall reinforcement was not continuous across the building height and width, respectively. In other cases, vertical wall reinforcement was made continuous through the floor system. To develop analysis and design recommendations, aimed at applying performance-based design rules, a dataset of tests on the addition of RC walls was assembled. Emphasis was given to identify the distinct modes of failures, including those related to connections and interface shear transfer between wall edges and existing frame members. Most significant results of the analysis of the dataset are discussed. Comments related to connection modeling and design are presented.

1 INTRODUCTION

Seismic rehabilitation of buildings by adding new reinforced concrete (RC) walls is one of the most used techniques worldwide. The addition of walls has been suitable for buildings with deficient stiffness and strength, as well as for buildings with torsional effects, flat slabs and/or weak stories. In Mexico City, in the aftermath of the 19 September 2017 earthquake, most buildings that exhibited inadequate performance were retrofitted with new RC walls. Distinctly different wall configurations have been observed in the field. Many of them have been tested in the laboratory. Most specimens tested are scaled models, typically with one or two stories. Some specimens have studied the effect of openings in the new added RC walls. Experimental data from those tests have been used to develop analysis and design recommendations. A detailed analysis of experiments studied may be found elsewhere (Moctezuma 2022). In this paper, tests with failure at the connections are primarily discussed. Emphasis is given to the calculation of connection strength and to the effect of connection failure type on backbone curves for performance-based design.

1.1 *Addition of RC walls in buildings rehabilitates after the earthquake of 2017*

After the earthquake of 2017, different configurations of RC walls were observed in the 94 rehabilitated buildings that were studied: wing walls (wall segments connected to existing columns), concentric walls (walls with a collinear axis with the frame and continuous vertical reinforcement), eccentric walls (walls built against the exterior face of the building), infill walls, and thickening of existing walls (building a concrete shell against the wall). The most widely used configuration were concentric walls, used in 46% of buildings analyzed. Three types of connections between floor system and concentric walls were observed (Figure 1). An opening with a width equal to the new wall thickness was made in the beam or slab, without damaging existing reinforcement, to allow concrete casting and for the continuity of the new wall vertical reinforcement. In one building, holes through the slab were made to pass the new wall vertical

reinforcement. In four other buildings, an opening was created in the floor system only where boundary elements next to columns were to be built. This procedure permitted new wall vertical reinforcement at the edges to be continuous while the vertical reinforcement of the new wall web was anchored to the floor system with epoxy resin. When concentric walls were built adjacent to columns, wall connection consisted of anchoring wall horizontal reinforcement to the RC column jacket or by overlapping wall horizontal reinforcement with epoxied dowel bars. For eccentric walls, connection to the floor system consisted of epoxy grouted dowels with a 90-degree standard bent. When infill walls were used, the connection with the original frame was made with epoxy grouted post-installed anchors or dowel bars.

Figure 1. Connection of concentric walls with floor system: a) opening in the slab along the wall; b) holes to allow placement of vertical reinforcement; and c) openings at wall edges adjacent to columns.

2 DATASET OF RC FRAMES REHABILITATED WITH RC WALLS

A dataset of experiments on RC frames rehabilitated with RC walls was assembled. A total of 93 specimens of different countries, including Greece, Japan, Türkiye, and USA, were studied (Altin et al. 1992, Anil & Altin 2007, Aoyama et al. 1984, Canbay et al. 2003, Chrysostomou et al. 2012, Gaynor 1988, Hayashi et al. 1980, Higashi et al. 1980, Jiménez 1988, Kara & Altin 2006, Moretti et al. 2014, Papatheocharis et al. 2019, Sonuvar et al. 2004, Strepelias et al. 2014, Teymur et al. 2014). Wall configuration included: bare frames, monolithic walls where the infill wall was cast together with the frame, full infill walls, partial infill walls (wing walls or wall panels located at the center of the bay), infill walls with openings and eccentric walls. Most specimens (86.0%) were designed to a 1:3 scale. The following frame configurations were observed: one story and one bay (59.1% of specimens), two stories and one bay (33.3% of tests), four stories and one bay (3.2% of models), two stories and three bays (2.2% of specimens) and four stories and three bays (2.2% of tests).

Different configurations of connections between new walls and existing frames have been tested (Figure 2). The most widely connection studied consists of post-installed anchors with epoxy resin. Other types of connections include expansive anchors, shear keys, wall reinforcement welded to existing column reinforcement and anchoring of the horizontal wall reinforcement in the concrete jacket of the columns. In the specimen with an eccentric wall, the connection with the beam consisted of epoxy grouted anchors and the horizontal reinforcement of the wall was anchored in the RC column jacket. Another variable included in the experiments is the location and distribution of anchors, either by placing anchors along the entire wall perimeter or only along the upper beam and the foundation. In one specimen, anchors were placed only along the wall interface with the upper beam. In three specimens, no special connection detailing was provided between wall and frame. Surface roughness of the old concrete along the wall-column and wall-beam interfaces was also included in the dataset. In 31.9% of the retrofitted frames, surface roughness along the wall interface was purposely increased. No surface preparation was found in 14.5% of the specimens; no data about surface roughening was available for 53.6% of the tests.

3 STRENGTH OF SPECIMENS WITH A FAILURE MECHANISM AT THE CONNECTION

Three methods were compared to evaluate the resistance of the specimens that exhibited a failure mechanism controlled by the connection between the infill wall and the beam or the

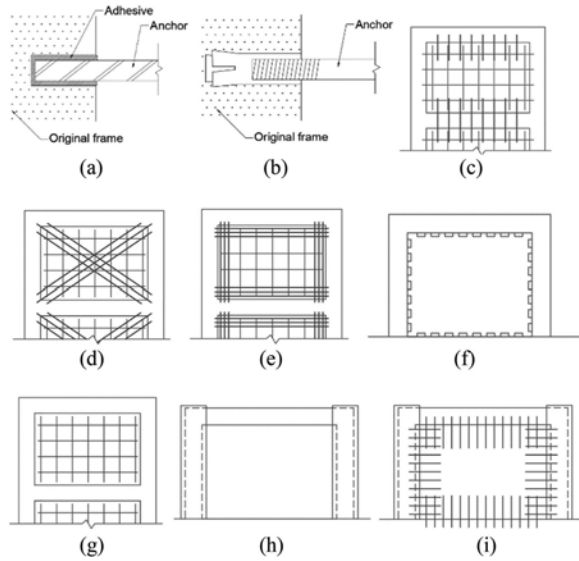

Figure 2. Connection between new wall and original frame: a) post-installed anchors with epoxy resin and epoxied dowel bars; b) expansion anchors; c) epoxied dowel bars in beams and horizontal reinforcement welded to existing column reinforcement; d) diagonal reinforcement welded to column reinforcement; e) wall bars concentrated at wall edges welded to the frame reinforcement; f) shear keys connected to the frame with epoxy; g) no connection of wall reinforcement nor intended surface preparation; h) RC column jacketing cast monolithically with RC infills without anchors; and i) epoxied dowel bars and RC jacketing of columns.

foundation. Models with this failure mechanism without anchors along the connection with the foundation and the beam were not included. The first method (JBDPA method) is that proposed by the Japan Building Disaster Prevention Association (JBDPA 2001) in Equation 1:

$$Q_{Wsu} = Q_j + Q_{pc} + \alpha \cdot Q_c \quad (1)$$

where Q_j = the sum of the shear resistance of each anchor in the connection with the beam; Q_{pc} = direct shear strength at the top of the column; α = reduction factor depending on the type of failure of the column (1.0 in case of shear failure and 0.7 for flexural failure); and Q_c = lesser value between the column shear resistance and the shear force at column yielding. In the second method, a new model was proposed to estimate the strength of the specimens using the design equations of the Mexico City Concrete Standards -NTC-Concrete- (Gobierno 2017) for shear friction and the strength of the columns. The shear strength of the connectors below the beam was calculated with ACI 318-19 Chapter 17 design equations. ACI 318-19 was used because no design requirements for anchors are yet provided in NTC-Concrete. Strength of specimens was estimated with Equation 2:

$$V_{calc} = V_j + V_{Fr} + \alpha \cdot V_c \quad (2)$$

where V_j = shear strength of the connection calculated as the lesser between the sum of the steel strength of each connector in shear V_{sa} (Equation 3) and the nominal concrete pryout strength of the group of connectors in shear V_{cpg} (Equation 4); V_{Fr} = shear friction strength in the upper end of the column calculated as the lesser of the Equations 5, 6 and 7; α = reduction factor according to the column failure type (1.0 in case of shear failure and 0.7 for flexural failure); and V_c = lesser value of the column shear strength and the shear force at flexural strength of the other column, according to NTC-Concrete.

$$V_{sa} = 0.6A_{se}f_{uta} \quad (3)$$

where: $A_{se,v}$ = effective cross-sectional area of an anchor in shear, mm^2 ; and f_{uta} = specified tensile strength of the connector steel, .

$$V_{cpg} = k_{cp}N_{cpg} \quad (4)$$

where: $k_{cp} = 1.0$ for $h_{ef} < 63.5 \text{ mm}$; $k_{cp} = 2.0$ for $h_{ef} \geq 63.5 \text{ mm}$; h_{ef} = effective embedment depth of the connector; in the case of adhesive anchors N_{cpg} was the lesser of the nominal bond strength in tension of the group of connectors N_{ag} (Equation 17.6.5.1b of ACI 318-19) and the nominal concrete breakout strength in tension of the group of connectors N_{cbg} (Equation 17.6.2.1b of ACI 318-19); in the case of expansion anchors N_{cpg} was the nominal concrete breakout strength in tension of the group of connectors N_{cbg} (Equation 17.6.2.1b of ACI 318-19).

$$V_{Fr} = F_R\mu(A_{vf}f_y + N_u) \quad (5)$$

$$V_{Fr} = F_R[1.4A + 0.8(A_{vf}f_y + N_u)] \quad (6)$$

$$V_{Fr} = F_R0.25f'_c A \quad (7)$$

where: F_R = strength factor (to evaluate the strength of the specimen a $F_R = 1.0$ was used); f_y = specified yield strength of the longitudinal reinforcement, N/mm^2 ; f'_c = compressive strength of the frame concrete, N/mm^2 ; A_{vf} = total area of the longitudinal reinforcement of the column, mm^2 ; A = cross-sectional area of the column, mm^2 ; N_u = axial load in the column, N ; and μ = friction coefficient ($\mu = 1.4$ for monolithic concrete).

In the third method, the strength of the connection V_j was studied considering two interface shear mechanisms: a) the friction between old and new concrete along the interface; and b) the dowel mechanism. The total strength was computed with the Equation 8 proposed by Palieraki et al. (2022):

$$\tau_u = \beta_d\tau_d + \beta_f\tau_f \quad (8)$$

where β_d = contribution factor of the dowel action; $\beta_d = 0.7$ was used for dowels with a minimum embedment length of $8d_b$ (this factor was multiplied by an additional 0.5 to consider the degradation of the dowel action due to cycling); τ_d = strength of the dowel mechanism using Equation 9; β_f = contribution factor of the friction mechanism ($\beta_f = 0.40$ for mechanically roughened interface with normal strength concrete, cyclic loading and an embedment length between $6d_b$ and $12d_b$ or $\beta_f = 0.20$ for smooth interface); and τ_f = strength for the friction mechanism calculated with Equation 10.

$$\tau_d = \left(1.3nd_b^2\sqrt{f_c f_y}\right)/A_c \quad (N/mm^2) \quad (9)$$

where n = number of reinforcing bars across the connection; d_b = diameter of reinforcement across the connection mm ; f_c = the lesser value of the compressive strength of concrete of the frame and the wall, N/mm^2 ; f_y = yield strength of the reinforcement across the connection, N/mm^2 ; and A_c = area of the interface, mm^2 .

$$\tau_f = 0.44\sqrt[3]{f_c^2\sigma_c} \quad (N/mm^2) \quad (10)$$

where f_c = the lesser value of the compressive strength of concrete of the frame and the wall; $\sigma_c = f_c A_s/A_c$ (this value can be adjusted to consider the degree of anchorage of the reinforcement across the connection. This adjustment was not included in this analysis because the bond strength was not available), N/mm^2 ; f_y = yield strength of the reinforcement across the connection, N/mm^2 ; A_s = total area of reinforcement in the connection, mm^2 ; and A_c = area of the interface, mm^2 .

The strength of each specimen was obtained by replacing the connection strength V_j in the Equation 2 (obtained using ACI 318) with the total connection strength computed with the method proposed by Palieraki et al. (2022). In Figure 3 the ratio of experimental strength V_{exp}

to calculated strength V_{calc} for each specimen for the three methods is shown. For tests AO 7, HA 5, HA 6, PA 7, MO 1, MO 2 and MO 3 (Aoyama et al. 1984, Hayashi et al. 1980, Moretti et al. 2014, Papatheocharis et al. 2019), results for the first two methods were comparable. With the JBDPA method, calculated strengths for all specimens were closer to the experimental strength (e.g., the ratio was closer to 1) compared to those computed using the method that combined ACI 318 and NTC-Concrete. The connection strength computed ACI 318-19 Chapter 17 was significantly lower than that calculated using the JBDPA method. It is apparent that strengths calculated with the combined method by NTC-Concrete and ACI are too conservative. ACI 318 design equations provide a more comprehensive analysis of the connection by considering, among other variables, the steel anchor shear resistance, connectors effective depth, connector spacing, and the effect of the distance of anchors to the edge of the element. In the JBDPA model, steel anchor shear strength of the steel is also considered, but the other variables in ACI 318 are not. Although ratios obtained with both methodologies were conservative (e.g., larger than 1.0), ratios for the JBDPA method were closer to 1.0 and with a smaller coefficient of variation, CV (0.29 and 0.21 for ACI 318 and JBDPA methods, respectively). Only for specimen MO 3, V_{exp}/V_{calc} was less than 1.0 (actual ratio was 0.92).

With the third method, which used the Palieraki et al. approach, lowest V_{exp}/V_{calc} ratios were calculated. In this method, roughness along the interface was an important parameter in calculating specimens' strength. In models where surface of the old concrete at the connection was roughened (specimens AO 6, AO 7, AO 9 and PA 7) calculated strength was conservative. In effect, V_{exp}/V_{calc} was greater than 1.0, with an average of 1.31 and CV=0.15. For tests where no additional roughness was provided (specimens PA 4, PA 5, MO 1, MO 2 and MO 3), calculated strength was conservative only for the specimen PA 5. In Figure 6, V_{exp}/V_{calc} for tests PA 4, PA 5, MO 1, MO 2 and MO 3, was 0.90 on the average, with a CV=0.11. The strength of the specimens HA 5 and HA 6 was not calculated with this method because no specimens with an embedment length smaller than $6d_b$ were included in the database used to calibrate the proposed method.

Figure 3. Ratio of experimental to calculated strength of the specimens with a failure mechanism at the connection.

4 BACKBONE CURVES FOR PERFORMANCE-BASED SEISMIC DESIGN

Performance-based seismic design of new and rehabilitated buildings requires modelling of the structure and its components to large deformations. Aimed at providing guidance on the modelling of RC frames rehabilitated by the addition of new RC walls, backbone curves were developed. Backbone curves of specimens with a failure mechanism at the connection between the infill wall and the upper beam and/or the foundation are shown in Figures 4 and 5. Backbone curves for other failure mechanisms, outside the scope of this paper, have been developed and may be found elsewhere (Moctezuma 2022). The behaviour was different among tests although a “connection failure” was reported. Based on this observation, the envelope curves of the specimens were divided into four different types. Each type corresponded to a specific mode of failure within the connection. Envelopes were obtained by digitizing the published hysteresis

loops or, when available, envelope curves (Rohatghi 2021). The curves were normalized by the shear friction strength computed as the product of the connection transverse area (infill wall and columns) and the reported yield strength of the reinforcement across the connection (either expected or measured yield strength) (Equation 11).

$$V_N = V / [(A_C + A_w)f_y] \tag{11}$$

where: V_N = the normalized lateral force; V = measured lateral force N , A_c = sum of the cross-sectional area of each column mm^2 ; A_w = cross-sectional area of the wall, mm^2 ; and f_y = yield strength of the connectors, N/mm^2 .

In general, curves exhibit a trilinear or tetra-linear form. The first linear elastic branch ends at cracking; the second branch is limited by the strength, while the third represents the descending portion of strength in the experiment. When at large drift angles a residual strength was identified, a fourth horizontal branch was used in the model. The backbone curves obtained from the envelopes of the specimens HA 6 and HA 7 are presented in Figure 4a. In these specimens, the connectors were sheared off resulting in the failure of the retrofitted frame; once strength was reached, loss of resistance and stiffness was observed. For PA 4 and PA 5 (Figure 4b), failure was due to a combination of shearing of the dowel bars at the connection with the foundation with shear failure at the column base. In this case, the backbone curve could be approximated as a curve with a yielding plateau.

Figure 4. Backbone curves of specimens: a) HA 5 and HA 6 (Higashi et al. 1980); b) PA 4 and PA 5 (Papatheocharis et al. 2019).

In specimen PA 7 (Figure 5a), columns of the existing frame were retrofitted with a RC jacket. At yielding, strength was maintained prior to loss of strength and stiffness, following a linear degradation. Failure of PA 7 was attributed to shearing of the connectors from the beam and shear failure at the top of the columns. In specimens MO 1 and MO 3 (Figure 5b), failure at the connection was credited to shearing of the dowel bars of the connection with the foundation. For these tests, the backbone curves feature three branches.

Figure 5. Backbone curves of specimens: a) PA 7 (Papatheocharis et al. 2019); b) MO 1 and MO 3 (Moretti et al. 2014).

PA 4 and PA 5, PA 7, MO 1 and MO 3 exhibited significant slip between the wall and the frame led to the failure of the specimens and a conspicuous strength and stiffness decay. From the graphs, it is apparent that normalized peak strength and drift at strength depended on the characteristics of the failure mechanism.

5 CONCLUSIONS

Addition of RC walls to rehabilitate RC frames is a very widely used technique. To develop analysis and design guidelines for building rehabilitation, test results of different wall configurations and its connections to the frame were studied. Experimental investigations on infills, wing walls, concentric and eccentric walls, and on walls with window and door openings were gathered and revised. A dataset of tests was assembled. Different failure modes were observed; details may be found elsewhere (Moctezuma 2022). In this paper, tests with a failure at the connections between the new wall and the existing frame elements have been discussed. Experimental strength was compared to calculated strengths using three methods: a) the Japanese approach (referred to as JBDPA method); b) a combination of the Mexico City Concrete Standards (NTC-Concrete) design equations and the ACI-318-19 Chapter 17 requirements; and c) a combination of the design equation of NTC-Concrete and the interface shear model proposed by Palieraki et al. (2022). Additionally, backbone curves for other different types of failure mechanism at the connection were developed but are not presented here. Based on the analysis of data, the following conclusions were drawn:

Addition of new RC walls for frame rehabilitation is a very common technique. In the aftermath of the 2017 earthquake in Mexico City, concentric walls (walls with a collinear axis with the frame and the vertical reinforcement is continuous) were the most used configuration.

Strength of the connection depended on the type of detailing used. Superior behaviour was observed where surface roughness along the connection interface was implemented and sufficient amount of properly anchored reinforcement was placed across the connection.

From the three methods used to calculate connection strength, the JBDPA methodology and the combination of NTC-Concrete and the ACI 318-19 Chapter 17 requirements led to conservative estimations. Strength estimations with the JBDPA method were closer to experimental strength and with lower coefficient of variation than those calculated using the combination NTC-Concrete/ACI 318-19. With the third method, that considers friction along the interface and dowel action, strength calculations were conservative where intentionally roughened interface surface was implemented. When the surface was not prepared, results were unconservative, but close to experimental values (average measured-to-calculated strength ratio of 0.90).

Composite action in tunnel linings by use of shear connectors in concrete interfaces

ABSTRACT: The standard construction method of the sprayed concrete lining (SCL) in soft ground tunnelling comprises a temporary primary lining of sprayed concrete, a permanent cast-in-situ or sprayed secondary lining and a waterproofing membrane interface between them. In the last twenty years, a novel design philosophy suggests the primary lining to be part of the permanent structure contributing to the long-term structural response of the tunnel's SCL system. Also, if the sheet membrane is substituted with a sprayed one, some bond and shear capacity can be assumed between the concrete linings. This could lead to a composite behaviour and load sharing between the linings, potentially reducing the secondary concrete lining thickness and improving the overall system's efficiency, e.g., by reducing excavation volumes and lining material consumption. This paper presents research for this composite configuration by use of mechanical shear connection in relation to the tunnel's geometry. This is further compared to the boundary situations with frictionless interfaces and full monolithic bond. This paper delivers first insights on this novel concrete lining philosophy aiming to significantly improve the overall sustainability and life-cycle load bearing performance of critical underground infrastructure assets.

1 INTRODUCTION

In soft ground tunnelling, the standard construction method of a sprayed concrete lined tunnel (SCL) includes a temporary primary lining of sprayed concrete, a permanent cast-in-situ or sprayed secondary and a sheet waterproofing membrane between them. Over the last two decades, an innovative tunnel design philosophy has been established considering the traditionally primary lining as part of the long-term structure. According to (Spyridis 2014), a long service life for primary lining sharing the loading with the secondary lining can lead to a material reduction of 40-45% for tunnel construction, while the savings in concrete consequently result in additional savings in excavation volumes. Moreover, the use of a new sprayed membrane material as a structural bonding connection between the concrete linings has been introduced leading to a composite bonded action of the two lining layers. This denotes the ability of the concrete linings to transmit shear stresses within them leading to a composite action of the whole tunnel's SCL system. Several experimental investigations have been conducted in recent years (Nakashima et al. 2015; Johnson et al. 2016; Su & Bloodworth 2016, Vogel et al. 2017), including both laboratory and on-site testing procedures, in order to evaluate the degree of the bond and the shear transfer between the linings. Detailed studies on the sustainability performance of such lining configurations on the basis of Global Warming Potential (GWP) metrics are presented in (Spyridis & Bergmeister 2023a; Spyridis & Bergmeister 2023b).

Besides, the topic of the shear transfer between concrete interfaces in general has gained a lot of scientific interest for more than 60 years (Palieraki et al. 2021). This is reflected in the amount of existing experimental investigations and the number of design provisions that have been published throughout the years covering this specific topic. Significant recent paradigms include references to the ACI 318 (Palieraki et al. 2022), fib Model code 2010 (Randl 2013) and the EOTA TR 066 (EOTA 2019). More profound information regarding composite structures can be found in (Johnson 2018). In addition, (Palieraki et al. 2021) (Randl 2013) deliver a thorough description of the design recommendation of the fib model code 2010 and the theory behind them, alongside the summary of more than a thousand experiments from the last 60 years.

There are many ways to introduce a composite behaviour between the interface of concrete constructions that were cast in separate time frames. One of the most efficient methods due to its applicability and fast implementation is with post installed anchors that behave as shear connectors. These post installed anchors are commonly used with success for repairing or strengthening applications considering both static and life-cycle actions (recurring and extreme loads); examples can be seen in (Vintzileou & Palieraki 2007) and (Kwon et al. 2010). Particularly the latter indicates that post installed anchors have a significantly higher performance than the corresponding conventional shear studs. (Palieraki et al. 2021) suggests a new modified design formula for monotonic and cyclic actions based on investigations and verification accounting for more than 1240 previous experiments on post-installed dowels. In the same spirit, (López-Carreño et al. 2020) and (Heinrich et al. 2019) conducted a series of real-scale experimental investigations on the performance of post-installed anchors as shear connectors between concrete elements. In both studies, the performance of the dowels is tested under both static and cyclic long-term loading. The results proved that the performance of mechanical post-installed anchors has a very satisfactory behaviour in terms of shear load transfer.

The main focus of the present study is to provide preliminary insights into an innovative approach for composite sprayed concrete linings (SCL). By means of post-installed dowels as shear connectors, the overall thickness of the concrete linings can be reduced while increasing the sustainability of this construction methodology. The performance of post-installed dowels as a shear transfer mechanism has been well established but still, there is no sufficient research on how they operate in conjunction with the tunnel geometry and SCL linings. Moreover, this study aims to highlight the influence of the shear connectors' geometrical distribution throughout the length of the tunnel linings. For the purpose of the present study, two different finite element (FE) software are used. Rocscience2 (RS2) as exclusively geotechnical FE software is utilized to evaluate the loading conditions at a shallow tunnel's linings caused by the ground in long term conditions. Subsequently, the critical tunnel's cross sections derived, are designed in ANSYS FE with interface shear connectors and the system's overall structural performance is assessed.

2 GROUND – STRUCTURE INTERACTION SIMULATION

2.1 *Geotechnical model*

In order to simulate the long-term geotechnical conditions and the construction sequence of a shallow tunnel (20m below ground level), a multi-stage model is demanded. RS2 as a geotechnical finite element (FE) software is able to simulate the tunnelling process step by step assuming full-face excavation. The model of the present study consists of the following four stages:

- Initial ground conditions
- Ground relaxation, to simulate unloading and convergence prior to lining installation
- Full-face excavation and installation of the concrete lining
- Long-term ground conditions in interaction with the tunnel

In RS2, a rectangular block is designed to represent the geological model of the study. The tunnel's cross section is placed at a distance of 5 tunnel diameters from the block's edges. Based on research of available geotechnical information in relevant publications (Spyridis et al. 2016), this geological model is assumed to represent a typical London clay soil with an initial drained Young's modulus (E_{clay}) equal to 300 MPa and Poisson's ratio equal to 0.3.

Two tunnel geometries were chosen for the present study. The first one has a height/width ratio < 1 and is referred to as a wide (long) tunnel shape. The second one has a height/width ratio > 1 and is referred to as a tall tunnel shape. Both of them, have an excavation area equivalent to a typical circular tunnel with 8m diameter. All the geometries were designed in AutoCAD software and imported to RS2. The numerical models implement 2D plane strain analyses following the Mohr Coulomb failure criterion. The ground is modelled by 3-noded triangular solid elements, and the concrete lining is modelled by the Timoshenko-standard beam elements. The lining is assumed 0.6 m thick and is modelled by an elastic concrete material with Young's modulus of 25000 MPa and Poisson's ratio of 0.2. The support configuration assumes two separate 0.3 m thick linings with a fully bonded contact between them, representing a monolithic connection. The mesh of the model for the indicative long shape cross section is shown in Figure 1. The model block is simply supported at the two sides allowing the vertical displacement. The bottom of the block is simply supported allowing the horizontal displacement while the bottom corners are considered fixed. The upper limit serves as the free surface of the ground. Underneath the tunnel's cross section, there are three soil regions with different properties compared to the surrounding ground. The yellow layers have a drained Young's modulus equal to 600 MPa ($2 \times E_{\text{clay}}$) and the green one has a drained Young's modulus equal to 900 MPa ($3 \times E_{\text{clay}}$). The basic purpose of this consideration was to achieve better results regarding the ground's unloading heave at the tunnels' invert. During the excavation sequence, the anticipated heave at the invert has a ratio of approximately 1/3 of the settlement at the crown. In general, this consideration aims to account for a stiffer ground response during unloading phase. Hence the material properties of the surrounding ground are modified in the fourth stage, except for the unloading layers which remain unaffected. Specifically, there is a reduction in Young's modulus value which is equal to 140 MPa (E'_{clay}) and an increase in Poisson's ratio value which is equal to 0.45. With this, the geotechnical conditions are simulated more accurately in interaction with the tunnel structure at the final stage, after the lining's installation.

2.2 Probabilistic model – Stochastic input parameters

The geotechnical conditions play a primary role in tunnels designing. Due to their inherent uncertainty and spatial variability, a probabilistic analysis is needed. A 1000-point sample of unput parameters is populated using a Latin Hypercube simulation in order to assess the variability of the lining section because of the uncertainty of the surrounding ground. The selected stochastic parameters are assumed to follow a normal distribution. The same 1000-point sample is used in the FE analyses of the cross sections. The ground's Young's modulus (E_{clay}) and the lateral earth coefficient (K_o) are the stochastic parameters while the material properties of the concrete are kept deterministic. Table 1 provides an overview of the geotechnical input parameters of the probabilistic analyses.

Figure 1. RS2 finite element model of the wide shape tunnel.

Table 1. Geotechnical stochastic input parameters.

Soil Property	Units	Mean value	Standard deviation
E_{clay}	MPa	300	75
E'_{clay}	MPa	140	35
Soil layer (2x E_{clay})	MPa	600	150
Soil layer (3x E_{clay})	MPa	900	225
K_o	-	1	0.1
Unit weight	MN/m ³	0.02	-
Peak friction angle	°	25	-
Peak cohesion	MPa	0.1	-

Figure 2. Vertical displacement – Bending moment diagrams of wide cross section (top) and tall cross section (bottom) in RS2.

2.3 RS2 Probabilistic analyses results

The results of the probabilistic analyses, under gravity load, confirm that the expected ground's heave occurs only underneath the tunnel's cross section while the expected settlement occurs at the crown respectively. Hence for both the cross sections, the heave/settlement ratio in long-term ground conditions is approximately equal to 1/3, proving the initial theoretical assumption about ground stiffer unloading response. According to the bending moment diagrams displayed at cross sections circumference (Figure 2), two curvatures for each tunnel shape are obtained and are utilized as study cases in Ansys structural analyses. The points where the bending moment is equal to zero at tunnel's crown define the cross section that is used subsequently in Ansys software assumed as an approximate location of hinge support (see horizontal line in Figure 2). The selected curvature is considered as the most critical for the function of the whole tunnel structure. The vertical displacement at the crown is 17 mm and 14 mm for the wide and tall cross section geometry respectively. Based on these values, the load conditions in Ansys are back-analysed accordingly in order to achieve the same displacements.

3 STRUCTURAL FINITE ELEMENT SIMULATION

3.1 *Simulation design process*

In the present study, the Static Structural system of Ansys workbench (Version 2020 R1) is utilized for the finite element analysis (FEA), as the most suitable for the investigation of the behaviour of tunnel concrete linings with interface shear connectors. The two cross sections extracted from the RS2 bending moment diagrams are designed accordingly in Ansys design modeler. The curvature for both cross sections is different due to the different bending moment diagrams in RS2 as a result of the unlike tunnel shape. The wide shape's cross section length is 5m while the tall shape's length is 5.7m respectively. 2D plain strain analyses are implemented. The two tunnel linings are 0.3m thick and are modelled with a bilinear material law for concrete with yield stress equal to 50 MPa. The steel Young's modulus is equal to 25000 MPa and the Poisson's ratio is equal to 0.2. The mesh is modelled by triangular-rectangular linear elements with a size of 0.05m. Each lining is supported by nodal supports at the middle of their thickness for both edges. Rotational movement is permitted by the left nodal support while horizontal displacement is allowed by the right one.

In order to achieve the RS2 crown displacement in Ansys, several preliminary parametric analyses were carried out. The scope of these parametric analyses was to identify the load which causes the same crown displacement indicated by Table 2. For both cross sections, the interface's contact was considered fully bonded, assuming a system thickness of 0.6m, and a uniform load was applied at the upper surface of the primary lining. Nodal supports were selected at the mid-span of the system's thickness allowing rotational displacement on the left side and horizontal movement on the right one. The concrete material was kept elastic with Young's modulus of 25000 MPa and Poisson's ratio of 0.2. Indeed, this led to identical crown displacements for both cross sections and the estimated uniform load was used subsequently for the FE structural analyses of the two concrete linings with mechanical interface shear connection.

3.2 *Specifics of modelling of dowel interface reinforcement*

As mentioned before, the scope of the present study is to report investigations on the novel theory of connecting tunnel concrete linings with shear connectors, e.g., dowels, which potentially may lead to composite behaviour. Given the complexity of the problem, a series of assumptions were adopted. In construction, the shear connectors are spatially dispersed throughout the entire length of the tunnel. Considering the two-dimensional design of the simulations, the diameter of the shear connectors was intentionally increased in order to correspond to one-meter investigation length. The total cross-sectional amount of steel was 36 cm². In total two configurations of shear connectors were investigated. The first configuration consists of 2 shear connectors placed at a distance of 1/4 of the linings' total length from the supports. The second configuration consists of 4 shear connectors that are placed at an even distance of 1/4 of the linings' length from each other, thus allowing a clearance of 1/8 of the total length from the supports (see Figure 3). The shear connectors in both configurations have a length of 0.3m and are placed in such a way in order to bridge the two concrete linings forming the interface connection between them. Each lining is penetrated equally by 0.15 m shear connectors length. In the configuration of the two shear connectors, the 2D width of each is equal to 0.060 m while in the four shear connectors configuration, the 2D width of each is equal to 0.030 m. The shear connectors were modelled by surface elements with a typical elastic material of steel with Young's modulus of 200000 MPa and a Poisson's ratio of 0.2. For the simulation of the interface between the concrete linings and the shear connector, a perfectly bonded contact was applied. The slip of the shear connectors was considered to be outside of the scope of this study. The interface between the concrete linings was considered frictionless in order to highlight the contribution of the shear connectors to the performance of the whole system. Two extreme cases without shear connectors were additionally evaluated, that of two concrete linings with frictionless interface and a fully bonded one. These two served as benchmarks in order to estimate the influence of the shear connectors on the system's structural response. The study cases in conjunction with the number of shear connectors and the concrete linings interface are summarized below:

- Case study 1: No shear connectors, frictionless interface
- Case study 2: Two shear connectors, frictionless interface

Figure 3. Wide shape cross section mesh in conjunction with shear connectors and boundary conditions (left); locations of interest/points of data extraction for the structural assessment (left).

- Case study 4: No shear connectors, fully bonded interface

3.3 Simulation results of arch with advanced interface configuration

For both cross sections, the most critical area is at the mid span where the maximum vertical displacement occurs. Two study points for each lining were chosen, one at the upper part of the lining and one at the bottom part. All the study points were aligned vertically at the centre of the linings mid-span. Vertical displacements, stresses and strains are the structural parameters which are evaluated by the structural analyses. Figure 3 shows the four investigating points. For these four locations, both strains and stresses are recorded while the vertical displacement is recorded only for the bottom points i.e., Points B and D. This differentiation is due to the fact that the vertical displacements at both points of each lining have insignificant differences.

From the first sight of the vertical displacement results, it can be seen that the concrete linings geometry plays a significant role. This becomes more evident when there is no means of shear transfer at the interface of the two linings i.e. frictionless interface. The frictionless case is the worst study case scenario in terms of maximum displacement and the most uneconomical design methodology (Figure 4). In these figures, it can be observed that there is a significant difference in distribution of the vertical displacement. The most uniform case is that of the two fully bonded linings which proves that they perform as a composite system. For both cross sections, the case with the four shear connectors exhibits a very similar behaviour to that of the fully bonded linings. On the other hand, the study case with the two shear connectors presents a unique vertical displacement distribution where the secondary lining has a greater deformation than the primary lining. This phenomenon becomes more obvious in the case of the tall cross section. Such a differential displacement between the primary and the secondary lining can potentially pose a threat to the performance of the waterproofing membrane and overall system's safety..

In Figure 5, the distribution of the stresses within the concrete layers is presented by the contour plots. Like in the case of the vertical displacement, the geometry, the interface connection and the combination of them impact the stresses distribution within the concrete linings. The frictionless case exhibits the highest stresses for both cross sections. It can be seen that in both linings there are both compression and tension zones. This proves that the two concrete linings work as two discrete bodies. On the contrary, for the bonded scenarios, there is clearly one single compression and tension zone indicating that the concrete linings work together as one body. The more evenly installed shear connectors can lead to a behaviour closer to that of the fully bonded. A high concentration of normal stresses is observed around the area of the shear connectors. This phenomenon is more intense in the case of the two shear connectors. Furthermore, it becomes evident that the shear connectors perform under shear loading conditions. The further the distance of the shear connectors installation position from the mid -span of the cross sections, the greater the induced load. In the case of two connectors, further insight is provided by the stress distribution regarding the phenomenon of differential vertical displacement. In the upper lining, compressive stresses are mostly observed, while the bottom lining works under significant tensile stresses. This indicates that between the two connectors, the linings behave as a truss system. Where the upper lining operates as a compression element and the bottom part as a tensile element. As

mentioned above, the material law for the concrete linings is that of a bilinear perfectly plastic material with a yield stress of 50 MPa. Therefore, some significantly high tensile stresses that are unrealistic for concrete elements can be seen, especially for the frictionless case.

4 CONCLUSIONS

This study investigates the ability of dowels (considered here predominantly as post-installed anchors) to act as structural fastening to reinforce the interface between the primary and secondary sprayed and cast concrete tunnel linings. The composite performance of such a system is examined in relation to the tunnel geometry and the dowels' spatial arrangement. In total, two different cross sections are simulated based on a combination of geotechnical and structural FE software.

Figure 4. Vertical displacement (mm) contour plots of the wide cross section (left) and the tall cross section (right) for every case (top down view: frictionless, 2 shear connectors, 4 shear connectors and bonded).

Figure 5. Stress (MPa) distribution contour plots of the wide cross section (left) and the tall cross section (right) for every case (top down view: frictionless, 2 shear connectors, 4 shear connectors and bonded).

For each configuration, two scenarios of dowels' arrangement are assumed and compared with two extreme cases of interface connection. Besides two types of ovalized cross sections (long and tall) are considered. According to the findings, the cross sections geometry plays a significant role in the structural behaviour of concrete linings with any type of combined or composite action in the long-term. The most influential factor though is the ability to transfer shear through the interface between the concrete linings. Particularly, the configuration with the four shear connectors, for both cross sections, tends to acquire a composite behaviour identical to the one with a fully bonded interface. On the other hand, the configuration which consists of two shear connectors allows some slippage between the linings: a relative displacement between the secondary and the primary lining is observed which could potentially lead to higher bending resistance requirements

Table 2. Concentrated strain values for the study points A to D.

Type	Case	Primary lining		Secondary lining	
		Point A	Point B	Point C	Point D
Wide shape cross section	Frictionless	-2.1	2.1	-2.1	2.1
	2 dowels	-1.3	0.2	-1.0	1.8
	4 dowels	-1.2	0.0	-0.4	1.3
	Bonded	-1.7	-0.1	-0.1	1.6
Tall shape cross section	Frictionless	-1.7	1.2	-1.6	1.8
	2 dowels	-0.6	0.0	-0.5	0.8
	4 dowels	-0.5	-0.1	-0.2	0.6
	Bonded	-1.0	-0.2	0.0	0.9

and hence additional material consumption (concrete/steel) and, accordingly, excavation volumes, with immediate impacts on the overall system's structural as well as sustainability performance. This highlights the necessity to consider the geometrical particularities of such systems and optimise them in terms of curvature and fasteners distribution. Further investigations on the application of post-installed dowels between sprayed/cast concrete tunnel linings can lead to enhanced reliability in the composite lining behaviour of the system and open the ways for more sustainable design solutions by reducing the concrete lining thickness and overall life-cycle requirements for materials.

SHM-informed management of bridges in a life-cycle perspective

L. Ierimonti, F. Mariani, I. Venanzi & F. Ubertini

University of Perugia, Perugia, Italy

ABSTRACT: Recent bridge failures highlighted that bridges are key elements for guaranteeing the functionality of transportation systems. The main causes of bridge's deterioration are the exposure to environmental conditions and the steadily increase of traffic volume. Hence, timely maintenance interventions are crucial to guarantee adequate performance levels. To the purpose, the actual practice is mainly based on visual inspections. Recently, the "Guidelines for risk classification and management, safety assessment and monitoring of bridges" issued in 2020 by the Italian Ministry of Sustainable Mobility promoted the use of Structural Health Monitoring (SHM) systems. Hence, the goal of the present work is to develop a general framework able to evaluate the costs and benefits of different SHM-based strategies in a life-cycle perspective. The results highlight the twofold potentiality of the proposed framework in quantifying and updating in a unified manner the bridge's lifetime expenses, and in comparing different alternatives of SHM systems.

1 INTRODUCTION

The extensive use of SHM on real-world structures is strongly limited because of the difficulty in quantifying the benefit of monitoring systems, which have non negligible installation and maintenance costs. Recently, probabilistic-based framework are developed with the main objective of quantifying the value of SHM in a life-cycle costs perspective (Thöns 2018, Kamariotis et al. 2023). Indeed, Life Cycle Cost Analysis (LCCA) is commonly considered an important technique for assisting investment decisions, since it allows to compute, in a probabilistic setting, the total lifetime cost, accounting for all the possible cost sources like initial costs, repair and maintenance costs, inspection costs, SHM-related expenses, downtime costs and, eventually, disposal costs. The main idea is to assist decision making in allocating economic resources according to the best cost-benefit performance criteria. The LCCA is a widely used methodology in earthquake engineering (Wang et al. 2015) and in wind engineering (Ierimonti et al. 2019) and it is currently spreading in bridges applications (Frangopol et al. 2017, Venanzi et al. 2019, Torti et al. 2022). As underlined in (Biondini & Frangopol 2016) there is the need to further investigate the field of life-cycle performance of bridges under uncertainty in order to fill the gap between theory and practice by incorporating life-cycle concepts in structural design.

In order to gather the slowly evolving deterioration processes over the lifetime of a bridge it can be appropriate to collect relevant data continuously over time, and incorporate the extracted information into a time-dependent reliability analysis (Kim & Song 2021). In light of this, an important parameter for the buildings safety evaluation is the deflection. The inclinometers can be used as simple and inexpensive method to control the deflection during the construction life-cycle. Indeed, the measured data can be processed by analytical functions that link the values of the rotation angle with the deflection curve (Lan et al. 2019, Hou et al, 2005).

In recognition of the above mentioned needs, a LCCA-based approach in conjunction with the use of a continuous SHM system is proposed, with the aim to highlight the advantage of the use of an SHM system. The main novelty of the approach is that the structural reliability is automatically evaluated and updated continuously over time as a support to visual inspections, accounting for real time SHM data related to different Damage Limit States (DLS).

Moreover, the use of a LCCA-based framework allows to quantify in a unified manner the bridge's lifetime expenses and to perform a quantitative comparison between different alternatives of SHM systems, in terms of life-cycle costs.

The feasibility of the method is explored through numerical simulations aimed at controlling the span deflection during the years of a post-tensioned single-span concrete bridge including bridge's damage over time, environmental noise and instrumental errors.

The rest of the paper is organized as follows. Section 2 gives an overview of the theoretical background. Section 3 presents the proposed framework. Section 4 illustrates the case study. Section 5 highlights some preliminary results and Section 6 concludes the paper.

2 THEORETICAL BACKGROUND

The concepts of LCCA with a general formulation for the evaluation of the expected life-cycle is presented in (Wen & Kang 2001). According to LCCA approach, the life-cycle cost can be computed as follows:

$$E[C(T)] = C_I + \sum_{t=1}^T \left[\frac{E[C_M(t)] + E[C_F(t)]}{(1+r)^t} \right] \quad (1)$$

where $E[\]$ is the expected value, C_I is the initial cost which can be defined as the sum of the initial construction cost and the cost of the SHM system $C_I = C_0 + C_{SHM}$, C_M is the maintenance cost at time t , C_F is the cost of failure at time t , T is the bridge's lifetime, and r is the discount rate. The cost of failure C_F depends on the analyzed DLS and can be formulated as:

$$E[C_F(t)] = \sum_{s=1}^S \sum_{x=1}^K P_{f,s,x}(t) n_s c_{R,s} \quad (2)$$

where S is the total number of independent DLS s ; K is the total number of relevant sections x along the structural members; $P_{f,s,x}(t)$ is the time-dependent probability of failure evaluated for the s -th limit state at section x ; $c_{R,s}$ is the repair cost for limit state s for unit element, and n_s is the number of unit elements subjected to limit state s .

In order to compute the failure probability $P_{f,s,x}(t)$ in Equation (2), for each considered limit state and for each section, the Hasofer-Lind procedure is adopted. Probabilities of failure are calculated considering stochastic independence between all the involved random variables and treating them as normally distributed. In this way, the probability of failure is related to the well-known reliability index, which represents the shortest distance of the selected limit state function from the origin of the reference system in the space of normal standard random variables.

$$P_{f,s,x}(t) = \Phi\left(-\beta_{j,k}(t)\right), \quad (3)$$

3 THE PROPOSED FRAMEWORK

The proposed methodology consists of the steps presented in Figure 1 and summarized as follows:

1. Select possible DLS which can be monitored through the available SHM system. The sensors located along the structures allow to monitor one or more DLS.
2. Perform data analysis and pre-processing. In this phase environmental effects must be removed from original signals by means of statistical models after analyzing the time series of ambient and material temperature measurements during a training period, typically 1 year ensures the optimal calibration of the statistical models.
3. For each selected j -th DLS (such as bridge deflection) perform the reliability analysis as follows:

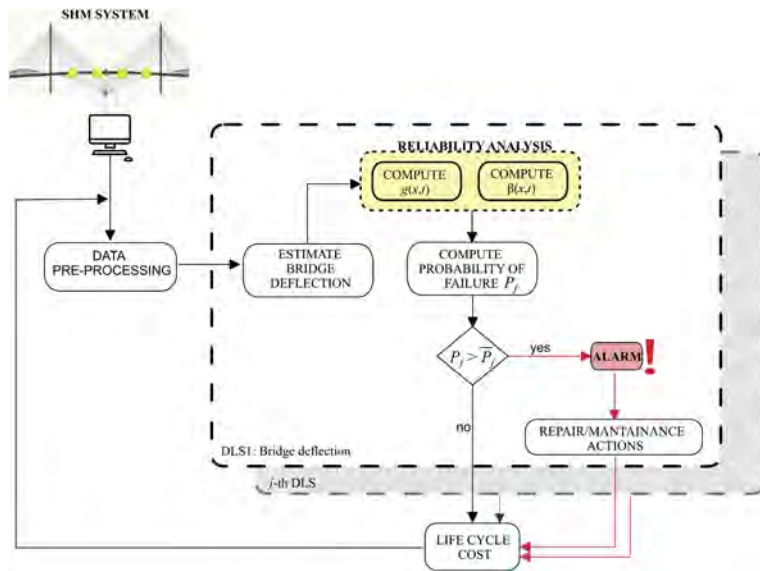

Figure 1. The proposed methodology.

DLS: BRIDGE DEFLECTION

- online estimation of bridge deflection $w(x, t)$, where x indicates the position along the bridge and t stands for time;
 - definition of limit state function $g(x, t)$;
 - online evaluation of reliability index $\beta(x, t)$;
 - evaluation of the corresponding Probability of failure P_f ;
 - if P_f exceeds a pre-defined threshold \bar{P}_f an alarm is activated and further actions are needed, then go to step 5;
 - if P_f does not exceed the threshold \bar{P}_f go to step 5.
-

4. Repeat step 3 for each DLS;
5. Evaluate the LCC and go back to step 1.

4 THE CASE STUDY

A simply supported, post-tensioned single-span concrete bridge is considered as a case study. The concrete slab, with a thickness of 0.2m is supported by 3 beams with a I-shaped cross section, modified in rectangular sections in correspondence of the supports, as represented in Figure 2. Each beam is supported by 2 gravity abutments. The total span of the bridge l is 32 m. The post-tensioning system consists of a total of 5 cables characterized by different strands. Each strand has a diameter Φ of 7 mm. Cables no. 1 and 2 at the beam extrados are composed by 32 strands, while the remaining cables (no. 3, 4 and 5) have 42 strands.

For the numerical simulations, only the permanent loads q and the pre-stress loads $q_{p,eq}$ are included in the model. The value of q is determined considering the influence area of each supporting beam as: $q = q_d + q_s + q_p + q_e$, where q_d is the beam's dead load equal to 15.8 kN/m; q_s is the upper slab load equal to 14.30 kN/m; q_p is the pavement's load equal to 3.26 kN/m; q_e refers to the superstructure's equipment and it is equal to 2 kN/m.

The equivalent pre-stress loads $q_{p,eq}$, evaluated as a uniformly distributed load, is calculated as: $q_{p,eq} = \frac{8Ne_0}{L^2}$, where N is the total axial force applied to the tendons, e_0 is the distance between the section center of gravity and tendons at the middle-span and L is the length of the tendons.

For the analyzed case study $q_{p,eq}$ is equal to 36 KN/m.

Table 1. Properties of inclinometers used in case study [Huseynov et al. 2020].

Type	Measurement Range [°]	Precision [°]	Resolution [°]	Sampling Rate [Hz]
1	±85	±3·10 ⁻²	3·10 ⁻³	100
2	±1	±4·10 ⁻³	1·10 ⁻⁴	125

Figure 2. The case study: Longitudinal and cross sections of the bridge.

4.1 SHM system

In order to demonstrate the feasibility of the proposed framework, a monitoring system is considered installed along the structure consisting of 5 inclinometers (Figure 3), which is commonly considered the minimum number of sensors to accurately reconstruct the bridge's deflection (Lan et al. 2019). Then, monitoring data (rotations) θ^* are artificially simulated as follows:

$$\theta^* = \theta_0^*(1 + \epsilon), \quad (4)$$

where θ_0^* is the analytically measured nodal rotation at each inclinometers' position and ϵ represents the noise coefficient which accounts for measurement uncertainty associated with sensors precision.

Figure 3. SHM system consisting of 5 inclinometers installed along the beam of the bridge.

For this application, two different types of inclinometer, designated as type 1 and type 2, with a different precision level are selected. Sensor's properties are summarized in Table 2 (Huseynov et al. 2020).

4.2 Degradation model

For the numerical simulations, a degradation model is adopted to reproduce the progressive decrease of concrete elastic modulus due to damage. For the purpose, a simplified degradation model is selected (Venzani et al. 2019, Biondini & Marchiondelli 2008): $E(t) = [1 - \delta(t)]E_0$ where E_0 is the nominal value and $\delta(t)$ is evaluated according to (Venzani et al. 2019).

4.3 Reliability analysis

In order to perform the reliability analysis continuously over time t , the bridge deflection is selected as a DLS and the following limit state equation is defined.

$$g_w(x, t) = \frac{L}{250} - w(x, t), \quad (5)$$

where $w(x, t)$ is the bridge's deflection that can be evaluated by means of analytical methods under predefined assumptions ($w_0(x, t)$) or experimentally using SHM data ($w^*(x, t)$). Analytically, the deflection can be evaluated according to the well known Euler-Bernoulli beam theory as follows:

$$w_0(x, t) = \left[\frac{(q(t) - q_{p,eq(t)})x}{24E(t)J(t)} \right] (l^3 - 2lx^2 + x^3) \quad (6)$$

where E_c is the concrete elastic modulus; J is the moment of inertia; l is the span of the bridge; q and $q_{p,eq}$ are defined in Section 4. Deriving Equation (6) it is possible to evaluate the rotation at the position x as follows:

$$\frac{\delta w_0(x, t)}{\delta x} = \theta_0(x, t) = \left[\frac{(q(t) - q_{p,eq(t)})}{24E(t)J(t)} \right] (l^3 - 6lx^2 + 4x^3). \quad (7)$$

According to (Lan et al. 2019), assuming that a certain number of inclinometer N are installed along the bridge, it is possible to reconstruct the bridge's deflection based on inclinometer data by means of an appropriate polynomial function:

$$w^*(x, t) = A(x) [a_1(t)x^3 + a_2(t)x^2 + a_3(t)x + a_4(t)] \quad (8)$$

where $A(x)$ is a function that respects the boundary conditions of a simply supported beams, defined as $A(x) = x(x - L)$; the terms $a_i(t)$ ($i = 1, \dots, 4$) are the unknown coefficients to be calibrated through experimental data at each time step t . Deriving Equation (8) the rotation angle function is obtained:

$$\theta^*(x) = A'(x) [a_1(t)x^3 + a_2(t)x^2 + a_3(t)x + a_4(t)] + A(x) [3a_1(t)x^2 + 2a_2(t)x + a_3(t)] \quad (9)$$

It is clear that an accurate reconstruction of the bridge deflection require at least 5 or more inclinometers (Hou et al, 2005).

A group of optimal solutions for coefficients $a_i(t)$ can be obtained by using the least square method (Lan et al. 2019) consisting in minimizing the following objective function:

$$J(a_1, a_2, a_3, a_4, t) = \sum_{j=1}^N (\theta^*(x_j, t) - \theta_j(t))^2 \quad (10)$$

where $\theta^*(x_j, t)$ is evaluated according to Equation (9) while $\theta_j(t)$ is the inclinometer's measurement recorded at position x_j .

Once the limit state function is defined, the reliability analysis can be performed and the corresponding probability of failure $P_{f,s,x}(t)$ can be evaluated, according to Equation (3). Table 1 summarizes the parameters of the probabilistic distribution of random variables (mean values and co-variance CoV) that have been used in this study (Joint Committee on Structural Safety 2000).

Table 2. Reliability analysis: the selected random variables.

No.	Variable	Symbol	Mean Value	CoV
1	Concrete Elastic modulus	E_c	32600 MPa	0.15
2	Permanent load	pp	nominal value	0.04
3	Equivalent prestress load	$q_{p,eq}$	nominal value	0.04
4	Measured deflection type 1	$\theta^*(x)$	daily measured value	0.3
5	Measured deflection type 2	$\theta^*(x)$	daily measured value	0.2

Without loss of generality the following cases are analyzed and compared in the numerical simulations: (1) case a), without SHM (w/o SHM), i.e., without the use of monitoring data (selected no. variables 1,2 and 3);(2) case b), with SHM type 1 (selected no. variable 4); (3) case c), with SHM type 2 (selected no. variable 5).

4.4 Life-cycle cost analysis

Total expected life-cycle cost is computed according to Equations (1)-(2) where a discount rate $r = 0.05$ is adopted. Preliminary, in order to demonstrate the potential benefit of the proposed framework, initial costs C_I and maintenance costs C_M are neglected. The repair cost is defined according to (Zhang et al.2022): $c_R = 2 \cdot 10^2 \text{ €}$.

5 PRELIMINARY RESULTS

This section summarizes preliminary results and observations from the LCC-based analyses conducted on the selected case study.

Preliminary, in order to study the influence of the CoV values presented in Table 2, a parametric analysis is carried out by varying CoV from 0.02 to 0.2 for E , q and $q_{p,eq}$. Results illustrated in Figure 4 highlight that index β is strongly influenced on CoV variations of E , meaning that adopting different CoV values for q and $q_{p,eq}$ would not significantly affect the results.

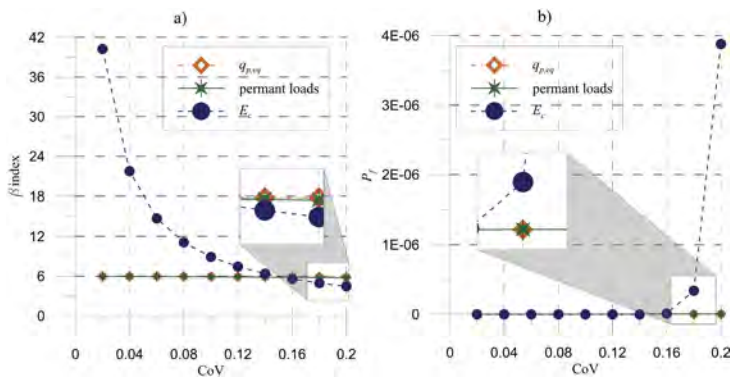

Figure 4. Parametric analysis for the case w/o SHM carried out by varying CoV from 0.02 to 0.2 for E , q and $q_{p,eq}$: a) minimum value of β ; b) corresponding values of P_f .

Then, SHM data are simulated according to Equation (4) with $T = 182500$ days, i.e. 50 years, on a hourly basis. The simulation accounts for the possible concrete degradation, e.g. time-dependent reduction of the Elastic modulus, as reported in Section 4.2. The simulated θ values are averaged on a daily basis.

In Figures 5a)-b) can be depicted some realizations of the bridge's deflection, numerically reconstructed from the simulated SHM data considering type 1 and type 2 inclinometers for a time period $t=35$ days with 1 realization per day. From the figure it can be noted that type 1 results (Figure 5a) have a higher dispersion, due to the lower precision of the selected sensor (see Table 1).

Finally, Figures 6a)-b) summarize the minimum values of β for the cases w/o SHM, with SHM type 1 and with SHM type 2 for the E -related degradation model. It can be observed that the degradation model has a non negligible influence on the reliability index, whose values decreases with time. Moreover, it can be observed the use of a SHM allows to dramatically reduce the intrinsic uncertainty related to the reliability analysis, thanks to the increased level of knowledge, providing higher values of β , which correspond to almost null values of the probability of failure during the analyzed bridge's lifetime (50 years). In addition, the different precision of the sensors type 1 and type 2 leads to a percentage difference of about 25 % in the evaluation of β . It is worth noticing that the values of β obtained in the cases with SHM entail very small values of $E[C_F]$,

due to the very small values of the associated probability of failure. Table 3 summarized the percentage of $E[C_F]$ evaluated at $t=100$ years. For instance, the cost $E[C_F]$ evaluated for the case w/o SHM has an increment of $1.15 \cdot 10^3$ % for the case with SHM type 1 and of $5.3 \cdot 10^{13}$ % for the case with SHM type 2, while type 1 has a percentage increment of $4.6 \cdot 10^{10}$ % with respect to type 2. Without loss of generality, these preliminary results highlight the benefit related to the use of SHM systems in terms of reliability and the potential benefit in terms of LCC, considering the fact that a complete LCCA needs accounting for all the possible DLS and cost components along the bridge's lifetime.

Figure 5. Realizations of simulated deflections (in mm) using type 1 (a) and type 2 (b) inclinometers.

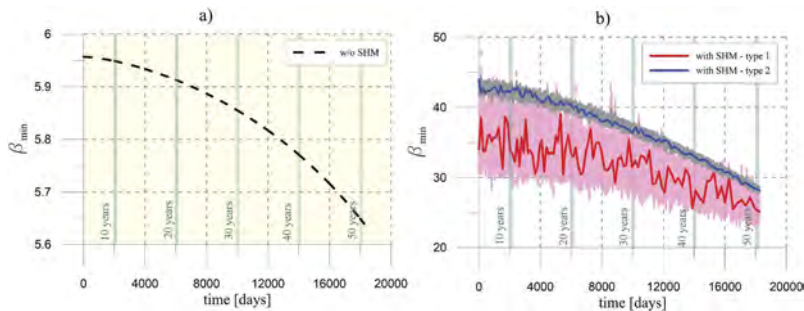

Figure 6. β index over time: a) w/o SHM; b) with SHM type 1 and type 2.

Table 3. Percentage difference (increment) for the total repair cost $E[C_F]$ at $t=100$ years evaluated considering type 1 and type 2 cases with respect to the case w/o SHM and type 1 vs type 2.

	w/o SHM vs type 1	w/o SHM vs type 2	type 1 vs type 2
Increment [%]	$1.15 \cdot 10^3$	$5.3 \cdot 10^{13}$	$4.6 \cdot 10^{10}$

6 CONCLUSIONS

The present paper has proposed an automatic framework for the life-cycle cost analysis of bridges. The feasibility of the method is explored through numerical simulations aimed to control the span deflection during the years of a post-tensioned single-span concrete bridge, including damaging and pres-tress losses, environmental noise and instrumental errors suffered by the measurements. The procedure accounts in a simplified manner for material degradation by introducing the dependency on time of a damage-dependent parameter. Preliminary results confirm that the use of SHM systems allow to reduce the probability of failure and, consequently, the LCC over time, due to the higher knowledge acquired on the structural condition.

The framework facilitates the estimation of the benefits associated with continuous SHM information in order to optimize the SHM strategies before implementation. The procedure is general and can be easily populated with different DLS. The idea is to develop an efficient and adaptive strategy including other types of DLS in conjunction with different sources of information (such as visual inspections and so on) in order to firstly identify the best SHM strategy and then optimize maintenance works over the service life of a deteriorating structure under changing environments.

ABSTRACT: Due to their location, across rivers and streams, bridges often interact with torrential, erosive flows, suffering (1) transient loads of high magnitude, due to flow obstruction, and (2) loss of support, due to scour. To take both components (1) and (2) into account, hazard evaluation is here based on the introduction of an integrated indicator of flood hazard intensity (IFHI). This is an extension of the existing Flood Hazard Index, which is increasingly used to map flood inundation. IFHI is appropriate for the evaluation of bridge susceptibility because it embeds the key parameters of flow velocity, flow obstruction, and sediment characteristics, in addition to inundation height. IFHI is found useful for streamlining the application of the scour hazard indicators recently included in the French guidelines (CEREMA, 2019). Combined with a high-level vulnerability model, it is implemented for a prediction of flood-induced bridge damages across the road and rail network of the Karditsa county in Central Greece. The region was the hot spot of large-scale flooding after a Mediterranean cyclone in September 2020. Comparison between predicted and observed response for 16 bridges, which were inspected after the same flood, allowed validation of the framework's predictive accuracy across the entire range of damage levels, from minimal damage to complete failure. Results verify that IFHI is a suitable hazard indicator yielding reasonably accurate predictions of bridge response to flood hazard impacts, for engineering applications.

1 INTRODUCTION

The Multi-Criteria Decision-Making (MCDM) method is the most popular empirical approach to flood hazard assessment (e.g.: Arabameri et al., 2019; Dodangeh et al., 2020; Kazakis et al., 2015; Papaioannou et al., 2015; Tripathi et al., 2022). It relies on the expert judgment of a decision-maker for the identification and ranking of a set of conditioning criteria (flood controlling parameters).

To the authors' best knowledge, the MCDM framework has been used to date for the characterization of flood hazard only in terms of a location's susceptibility to inundation,

parametrized by floodwater height (h_w). The approach is useful when the main concern is functionality loss due to the submergence of land or infrastructure. However, h_w alone is not adequate to describe the impact of flooding on bridges, because structural failure is influenced by flow – soil – structure interaction mechanisms. The latter are critically dependent on flow velocity (U), which affects the magnitude of hydrodynamic loads as well as scour penetration. Therefore, incorporation of U in the description of flood hazard intensity is key for the evaluation of flood impacts on bridges, especially as they often interact with high-velocity, torrential flows, depending on the type of flood and on the environment.

Here, it is advocated that the AHP-based MCDM method, as implemented in the relevant literature, can be adopted for mapping the spatial variation of U , as well as h_w , provided that the controlling parameters are ranked and evaluated appropriately (as detailed in Loli et al., 2022b). This enables a more comprehensive assessment of hydraulic actions for bridge-specific analysis of flood risk.

The MCDM framework is implemented for the evaluation of the impact of flooding on bridges, through an approach that considers the mechanisms governing flow–structure interaction. The endeavor relies on the extension of the existing methodology, currently used to evaluate the height of floodwater, to simultaneously consider the spatial variation of flow velocity. A new index, namely the Index of Flood Hazard Intensity (IFHI), is introduced combining both components in one measure of flood hazard intensity. IFHI fits squarely in the risk-based framework for the assessment of scour risk, recently included in the French guidelines (CEREMA, 2019; Durand et al., 2018). This paper provides a synopsis of a recent study (Loli et al., 2022b), setting a roadmap for use of a bridge-specific flood risk assessment framework, focusing on the realistic prediction of bridge damage in intense flood events.

2 METHODOLOGY

Figure 1 displays the methodological framework. It includes three core modules, where hazard, vulnerability, and consequences are assessed independently. Assessment of damage is carried out at the asset scale integrating hazard (through the IFHI) with a simple, but reliable, vulnerability model, fused with basic engineering parameters relevant to the design, construction, and maintenance characteristics of the structure. By contrast, a systemic perspective is adopted for the assessment of consequences. The three components are integrated via interaction matrices. The classification of hazard and vulnerability in three classes from 1– 3, i.e., from low to high, allows the construction of a 3x3 damage prediction matrix, which yields the predicted DL of the specific asset.

C is the key to the scaling-up of the analysis from asset level to the system level. It is evaluated based on parameters that correlate bridge damage with the associated impact on the transport network and its users. Considering C in conjunction with DL yields an estimate of Risk (R), on a scale from of 1 to –5.

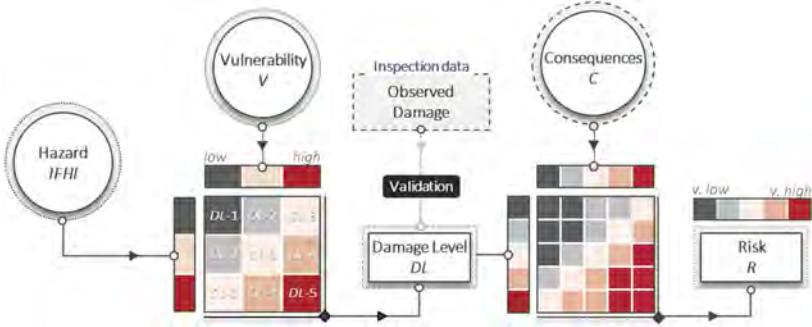

Figure 1. The methodological framework for the assessment of flood-induced bridge damage and the associated system (network) risk.

The framework is implemented to study flood risk in the county of Karditsa, (Central Greece), a flood-prone area which suffered widespread devastation, including tens of failed bridges, after the passage of a catastrophic cyclone in September 2020 (known as Medicane Ianos, Loli et al., 2022a,b; Zekkos et al., 2020). The analysis of this case study offered an opportunity for verification of the method based on a comparison of predicted bridge damage with damage observed in the field.

2.1 Index of Flood Hazard Intensity (IFHI) for bridges

The two main factors of flood-induced damage on bridges, namely the hydrodynamic loads and scour, are essentially dependent on the magnitude of flow velocity (U), as well as water height (h_w). Importantly, high values of U are generally expected in steep terrains, while, on the contrary, increased water heights are expected on flat grounds. Owing to this antithesis, assessment of bridge response to flooding on the basis of h_w alone can lead to misleading, even unsafe, predictions, although h_w is broadly used as a flood intensity measure, suitable for problems where functionality loss due to accumulation of water volumes is the main concern.

Here, U and h_w were considered in the evaluation of hazard by introduction of a combined indicator, namely the Index of Flow Intensity (IFI). As shown in Figure 2, IFI can be evaluated at regional scale after classification and synthesis of qualitative maps of the expected water height (represented by the Water Height Index, WHI) and the expected flow velocity (according to the Water Velocity Index, WVI). As presented in detail in Loli et al. (2022b), layers of WHI and WVI can be produced using MCDM analysis of geomorphological, meteorological, hydrological, and land use/cover data, based on the exploitation and processing of satellite images and relevant global datasets in GIS.

To also account for scour, *IFI* is integrated with a set of indicators (namely $A1$, $A2$, and $A3$) which represent susceptibility to scour (general scour, contraction scour, and local scour, respectively). To this end, the scoring method for scour hazard assessment proposed by the CEREMA guidelines is adopted, as summarized in Table 1.

Then, *IFHI* is introduced as an indicator that incorporates all the above components in one index of flood hazard intensity:

$$IFHI = (A1 + A2 + A3) IFI \quad (1)$$

Table 1. Indicators of scour susceptibility.

Symbol	(Sub)Indicator of	Scoring
A1.1	Flow conditions	=1, if U = very low; 2, if U = low; 3, if U = medium; 4, if U = high; 5, if U = very high.
A1.2	Riverbed	=0, for rock; 1, for blocks; 1.6, for gravel; 2.8, for cohesive soil; 3.5, for sands.
A1	General scour susceptibility	= 2A1.1A1.2-5
A2	Contraction scour susceptibility	=0.5 for $l/W < 0.1$; 1, for $0.1 \leq l/W < 0.2$; 2.5, for $0.2 \leq l/W < 0.3$; 4, for $0.3 \leq l/W < 0.4$; 6, for $l/W \geq 0.4$, where l is the bridge length and W is the channel width.
A3.1	Indicator of local scour susceptibility	=0 for $B/W < 0.02$; 1.5, for $0.02 \leq B/W < 0.1$; 2.5, for $0.1 \leq B/W < 0.2$; 3.5, for $B/W \geq 0.4$, where B is the width of the widest support obstructing the flow.
A3.2	Support Alignment/ Shape effects	=0 for symmetric supports and well aligned with the flow; 2, for oblong supports; 3. For highly skewed supports.
A3.3	Riverbed morphodynamics	=1.1 for a fixed riverbed; 1.3 for riverbeds with dunes/mobile sandbags.
A3.4	Sub-indicator: Riverbed	=0, for rock; 0.4, for blocks and gravel; 1, for soil.
A3	Indicator of local scour susceptibility	= 1.2 A3.1A3.2A3.3 A3.4A1.1

2.2 Scoring of bridge vulnerability to flood impacts

The predisposition of a structure to be adversely affected by a flood of standard magnitude is viewed as a function of the structure’s physical characteristics and assessed based on a simple but reliable model, fused with basic engineering parameters relevant to the design, construction, and maintenance properties of the structure, using the indicators that are summarized in Table 2.

Following the CEREMA guidelines, vulnerability (V) is defined as the total of three components: the vulnerability of the foundations (V1), the vulnerability of the superstructure (V2), and the sensitivity of the deck to the movements of its supports (V3).

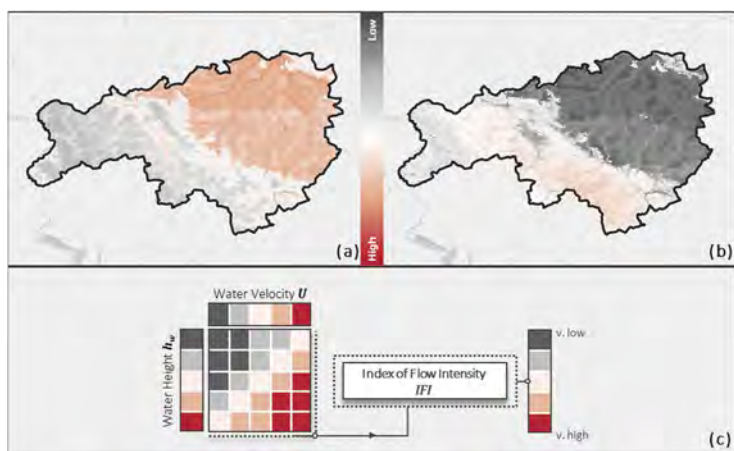

Figure 2. Flood hazard assessment integrating (a) prediction of water height (WHI) and (b) prediction of water velocity (WVI) for estimation of (c) flow intensity (IFI).

Table 2. Indicators of bridge vulnerability.

Symbol	(Sub)Indicator of	Scoring
V1.1	Construction age	= -1, for structures constructed after 2000; 1, for constructions dating from 1985 – 1999; 3, for constructions dating from 1955 – 1984; 5, for constructions dating before 1954.
V1.2	Foundation type	= 2, for piles and deep caissons; 5, for embedded foundations; 6, for RC surface footings; 10, for masonry or wooden foundations.
V1.3	Surveillance level	= 0, if surveillance data exist showing good condition; 4, in case that no surveillance information is available.
V1	Indicator of foundation vulnerability	$V1 = V1.1 + V1.2 + V1.3$
V2.1	Construction material	= 1, for metal/RC in good condition; 2, for metal/RC in bad condition; 3, for masonry structures.
V2.2	Pier shape	= 0, for sharp cutwater; 0.5, for cylindrical support or circular cutwater; 1, for rectangular supports.
V2	Indicator of superstructure vulnerability	$V2 = V2.1 + V2.2$
V3	Indicator of deck stability	= 2, for culverts of truss-bridges; 4, for other cases.

3 INSPECTION OF BRIDGE DAMAGES AFTER AN EXTREME FLOOD EVENT

On 17 September 2020, the “Ianos” Mediane struck Greece causing heavy precipitation that exceeded in various locations the mean annual precipitation. It was an extreme weather event, classified as one of the most powerful Mediterranean Cyclones recorded since 1969 (Zekkos et al., 2020; Lagouvardos et al., 2021). It affected a relatively wide area, extending from the Ionian islands to the eastern coast of the mainland. The maximum daily accumulated values,

as measured by the network of automatic meteorological stations of the National Observatory of Athens, reached up to 317 mm (peak recorded in Pertouli) and were among the highest recorded in Greece during the past decade.

The severity and spread of destruction were unprecedented. In the mountainous regions, the catastrophic consequences of flash flooding included numerous landslides, debris flows, and erosion, impacting buildings, transportation infrastructure, and powerlines. In the low-lying areas of the Thessaly Plain, large scale flooding with the inundation of over 400 km² of agricultural and urban land, caused widespread disruptions to communities and severe effects on the economic activity, especially in the city of Karditsa. The town of Mouzaki was harshly impacted. Flash flooding and overflowing of Pamissos river led to widespread erosion of its gabion-protected riverbanks, sweeping away roads, cars (causing one fatality), and riverside structures.

The reconnaissance of damage in the aftermath of Ianos offered a wealth of field evidence on the response of bridges to flood-associated impacts. Tens of bridges suffered substantial damage or complete failure, several of which were inspected during the field surveys carried out a few days after the event (Zekkos et al., 2020). Later, selected cases were also mapped in detail by employing aerial imagery captured by UAVs, as reported in Loli et al. (2022c). In the area of interest, a total of 16 bridges were inspected between 3 – 15 October 2020 (i.e., up to one month after the passage of the Medicane). Figure 3 shows a selection of representative photographs.

Figure 3. Photos of bridges in the lowlands of Karditsa: (a) No.3; (b) No. 4; (c) No. 6; and in the mountainous region W and NW of the city: (d) No. 7; (e) No. 8; (f) No. 9; (g) No. 10; (h) No. 11; (i) No.12.

Failures were dominated by extreme hydrodynamic loading of structures, due to flow obstruction, often facilitated by scour. A general shortcoming of hydraulic sections (bridge openings) was observed resulting in overflowing of rivers and streams and failure of bridge supports in locations where flow velocity was high enough to produce loads that transiently exceeded the capacity of load-bearing elements. This was the case along the Pamissos river, where torrential water flow caused partial or complete failure of five bridges (e.g., Figure 3d – 3h). On the contrary, the bridges in the Plain area were found structurally unscathed (Figure 3b – 3c). Out of the seven bridges inspected in the lowlands, none showed evidence of considerable structural displacements, despite the reports of their inundation and the abundant evidence of overflowing in their perimeter. Nevertheless, substantial debris masses were found concentrated upstream of bridges, especially those having in-stream piers. It is anticipated that the lowland bridges owe their survival to the flat ground morphology which, naturally, reduced flow velocities and hence the magnitude of erosive actions. This observation has guided the development of the Index of Flood Hazard Intensity (IFHI), as a bridge-specific indicator of flood hazard.

3.1 Bridge Damage Levels (DL)

Five bridge performance states have been defined and associated with relevant damage levels (DL), as follows:

- DL-1 implies no impact on the structural integrity and/or the functionality of the bridge. Figure 2b shows an indicative example of this category.
- DL-2 is equivalent to minimal damage, such as minor spalling, and functional loss due to debris built-up (Figure 2c), which poses no threat to the stability of the structure and the operability of the network.
- DL-3 is assigned in cases of moderate damage necessitating repair works which, however, did not result in complete closure of the bridge with at least one lane remaining operational (Figure 2d).
- DL-4 refers to cases of significant, albeit repairable damage, where temporary closure of the bridge is deemed necessary (examples shown in Figure 2e – g).
- DL-5 is the ultimate failure state, associated with complete collapse or unreparable damage, as is the case for the structures shown in Figure 2h – j, where replacement of the entire or large part of the asset would be required.

Table 3 lists the coordinates of inspected structures summarizing observations and damage levels (DL).

Table 3. Summary of observed damage to bridges after the Ianos Medicanе.

No.	Lat., Lon. (WGS 84)	DL	Damage description
1	39.25381, 21.71591	4	Scour at abutments and backfill wash-away. Collapse of approach roadway with no structural damage.
2	39.32248, 21.79625	4	Erosion and scour. Partial, repairable abutment failure.
3	39.34473, 21.89406	1	Signs of overflowing with no damage.
3A	39.34474, 21.89400	2	Signs of overflowing with no damage. Debris built-up.
4	39.34858, 21.90459	2	Overflowing and debris built-up.
5	39.34652, 21.92067	2	Overflowing and debris built up.
6	39.34506, 21.92634	2	Overflowing and debris built up.
7	39.42734, 21.92634	4	Scour and erosion at the abutment. Collapse of approach roadway with no structural damage to the bridge.
8	39.42580, 21.66623	5	Settlement of mid-pier. Erosion of abutment backfills. Severe, non-repairable structural damage.
9	39.40610, 21.66315	5	Abutment scour and backfill erosion. Collapse due to fracture of concrete walls.
10	39.40184, 21.66842	3	Abutment erosion and partial collapse of roadway.
11	39.40117, 21.65286	5	Collapse of consecutive piers and deck segments due to excessive scouring, hydrodynamic loads, and debris.
12	39.30350, 21.68657	5	Erosion of backfill and collapse of approach roadway.
13	39.30956, 21.71081	4	Abutment erosion with partial collapse of roadway and partial wash-away of masonry abutment. No damage to the RC part.
14	39.09779, 21.87822	1	Overflowing with no damage.
15	39.47911, 21.84343	1	Overflowing with no damage.

4 PREDICTION OF BRIDGE DAMAGE: RESULTS AND VALIDATION

Figure 4a Shows the spatial distribution of the hazard index (IFHI), as calculated at the location of every bridge in the area of study (Karditsa county), considering an inventory of 117 bridges, for the rainfall produced by Medicanе Ianos. Despite the severity of the event, calculations show that over 60% of the bridge stock (79 out of 117) faces a relatively low-intensity hazard. Only 18 structures are exposed to high hazard levels. Unsurprisingly, all are in the western (mountainous) area of the county, where steep topography amplifies flow intensity.

Figure 4b reveals the county's highly vulnerable bridge stock, showing that 56 moderately vulnerable and 35 highly vulnerable structures are randomly distributed across the region. Prediction of damage (in terms of DL) is carried out at the asset scale, according to Figure 1. DL predictions for Medicane Ianos are plotted against actual (observed) DL in Figure 5a, for the 16 bridges that were inspected during the post-flood reconnaissance study (the inspected sample equals to 14% of the entire inventory). A very satisfactory correlation ($R^2 = 0.71$; $p < 0.05$) is achieved. This is largely thanks to the introduction of IFHI, as a combined indicator of flood water depth and flow velocity, as indicated by the significantly poorer comparison between observed and predicted DL in Figure 5b. In the latter image, damage prediction has been based on the same method, but using only h_w as an indicator of hazard intensity, i.e., ignoring flow velocity (U).

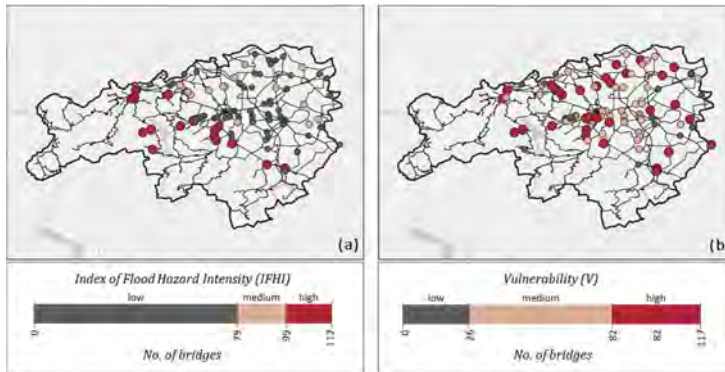

Figure 4. Analysis of the impact of Medicane Ianos on the bridges of the Karditsa county: spatial variability (a) of the IFHI, (b) V.

Figure 5. (a) Predicted damage against damage observed in the field; compared to (b) DL results when hazard is evaluated solely based on flood water depth (h_w).

5 CONCLUSIONS

The developed flood risk assessment framework is appropriate for the prediction of bridge susceptibility to flooding. It has been supported by a combination of field-based and theoretical research into the parameters that control the intensity of hydraulic actions on stream-crossing bridges. All of them have been incorporated, either directly or indirectly, into the proposed, bridge-specific Index of Flood Hazard Intensity (IFHI). Of major importance has been the recognition that U is a primary contributor to the flood-induced bridge distress. The generation of

a regional-scale prediction of U , albeit qualitative, has been decisive for the accurate prediction of bridge damage, as judged by the comparison against field observations after a severe flooding event (Figure 5a – 5b). Importantly, high values of U are generally expected in steep terrains, while, on the contrary, increased water heights (h_w) are expected on flat grounds. Owing to this antithesis, assessment of bridge response to flooding based on h_w (following the current state of the art) can lead to misleading, even unsafe, predictions. Indeed, as illustrated in Figure 5b, prediction of DL using only h_w as the indicator of flood hazard intensity, leads to unrealistic results that compare poorly with the recorded damages (as per Table 3).

The use of an empirical classification-based approach by MCDM analysis is the reason for the qualitative nature of the proposed framework. Although quantitative estimates would be possible, if the results of hydraulic analysis of flood propagation in the basin of interest became available to provide quantitative estimates of h_w and U , the developed MCDM-based framework has the advantage of being easily and relatively rapidly implementable, requiring the use of a comparatively reduced amount of data

Assessment as to the best strategies for the maintenance of existing bridges

A. Contardi & G. Pasqualato

SINA S.p.A. – ASTM GROUP, Milan, Italy

ABSTRACT: According to the new Italian standards, all existing bridges that have been declared not compliant with the current applicable rules (Norme Tecniche 2018) shall be subject to assessment in the next years. Due to the high number of non-compliant bridges, the Administrations and the infrastructural managers are asked to choose the appropriate maintenance activities to be performed. The question as to how to schedule a long-term planning for the interventions still remains unanswered. The managers are not only asked to assess an order of priority for the works to be done – which simply allows to decide the bridges to be restored – but also to conduct a more complete assessment so as to define the type of the restoration works needed and the relevant timeframe. By carrying out a complete risk analysis for each bridge, the best maintenance strategy appears to be the one that entails the lowest possible effort, such cost for each bridge expressed not only as the sum of the construction costs but including also all possible damages of the structure multiplied by their probability of occurrence (calculated with respect to a reference time period). By treating the probability of collapse or damage to the structure over time as a living cost, the manager will have the most efficient and reliable rational tools to determine the best maintenance strategy to follow.

1 INTRODUCTION

1.1 Requirements

The new Italian standards (Existing Bridge Guidelines), based on a multilevel risk analysis (the “**Italian Guidelines**”)¹, require “*de facto*” infrastructural managers to restore historical and aged bridges characterized by:

- significant degradations or high defect level;
- structural critical elements (such as “Gerber” support or bearings) deteriorated;
- girders with criticalities due to post-stressed precompression cables;
- high risk exposure from a social or economic standpoint.

Restoration works of so-called “accessible” (*transitabili*) bridges (the worst one) are required to be implemented in a very limited timeframe (5 years, as possibly extended to 10 years in case a long term monitoring activity thereon is pending). For all the other structures denominated “operational” (*operative*) – characterized by limited non-compliance with the applicable standards and quite good conditions – representing the vast majority, managers can choose the maintenance activity to be conducted in a long term timeframe (maximum 30 years).

1. Ref. is to Ministerial Decree 1 July 2022, No. 204, *Linee guida per la classificazione e gestione del rischio, la valutazione della sicurezza ed il monitoraggio dei ponti esistenti*

The need for some structures to comply with the requirements of the 2018 standards² arises from the recent guidelines. This said, the question for managers now is how to implement an effective Bridge Management System (BMS), that is, how to schedule a long-term planning of such maintenance works, with the purpose of achieving the maximum level of safety in a best cost benefit approach.

1.2 *Current tools*

Chapter 7.7 the Italian Guidelines introduces the new structural reliability index **R**, without providing for an explanation as to the relevant calculation method, its variation over time and the determination of the attention threshold above which the procedure for securing the structure should be triggered. To this end, the legislation seems to suggest the adoption of the sum of the relative defects $D_R = \sum Gk_1k_2$, obtained through normal visual inspection activities, where, for every defect, *G* means the weight, *k*₁ means the extension and *k*₂ the relevant intensity. However, this parameter is indicative of the condition of the bridge only for structures with very low and limited levels of deterioration and it is not suitable for highlighting more serious problems that may concern the safety of the bridge.

Conversely, it would be possible to use the classic reliability index **β** as **R**, a direct expression of the probability of collapse, estimated by calculating the safety factor with respect to the rules for new structures and taking into account all the calculation uncertainties; in this case, instead, the index reflects the degree of safety of the bridge but does not give any indication as to need to conduct the ordinary maintenance works to be implemented to prevent future emergency situations that are not yet detectable.

To date, managers are essentially working on defining two simple classifications of bridges in parallel, one category to be targeted with ordinary maintenance works and the other one with extraordinary maintenance works:

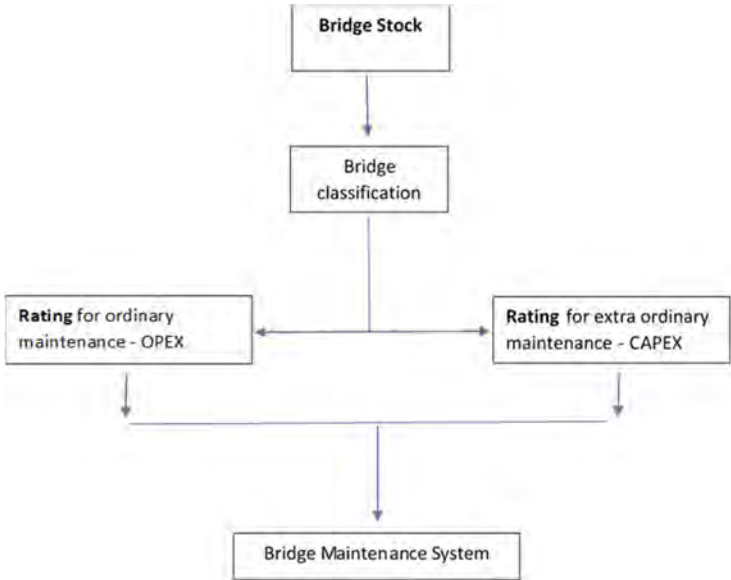

Figure 1. Flowchart of BMS application.

2. Ref. is to Ministerial Decree 17 January 2018, *Aggiornamento delle 'Norme tecniche per le costruzioni'*

- the first category, by collecting degradation data in order to address a continuous maintenance to guarantee a standard level of functionality (in general, this applies to bridges in a good level of condition or not presenting structural problems);
- the second category, on the basis of the safety factors obtained by an accurate assessment compliant with Eurocodes (Level 4 procedures of the Italian Guidelines) applying to aged bridges that have a lack of structural functionality.

It should be noted that managers' need is not to be provided with a simple order of priority for works, that just allows to decide which bridges are to be restored, but with a more complex and complete system that permits to define also the type of the needed restoration works and the relevant timeframe.

The following paragraphs provide for a calculation method aimed at planning the maintenance of the bridges by targeting a predetermined time frame and, at the same time, obtaining a single order of priority for the interventions to be carried out in the near future.

2 GENERAL “BMS” METHOD FORMULATION

Consider a reference time period t_{ref} during which it is necessary to ensure the safety and operation of the bridges of an infrastructure, e.g. 50 years. Throughout the time span considered, maintenance is carried out on each bridge by performing a certain number of activities. Each of these activities can be categorised as follows:

1. ordinary maintenance intervention aimed at increasing the durability of the bridge, without any increase in its resistant capacity;
2. repair intervention through which the individual structural elements can be modified in order to increase the resistant capacity of the bridge;
3. reconstruction of the deck or of the entire bridge.

The basic idea of the following method, based on what is indicated in Bulletin FIB 80 “*Partial factor methods for existing concrete structures*”, chapter 3.2.2., is that the preferable maintenance strategy is the one which involves the lowest possible total cost for the community, where for each bridge the total cost is expressed by the following formula:

$$C_{tot} = \sum C_i + \sum D_j P_j \quad (1)$$

where:

- C_i means total cost of the i -th intervention on the bridge in question.
- D_j means total damage caused by exceeding the j -th limit state.
- P_j means probability of exceeding the j -th limit state, calculated with respect to the time interval considered, as a function of the pre-selected maintenance actions.

As far as possible, the limit states should be chosen and treated so that they are statistically independent.

For example, those that could typically be adopted for a medium-sized viaduct are the following:

- collapse of a beam (and therefore of an entire part of the deck) due to vertical traffic loads;
- collapse of a slab mirror due to a concentrated vertical load;
- collapse of a pile or a group of bearing devices (and therefore of an entire part of the deck) due to a seismic event, wind or braking on the deck;
- collapse of the entire structure or part of it due to a hydrogeological event.

A maintenance strategy that contemplates a series of demanding interventions will involve very high costs and therefore will maximize the first addendum of the formula, but at the same time it will allow to reduce the probability of collapse and therefore to minimize the second term. Conversely, a strategy with much less invasive interventions (at least even

one that envisages doing nothing for the entire reference period) will make it possible to eliminate costs but will also lead to the maximum probability of collapse.

The indicated formula, although quite simple from a conceptual point of view, cannot be used yet due to the unavailability in current literature of practical procedures allowing the calculation of all the indicated parameters without uncertainties. In particular, while the costs of the interventions could be easily estimated in a parametric way even without carrying out preliminary complete projects, it would be important to develop two lines of research, described below, relating to the calculation of the probability of collapse and of economic and social costs and damages.

3 ESTIMATION OF THE PROBABILITY OF COLLAPSE “ P_j ”

The total probability of exceeding a limit state P_j shall mean the probability that limit state can be exceeded in the period t_{ref} depending on all actions taken.

The total probability could be calculated directly by assessing the structure applying Eurocodes as if it were new and considering the current level of degradation, as it is normally done in the first part of the safety checks. However, the result would not be correct since, for a historic structure, deterioration can evolve much more rapidly than for a new structure and in the period of time considered the probability of collapse could be considerably underestimated.

The most convenient way to proceed is to estimate preliminarily the probability of collapse p_j relating to a single year. As is known, p_j is not constant in the reference period but increases very slowly at first, then increasing rapidly following the progress of the deterioration phenomena. Simplifying the formula, it is possible to calculate the total probability as the sum of the probabilities of the individual years:

$$P_j = 1 - \prod_i^{t_{ref}} (1 - p_j(t_i)) \cong \sum_i^{t_{ref}} p_j(t_i) \quad (2)$$

It is therefore advisable to proceed according to the methodology described in the following paragraphs. For the sake of conciseness, further elaborations have been omitted and will be the subject of next studies.

3.1 First year probability

The structure is verified considering the current degradation and using, only for accidental and exceptional loads, reduced safety factors which reflect the fact that the structure is no longer verified with respect to a useful life of 50 years but considering only one year.

For example, for traffic loads the values indicated by the Eurocodes, since they refer to a return time of 1000 years, in this analysis are no longer related to the 5% exceedance but to 0.1% and for this reason the safety factor should be much lower. For traffic loads, it is suggested to use a coefficient equal to 1.0.

The safety factor of a structure with respect to the j -th limit state is defined as the ratio $S_{Fj} = R_{dj}/E_{dj}$ between the resistance (calculated as if the structure were new, but also considering the reductions in bearing capacity due to degradation) and the effect of external loads at the point of the structure under consideration. The safety factors can be conveniently used as the final result of the structural analysis carried out with the reduced partial coefficients of the loads. It should be noted that this information can be obtained with both in-depth FEM analyses and with simplified analyses (Level 4 or 3 of the mentioned Italian Guidelines).

More in detail, it is possible to estimate the reliability index β_j , which is linked to the probability of collapse by the relation $p_j = \Phi(-\beta_j)$, assuming a log-normal statistical distribution for the safety factor and therefore using the following formula:

$$\beta_j = \beta_1 + \ln(SF_j)/\sigma_j \quad (3)$$

A very similar formulation has already been proposed in a study conducted by the University of Trento referred to under a circular from the Ministry of Infrastructure³.

Parameter β_1 is constant for all limit states and for all structures. The standard deviation σ_j , on the other hand, is different for each structure and for each limit state and can normally be calculated only using the data available in literature.

However, for all limit states dependent on traffic loads, it is proposed to use a simpler and more transparent approach in order to obtain results in full compliance with Italian current standards. In fact, it is possible to obtain the value of the two parameters by directly imposing that a structure respects the following two conditions:

1. according to the Eurocode, the minimum reliability index of new structures correctly designed in consequence class CC3 is equal to 3.8, i.e. the maximum collapse probability over 50 years of a correctly designed bridge is $\Phi(-3.8) = 7 \cdot 10^{-5}$. Assuming for simplicity that the probability does not change over time, over one year it is possible to introduce the following parameter:

$$\beta_{EC} \triangleq \beta_1 + \ln(SF_{EC})/\sigma_j = -\Phi^{-1}\left(1 - (1 - \Phi(-3.8))^{\left(\frac{1}{50}\right)}\right) = 4.7 \quad (4)$$

2. A structure - which in the safety verification is on the threshold between Operativo and Transitable - has a reliability index of 2.8 over 50 years.

$$\beta_{OP} \triangleq \beta_1 + \ln(SF_{OP})/\sigma_j = -\Phi^{-1}\left(1 - (1 - \Phi(-2.8))^{\left(\frac{1}{50}\right)}\right) = 3.9 \quad (5)$$

Therefore, estimating the indexes SF_{EC} and SF_{OP} for one year and replacing the values in (3), the followings apply

$$\sigma_j = \ln(SF_{EC}/SF_{OP})/(\beta_{OP} - \beta_{EC}) \quad (6)$$

$$\beta_1 = \beta_{EC} - \ln(SF_{EC})/\sigma_j \quad (7)$$

For example, if the effect of dead loads and live loads is very similar, which is often the case with historical reinforced concrete structures, the safety factors are $SF_{EC} = 1.16$ and $SF_{OP} = 1.00$ and therefore $\sigma_j = 0.18$ and $\beta_1 = 3.87$.

The value of σ_j should then be appropriately modified considering, with respect to the design of a new structure, the additional factors of uncertainty that influenced the performed analysis. Typically, in the structural analysis these factors are the effect of degradation and the resistance of the materials obtained through laboratory tests; moreover, in simplified analyses it would be advisable to consider also the greater uncertainties inherent in the type of analysis. These calculations can be found in a PIARC paper in course of publication⁴.

3.2 Evolution of probability over time

In this historical moment, the subject matter of research should be the estimation of the evolution over time of the probability p_j . As is known, this changes over the years according to the age of the bridge and the progress of the deterioration phenomena.

3. Ref. is to Ministero delle infrastrutture e dei trasporti – 29 November 2019, *Criteri di priorità e programma delle manutenzioni autostradali*

4. Ref. is to PIARC ITALY National Committee – Technical Committee 4.2 – Bridges – 2019-2023 cycle, *Bridge safety monitoring and classification - State of the art and operational recommendations*

The causes of material degradation over time can be several and often coexist. The most evident phenomena are usually linked to the action of water and the salts it contains which encounters the surfaces of the structures due to malfunctions in the platform water disposal system or expansion joints. However, these problems in most cases are due to carelessness and can be solved through relatively simple and cheap repairs. Some degradation phenomena occur above all in the first years of the bridge's life, such as shrinkage and movements of the ground, or are due to construction defects, such as the failure to inject the sheaths of the post-tension cables; other phenomena are difficult to predict, such as shocks or fires.

For the purpose of calculating $p_j(t)$ it is advisable to focus attention on the phenomena that are inevitable and therefore easily predictable, such as carbonation for concrete and oxidation for steel.

With respect to reinforced concrete, it is necessary to correlate the reduction of the safety factors SF_j with the progress of the carbonation as a function of the quality of the concrete and the steel of the reinforcements and the thickness of the concrete cover. Since these features can be known *a priori*, it is possible to construct the resistance reduction curve of each section. Similar reasoning applies to the oxidation of steel.

The curves obtained should then be updated according to the inspection results. If phenomena of crumbling and detachment of the concrete surfaces appear in a bridge earlier than expected, the carbonation progress curve should be corrected accordingly.

Finally, the probabilities must consider the actions taken by the maintainers. Each of the three types of interventions presented in chapter 2 modifies the $p_j(t)$ curve in one of the following ways:

1. In case of ordinary maintenance intervention, the function remains continuous but - at least in the first period - constant, then it returns to increase within a relatively short time.
2. In case of repair, the function is discontinuous as p_j is lowered to a target value (usually the probability corresponding to β_1). In the first period it is also constant, and then it returns to rise in a relatively slow time.
3. In case of renovation, the function is discontinuous since from the instant of the intervention onwards $p_j(t)$ is the characteristic of the new structures.

4 DAMAGE ESTIMATION “ D_j ”

The most delicate and most complex part of the method is the determination of D_j , since the uncertainties involved are many and the values of these parameters may significantly impact on the final results of the calculation. Each damage can be estimated as the sum of the following contributions:

- Cost of replacing the collapsed structural part.
- Cost of infrastructure disruption for the managing company. Economic damage in term of missing payment (applicable to the toll road).
- Economic losses due to non-availability or malfunction of the structure for the whole community. In this case, it shall be considered that from the date of the collapse to the date of the reopening of the bridge, users must take an alternative route, thus taking longer to reach their destination. This damage is usually calculated assuming an hourly amount for light vehicles and one for heavy vehicles. The greater accident rate of the routes, due to the presence of road construction sites, must also be considered. If material, other costs to the regional economy are also taken into account.
- Social consequences (costs of injuries and fatalities) and unfavourable environmental effects. Bulletin FIB 80 contains a very simple formula to estimate the probability of casualties as a function of the length of the collapsed structural part. For the average compensation for a victim, the Italian *Decreto Dirigenziale* No. 189 dated 24 September 2012 by *Ministero delle Infrastrutture e dei Trasporti* provides the figure to be used. The damage caused to the areas underlying the bridge must be considered on a case-by-case basis, since these can be extremely variable. In the case of viaducts passing through uninhabited areas, only

environmental damage should be considered. Conversely, if the bridge crosses urbanized areas or near houses, the damage will obviously be much greater and must be carefully evaluated.

- Psychological effects (loss of reputation). This damage could be more significant for a private concessionary company, exposed to the financial market. To value this item, which could be extremely remarkable, a reliable estimate could be provided by calculating the immediate decrease in value of the shares suffered by companies that have had incidents with a certain media coverage in the past.

It should be noted that each limit state is assigned its own economic impact, which can be very different from that of the other limit states. For example, the damages associated with the breakage of a part of slab is much less than those related to the breakage of a girder.

It is important to remember that Bulletin FIB 80 also stated that in developed countries it is not accepted that the probability of becoming the victim of a structural failure could be larger than the normal probability of dying as a result of an accident (chapter 3.3). This requirement (not considered by the Italian Guidelines) could be respected by this method simply properly calibrating the damage estimation.

It is important to notice also that the vast majority of the damages involves the community and not the managing company.

The greater the importance and exposure of the bridge, the greater the damage will be. It should also be emphasized that this estimate is also a function of the *robustness* of the structure since many damages are more or less proportional to the length of the deck that collapsed as a result of the crisis.

5 BMS RATING

The search for the minimum value of C_{tot} (referring to the formula $C_{tot} = \sum C_i + \sum D_j P_j$) must be carried out bridge by bridge to determine which is the most effective maintenance strategy in the time t_{ref} . However, since for all the structures for which a type 3 intervention - i.e. the complete renovation - is convenient, the investment is always cheaper if made as soon as possible, but if all the maintenance plans were carried out all together as established, it could be unsustainable from an economic and traffic management point of view on the infrastructure due to huge number of construction site on the road.

It is therefore advisable to immediately focus on the most significant interventions and postpone the less important interventions to the next planning moment. For this reason, having discarded all the bridges for which it is not convenient to carry out interventions, it is suggested to order the maintenance giving priority to the structures for which the cost of the postponement C_p is maximum:

$$C_p = \sum D_j p_j \quad (8)$$

It should be noted that the indicated probability is the initial annual one.

The costs of the construction site should then be added to the costs due to the postponement of some urgent interventions, in terms of traffic diversion and lower efficiency of the infrastructure and greater accidents, this to penalize a choice of isolated and distant structures versus a set of interventions involving construction sites with less impact and therefore fewer problems with road traffic.

This rating procedure cannot be adopted without taking into account the considerations made in the previous chapters. The optimal maintenance strategy must always be determined at first instance and only afterwards the rating shall be calculated to establish which interventions shall be implemented in the short term. Once these interventions have been carried out, the overall calculation shall be updated with respect to the most recent inspection results of the bridges.

6 CONCLUSION

The methodology proposed in this paper is supposed to potentially integrate to the procedures proposed by the current Italian Guidelines, as it could suggest the implementation of a single classification of interventions to be put in place, without making distinctions between safety issues and durability problems. For sure, the next step of this research could be a test application on a case study bridge stock.

Maintenance policy which privileges more limited interventions would entail a lower cost in the first term in (1) and higher costs in the second one. On the other hand, the complete reconstruction of the bridge with a new one entail high costs (first term) but a much more significant risk limitation. By treating the probability of collapse or damage to the structure over time as a living cost, the Administrations and the managers will be provided with the most efficient and reliable rational tools for determining the maintenance strategy to be implemented.

ABSTRACT: The VBISI (Vehicle-Bridge Interaction System Identification) method is a drive-by monitoring method that measures and collects a large amount of vibration and route data from a group of vehicles, and simultaneously identifies the mechanical parameters of each vehicle and the bridges. The identification process randomly assumes the mechanical parameters of each vehicle and bridge, and solves two processes, namely the vehicle IEP (Input Estimation Problem) and the bridge DRS (Dynamic Response Simulation) to estimate the road unevenness. Bridge DRS is not required if bridge vibration data is available. However, if the bridge DRS is replaced by the measured value, the identification accuracy tends to decrease. Therefore, this study proposes a method to obtain the maximum likelihood value of bridge vibration from DRS-estimated values and measured values using sequential processing.

1 BACKGROUND

1.1 *Social demand for SHM*

Bridges are usually inspected by visual inspection and hammering. This is the most popular and reliable method, but it is costly because inspectors often have to carefully look at, tap and evaluate every component of the bridge. In other words, the bridge inspection is still a tough business. Even today, the total length of roads continues to grow and the number of bridges continuously increases. As building more bridges, the total cost of regular inspections also become more of a burden for governments. The biggest problem is the need for more veteran engineers who can properly inspect bridges. Bridges should be classified based on the probability of damage, and detailed inspections should be carried out with priority given to bridges with a high likelihood of damage, thereby reducing maintenance costs.

1.2 *Previous studies*

Bridge monitoring based on vehicle vibration data has been proposed in previous studies to estimate the damage probability. For example, Y.B. Yang et al. (2004) measured the vibration of vehicles travelling on bridges and estimated the natural frequencies of bridges from their power spectra. This method can be used to evaluate a large number of bridges at low cost, without the need to install sensors on the bridges. Wang et al. (2019) estimated the first-order natural frequencies of bridges with relatively good accuracy by fixing a smartphone to

a standard car and driving it over a real bridge, which also increases the potential for bridge damage detection. Yang et al. (2009) have also shown analytically that the natural frequencies of bridges can be extracted from vehicle vibrations. In addition to natural frequencies, some studies use mode shapes for damage assessment. Yamamoto et al. (2021) proposed a method for estimating bridge mode shapes using towing vehicles and confirmed its effectiveness numerically. Yang et al. (2022) also estimated the bridge first-order mode shape using two towing vehicles in a real environment. However, health assessments based on vibration indices such as natural frequencies and mode shapes require values prior to damage. In situations where ageing has already progressed, there is also a need for a method to directly estimate the existing performance. Nagayama et al. (Xue, 2020 and Zhao, 2019) proposed a method for simultaneously estimating vehicle dynamics parameters (mass, damping and stiffness) and road unevenness from vehicle vibration. This method assumes a random vehicle system and applies a Kalman filter to the vehicle vibration data to obtain the road unevenness as a system input. When the vehicle passes over a bridge, the system input includes a bridge vibration component. Acquiring the bridges' state by Drive-by Monitoring method will make bridge inspections more efficient. However, the drive-by method has low accuracy. A way to improve accuracy is required while maintaining efficiency.

Therefore, this research proposes drive-by monitoring using bridge vibration in addition to vehicle vibration. Specifically, the VBISI (Vehicle-Bridge Interaction System Identification) method proposed by Yamamoto et al. (2022) is extended. The VBISI method is a drive-by monitoring method that measures and collects large amounts of vibration and route data from fleets of vehicles and simultaneously identifies mechanical parameters of each vehicle and bridge. The identification process randomly assumes the mechanical parameters of each vehicle and bridge and solves two processes: vehicle IEP (input estimation problem) and bridge DRS (dynamic response simulation) to estimate road unevenness. Bridge DRS is not required if bridge vibration data is available. However, replacing the bridge DRS with the measured value tends to reduce the identification accuracy. In this study, we propose a method to obtain the maximum likelihood value of bridge vibration from the DRS estimated value and the measured value by sequential processing. This research is limited to proposing the basic mathematics, and numerical simulation is a future topic. In addition, since Yamamoto et al. (2022) have already explained the mathematical formula for the VBISI method, this study only describes the extension of the Kalman filter.

1.3 The purpose of the study

Therefore, it is considered to perform vibration measurement on vehicles and some bridges and to perform high-accuracy vehicle and bridge identification using vehicle and bridge vibration data. Although this scheme is applied to some bridges, the accuracy improvement effect may spread to the surrounding area of the monitoring bridges when the vehicles identified with high accuracy pass through other bridges. Therefore, this study constructs the theory of the VBISI method using simultaneous vehicle-bridge vibration measurement data.

2 NUMERICAL EXPERIMENT

2.1 Finite element model for the bridge

According to Yamamoto et al. (2022), the finite element formula of a bridge is expressed as follows.

$$\mathbf{M}_b \ddot{\mathbf{y}}(t) + \mathbf{C}_b \dot{\mathbf{y}}(t) + \mathbf{K}_b \mathbf{y}(t) = \mathbf{L}_v(t) \mathbf{P}(t) \quad (1)$$

$$\mathbf{M}_b = \left[\int_0^L \rho A \mathbf{N} \mathbf{N}^T dx \right] \quad (2)$$

$$\mathbf{C}_b = \alpha_c \mathbf{M}_b + \beta_c \mathbf{K}_b \quad (3)$$

$$K_b = \left[\int_0^L EI \frac{\partial^2 \mathbf{N}}{\partial x^2} \frac{\partial^2 \mathbf{N}^T}{\partial x^2} dx \right] \quad (4)$$

$$\mathbf{L}_v = [N(x_1) \ N(x_2)] \quad (5)$$

$$\mathbf{P} = \{P_1 \ P_2\}^T \quad (6)$$

where $\mathbf{y}(t)$ is the numerical solution vector of bridge vibration, $N(x)$ is the basis function vector, EI is flexural rigidity, ρA is mass per unit length, x_1 and x_2 are the position of front and rear axle of the vehicle, and P_1 and P_2 are the contact force due to the front axle and rear axle of the vehicle.

2.2 Rigid-body-spring model for vehicle

According to Yamamoto et al. (2022), the rigid-body-spring model for vehicle is expressed as follows.

$$\mathbf{M}_v \ddot{\mathbf{z}} + \mathbf{C}_v \dot{\mathbf{z}} + \mathbf{K}_v \mathbf{z} = \mathbf{f}_v \quad (7)$$

where $\mathbf{z}(t)$ is vehicle vibration vector, \mathbf{f}_v is input vector. In this model, m_s is the mass of the vehicle body and c_{si} , k_{si} , d_i , m_{ui} and k_{ui} represent the suspension damping, the suspension stiffness, the distance from the gravity point, the unsprung mass, and the tire stiffness of i -th axle, respectively. The system parameter matrices and input/output vectors of the vehicle can be given by

$$\mathbf{z} = \{z_{s1} \ z_{s2} \ z_{u1} \ z_{u2}\}^T \quad (8)$$

$$\mathbf{f}_v = \{0 \ 0 \ k_{u1}u_1 \ k_{u2}u_2\}^T \quad (9)$$

$$\mathbf{M}_v = \begin{bmatrix} \frac{d_1 m_s}{d_1 + d_2} & \frac{d_1 m_s}{d_1 + d_2} & & \\ \frac{d_1 m_s}{d_1 + d_2} & \frac{d_1 m_s}{d_1 + d_2} & & \\ & & m_{u1} & \\ & & & m_{u2} \end{bmatrix} \quad (10)$$

$$\mathbf{C}_v = \begin{bmatrix} c_{s1} & c_{s2} & -c_{s1} & -c_{s2} \\ c_{s1}d_1 & -c_{s2}d_2 & -c_{s1}d_1 & c_{s2}d_2 \\ -c_{s1} & & c_{s1} & \\ & -c_{s2} & & c_{s2} \end{bmatrix} \quad (11)$$

$$\mathbf{K}_v = \begin{bmatrix} k_{s1} & k_{s2} & -k_{s1} & -k_{s2} \\ k_{s1}d_1 & -k_{s2}d_2 & -k_{s1}d_1 & k_{s2}d_2 \\ -k_{s1} & & k_{s1} + k_{u1} & \\ & -k_{s2} & & k_{s2} + k_{u2} \end{bmatrix} \quad (12)$$

Each system parameter corresponds to the Figure 1.

2.3 The contact force

According to Yamamoto et al. (2022), the contact force matrix $\mathbf{P}=[P_1 \ P_2]^T$ is expressed as:

$$\begin{aligned} \mathbf{P} &= \begin{bmatrix} -m_{s1}(g + \ddot{z}_{s1}) - m_{u1}(g + \ddot{z}_{u1}) \\ -m_{s2}(g + \ddot{z}_{s2}) - m_{u2}(g + \ddot{z}_{u2}) \end{bmatrix} \\ &= -\mathbf{M}_p \ddot{\mathbf{z}} - \gamma \mathbf{g} \end{aligned} \quad (13)$$

Figure 1. Rigid-Body-Spring model for the vehicle.

where

$$\mathbf{M}_p = \begin{bmatrix} m_{s1} & 0 & m_{u1} & 0 \\ 0 & m_{s2} & 0 & m_{u2} \end{bmatrix} \quad (14)$$

$$\boldsymbol{\gamma} = \begin{bmatrix} m_{s1} + m_{u1} & 0 \\ 0 & m_{s2} + m_{u2} \end{bmatrix} \quad (15)$$

$$\mathbf{g} = [g \quad g]^T \quad (16)$$

g is the acceleration of gravity.

3 STATES ESTIMATION METHOD

Numerical experiments were carried out using the Newmark Beta and Newton-Raphson methods, following previous studies (Yamamoto et al., 2022). The numerical experiment simulates the measured data. The proposed method estimates the vehicle vibration $\mathbf{z}(t)$, the bridge vibration $\mathbf{y}(t)$, and the road profile $\mathbf{r}(t)$.

3.1 Observation equation

Let $w_i(t)$ be the displacement of the bridge sensor at $x = x_i$,

$$\mathbf{w} = \mathbf{L}_b^T \mathbf{y}(t) \quad (17)$$

where

$$\mathbf{w} = \{w_1 \quad w_2 \quad \cdots \quad w_m\}^T \quad (18)$$

$$\mathbf{L}_b = [N(x_1) \quad N(x_2) \quad \cdots \quad N(x_m)] \quad (19)$$

3.2 State space model

The state space model of the vehicle and bridge can be given by the following equations. The state variable $\mathbf{X}(t)$ is composed of the vehicle vibrations $\mathbf{z}(t)$ and $\dot{\mathbf{z}}(t)$, the bridge vibrations $\mathbf{y}(t)$

and $\dot{\mathbf{y}}(t)$, and the input profiles $\mathbf{u}(t)$ and $\dot{\mathbf{u}}(t)$. The observation variable $\mathbf{s}(t)$ consists of the bridge vibrations $\dot{\mathbf{w}}(t)$ and $\mathbf{w}(t)$ which is delivered by numerical integration.

$$\dot{\mathbf{X}}(t) = \mathbf{A}(t)\mathbf{X}(t) + \boldsymbol{\omega}(t) \quad (20)$$

$$\mathbf{s}(t) = \mathbf{B}(t)\mathbf{X}(t) + \boldsymbol{\epsilon}(t) \quad (21)$$

where

$$\mathbf{X}(t) = \{ \mathbf{z}^T \quad \dot{\mathbf{z}}^T \quad \mathbf{y}^T \quad \dot{\mathbf{y}}^T \quad \mathbf{r}^T \quad \dot{\mathbf{r}}^T \quad \mathbf{g}^T \}^T \quad (22)$$

$$\mathbf{s}(t) = \{ \dot{\mathbf{z}}^T \quad \mathbf{z}^T \quad \dot{\mathbf{w}}^T \quad \mathbf{w}^T \quad \mathbf{g}^T \}^T \quad (23)$$

$$\mathbf{M}_A(t) = \mathbf{M}_b^{-1} \mathbf{L}_v(t) \mathbf{M}_p \mathbf{M}_v^{-1} \quad (24)$$

$$cA(t) = \begin{bmatrix} \mathbf{O}_{4 \times 4} & I_{4 \times 4} & \mathbf{O}_{4 \times 2n} & \mathbf{O}_{4 \times 2n} & \mathbf{O}_{4 \times 2} & \mathbf{O}_{4 \times 2} & \mathbf{O}_{4 \times 2} \\ -\mathbf{M}_v^{-1} \mathbf{k}_v & -\mathbf{M}_v^{-1} \mathbf{C}_v & \mathbf{M}_v^{-1} \mathbf{F}_v \mathbf{L}_v^T & \mathbf{O}_{4 \times 2n} & \mathbf{M}_v^{-1} \mathbf{F}_v & \mathbf{O}_{4 \times 2} & \mathbf{O}_{4 \times 2} \\ \mathbf{O}_{2n \times 4} & \mathbf{O}_{2n \times 4} & \mathbf{O}_{2n \times 2n} & \mathbf{I}_{2n \times 2n} & \mathbf{O}_{2n \times 2} & \mathbf{O}_{2n \times 2} & \mathbf{O}_{2n \times 2} \\ \mathbf{M}_A \mathbf{k}_v & \mathbf{M}_A \mathbf{C}_v & -\mathbf{M}_A \mathbf{F}_v \mathbf{L}_v^T - \mathbf{M}_b^{-1} \mathbf{k}_b & -\mathbf{M}_b^{-1} \mathbf{C}_b & \mathbf{M}_A \mathbf{F}_v & \mathbf{O}_{2n \times 2} & -\mathbf{M}_b^{-1} \mathbf{L}_v \boldsymbol{\gamma} \\ \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} \\ \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} \\ \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} \end{bmatrix} \quad (25)$$

$$\mathbf{B}(t) = \begin{bmatrix} -\mathbf{M}_v^{-1} \mathbf{k}_v - \mathbf{M}_v^{-1} \mathbf{C}_v & \mathbf{M}_v^{-1} \mathbf{F}_v \mathbf{L}_v^T & \mathbf{O}_{4 \times 2n} & \mathbf{M}_v^{-1} \mathbf{F}_v & \mathbf{O}_{4 \times 2} & \mathbf{O}_{4 \times 2} \\ \mathbf{I}_{4 \times 4} & \mathbf{O}_{4 \times 4} & \mathbf{O}_{4 \times 2n} & \mathbf{O}_{4 \times 2n} & \mathbf{O}_{4 \times 2} & \mathbf{O}_{4 \times 2} \\ \mathbf{L}_b^T \mathbf{M}_A \mathbf{k}_v \mathbf{L}_b^T \mathbf{M}_A \mathbf{C}_v - \mathbf{L}_b^T (\mathbf{M}_A \mathbf{F}_v \mathbf{L}_v^T + \mathbf{M}_b^{-1} \mathbf{k}_b) & -\mathbf{L}_b^T \mathbf{M}_b^{-1} \mathbf{C}_b & -\mathbf{L}_b^T \mathbf{M}_A \mathbf{F}_v & \mathbf{O}_{m \times 2} & -\mathbf{L}_b^T \mathbf{M}_b^{-1} \mathbf{L}_v \boldsymbol{\gamma} \\ \mathbf{O}_{m \times 4} & \mathbf{O}_{m \times 4} & \mathbf{L}_b^T & \mathbf{O}_{m \times 2n} & \mathbf{O}_{m \times 2} & \mathbf{O}_{m \times 2} \\ \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 4} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2n} & \mathbf{O}_{2 \times 2} & \mathbf{O}_{2 \times 2} \end{bmatrix} \quad (26)$$

The discretized model of Eq. (39) and Eq. (40) can be expressed as

$$\mathbf{X}_k = \mathbf{A}_k \mathbf{X}_{k-1} + \boldsymbol{\omega}_k \quad (27)$$

$$\mathbf{s}_k = \mathbf{B}_k \mathbf{X}_k + \boldsymbol{\epsilon}_k \quad (28)$$

Eq. (50) and (51) are discretized by Δt .

$$\mathbf{X}_k = \mathbf{X}(k\Delta t) \quad (29)$$

$$\mathbf{s}_k = \mathbf{s}(k\Delta t) \quad (30)$$

$$\boldsymbol{\omega}_k = \boldsymbol{\omega}(k\Delta t) \quad (31)$$

$$\boldsymbol{\epsilon}_k = \boldsymbol{\epsilon}(k\Delta t) \quad (32)$$

$$\mathbf{A}_k = \exp(\mathbf{A}(k\Delta t)\Delta t) \quad (33)$$

$$\mathbf{B}_k = \mathbf{B}(k\Delta t) \quad (34)$$

The covariance matrix of model error $\boldsymbol{\omega}_k$ and observation error $\boldsymbol{\epsilon}_k$ is \mathbf{Q}_k and \mathbf{R}_k .

$$\mathbf{E}[\boldsymbol{\omega}_k \boldsymbol{\omega}_k^T] = \mathbf{Q}_k \quad (35)$$

$$\mathbf{E}[\boldsymbol{\epsilon}_k \boldsymbol{\epsilon}_k^T] = \mathbf{R}_k \quad (36)$$

where $E[\]$ denotes an expected value.

3.3 Karman filter

The observability matrix of the state-space model is

$$\mathbf{O} = \begin{bmatrix} \mathbf{B}^T & \mathbf{A}^T \mathbf{B}^T & (\mathbf{A}^T)^2 \mathbf{B}^T & \dots & (\mathbf{A}^T)^{n-1} \mathbf{B}^T \end{bmatrix}^T \quad (37)$$

where N is the degrees of freedom of the state vector, which in this study is $N = 12 + 4n$. A necessary and sufficient condition for a system to be observable is that the observable matrix must satisfy $\text{rank}(\mathbf{O}) = N$. The initial values of the posterior state estimate $\hat{\mathbf{X}}_k$ and the posterior error covariance matrix $\hat{\mathbf{P}}_k$ are

$$\hat{\mathbf{X}}_0 = E[\mathbf{X}_0] \quad (38)$$

$$\hat{\mathbf{P}}_0 = E[(\mathbf{X}_0 - E[\mathbf{X}_0])(\mathbf{X}_0 - E[\mathbf{X}_0])] \quad (39)$$

The prior state estimate $\hat{\mathbf{X}}_{k+1}^-$ and the prior error covariance matrix $\hat{\mathbf{P}}_{k+1}^-$ are

$$\hat{\mathbf{X}}_{k+1}^- = \mathbf{A}_k \hat{\mathbf{X}}_k \quad (40)$$

$$\hat{\mathbf{P}}_{k+1}^- = \mathbf{A}_k \hat{\mathbf{P}}_k \mathbf{A}_k^T + \mathbf{Q}_k \quad (41)$$

where \mathbf{Q}_k is the process noise variance-covariance matrix. The Kalman gain \mathbf{G}_{k+1} , the posterior state estimate $\hat{\mathbf{X}}_{k+1}$ and the posterior error variance-covariance matrix $\hat{\mathbf{P}}_{k+1}$ at step $k+1$ is

$$\mathbf{G}_{k+1} = \hat{\mathbf{P}}_{k+1}^- \mathbf{B}_{k+1}^T \left(\mathbf{B}_{k+1} \hat{\mathbf{P}}_{k+1}^- \mathbf{B}_{k+1}^T + \mathbf{R}_{k+1} \right)^{-1} \quad (42)$$

$$\hat{\mathbf{X}}_{k+1} = \hat{\mathbf{X}}_{k+1}^- + \mathbf{G}_{k+1} \left(\mathbf{s}_{k+1} - \mathbf{B}_{k+1} \hat{\mathbf{X}}_{k+1}^- \right) \quad (43)$$

$$\hat{\mathbf{P}}_{k+1} = (\mathbf{I} - \mathbf{G}_{k+1} \mathbf{B}_{k+1}) \hat{\mathbf{P}}_{k+1}^- \quad (44)$$

3.4 Results and discussion

In order to verify the theoretical best performance of the state estimation algorithm, noise-free and correct dynamics parameters are substituted into the state equation. The bridge length is 30 [m] and the vehicle speed is constant at 10.0 [m/s]. When $t = 1.0$ [s], the front wheels enter the bridge, and the bridge begins to forced vibration. Then at $t = 4.4$ [s] the rear wheels exit the bridge. After that, the bridge is in the state of free vibration. Figure 2 shows the simulated and estimated values of the bridge's displacement vibration at the center of the bridge.

According to Figure 2, the estimated and simulated bridge vibration are different. In Figure 3, there is an error between the simulated and the estimated values between times $t = 1$ [s] to 4.4 [s]. because the vehicle is on the bridge.

Figure 3 shows the simulated and estimated road profile of the front wheel. From Figure 3, the road profile when the vehicle is not on the bridge matches the simulation. However, the estimation accuracy of the road profile of the front wheels decreases when the vehicle is on the bridge. The reason for the error is thought to be that the estimated value of bridge vibration contains an error.

In this study, the Newmark- β method is used to simulate bridge vibrations. However, in the state estimation algorithm, bridge vibrations are calculated by the difference method. It can be said that the estimation error is accumulated due to this difference and the accuracy of the bridge vibration estimation decreases.

Figure 2. Simulated bridge vibration and Estimated bridge vibration.

Figure 3. Simulated road profile and Estimated road profile.

Figure 4 shows the estimated road unevenness at the front and rear axles. The bridge section is $x = 0$ to 30 [m]. The road unevenness estimated by the front and rear axles are different. In the VBISI method, the road unevenness estimated by the front and rear wheels must match when the dynamic parameters are correct. Therefore, the VBISI method could not be applied with the proposed state estimation algorithm.

Figure 4. The estimated road unevenness.

4 CONCLUSION

In this paper, a new scheme to apply vehicle and bridge vibration data to Drive-by Bridge Monitoring, when vibration data of some bridges is obtained. However, it is expected that the proposed method cannot identify the bridge system because the estimation accuracy of the state variables is still low. Future works are to identify the error sources and to improve the estimation accuracy of state variables.

S. Gomolluch

City of Münster, Germany

ABSTRACT: Road construction is a major contributor to CO² emissions, but it also plays a crucial role in connecting people and enabling economic growth. Municipal road construction must consider not only ecological factors such as resource efficiency and mobility change, but also economic factors such as costs and depreciation, as well as socio-cultural factors. To manage these factors, sustainable asset information management (AIM) is needed, which involves using modern procedures and efficient data systems to manage asset information at strategic, tactical, and operational levels. This paper aims to identify the factors that influence sustainable AIM and translate them into requirements for the maintenance management of the city of Münster. By recording trends and changes in the municipal organisation, the paper provides insights into the structured management of AIM to ensure a sustainable road construction in the future.

1 INTRODUCTION

The majority of our road infrastructure was built during reconstruction or was rebuilt or expanded to meet actual needs. Thus the political focus was on new construction, reconstruction and expansion. While in the area of trunk roads, the constantly growing heavy traffic and the increasing axle loads have been causing an ever-increasing need for maintenance and considerable costs for years, in the subordinate network of municipalities, which comprises about 2/3 of the total road network in Germany (Knoll 2012), there has been a constantly growing need for maintenance and financing for years. However, our modern way of life is no longer possible without a demand-oriented and well-maintained transport infrastructure. Further constraints on such an infrastructure result, for example, from changing mobility, digitisation and the increasingly clear consequences of climate change. These aspects are associated with major financial burdens and personnel expenses for the public sector and considerable restrictions for the public due to the increasing interventions in municipal infrastructure. From a fiscal policy perspective, transportation infrastructure represents an enormous fixed asset that must be maintained on a sustainable basis. Failure to maintain it as needed threatens major financial risk. Qualified comprehensive maintenance management is required to avoid this.

Entrepreneurial thinking and methods have already found their way into German municipal administrations. Citizens are seen as stakeholders or customers for whom services or products are provided. The provision of transport infrastructure represents a product and, in order to provide it, the necessary infrastructure must be built and maintained. The infrastructure already in place had to be accurately recorded and monetised as a fixed asset. In addition to the technical view, the commercial view and life cycle cost considerations were also incorporated into the maintenance management.

The goal of the municipalities should be to carry out the necessary interventions in the road infrastructure in proper time, to proceed in a coordinated manner and to minimise the total number. In this way, the available financial resources can be used optimally to achieve the useful lives, to ensure that the value of the fixed assets is maintained and to realise the new requirements for the infrastructure. This requires a suitable management tool, such as municipal asset management (AM). Using the example of the municipal maintenance management in the Office for Mobility and Civil Engineering of the City of Münster, it will be shown how such an AM can be realised. Furthermore, the potentials emerging due to current changes and the relevance of integrating additional data and information into the existing AM will be presented.

2 MUNICIPAL ASSET MANAGEMENT

2.1 *What is the additional value of AM?*

AM is a tool to support leadership and management tasks. While quality management describes the process flow for task completion, AM in this context comprises coordinated, multidisciplinary processes within an organisation that deploys resources in the form of personnel, equipment and finances for tangible assets throughout their life cycle in order to achieve defined performance and cost targets at an acceptable level of risk, taking into account the relevant legal, geopolitical, economic, social, technological and environmental framework conditions (Ruitenburg et al. 2014). It is used for task- and result- or target-oriented management. Which assets represent a value contribution depends on the organisation (ISO 2014b). In the maintenance management of the city of Münster, for example, the assets sewer, road, bridge, traffic control and parking guidance systems (Buttgereit et al. 2021) are combined to form the asset portfolio.

Internationally, AM in civil engineering is a well-researched and practicable discipline (Abdirad and Dossick 2020), but in Germany in particular, there is a lack of comprehensive and integrated use, especially at the municipal level. Thus, it is the authors' intention to develop a long-term strategy to accelerate the implementation of AM in German municipalities. In contrast to Asset Management Systems (AMS), many municipalities still use Pavement Management Systems (PMS), which are technical data repositories of information for road maintenance, but focus primarily on economic evaluations, i.e. the monetary valuation of assets, and do not cover the life cycle.

2.2 *What are the limits of strategic PMS in municipalities?*

For decades, systematic maintenance planning has been searching for efficient solutions to determine, for example, the operational and strategic financial requirements. So far, a PMS supports the municipality in the preparation of the operational construction program and provides indications for the development of condition values with a limited budget (budget scenario) (Maerschalk et al. 2013).

Since the complexity is many times higher in urban areas than in non-urban areas, algorithms were initially developed for non-urban roadways and included in the regulations (FGSV 2001), which, for example, calculate maintenance programs for the next 3-5 years on the basis of systematic condition surveys and assessments of the roads (mainly the carriageways) using forecast functions for the expected development of the road condition (operational maintenance management) or attempt to estimate the financial requirements in the longer term (strategic maintenance management). In the vast majority of cases, the approaches and models used are condition-driven, whether based on simple thresholds that elicit an appropriate maintenance action or based on highly complex simulations of condition development. These condition-driven approaches can be described as "reactive" processes that allow for short-term to at most medium-term maintenance planning. Already obtaining the data of suitable quality required for the maintenance management of non-urban roads is a major challenge.

For municipal roads, it is usually many times more difficult, as there are no uniform or even standardised assessment procedures for the majority of municipal surfaces such as ancillary facilities to date. In addition, there are municipal peculiarities and requirements, e.g. complex forecasts of traffic load or heavy traffic as well as lack of forecasting function for the condition development

of municipal roads. In the same way, paved areas, such as work by utility companies and third parties, have so far been left out of the PMS and thus also left out of the determination of financial requirements. These aspects, on the other hand, can be indirectly represented in an AMS, if necessary. In parallel, a further development of a computer-aided municipal maintenance system should take place, which supports the engineer and the financial expert in his decisions in the AM.

2.3 *How can AM be structured?*

From the management function circle, namely the continuous sequence of goal definition and planning, decision, implementation and monitoring, management models for road maintenance can be developed in an analogous manner, in which the diverse tasks for safety and performance, construction and maintenance of road pavements are combined and linked. Different organisational forms are conceivable depending on the management structure, task definition, task weighting and standards. The foundations of an AM are outlined in ISO 55000 (ISO 2014b). The requirements are part of ISO 50001 (ISO 2014a). The AM is thus described as an international standard. However, it has not yet been transferred to the German regulations of the FGSV or specifically for road maintenance management. The systematics of asset management corresponds well with the life cycle considerations and can be used for orientation when setting up an AM system.

The basis of systematic road maintenance in Germany is a condition-based target system with target criteria to be defined individually. For this purpose, the current condition of the road pavements must be known, i.e. recorded and evaluated in consideration of the target criteria. At the same time, a forecast of the condition to be expected if a measure is not taken is to be estimated (deterioration). On the basis of the condition assessment, the measures to be implemented are then planned on the basis of a listed selection of measures, an order of urgency and the preparation of a program of measures with the budgetary resources required for implementation (financial requirements). In a next step, the individual measures are planned in more detail. In addition, possible alternatives with regard to the design and dimensioning of the pavements as well as alternative maintenance strategies must be identified and evaluated before a measure is then implemented. After completion of the construction measure, the basic data of the measure, such as the time of execution, the road structure, the results of quality assurance and the materials used must be recorded in a road database.

The management of road maintenance is therefore a special planning task in which, on the one hand, strategic decisions on maintenance measures or measure strategies are made network-wide (FGSV 2019). On the other hand, the preparation of a construction program and the preparation and implementation of maintenance measures are carried out object-by-object. The road network recorded in a road database forms the basis for this planning. In order to better incorporate financial aspects into construction decisions, a road database should be linked to information from asset accounting, such as residual book value and remaining useful life. This is usually no longer part of the PMS, but the step towards AM. In order to be able to control efficiently in terms of AM, it is necessary to define targets, metrics for target achievement as well as associated key figures. Based on the defined goals and key figures, long-term or short-term control options can be developed. Long-term management (strategic level) should create inter-generational equity, i.e. not burden future generations, or be sustainable. To this end, it is necessary (in the medium term) to achieve a balance between resource consumption and resource generation. Depreciation and provisions must be earned in the respective year. This would ensure the long-term performance of a municipality (Buttgereit et al. 2021). Short-term control (operational level) is primarily concerned with achieving a balanced annual result, i.e. the resource consumption of the financial year is covered by the resource revenue of the same financial year. Performance control can be carried out, for example, by time comparisons, operational comparisons or by target/actual comparisons. Short-term control of the budget should be carried out with the help of target agreements within the framework of contract management. The prerequisite for this is that product information is known about monetary variables, quantities and qualities, which are mapped and controlled in a management system (Figure 1).

Compared to PMS, AM focuses on maintaining the value of the assets over their life cycle. Synergies can be achieved through appropriate maintenance strategies for the respective assets as well as a coordinated maintenance strategy for the assets (especially sewers and roads). This

Figure 1. Continuous effect of the maintenance management organisation (right) on the asset portfolio to be managed depending on the respective life cycle phase (left).

ensures that the available financial resources are used economically and that the environmental impact and the impact on road users are kept to a minimum.

2.4 What is the additional value of information management respective BIM?

Infrastructure data, which is collected successively during the life cycle and also comes from different sources, is often subject to errors (Hajdin et al. 2022). However, different stakeholders also frequently provide data whose depth of content and accuracy deviates from the real information needs of maintenance management. To correct this deficiency, the use of the BIM method lends itself. Through the clear and also contractually secured definition of information exchange processes and the Level of Information Need (EN 2020), the information quality is ensured and thus represents an excellent supplement for asset information management. For the exchange of model data, the open exchange format Industry Foundation Classes (IFC) is used, which is also mandatory to be requested by public clients. Current further developments of buildingSmart, such as IFCalignment or IFCroad, will in the future also cover specific object classes from the infrastructure sector more precisely in the future. Garramone et. al. name frequent advantages present in the literature that can be achieved by BIM in AM (Garramone et al. 2022). In terms of information management, BIM allows information to be mapped throughout the asset life-cycle (Abdirad and Dossick 2020). In this regard, it is recommended that BIM models be used from the beginning of the project. In addition, differentiation support for both strategic and operational action planning is cited. Precise geometric information greatly facilitates the planning of maintenance measures, but strategic decisions in particular are often linked to network-level issues. The integration of BIM and GIS is a particular focus of attention here (Bradley et al. 2016). Moreover, many municipal road databases have already been implemented on the basis of GIS systems and are thus already an integral part of AMS. One concrete integration option is the conversion of IFC files into shape format, which can then in turn be transferred into the GIS system (Zhu et al. 2018). Among many other approaches to integrate both domains (Celeste et al. 2022), there are efforts by the Open Geospatial Consortium and buildingSMART International to develop a Common BIM/GIS Data Standard (OGC 2020). Another integration option may be to link external data sources in the prevailing system (Bradley et al. 2016), such as using information containers to map BIM data into the AMS (Hagedorn et al. 2022). Although this potential has not yet been fully exploited in Münster, various pilot projects are being carried out.

3 METHODOLOGY: FACTORS OF PESTEL

With the help of the PESTEL analysis, a conceptual framework is created in which the requirements for holistic asset information management can be ascertained in a structured manner. The PESTEL analysis is a strategic tool that is used to identify external influencing factors (Haynes and Nunnington 2010). PESTEL is to be understood as an acronym.

- Political includes the consideration of current government policy decisions and regulations that have an impact on the organisation or its sphere of influence.
- Economical factors look at monetary influences, such as price of building materials.
- Social cultural considers factors related to people and the way they live together.
- Technological encompasses factors that enable organisations and employees to leverage existing technologies and innovations and ensure future viability.
- Ecological includes energy efficiency, recycling and sustainability.
- Legal looks at the regulatory framework in which an organisation operates. For example, it examines the general legal certainty, the expression of guidelines as well as the approval procedures for new products or services.

The PESTEL analysis focuses primarily on external trends or mega trends, but also looks at external factors that are changing to a particular extent. As an example, road safety has always been a relevant topic in transport planning, but due to the increase in traffic, this topic now also plays an increasing role in maintenance management, thus changing the requirements accordingly.

4 INFLUENCING FACTORS AND REQUIREMENTS ON ASSET INFORMATION MANAGEMENT

4.1 *Results from PESTEL and requirement analysis*

An excerpt of the results of the PESTEL analysis is shown in 1 and 2. The focus of the analysis here is on the sphere of influence of the organisation that conducts maintenance management. The structure of the table is to be seen from left to right in logical consequence. External trends or changes in the organisational environment often result in positive or negative consequences that have an impact on maintenance management. In the next instance, this results in concrete requirements that are to be implemented by the AM, or already from the external factor if no assessable consequences can be derived.

4.2 *The need of asset information management*

One way of meeting these requirements and taking the above-mentioned future aspects into account is to set up an AIM. This can be understood as a digitally supported system that enables all management levels of an organisation to have an overview of the current situation, to make decisions based on facts, and to recognize and implement optimizations in the course of quality assurance, effectiveness control, and continuous improvement. Flanked by risk management, decisions can be weighed up in terms of relevance, among other things. In addition, in the case of planned and unplanned changes, an analysis should be carried out at short notice and corrective decisions made if necessary. There is already good experience from road construction technology as well as from environmental issues, which can be supplemented by the new challenges. The further development and limits of an existing AMS into a system that is capable of answering holistic questions can be illustrated below using the use case of the city of Münster.

5 CLIMATE CHANGE INFLUENCE ON THE MATERIAL

An increased risk in the course of climate change is the increase of future extreme weather events (heat, floods, storms) and the general expansion or shift of the temperature range of the service temperature range of asphalt surfaces. This results in changed and stronger physical loads on the infrastructure in terms of deformation or relaxation behavior. Consequently, the determination of weather data and the structural substance recording are of fundamental importance (determination of the actual condition). The resulting assessment of the infrastructure in terms of resilience must be integrated into a risk management system and opened up for forecast calculations (response to potential climatic changes). The results of the assessment are to be taken into account proactively in future action planning and supported by regular monitoring of the structural substance during the service life (sensor technology).

The road maintenance including bridge construction and traffic engineering of the city of Münster is the first in Germany to be certified according to ISO 55000 since April 2018. The

Table 1. Identified external factors, their consequences and concrete requirements for the organisational maintenance management.

External factors	Consequences	Requirements
Political		
- digital administration	- more transparency, data access for citizens, high implementation costs	- adapt network, hardware and software, train employees, security concepts
- federal and state level committed to the use of BIM	- provide human and IT resources and structures	- mutual integration of BIM and asset database
- citizen involvement and participation	- demand for more transparency, higher acceptance	- train employees, provide finances, present information appropriately, define information security needs
- transformation of mobility	- reallocation of land, redefinition of urban development standards, adaptation of maintenance management, increase in cycling	- prioritisation of construction measures (motorised individual traffic to individual traffic), potential analysis, decision-making basis for long-term strategy
- consolidation of finances	- savings in personnel and material resources, ...	- coordinated construction site management across all assets, dealing with short-term changes in the budget plan, sustainable value preservation of the infrastructure
Economical		
- shortage of building materials	- refurbishment backlog increases, delays in project plan	- resource-efficient construction, detection of sources of recyclable material, dynamic adjustment of system variables
- inflation	- loss of value exceeding regular asset degradation, deviations from the budget plan	- consideration of inflationary trends
- energy prices	- deviations from budget	- long-term energy savings, use of low-consumption technology (e.g. adaptive lighting), retrofitting measures
- out- or in-sourcing	- change in "business model", changes in responsibilities, changed need for coordination	- changes in the management system (personnel and competencies, information flows, etc.)
- refurbishment backlog	- action deadlines are exceeded, isolated decommissioning of assets, structural damage	- optimisation of the programme of measures, rapid awarding and approval, dynamic prioritisation
Socio-cultural		
- mobility participation and accessibility	- reallocation of space, redefinition of urban development standards, adaptation of maintenance management	- potential analysis, identifying obstacles, adapting infrastructure (e.g. traffic lights, bus stops) etc.
- demographic change	- such as mobility participation and accessibility, additional threat of loss of knowledge within the organisation, more difficult acquisition of personnel	- such as mobility participation and accessibility, ensuring knowledge transfer, more efficient processes, municipality as an attractive employer
- changes in urban planning	- change of land use, e.g. development of new building areas, shortage of capacities in supply and disposal security	- strategic alignment of the action plan, increase asset capacity or change in asset use
- increase in traffic	- traffic jam, impaired traffic safety due to spatial constriction, noise emissions, air pollutants, increased strain on transport infrastructure, faster material exhaustion	- reduce traffic disruption, use improved methods and materials (e.g. low-noise pavements), expand public transport, ensure health protection, coordinated construction site management across all assets
Technical		
- technological development of building materials and processes	- technological innovation, improvement and savings potentials, regulations and state of the art change	- technical recording of new information
- automation of machines and processes	- changing demands on personnel and hardware and software	- retraining and advanced training for employees, consider new apprenticeship professions
- increasing amounts of data	- IT infrastructure of public administrations reach their limits	- IT infrastructure must be improved
- artificial intelligence	- potentials for e.g. forecasting possibilities arise	- information systems should be usable by AI services in the long term

(Continued)

Table 1. (Continued)

External factors	Consequences	Requirements
Ecological		
- climate change	- risk of extreme weather (heat, flood, storm), risk of material expansion, shift in temperature ranges (service temperature range), hanging physical load on infrastructure	- consolidation of weather data, opening the system for forecasts, inclusion of risk management, assessment of the structural substance of the existing infrastructure with regard to resilience, result-based proactive action planning, monitoring of the structural substance during the useful life (sensor technology)
- resource-efficient construction	- more recycling and reuse, less primary building materials, life cycle material passport	- integration of new relevant developments, technical collection of new information, training of staff, asset consideration in the entire life cycle
- concept of the "Sponge City"	- more infiltration-capable traffic areas, increase proportion of green spaces, delayed water runoff	- potential analysis, circular water management concept, adaptation of the regulatory framework, designation in the development plan
Legal		
- environmental protection laws (e.g. Water Framework Directive)		- continuous consideration of all applicable legal requirements
- EU taxonomy		
- EU Construction Products Directive		
- changes in procurement and contracting		
- EU-MAK values (occupational health and safety in construction)		

AM is a task-oriented management tool for the management levels for strategic decision support in the context of generation-oriented, target- or result-oriented maintenance management over the entire life cycle of the assets.

In order to respond adequately to the aforementioned use case, it must be possible to integrate new data sources into the AM of the city of Münster. The DaRkSeit project is investigating the extent to which existing traffic monitoring data can be combined with available climate data and material data from existing road sections in order to make more precise statements about the progress of degradation and the remaining useful life (BMDV 2021). For sustainable maintenance management and to achieve the goal of climate neutrality, the RekoTi project is investigating, among other things, new alternative, resource-efficient construction methods and construction methods, approaches for efficient material flow management by means of information on the type, location, quantity and quality of resources used, as well as examining integration options for LCA data (Maibaum et al. 2022, Flamme et al. 2022). If the evaluation is positive, the knowledge of these projects gained will be transferred to the city's AM.

6 CONCLUSION

The holistic view in an Asset Information Management (AIM) means infrastructure management in the sense of responsibility for the entire infrastructure over the entire life cycle by combining the technical and commercial aspects with the goal of generational equity.

According to the authors, AM is a useful tool, also in public administration. AM helps, for example, both in the development of investment decisions and in safeguarding services of general interest. At the same time, it gives the opportunity to make quick forecasts and thus enables the administration to react to current political topics or issues. Likewise, future relevant topics can be better analyzed with the help of AM and implemented in the existing work environment. The same applies to the consideration of new technologies.

In order to be able to answer questions in the context of global (climate change, mobility transition) or national trends (digital administration), it is increasingly necessary to obtain new or supplementary information and to make it available to relevant interest groups in a quality-checked manner. This effort is often shied away from, with the result that more complex questions are not answered at all or are dealt with on the basis of insufficient information at considerable additional expense. At this point, a conscious turn towards Asset Information Management should take place. By combining AM and BIM as well as risk management towards an AIM, the decision makers of the municipality are supported in their work for more sustainability, also in infrastructure.

In Münster, strategies and concepts have already been developed to complement the existing regulatory framework, and some have already been tested and implemented in pilot projects. The potential identified in the process is enormous. The successive realignment of individual processes, the courage to carry out pilot projects, and the will to innovate and consistently develop further will enable Münster to meet future challenges.

Towards environmental design decision-making for infrastructure planning using parametric BIM

J. Hofmeyer, K. Forth, S. Esser & A. Borrmann

Technical University of Munich, Munich, Germany

ABSTRACT: The AEC industry is responsible for 32% of the global greenhouse gas (GHG) emissions. The greatest potential to reduce the environmental impacts of infrastructure projects has been identified to be in the early design stages, where trailblazing decisions of the road corridor and the construction type must be made. We propose a methodology for an automated calculation of embodied and traffic emissions based on Building Information Models (BIM) of infrastructure assets. Our approach supports decision-makers in identifying optimal road corridors not only by means of design aspects but also by taking environmental impacts into consideration. Hence, we introduce predefined, parametric LCA profiles including cut-and-fill considerations, various road profiles, and structural assets like tunnels and bridges. The bill of quantities is automatically derived from the BIM model for the subsequent LCA calculation. Finally, the resulting GHG emissions of different routing variants can be automatically calculated and compared for holistic design decision-making.

1 INTRODUCTION & MOTIVATION

In terms of climate change and the scarcity of resources, it is necessary for the AEC sector to sufficiently evaluate and justify the decision-making for construction projects. In addition to building construction, this is also of utmost importance for infrastructure projects. For the continuous reduction of CO₂ emissions, the embodied and traffic emissions of different routing alternatives should be considered at an early design stage (Liljenström 2021, Sauer 2016).

For the calculation of the embodied and traffic emissions over the entire lifecycle, the methodology of life cycle assessment (LCA) is used. LCA is a standardized approach to calculate the environmental performance of products and processes and “can be used to identify the highest points of concentration of emissions and analyze which actions can be taken to achieve their reduction more efficiently” (de Oliveira et al. 2021).

The greatest opportunity to reduce the environmental impacts of a road design is located in the early design stage where the choice of the road corridor and the construction type is made (Liljenström et al. 2021). However, the required information for conducting an LCA, such as the quantity of construction material, is hardly available and time-consuming to collect in an early planning stage. The relevant information becomes available in later design stages when fewer opportunities exist to reduce the environmental impacts.

A possibility to balance the conflicting objectives is the application of BIM methods to accelerate the time-consuming data collection and design evaluation of different routing alternatives. The BIM methodology shifts the design efforts into earlier design stages as semantic 3D models are developed and their relevant information is collected to conduct analyses. Therefore, the evaluation of different design possibilities can be conducted earlier where changes have greater effectiveness and possible conflicts can be resolved in time which improves the design quality (Borrmann et al. 2018).

The objective of this research is the development of an integrated evaluation system that provides end-users with a quick assessment of different routing alternatives by considering emissions caused by constructing and operating the infrastructure assets in question.

The rest of the article is structured as follows. Section 2 provides an overview of related research activities and motivates the identified research gap. Section 3 introduces the conceptual approach and elaborates on the assumptions made to implement a holistic yet flexible approach for LCA considerations in the early design stages of civil infrastructure projects. The proposed workflow has been tested in a case study, which is summarized in section 4. Section 5 concludes the findings and discusses future improvements.

2 BACKGROUND & RELATED WORKS

Currently, the environmental impacts of built assets are mostly considered within the framework of a rating system in the context of a sustainability assessment. The ecological aspects of sustainability are thereby determined with the help of an LCA. For example, a proposal for an indicator system by Schmellekamp (2016) evaluates the different sustainability aspects with a degree of fulfillment depending on a point system. Even though, no evaluation system for the sustainability of infrastructure projects has been officially introduced (Zinke et al. 2021).

Sustainability tools are mostly developed for end-product evaluation. The design phase must be completed to a certain extent in order to be able to carry out a sustainability assessment. However, decisions that have the highest impact on the environmental effects need to be made during the early design stages as the choice of the road corridor. For conducting an LCA for the choice of the road corridor, a simplified LCA is required (van Eldik et al. 2020). A European research project about Life Cycle Consideration in EIA of Road Infrastructure (LICER) addressed this issue. They developed an LCA tool in Microsoft Excel to calculate the annual energy use and related annual GHG emissions over the life cycle of the infrastructure project (Brattebø et al. 2013). However, it is still necessary to enter the data manually from the road model to the LCA model.

In a simplified LCA, traffic as well as embodied emissions should be considered. Traffic emissions are the emissions emitted by vehicles due to fuel consumption in the operation phase. Embodied emissions are associated with the life cycle of an infrastructure asset and include the construction, operation, maintenance, and demolition of the engineering constructions such as the superstructure of roads, bridges, and tunnels. According to Sauer (2016), the construction of a tunnel in mountainous regions might reduce GHG emissions as a smaller longitudinal gradient is achieved. The emissions from the reduced traffic will compensate for the higher emissions during the construction phase after several years.

The implementation of a BIM-based LCA has rarely been performed so far in infrastructure projects. The consideration of traffic emissions and the combination of road superstructures and civil engineering assets has not yet been carried out. In previous studies, only the embodied emissions were evaluated for different engineering constructions. Differences in previous studies exist in the functional unit, the consideration of different life cycle stages, different environmental indicators, and the integration process of BIM and LCA. Slobodchikov et al. (2019) and Maibaum & Block (2022) both conducted a BIM-based LCA for calculating the embodied emissions of the superstructure of a road. Van Eldik et al. (2020) evaluated the environmental impacts of a bridge in a cradle-to-grave consideration. As part of the Integridge research project, a BIM-based LCA has been developed for steel bridges. In addition to the ecological aspects, the other two dimensions of sustainability are also taken into account (Zinke et al. 2022).

The literature overview has unveiled deficiencies in BIM-based LCA calculations that consider the construction process as well as the operation phase of infrastructure assets. Therefore, the next section introduces a comprehensive framework that aims to close the gap identified.

3 METHODOLOGY FOR ENVIRONMENTAL DESIGN DECISION-MAKING

The objective of our proposed methodology is the automated assessment of different routing alternatives regarding their environmental impact with the help of BIM models in the early planning stages. Thereby, the routing alternatives consist of the road corridor and engineering constructions such as bridges and tunnels. The overall structure is illustrated in Figure 1.

In the first step, the LCA objectives, functional unit and system boundaries are defined as goal and scope. The functional unit of the conducted LCA is set as:

GWP [kg CO₂ e] over the life cycle of 100 years of different infrastructure routing alternatives enabling traffic between the same start and end point.

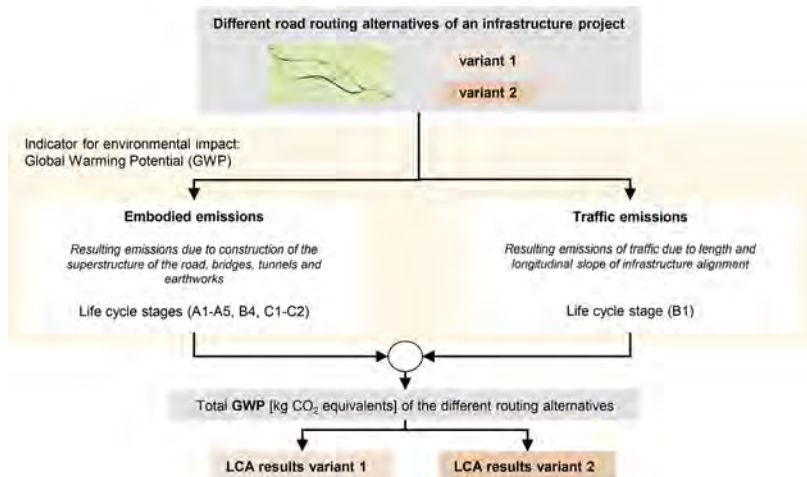

Figure 1. Defined goal and scope of the life cycle assessment.

Since engineering structures are designed for 100 years (EN 1990 2010), the same period is assumed here for LCA calculation. For the superstructure materials of a road, differentiated life cycles are accumulated over the period of 100 years. The different service life cycles depend on the type of material, which is divided into an asphalt and a concrete superstructure, and influence the replacement of components (B4) in the maintenance stage. For example, the service life for the top layer of asphalt superstructure is set to 10 years, and for concrete superstructure 60 years (according to Liljenström et al. 2021). As depicted in Figure 1, LCAs are conducted for each routing alternative of a road infrastructure project. The global warming potential (GWP) is selected for evaluation as the environmental indicator. The indicator is evaluated for both, the embodied and traffic emissions of the infrastructure asset in question. To oversee the infrastructure project over its entire life cycle, the embodied emissions of the product stage (A1-A3), transport to site (A4), construction process (A5), replacement of components (B4), and end-of-life stage (C1-C2) must be considered in the calculation. The traffic emissions are relevant for comparison with the embodied emissions (Sauer 2016), and therefore included and assumed here as the use stage (B1) for an infrastructure project. The final LCA result is the total GWP of each routing alternative created over the defined period.

3.1 Proposed workflow

In order to carry out a BIM-based LCA in an early planning stage, the parametric BIM models on the one hand and the predefined LCA profiles on the other hand are required. Their interactions are depicted in Figure 2.

Due to existing uncertainties in early design stages, BIM models mainly consist of sparse information and typically include information about the envisioned axes, terrain information, and assumed cross sections that are positioned along the envisioned track. Furthermore, many design decisions in early project phases build upon standards and regulations that take the expected traffic load into consideration. These guidelines enable resilient assumptions about the overall shape of the road body, the number of lanes per direction, and the envisioned overall width of the road. Furthermore, the analysis of the terrain information provides the basis for the axis design including the horizontal and the gradient layout. Subsequently, supporting structures like bridges or tunnels can be placed accordingly and are included in the resulting BIM models at least in a low level of detail.

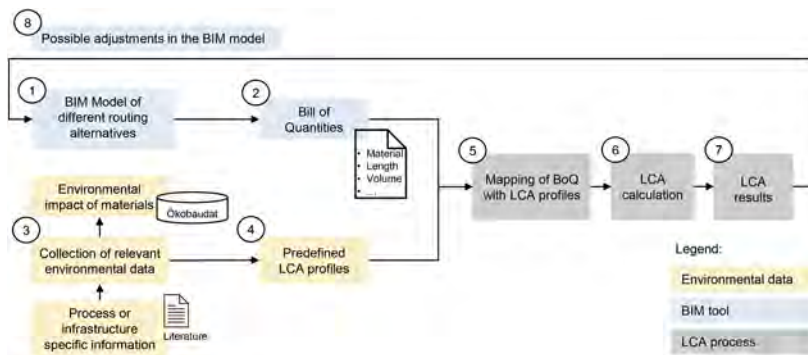

Figure 2. Overview of the proposed methodology including model preparation, calculation, result assembly, and impact evaluation.

After creating the BIM models, all information relevant to the subsequent LCA calculation is collected in the bill of quantities (BoQ). This includes, for example, the type of material such as concrete or asphalt for the superstructure and the associated volumes of the different layers. In the next step, the BoQ is automatically mapped with the LCA profiles.

For compiling suitable LCA profiles, different kinds of sources are considered. The first and main source is the ÖKOBAUDAT which is a German database with verified data quality and uniform data formats (Brockmann et al. 2019). Unfortunately, the ÖKOBAUDAT does not provide all information relevant to the evaluation of civil infrastructure assets yet. Therefore, missing information, such as transport distances caused by the location of the construction site and environmental coefficients for fuel consumption must be gathered from other sources. These sources consist of results from different research studies, which are explained in more detail in the following subsection.

Finally, the LCA calculation can be conducted using the predefined LCA profiles and the information extracted from the BIM models. The calculation of the LCA (indicated as step 6 in Figure 2) reports the GWP for each routing alternative (step 7). Depending on the results, the BIM model can be adjusted to optimize the routing alternative and iterate through steps 1, 2, and 5 to 8 until a sufficient design option is reached.

3.2 LCA profiles for the early planning stage

As outlined before, it is essential to choose suitable LCA profiles that are capable of representing environmental indicators for the different road features.

According to the data typically available in early-design BIM models, assumptions for the material choices and its specific service life cycles of the road superstructure must be taken. Furthermore, indicators for cut-and-fill considerations and engineering structures like bridges and tunnels are required.

For the superstructure of a road, the corresponding environmental indicators are compiled from the ÖKOBAUDAT for the life cycle stages A1-A3, A5, and C1-C2. For an asphalt superstructure, data concerning the different road layers are represented. However, the LCA data quality in the ÖKOBAUDAT for concrete road layers is incomplete. Therefore, it was necessary to compile different materials for individual layers. Since these were not available for all life cycle stages, a comparison at this point is not completely representative. Next to modules C3 and C4, data for the construction installation process (A5) of a concrete superstructure are missing.

In order to roughly estimate the GWP for the early planning phase of a tunnel, estimations developed by Sauer (2016) are utilized. These results in length factors (per tunnel meter) that depend on the selected standard cross-section and the type of excavation. Next to the construction, length factors for the annual GWP, resulting from the use phase, were determined. Thereby, a distinction is made between operation and maintenance. The emissions in the operational phase result from the electricity consumption for lighting and operating technology. Maintenance and servicing of the tunnel structure lead to emissions during maintenance.

The LCA profile for bridges contains area factors for the resulting GWP. These consist of an upper and lower limit value to address the level of uncertainty. As a lower limit, the assumption of Sauer is stored with a GWP of 1000 kg CO₂e/m² bridge area. For the upper limit, a reference value of 1370 kg CO₂/m² is applied which was determined in research projects for uniform sustainability criteria for infrastructure projects (Mielecke et al. 2016). The different life cycle stages are considered with a percentage share for production, maintenance, and end of life.

The amount of traffic emissions depends on the type of cross-section which determines the annual average daily traffic (AADT), the length of the route, and the type of vehicle. The latter is distinguished by car or truck, and both of them are powered by diesel or petrol.

The consideration of electric cars and the changing electricity mix are not part of this framework. In the LCA profiles, the GWP depending on the longitudinal slope for cars and trucks is stored. The associated factors are based on the assumptions of Fischer et al. (2012).

3.3 Required data from BIM model

For the proposed methodology, the information listed in Table 1 needs to be extracted from the BIM model. It is distinguished between information needed to calculate the embodied and traffic emissions. For the embodied emissions, the BoQ is needed which includes mostly the geometric information as volumes and quantities of the construction project. Whether the length, area, or volume of the road structure element is needed, is determined by the associated unit in the LCA profile. To estimate the traffic emissions, the length sections with a continuous longitudinal gradient are required from the BIM model.

Table 1. Required information to extract from the BIM model.

	Required information from BIM model
Embodied emissions	Road corridor with its superstructure layers Volumes of the different layers Cut and fill volumes of road corridor Kind of road structure element Tunnel length and corresponding cross-section type Bridge area
Traffic emissions	Length sections Corresponding longitudinal slope

4 CASE STUDY, IMPLEMENTATION & RESULTS

4.1 Prototypical implementation

A prototypical implementation has been made using well-established software tools. The model preparation takes place in Autodesk Civil 3D (version 2022), where the BoQ and all other relevant information can be extracted using the visual programming application Dynamo for Civil 3D. In addition, the predefined LCA profiles prepared in Excel are imported into Dynamo and linked with the data of the BIM model. The subsequent calculation of the LCA is directly performed in Dynamo and its results are exported to Excel.

The use of existing LCA tools for the calculation process was not possible as not all of the necessary data is available there. Data concerning environmental indicators for tunnel or bridge construction are for example missing. Therefore, as suggested by van Eldik et al. (2020) and Maibaum & Block (2022), visual programming language (VPL) is used for the integration and calculation process. In case of new aspects to consider in the future, visual programming tools offer high adaptability.

4.2 Case study project

In order to validate the presented methodology and its implementation, a case study was carried out. The case study evaluates different routing alternatives located at the Irschenberg in Bavaria and its results can be partially compared and validated with those of Sauer (2016).

Within the framework of a master’s thesis (Bracher 2010), several different routing variants of the motorway A8 in the area of Irschenberg were developed. The new variants should lead to a more optimal routing thus coping better with the considerable amount of traffic and reducing the number of accidents that occur.

Due to the difficult topography, there is a different need for engineering structures such as bridges and tunnels. In order to demonstrate the balancing of the GWP for tunnels, bridges, and roads, two variants are investigated in the following which is both adjusted to the same starting and end point. The alignment of the first variant mainly consists of a 4.3 km long tunnel that passes under the Irschenberg with a longitudinal gradient of 1%. Variant 2 consists of three bridges with a total length of 1.5 km additionally to the road corridor.

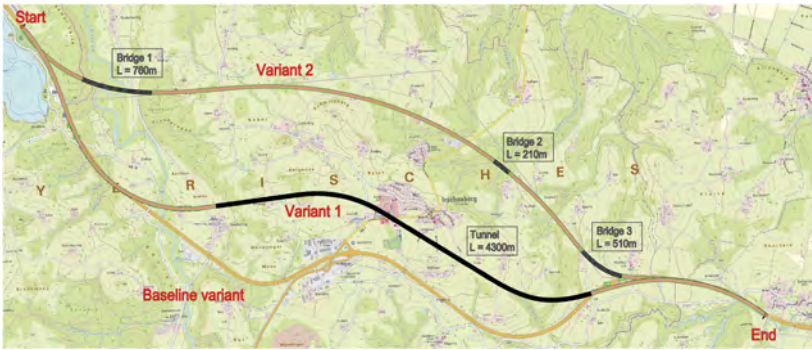

Figure 3. Overview of the case study project consisting of the different road routing alternatives.

4.3 LCA results

The LCA results are exported from Dynamo in an Excel file for each respective routing alternative. The results of the GWP-related emissions are provided in individual worksheets for the different infrastructure elements and the traffic emissions. A comparison over 100 years indicates the dominance of traffic-related emissions. The question arises, after how many years the embodied emissions are compensated by the relatively lower traffic emissions in comparison to the baseline variant. To assess this, the respective cumulative emissions of the different variants are considered over time. In order to assess the traffic emissions of the baseline variant, the results obtained by Sauer (2016) are applied. Exemplarily, only the results of the asphalt superstructure are presented in Figure 4. More detailed results can be found in an extended version (Hofmeyer 2022). The emission results of each

Figure 4. Cumulated emissions over a time period of 100 years of the different variants and its point of intersection (PoI) with the baseline variant.

variant were calculated and visualized cumulatively over the construction life cycle period of 100 years considering all LCA stages, such as production stage (A1-A5), usage (B1) and maintenance (B4) and End of Life (C1-C2). The replacement effects of the LCA results are hardly visible due to the dominating traffic emissions.

The construction of the tunnel in variant 1 results in the highest embodied emissions which leads to the largest GWP of this variant after the construction is completed (year 0). The baseline variant starts with the lowest GWP as no construction measures were applied. Since the baseline variant yields the highest traffic emissions, this approach displays the steepest slope. As a result of the construction of variant 2 and the reduced traffic emissions, the point of intersection (PoI) with the baseline variant is already reached after 4 years. For variant 1, the intersection with the baseline variant occurs after approximately 19 years. With regard to the GWP, the construction of variant 1 or 2 is an improvement over the baseline variant. When comparing variants 1 and 2, variant 2 performs better, as both embodied and traffic emissions are lower.

5 CONCLUSIONS

In the early design stage, only limited information regarding the rough construction parameters of infrastructure projects is available and can be represented in the BIM model. Nevertheless, the choice of different routing variants has a big influence on the environmental impacts of infrastructure projects. Hence, we propose a methodology for an automated calculation of embodied and traffic emissions based on BIM models reflecting infrastructure assets. The LCA results of the applied case study confirm that traffic emissions are responsible for the largest share of the GWP over a lifespan of 100 years. Therefore, it is important to raise awareness in the construction industry that fuel-efficient construction of infrastructure projects can significantly reduce the GWP impacts.

Since the designs for engineering structures, such as bridges and tunnels, have not been detailed at that early planning stage, length factors depending on the required cross-section or area factors are applied for determining the embodied GWP emissions of engineering structures.

As the implementation has shown, all relevant information can be extracted from the BIM model, including the volume of the individual road layers, the cut and fill volumes, the area of the bridge structures, and tunnel lengths. The manual, time-consuming process of calculating the BoQ can thus be reduced in time and increased in quality simultaneously.

The limiting factor in the presented methodology is the missing datasets specifically for infrastructure materials and construction processes. While comprehensive indicators for building construction are already available in the ÖKOBAUDAT, this is unfortunately not the case for infrastructure components. For example, datasets for the different layers of a concrete superstructure are not sufficient or fully missing.

For the future, the presented methodology can be extended due to limitations, which were initially made in order to limit the scope of the present work. The scope of the performed LCA only considers the GWP as an environmental indicator. If the availability of other indicators gets better in the future, the scope can be extended accordingly. At the sustainability level, only the environmental aspects have been evaluated. However, the economical and social dimensions could be extended for a BIM-based decision-making process. Another limitation is the type of traffic mode as only roads have been considered so far. An extension for railway systems would therefore be feasible and is also highly dependent on sufficient LCA data. Therefore, the enrichment of standardized and officially validated life cycle databases for infrastructure projects should be aimed for. In addition to material-specific environmental impacts, more information regarding the lifespan of the materials and transport distances is required. Since the highest embodied emissions in road construction occur during the maintenance phase, the applied maintenance cycles and lifespans are of great consequence. Another open research question considers the dynamic aspect of the LCA profiles and datasets. Different traffic scenarios, the development of fuel efficiency, and the share of electric, hydrogen, or petrol-powered cars lead to dynamic changes in the datasets rather than static ones. Data

from the ÖKOBAUDAT should also vary over time, as different energy sources and mixes change dynamically, too. These changes will lead to a different ratio of embodied and traffic emissions but will give a more realistic prediction of the overall environmental emissions of infrastructure projects.

BIM-based EPD adaption in the context of ecological sustainability and municipal infrastructures

ABSTRACT: Municipal infrastructure projects are mostly awarded, planned and financed at the municipal level. The quantities, materials, construction processes and construction equipment used in these projects are currently only recorded and linked to a limited extent. Therefore, it is presently not possible to record the entire inventory and environmental impacts in detail. Environmental product declarations (EPDs), which can be used for this purpose, are also incomplete at present, particularly for the infrastructure sector. To make progress in this field, a method has been developed to investigate, compare, validate and adapt digital EPDs. In addition, integration with the BIM methodology is being undertaken to enable a model-based life cycle approach for typical municipal road infrastructure structures. The methodology is based on existing EPDs and allows the inclusion of additional life cycle phases through data input options. In order to include the LC phases transportation, O&M and recycling, a generic and continuously extensible application was implemented.

1 INTRODUCTION

The construction of infrastructure is reported to be one of the most resource-intensive sectors and is responsible for a substantial amount of energy consumption, greenhouse gas emissions, and the high-demand binding and leveraging of raw materials (Backes Taverso 2021). In the context of the increasing awareness of sustainable and resource-conserving construction, various challenges emerge. The climate protection law passed in Germany for example demands, a significant reduction of emissions and the consumption of resources and energy. Simultaneously, recycling rates should be increased and material cycles closed, with the public sector client acting as a role model. The provision and maintenance of public infrastructure are key factors in considering sustainability. According to this, the public administration is responsible for the awarding of contracts, planning, maintenance, renovation, and demolition, and, if necessary, also for the execution of construction work. To enable the public administration to consider sustainability analyses in these processes, it needs reliable and consistent information management. This can be ensured by using Building Information Modeling (BIM). The fundamental assumption of BIM to comprehensively map the building life cycle in terms of information technology also coincides with the definition of the circular economy “an industrial economy that is restorative or regenerative by intention and design” (MacArthur 2012).

To provide circular information management, quantities, volumes, and conditions of infrastructure must be adequately quantified. Based on this, a comparison of financial requirements and ecological impact becomes feasible. The ecological impact can finally be assessed by using environmental product declarations (EPD). These can currently be used as a basis for a subsequent ecological evaluation of materials and, to a minor extent, processes (compare section 3.1). The contribution provides an approach for ecological sustainability considerations of municipal construction measures via the adaption of relevant EPD data sets.

2 RESEARCH FOUNDATION

In terms of sustainability in the field of infrastructure, the municipality is a player that has received little attention so far, even though it is responsible for more than two-thirds of the entire road network in Germany. The challenges listed are now being explored in the scope of a municipality, multi-criteria sustainability assessment, and the digital working method BIM to provide the scientific foundation and context for the EPD-related approach.

2.1 *Sustainability in municipal asset management*

Asset management (AM) is the organizational process of allocating human, equipment, and financial resources to physical assets throughout their life cycle to achieve defined performance and cost objectives at acceptable levels of risk, taking into account the relevant political, economic, social and technological context (Ruitenburg et al. 2014). In infrastructure AM, depending on the organizational orientation, road, road installations and equipment, parking guidance system, bridge, and sewer are understood as assets (Buttgereit et al. 2021). However, AM currently focuses primarily on safety and economic efficiency (Staubli et al. 2017). In the long term, sociocultural requirements such as generational equity and ecological aspects such as resource-efficient construction and efficient recycling management must also be included in this process. In this development, municipal AM in particular has a special social task. Currently, construction projects are often awarded solely on the basis of economic factors, with the result that quality and sustainability criteria only have a reduced impact on project awards. As a result of the transformation of the construction industry towards greater resource efficiency and sustainability mentioned in section 1, criteria such as these must also be increasingly taken into account when awarding contracts. In addition to numerous international assessment procedures, national assessment systems such as the Assessment System for Sustainable Building (BNB) and German Sustainable Building Council (DGNB) can also be used for building construction. For infrastructure construction, no assessment system is so far legally binding at the national level. The Federal Highway Research Institute (BAST) provides an assessment system for the infrastructure systems road, bridge, and tunnel, which equally takes into account ecological and socio-cultural criteria in addition to economic criteria (BAST 2016).

2.2 *Ecological sustainability assessment - Life Cycle Assessment (LCA)*

In terms of ecological assessment, the LCA method can be applied. It is specified in ISO 14040 and ISO 14044. Concerning these standards, the method follows a four-step iterative process (ISO 2006a, ISO 2006b). This process consists of the definition of the objective and scope, the Life Cycle Inventory (LCI), the Life Cycle Impact Assessment (LCIA), and the interpretation of the LCIA. The first step is to collect relevant data and quantify input and output flows. Next, direct environmental impacts are recorded based on the inventory. Linked to this, the total environmental impacts recorded are categorized, characterized, and finally interpreted and evaluated. LCI and LCIA data are generated for a material unit and, to a lesser extent, for a process unit as an EPD and stored in an EPD database. LCA data sets can be specified as the smallest modeling unit in a life cycle model. In the process, each of these data sets incorporates different inputs (resources) and outputs (emissions and waste products) (Pasetto et al. 2017). Several of these data sets are combined into one life cycle model. Data sets can be subdivided into cradle-to-gate, cradle-to-grave, and cradle-to-cradle data collections (Olivier et al. 2016). A cradle-to-gate data set covers the environmental impacts from extraction to the end of production. Cradle-to-grave also includes the impact of product disposal, and cradle-to-cradle additionally contains the impact when returning the product to the use phase. As a current challenge in the application of LCA Dossche et al. (2017) state that LCA provides a global framework, but not an exact technique to calculate environmental impacts. This makes it possible to perform LCA in different ways as various boundary conditions are applicable. LCA research is a fragmented state which makes a comparison challenging.

In general, several commercial and non-commercial LCA tools are available that can be used to determine the life cycle impact of road infrastructure (e.g. asPECT (British), ECORCE-M (France) PaLATE (USA)). For the building construction sector, several BIM-LCA-tools like Tally and One Click LCA which attempt to take the BIM method into account

are existing. For the infrastructure sector, however, this approach is still only feasible to a very limited extent. In particular, the non-transparent calculation methods, as well as the lack of certain LC phases, the poor comparability, and additionally the less implemented EPD product range, are to be seen as disadvantages (dos Santos et al. 2017). By integrating LCA into the BIM methodology, different challenges can be addressed. The work from Hausschild et al. (2018) points the challenges of the integration of LCA into BIM out by stating to focus on the digital and transparent quantification and calculation of environmental impacts, which leads to objective benchmarks. Despite the continuous progress of digitization and the application of the building information modeling (BIM) method in road construction, its dissemination is currently still limited. Furthermore, the integration of LCA into the BIM methodology is also still in the early stages (Dalla Mora et al. 2020). The heterogeneous software landscape is also cited as challenge in integrating LCA with BIM, which leads to incomplete BIM models. Moreover, it is stated that currently, no explicit data structure exists for the integration of environmental and BIM data (van Eldik et al. 2020).

When it comes to technical implementation Slobodchikov et al. (2019) showed a simplified possibility of linking LCA calculations in the BIM methodology using a generic approach as an example. The project uncertainties or the availability of data turned out to be a major challenge here. A first approach of BIM-based multi-criteria sustainability analysis is provided by Lammers and Forth (2022) by combining the methods of LCA and LCC with the BIM method. For this purpose, they use related databases and the IFC format in order to automatically evaluate the sustainability of buildings over their life cycle in early planning phases on the basis of the available data and calculation methods.

2.3 *Environmental product declarations - EPD*

Based on LCA, EPDs represent a standardized format for reporting LCA outcomes in a third-party audited and certified document. Within the European Union, the EN 15804 standard contains the core category rules for product EPDs in the building and construction sector as well as a subdivision of the life cycle into information modules (EN 2012).

An EPD database should provide uniform naming, comprehensive input/output flows for data sets, a consistent modeling approach, and documentation. The aggregation of process and inventory is done either individually or grouped depending on the database (Olivier et al. 2016, Pagnon et al. 2020, Takano et al. 2014). Databases such as GaBi and Ecoinvent provide mostly reference data, EPD platforms such as EcoPlatform EPD, IBU, INIES, ÖKOBAUDAT, and the international EPD system also offer ready-made EPDs.

In Germany BNB offers ÖKOBAUDAT, an open-source and -access web-based EPD database, and with eLCA, an online EPD analysis tool is available. The tool is launched and managed by the German Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR). The motivations for the digitization of the LCA infrastructure under the BNB were to enhance all data-related workflows, to ensure independence, and to reduce the cost of preparing LCAs for buildings (Brockmann et al. 2019). At the European level, with InData, a working group exists that aims to establish an open, web-based, international data network for EPD/LCA data using a common data format and open-source software. The main objective is to establish best practices for providing digitized EPD as a quality source of verified EPD/LCA data for BIM, as well as for construction LCA and other relevant uses. Globally, about 6000 registered EN 15804-compliant EPDs are currently available. Another reason for working on this topic is the high demand for linking EPD data with BIM-based building models (Brockmann et al. 2019).

Lasvaux et al. (2015) note that on the database level, the EPD values vary depending on the LCIA indicators and the building materials. The discrepancies are caused by the fact that in mixed EPD databases, different background data are used in the same EPD database, and, for certain construction materials, specific procedures created by the manufacturers in the national context are applied. Stapel et al. (2022) determined in their qualitative analysis of EPD data sets, that a large proportion of EPDs include a full life cycle with End-of-Life (EoL) options. However, nearly 45% of the data sets only consider phases A1-A3 (Production). This proportion is expected to change in the transition to EN15804+A2, when C1-C4

(EoL) and D (Recycling) will be included in the data set (c. f. 1). Thus, the study highlights the importance of transparency and more consistent guidelines for publishing data in the process of supporting LCA. According to the authors, collective EPDs or generic data from public databases are a valid instrument.

Nevertheless, when it comes to comparing alternatives in the bidding phase, a specific EPD from the manufacturer of the product to be installed is appropriate and should be required. For each project, a specific LCA should be performed at every design and construction phase based on data from product-specific EPDs adjusted to project-specific assumptions (ArcellorMittal 2022).

In contrast, the approaches of Palumbo et al. (2020) and Carstens et al. (2021) focus on a better understanding of existing EPD data sets. The first named quantified in terms of different types of EPDs that there have been limitations in matching impacts generated in Modules A4 to D (resulting from the boundaries of the LCA system). This is due to the lack of consistency between the different data granularities (generic versus specific). To meet this problem the authors generate safety factors and benchmarks. Further Carstens et al. (2021) also used various benchmark methods to make the results of EPDs more accessible to non-experts. They establish reference values through statistical analysis and develop single result benchmarks based on EPDs for better comprehension.

It should be concluded that the analysis and evaluation of EPD data sets and their background processes are already partially part of the research. However, especially for the infrastructure sector and the special features mentioned, the path to valid EPDs is currently still long.

3 METHODOLOGY AND CONCEPT

An approach has been developed that aims to address the current difficulties in using EPD databases and data sets at a technical level. Our implementation is based on the problems identified in section 2. In particular, the rudimentary availability of EPDs for the infrastructure sector leads to short-term assessments and cannot be used beneficially as in the municipal AM. The focus of the implementation is currently on the determination of the ecological impact of a construction measure in relation to the road infrastructure asset.

Table 1. Illustrative comparison of EPDs data sets from various databases for the main used infrastructure material asphalt (Selection); Grey: LC phases that currently receive low to no coverage in the available EPD data sets; Enclosed dots indicate that isolated data sets exist in the respective LC phase and database.

3.1 Proof-of-concept assessment of EPDs

As described in section 2 environmental product declarations are essential for being able to define ecology in the sustainability evaluation of municipal infrastructures and used to determine the environmental impact of materials and reduced construction processes. Furthermore, some of the production, transportation and construction processes are mapped indirectly in material EPDs, since the material EPDs are based on specific manufacturing processes. The

identified inventory and calculated environmental impact can be aggregated and incorporated into the ecological sustainability assessment of a planned construction measure. Economic and socio-cultural data are not included, so only a subset of the overall sustainability assessment is highlighted, which is relevant for the municipal AM.

An analysis and evaluation of the EPD availability were carried out as an example for the construction object asphalt surface course. An overview of the identified data sets, their completeness, and their source is shown in Table 1. Further, the table illustrates that the data sets are not valid for the complete life cycle. Especially the operation & maintenance phase as well as the phase of installation, demolition, and reuse are not accurately represented.

In addition, it should be inserted that the automated use of the data sets is only possible to a limited extent. Thus, it is necessary to implement an intermediate database in order to have a clear foundation for the subsequent integration of the LCA into the BIM methodology.

3.2 *Components of the implementation*

The contribution primarily provides a concept for the rational extension of existing EPD data sets and also offers the basis for the extension of economic and socio-cultural sustainability aspects. The example of asphalt pavement is used as a representative example to show existing EPD availability and which LC phases are included or not included so far. In national terms, asphalt road pavements account for the vast majority of road pavement types. Furthermore, it was quantified that the availability of asphalt EPDs is the highest compared to other infrastructure construction materials. In addition to the amount of EPD data sets, Table 1 also shows EPD data sets provided by organizations and individual companies in document format.

Especially in the case of EPDs provided in document format, automated use and linking with a BIM model is not directly applicable. An intermediate step has to be taken via a database to prepare the data for use in a machine-readable format and the ILCD structure. Subsequently, the data is imported and - if needed - adapted via an EPD editor. Our focus hereby lies on mapping the environmental impact of measures via EPDs in terms of certain resources and indicators. It is possible to adjust or add indicator data for individual LC phases. This is essential due to the special characteristics of infrastructure structures mentioned in section 1, since, as shown in Table 1, it is mainly the LC phases O&M that have to be mapped in a reliable and proper way. In addition to the adaptation of material EPDs, available EPDs of construction processes can also be adapted or extended accordingly. This is done - analogously to the EPDs - for individual LC phases. The interaction and aggregation of materials and processes are essential for the planning of measures.

Following this, the adapted EPDs are linked to the BIM model. This is realized via material or GUID matching, assigning the individual material layers of the BIM model to the material data of the EPDs. Based on this, a BIM-integrated determination of the LCI (life cycle inventory) and LCIA (life cycle impact assessment) data can be performed. The determined environmental data can be visualized via graphs or further used in a model-based way in the form of a property set. A high level of expertise in the planning, construction, and maintenance of individual infrastructure structures is required. The knowledge base for various procedures will be supplemented and the implicit knowledge, which is often contained in domain experts or documents, will be made machine-readable, graph-database driven, and retrievable. A clear illustration of the individual processes and sub-processes is provided in Figure 1.

3.3 *Technical implementation and proof of concept*

From a technical point of view, Autodesk products were used for the implementation and the open-source environment Dynamo was applied for visual programming. Dynamo is already integrated as a plug-in in the Autodesk software at installation. It can be observed that visual programming tools like Dynamo are being predominantly and increasingly applied for the integration of LCA into BIM methodology (Collao et al. 2021). This is in part due to the fact that Dynamo and other visual programming tools provide an intuitive and user-friendly interface for designers and analysts to seamlessly integrate LCA considerations into the design process.

In the first step of the implementation EPDs had to be partly converted manually from the documents into a structured data template. For this purpose, the guideline for the BIM-compliant use of data templates of EPDs for building products was used as a reference (ISO 22057). The EPD database is accessed via a Dynamo script and can be addressed in a user-defined way in order to first import and then customize the relevant data sets. This is accomplished via the integrated user interface of the EPD editor. Next, by implementing geometric and mathematical operations, both life cycle inventory data (LCI) and impact assessment data (LCIA) are transparently determined in the LCA implementation step. For the modeling of three-dimensional road infrastructure models Civil 3D was used. The infrastructure information model (IIM) is based on two-dimensional parametric road cross sections, to which the LCA property data sets are attached. In a final implementation step, relevant LCA data were linked to the model via a Dynamo script. Since there is currently no adequate application programming interface (API), the data sets were imported from Excel and finally exported again.

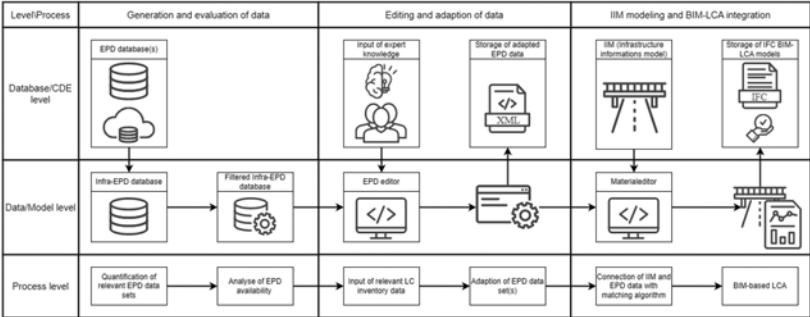

Figure 1. Implementation processes from data generation, adaptation and following the integration of LCA into BIM methodology classified into the database, data, and process level.

4 USE-CASE

The described methodological approach will be exemplified by a generic use case. A standardized parametric IIM, which is based on the national German building regulations, serves as a basis. The EPD adjustment and subsequent BIM-based LCA execution are subsequently performed for the main road construction material asphalt. Asphalt data sets shown in Figure 1 provide the data foundation for this. For this purpose, a typical construction measure in a municipal context is simulated with a renewal of a fictitious asphalt pavement. On the one hand, the material is relevant and, on the other hand, the renewal process of the construction. The material EPDs include the LC phases of production (A1-A3), transport (A4, C2), and demolition (C1) of the new road layer. The process EPD, meanwhile, contains data for the construction process (A5) of the layer. Operational, O&M (B1 -B7), and other LC phase data do not exist and can be added to the data set accordingly via the EPD editor (c.f. 2). The LCA results for a construction measure are subsequently composed of the partial LCA results of the material and construction process. The as-built measure LCA values can then be compared for various construction implementations. Thus, it is possible to derive conclusions about the environmental sustainability of infrastructure structures. The aim here was to show the sequence and execution of the implementation and to illustrate the potential of the method created.

5 CONCLUSIONS

The critical summary of the paper is intended to present the current implementation status, and identify problem areas and force future extensions and connecting factors that can be anticipated. In a nutshell, an approach for transparent, expandable EPD use was developed.

Figure 2. Left: Input of measure relevant material and process data to complete or adapt the existing EPD database for certain LC phase; Right: Linking of LCA data to IIM; At the edges: Relevant inputs and outputs for the implementation approach.

For this purpose, in a preliminary phase, available EPDs were quantified, considered, and finally qualitatively checked for completeness. By means of a low-threshold and modular EPD tool, the EPDs can be adapted for the respective use case and finally linked to the IIM for sustainability assessment. The approach currently focuses on the ecological aspects of sustainability assessment but suggests that economic and socio-cultural factors could also be included in the future. In particular, comprehensive sustainability assessment is important in the context of municipal asset management, particularly when it comes to planning and implementing infrastructure construction measures. For the digital tool-based implementation, the knowledge of domain experts is currently necessary, which will be countered in the future by the creation of a knowledge database, whereby the approach and implementation of the coherent holistic sustainability assessment within a digital transparent BIM-based application can be helpful in decision-making support for measures.

Currently, the existing EPD data sets and the linked properties of EPDs are not useful for the holistic sustainability assessment of infrastructure constructions and measures due to the lack of material EPDs and LC phases. Also the lack of transparency is a current drawback. In addition, only some EPDs exist in machine-readable formats and can be addressed via APIs. To address this, initial tools are emerging that allow EPDs to be edited, such as BNB's EPD Editor and the EPD-Analyzer. In particular, BIM-based approaches to EPD editing have not yet been part of the research. In addition, the current benefit of integrating the LCA methodology into the BIM methodology, especially for the municipal asset management of infrastructure construction assets, is to be assessed as rather low. The purely ecology-oriented sustainability survey is often insufficient here.

The approach presented in this paper also provides a number of conceivable methodological extensions and additional technical implementations. In the first step, the current structure can be extended by a database that can store and query highly interconnected data. The structure of graph databases is suitable for this purpose, as it can be used to map complex relationships, as for infrastructure construction measures. In the mid to long term, the current focus on quantifying ecological impact should at least be supplemented by the area of economics. An additional extension of the socio-cultural and technical domain would be useful to achieve a more comprehensive assessment of sustainability. Finally, it can be assumed that in the future, the holistic consideration of environmental impact aspects will become increasingly relevant, especially for municipal infrastructure construction projects. However, at present, there are neither BIM-integrated LCA tools nor a wide-ranging and reliable amount of environmental product declarations (EPDs) for infrastructure materials and processes defined.

ACKNOWLEDGMENT

The research project *RekoTi – Ressourcenplan kommunaler Tiefbau* created the context for this paper. It is funded by the German Federal Ministry of Education and Research (BMBF) [grant number 033R264] under the scientific program *Ressourceneffiziente Kreislaufwirtschaft – Bauen und Mineralische Stoffkreisläufe (ReMin)* and supported by the *Research for Sustainability (FONA)* platform. ABSTRACT: In order to establish a sustainable bridge assessment within a practical planning routine, it is necessary to reduce the calculation effort by applying automated algorithms. Information generated by the application of Building Information Modeling (BIM) can be used as project-specific input data for this purpose. For the method of life cycle assessment (LCA), the approach of linking the materials of the BIM-model with environmental data sets to calculate the ecological impacts has become widely established. This material-based approach provides sufficiently accurate results for an ecologic assessment in late planning phases. For early planning phases it is not directly applicable and the approach is not transferable to the application of the calculation methods life cycle costing and macroeconomic cost calculation.

The approach presented in this paper introduces a framework that can be used to calculate the life cycle impacts of a bridge by linking the objects of a BIM-model with the content of a hierarchically structured catalogue of elements. To establish this catalogue, individual items are pre-balanced and combined to generate base elements. To represent the entire life cycle of a bridge, follow-up elements, which occur after a specific time interval within the use and dismantling phase, are additionally defined. The individual base elements are combined into generalized major and macro elements into which the individual base elements are included with statistical shares. By applying the different element types, it is possible to use BIM-bridge models with different levels of detail for a holistic assessment and to include all impacts that occur during the complete life cycle.

1 INTRODUCTION

The sustainability assessment of bridges requires the application of different assessment methods. Some methods are based on qualitative and subjective evaluations and are therefore difficult or impossible to automate. For some quantitative assessment methods, Building Information Modeling (BIM) can be used to (partly) automate the calculation procedures and therefore reduce the manual effort significantly. This reduction is necessary to implement sustainability assessment as a method in everyday infrastructure planning. For life cycle assessment, a material-based approach using the volumes of BIM-objects and multiplying the derived material quantities with environmental impact datasets has been implemented in several software products. This paper discusses the shortcomings of such material-based approaches and introduces an element approach which can be used to calculate life cycle costs, ecological impacts and macroeconomic costs.

2 SUSTAINABILITY ASSESSMENT

In the following, the methodological principles and standards for the quantitative methods of life cycle assessment, life cycle costing and macroeconomic costing are shortly described. For these methods the element approach can be used to calculate the impacts of a bridge using data generated by Building Information Modelling as project specific input data.

2.1 *Life cycle assessment*

Life cycle assessment (LCA) is a method for quantifying the potential environmental impacts of product systems over their entire life cycle. The calculation is standardized since 1996. DIN EN ISO 14040 (2021) and DIN EN ISO 14044 (2021) provide the methodological basis. A specification for the building product level is made in DIN EN 15804 (2022). Framework conditions at the building level are given in DIN EN 15643 (2021). The calculation methodology is specified for buildings in DIN EN 15978-1 (2021) and for infrastructures in DIN EN 17472 (2022). All material and energy flows within the specified temporal and spatial system boundaries must be recorded by default to fulfill the requirements of the standards. This surveyed life cycle inventory is translated into a life cycle impact assessment using characterization factors. As a result, the potential environmental impacts within different impact categories are provided.

2.2 *Life cycle costing*

Life cycle costing (LCC) is a method for quantifying the costs incurred within firmly defined system boundaries for a product system. The method is standardized by DIN EN 17472 (2022) and ISO 15686-5 (2017). Costs that occur during the use phase and dismantling phase are discounted to the year of construction using a discounting rate.

2.3 *Macroeconomic costing*

Most construction, repair and maintenance measures on bridges result in an impact on traffic flow. Due to construction sites the capacity of adjoining roadways is reduced. This leads to traffic jams and therefore large time losses, especially on highly frequented routes, for the general public. In addition, the emission of pollutants from cars increases significantly in a stop-and-go mode of driving. All mentioned effects can be monetized which means that impacts are transferred into monetary units. For example, time lost due to traffic disruption can be monetized by a macroeconomic hourly rate. As a result, the calculated macroeconomic costs can be compared with the direct construction-related costs. It is noticeable that these macroeconomic costs can exceed the direct building-related costs by a far extend (Zinke 2016). The calculation is part of whole-life costing (WLC) according to ISO 15686-5 (2017) and DIN EN 17472 (2022). The calculation rules for different impact categories are based on state-of-the-art descriptions in different national and international studies, for example Axhausen et al. (2014).

2.4 *BIM-based life cycle analysis*

Most existing calculation approaches within a BIM-based sustainability assessment use a material-based methodology (Alvarez Antón & Diaz 2014) and they mainly refer to the method of life cycle assessment. The calculation process is normally designed as follows: The BIM-model is transferred from the authoring software to an environmental assessment software via an IFC-interface or a plug-in. In the environmental assessment software, an environmental product declaration (EPD)-dataset is assigned to each geometric BIM-object based on the assigned materials in the BIM-model. The selection should always be checked manually. The multiplication of the EPD-datasets with the material quantity of the geometric objects delivers the result in the single environmental impact categories.

An assessment applying a material-based approach leads to sufficiently accurate results in later planning phases for calculating the ecological impacts of the main materials used to erect a bridge. However, if the entire life cycle is to be considered, the problem arises that building materials used

in different elements possess different service lives and undergo different measures during the life cycle. The concrete which is part of a bridge edge beam, for example, is renewed on average every 33 years, while the concrete of the abutment survives the 100-year service life of a bridge. Accordingly, an assignment of specific life cycle measures to single materials is not appropriate.

Sustainability analyses in early phases can create great benefits as in these phases the greatest leverage for influencing the later impacts exists. However, BIM-models, especially in early planning phases, do not have the necessary level of detail for an analysis on a material basis. For example, connection details are usually not modelled within the design planning. Corrosion protection systems are often not represented as geometric objects at all and are therefore they are not considered in the material-based methodology.

Furthermore, depending on the selected system boundaries and calculation methods used, the material-based methodology can result in significant inaccuracies. This can be explained at the example of corrosion protection systems. While for LCA focusing on building products (equivalent with the modules A1-A3 defined in DIN EN 15643) the neglect of the materials used in the corrosion protection systems is partly understandable due to the relatively small quantities of coating. Significant effects arise in the energy-intensive application of coatings (A5), as well as the repair measures (B2) and renewal processes (B4, B5) during the life cycle. For the methods life cycle costing and macroeconomic costing, these components cannot be neglected due to the costly scaffolding and significant traffic disruptions.

3 ELEMENT APPROACH

The element approach comprises that instead of focusing on materials, elements are used for the different life cycle-oriented assessment methods. These elements consist of all the items needed to fully compose an element. As an exemplary element the organic corrosion protection for steel beams is described. For this element, different items consisting of materials (e.g. coating materials) and processes (blasting the surface, coating the surface, etc.) are used. For all items, the resulting costs, environmental impacts and traffic impacts are pre-balanced.

3.1 Considering different levels of detail

In early planning phases and sometimes also in later planning phases shear studs or coatings are normally not represented in BIM-Models as specific geometric objects. To enable an analysis in early planning phases, pre-balanced items are added to base elements which are combined to major and macro elements (see Figure 1). The quantities of the pre-balanced base elements are allocated in the major and macro elements with statistical shares.

Figure 1. Composition of base, major and macro elements using statistical shares (Müller 2023).

The workflow foresees that macro elements and major elements (depending on the detailing of the BIM-model) are used in early planning phases. Accordingly, results can already be created in early planning phases in which all non-modelled components are represented by statistical shares in the composed elements. In the course of planning, the major and macro elements are

replaced by base elements and thus the statistical shares are replaced by project-specific quantities which increases the accuracy of the calculation (see Figure 2).

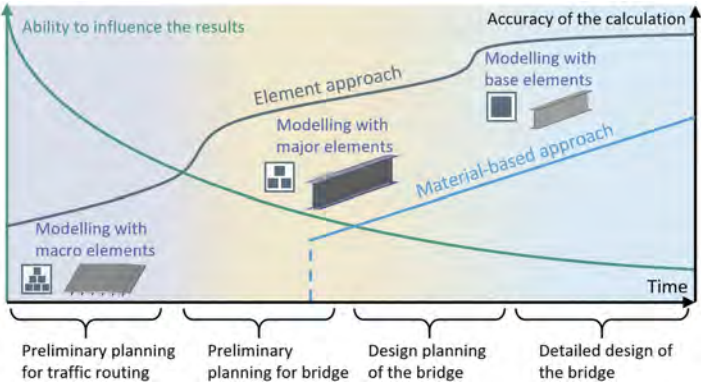

Figure 2. Life cycle dependent usage of different types of elements mapped with the corresponding accuracy of the calculations.

3.2 Life cycle maintenance measures

Base elements represent all bridge construction parts containing all potential impacts occurring in the production and erection phase. In order to represent all measures during the use and dismantling phase, follow-up elements are defined. Follow-up elements, like base elements, are composed of pre-balanced items, but only occur after a maintenance strategy-dependent time interval during the life cycle. In order to represent different measures, a distinction is made between measure specific types of follow-up elements. Maintenance and repair elements are elements, that occur during the service life of a base element. Selective dismantling and renewal elements occur after the underlying base element has reached the end of its service life. Once the service life on a structural level has been reached, a dismantling element occurs which represents the demolition of the complete structure. Figure 3 illustrates the interactions of base and follow-up elements.

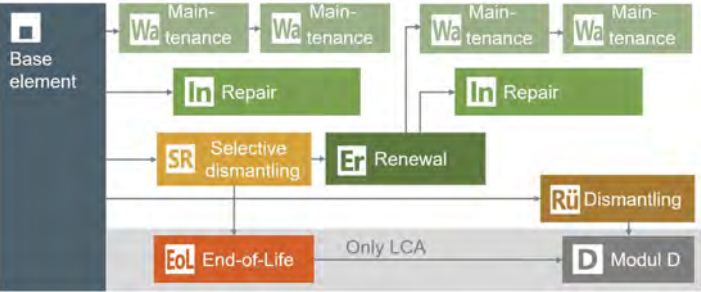

Figure 3. Interaction between base elements and follow-up elements (Müller et al. 2023).

4 LINKED BIM-MODEL APPROACH

All pre-balanced items as well as the base, major, macro and follow-up elements are stored in an element-database. To additionally use BIM-models as input data for calculations, the pre-balanced elements must be linked to the geometric objects of the BIM-model. An automated assignment based on the materials is not possible, because firstly, the elements are sometimes composed of several materials and secondly, elements made of the same material can have

completely different properties (costs, degree of traffic impact, service life). An example is described above for edge beams and abutment concrete.

For an automated linkage of BIM-objects with base-elements, the IFC-classes could be used. Thus, based on the entity IFCBEAM with IFCBeamtype: Edgebeam, it can be determined that a linkage to an element “edgebeam” has to be established. However, it cannot be completely automatically determined whether for the calculation a base element (only the edgebeam) or a major element (edgebeam with sealing and curbstone) should be used.

In order to enable a mapping between the BIM-objects and the element-database, each pre-balanced element of the element-database is given a unique label. This unique label must be attributed to every BIM-object that is modelled in the authoring software. How the attribute is integrated into the BIM-model is workflow dependent. The labels of all available elements can be exported from the database as a classification file and loaded into a BIM authoring software. Here, the elements can be linked to the BIM-objects depending on the level of detail. The next step is the transfer of the attributed object with its quantities into a software for impact calculation which is labeled here as evaluation software. In the evaluation software the quantities of the BIM-models are combined with the specific impacts of the different elements to calculate the economic, ecological and macroeconomic impacts of a bridge (see Figure 4).

Figure 4. Workflow to use a BIM-model for a holistic evaluation.

5 CASE STUDY

The presented framework is exemplarily implemented using a steel composite bridge. To reduce the complexity for this paper only one steel girder is covered in this case study. The evaluation takes place during the comparison of different bridge variants and uses a BIM-model with the appropriate level of detail (no explicitly modeled connection details).

5.1 BIM-model classification

To use the BIM-model as input for a sustainability calculation, each geometric object must be linked to a pre-balanced element of the database. This can be done, for example, via the classification manager in the authoring software Revit (see Figure 5).

Figure 5. Assigning a label to each BIM-object for the holistic evaluation in the authoring software Revit.

Depending on the level of detail of the model, a major or fine element must be selected for the assignment. Since in this case the corrosion protection system and the shear studs are not modelled, a major element “*Longitudinal girder S460 HL 1000A, with organic coating C4 and shear studs*” is used.

5.2 Calculation of impacts

To use the classified BIM-model for a sustainability assessment, an evaluation software as explained and prototypical implemented in (Müller et al. 2023) has to be used. When the IFC-File with the linked BIM-objects is transferred to the evaluation software, the corresponding sub-elements and follow-up elements with their corresponding items are loaded from the element-database into the evaluation software automatically. In this case a beam with the length of 36 meter was assigned with the label for a major element. In the evaluation software this steel beam is split up into 119 m² organic coating, 504 shear studs and 14 tons of steel profile (see Figure 6).

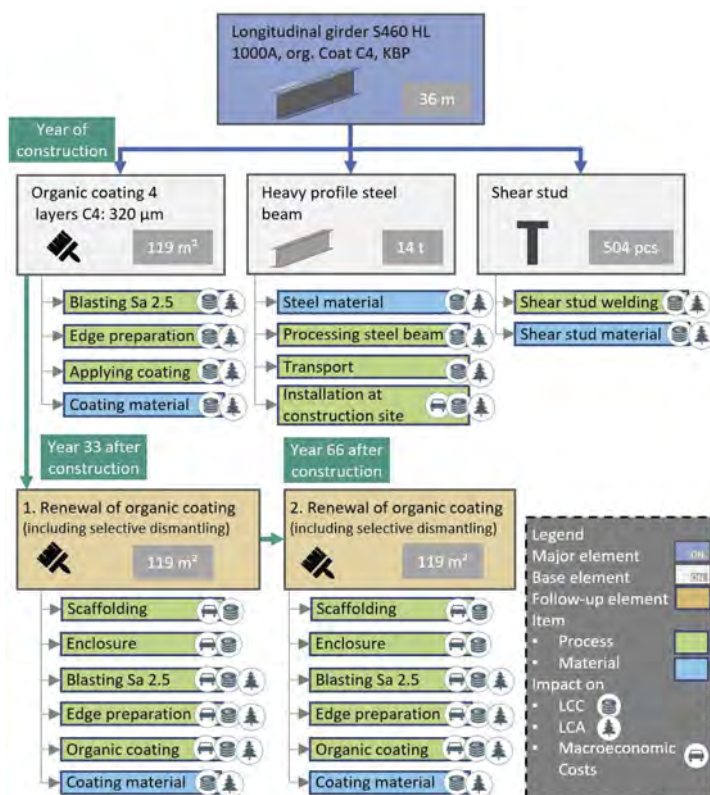

Figure 6. Elements and items used to calculate the impact of one steel beam.

For the steel profile and shear studs no measures occur during the complete life cycle of the bridge. The organic coating only has a service life of 33 years. Therefore, in the year 33 and 66 the selective dismantling and renewal elements of organic coating for 119 m² are used for the calculations. Each element consists of process and material items which can have an impact on LCC, LCA or macroeconomic costs. For example, the “Blasting SA 2.5” and “Applying coating” of the base element organic coating have an influence on LCA and LCC but not on macroeconomic costs since the coating is applied inside the production plant and therefore no traffic disruption occurs during the production. For the renewal of the organic coating the traffic must be disrupted and therefore these items lead to macroeconomic costs.

5.3 Comparison of results

Macroeconomic costs cannot be calculated when applying a material-based approach. For life cycle costs, the material-based approach is also generally not applied due to the poor interrelation between costs and pure material quantities. Nevertheless, this approach is often used for a BIM-based life cycle assessment. The deviations that arise with this approach compared to the introduced element approach are shown in the following.

When applying the material-based approach, the weight of the steel beam is multiplied with the values of a corresponding EPD-dataset. For the subsequent calculation the average data set for open rolled sections in Germany is utilized (bauforumstahl 2018). Therefore, the steel beam of 14 tons create a Global Warming Potential of 15.795 tons CO₂-eqv. (see first row of Table 1).

For the element approach, the same emissions result for the material of the steel beam. In addition, minor emissions for the welded head plate and end anchorage result in 0.175 t CO₂-eqv. The emissions for the 504 head bolt anchors lead to 0.280 t CO₂-eqv.

For the production of the organic corrosion protection system, emissions for the steel girder amount to 1.906 t CO₂-eqv. This results in additional emissions of 15% in the manufacturing phase. The major difference arises within the use phase. Bridge steel girders and head bolt anchors usually reach the 100-year service life. The corrosion protection must be replaced twice during this period. This results in high costs due to the required scaffolding and enclosure during the execution of the measures, as well as in high ecological impacts due to the energy-intensive blasting and application of the renewed coating. The ecological impacts for the renewal of the organic coating are higher than the ones of the initial organic coating applied in the production plant, due to the lower efficiency and higher overspray content of the processes on the construction site. In this case study, the emission calculated with a material approach underestimates the emissions by 30 % due to the neglected coatings and measures within the use phase.

Table 1. Comparison of LCA impacts calculated with a material and element approach.

Element	Quantity per functional unit	Year of Con. [t CO ₂ -eqv.]	Year 33 [t CO ₂ -eqv.]	Year 66 [t CO ₂ -eqv.]	Total [t CO ₂ -eqv.]
Steel beam (material approach)	14 t	15.795	-	-	15.795
Steel beam with shear studs and org. Coating (element approach)	36 m	18.161	2.169	2.169	22.498
- Steel beam with processing	14 t	15.970	-	-	-
- Shear Studs	504 pcs	0.283	-	-	-
- Organic coating production	119 m ²	1.906	-	-	-
- Renewal of organic coating	119 m ²	-	2.169	2.169	-

6 CONCLUSIONS

The introduced element approach allows to support a BIM-based sustainability assessment in different planning phases. Especially in early planning phases, in which an assessment can lead to major changes of the design, the element approach facilitates to create meaningful results. This is in particular the case when the underlying BIM-model do not have a level of detail with which a precise quantity takeoff can be performed. With an element approach, only the actual modeled content can be taken into account for an assessment and therefore the calculated potential impacts will be regularly underestimated.

6.1 Limitations

To apply the element approach to a specific structure, the corresponding elements and their items must be pre-balanced for all components of which the bridge consists of. This requires

large preparatory works. In addition, the required items for an element depend on many boundary conditions. For example, a huge difference regarding the results of the macroeconomic costs calculation arises depending on the chosen construction process. If the corrosion protection system on a valley bridge is renewed using a hanging scaffold, the traffic below the bridge is not disturbed. If for a motorway overpass a standard scaffold is applied, a partial closure of the lower roadway is necessary. Accordingly, two different elements must be pre-balanced for the same organic corrosion protection under different boundary conditions and stored in the element database. Users must consider for which boundary conditions the elements were pre-balanced when assigning a label to an element in the BIM-model.

6.2 Further steps

For a large-scale implementation, many elements must be pre-balanced representing different bridge types, different spans and different construction processes. All pre-balanced results must be kept up to date. Especially for costs a yearly update should be provided. This can be realized by using accounted and already realized bridge projects as input for the database. Ecologic background data as well as input for macroeconomic cost calculation can be update within a longer period (2 to 3 years). The continuous support should be ensured by implementing a foster home.

ABSTRACT: Pre-stressed concrete with post-tensioned (PT) cables historically represented an attractive alternative to ordinary reinforced concrete (RC). A wide portion of the world-wide existing concrete bridges was PT. As the nominal service life of those structures expires, several collapses occurred, highlighting the problem of the inspection. The main issue is that PT cables may be affected by relevant corrosion phenomena related to the presence of air or water inside the ducts: such ‘hidden’ defects need to be determined through reliable testing methodologies. This paper presents the in-progress research aiming to quantify the influence of the damage of the single cable on the entire structure. The case study is an Italian viaduct composed of simply supported beams connected by an upper slab. An extensive investigation campaign was carried out to locate and quantify the damage. Starting from the data collected on-site a series of damage conditions of cables can be simulated.

1 INTRODUCTION

Prestressed concrete bridges with post-tensioned (PT) cables represent a relevant percentage of the infrastructural heritage worldwide. The rise of this constructive technology coincided, especially in Italy, with the economic boom in the 60ties-70ties: most of the bridges and viaducts along the main infrastructure system own a PT system, since several advantages – among them the achievement of long spans, the use of less material and the partial prefabrication - were provided in comparison to Reinforced Concrete (RC) ones. Nevertheless, several issues became to appear with the decades: the constituting materials gradually degraded and recent events (see for instance the collapse of the Morandi bridge in Genoa in 2018), highlighted how urgent the assessment of PT structures is today.

The inspection of the PT structure is a very complex issue because of the impossibility to use the same test methods as for the RC structures and the inherent conformation of the PT cables, located within the concrete section and ducts. Indeed, the defectiveness of these structures can be visible or completely hidden. Visible defects can be worrying if localized on the cable itself, for instance when the wires or strands are exposed to the air due to loss of the concrete cover and corrosion of the duct, or they may appear less severe if they affect only the concrete or ordinary reinforcements. However, the less severe defectiveness may be symptomatic of a dangerous hidden situation, for instance dark spots following the trace of a cable may occur because of the actual presence of water within the ducts. Anyway, the worst scenario happens when defects are not visually detectable but there is

hidden defectiveness. One of the most dangerous situations for PT structures is the loss of bearing capacity due to the corrosion of the cables, which could lead both to the embrittlement of the steel and/or to the reduction of the cross-section and loss of bonding properties of the wires or the strands. This situation occurs frequently if the cable is not protected, therefore when the grouting is not efficient and air, or, in the worst cases, water can be within the voids between duct and cable due to an inaccurate grouting of the ducts after tensioning. Because of that, a large part of the testing proposed and employed in the assessment of PT structures aims to locate voids and the presence of air or water inside the ducts. Other important information about the conservation condition of a PT beam can be derived from the estimation of the remaining tension acting through the cables and/or through the concrete cross-sections. By investigating the actual acting tension in steel, it is possible to assess the efficacy of the post-tensioning in the single cable; by investigating the tensional state of a cross-section of the concrete, it could be possible to have an idea about the efficacy of the post-tensioning on all the cables. To achieve this information, several non-destructive (ND) and semi-destructive (SD) test methodologies were proposed. The present work aims to estimate the state of conservation of a PT bridge located in the North of Italy by the execution of SDTs and NDTs and their critical elaboration. Starting from the data collected on-site and verifying their mutual compatibility, as well as their compatibility with the design data, a series of damage conditions of cables will be simulated, and the corresponding width of the cracks computed.

2 A REVIEW OF TEST METHODOLOGIES

The assessment of PT bridges is a complex issue due to the inherent nature of the PT system. Whereas for reinforced concrete (RC) structures a visual inspection can give a general idea of the state of conservation, for PT bridges this is not sufficient. Furthermore, it is not possible to apply the same test methodologies as for RC, because the objectives of the investigation are different. The *Classification, risk management, safety evaluation, and monitoring guidelines of the existing bridges* (MIT CSLP, 2020) represent a useful tool for planning and designing the experimental test to be performed on PT structures. The Italian Guidelines require the execution of the so-called *Special Inspections* for PT bridges, providing necessary information about the layout of the cables, the location of the defects and their quantification. The tensional state of the concrete cross-section and the tension acting in the cables shall be investigated as well, thus providing relevant information about the efficiency of the PT system and/or to warn on the likely presence of damage. However, the Italian Guidelines give little information about the test's methodologies to follow and the instrumentation to use. Over the years, many non-destructive techniques have been proposed to investigate the PT system, proving more or less effective depending on the specific objective. For the location of ducts and defects, the most common available techniques are the Ground Penetrating Radar (GPR), the Ultrasonic Tomography (UT) and the Impact Echo (IE) (Giannopoulos et al., 2002; Sławski et al., 2016; Terzioglu et al., 2018; Wai-Lok Lai et al., 2018). The evaluation of the tensional state of the section can be performed by the investigation of the tension through the steel cables and/or by the determination of the tensional state of the concrete cross-section. Regarding the first issue, a promising NDT is the X-Ray diffraction method, historically employed to determine the residual stresses deriving from metal manufacturing processes in the field of the quality control and even applied to PT wires/strands (Brauss et al., 1998; Carfagno et al., 1995; Morelli et al., 2021; Zanini et al., 2022). The other possibility is to determine the tensional state acting through the concrete section, by using, for instance, the drilled-hole or the saw-cut method (Bagge et al. 2017, Kral'ovanec, Bahleda, et al., 2021; Kral'ovanec, Moravčík, et al., 2021). A quick revision of the test's methodologies relating to the specific objective is given, focusing in particular on the techniques employed in the present research work.

2.1 Identification of cables' layout

Cables' tracing is fundamental for checking the correspondence of the actual layout with the design documentation (if available) determining the eventual presence of substantial differences

which may need to be further investigated. Besides, since the in-depth investigation shall be focused on the cable itself, it is necessary to know its location. The GPR is a technique frequently used to identify the thickness of road pavement, tunnels, the presence and the trace of utilities, the reinforcements' location in the concrete structures and the trace of PT cables (Terzioglu et al., 2018). GPR technique is very sensitive to presence of metallic bodies, since it elaborates the echoed signals derived from the emission of high frequency electromagnetic pulses.

2.2 Identification of voids

Having reconstructed the cables' trace, it is possible to proceed with the identification of voids inside the ducts. A combination of ND and SD testing methodologies can be reliably used: the basic idea is to investigate the large part of the cables through NDT (e.g. ultrasonic tomography – UT), focusing the SDT (e.g. endoscopic investigations) mainly on the areas notified as defective by the previous testing. UT is frequently used to estimate the thickness of elements or layer and for the individuation of reinforcement in concrete, of voids (cracks, honeycomb, delamination) or water defects, ducts, tendons' location (Martin et al., n.d.; Muldoon et al., 2007; Shickert, 2002; Terzioglu et al., 2018). The endoscopic investigations shall be performed along the trace of the cable, both in the areas warned by UTs and in random areas. The results given by the two test methodologies can be combined, providing an overall idea of the accuracy of the UTs and reliable information about the presence of defects along the cables.

2.3 Assessment of remaining prestressing force

The definition of the actual prestressing tension in steel cables is a relevant information to evaluate a structure under both service and fatigue limit states. To obtain this information, it is possible to directly investigate the tension acting in the individual wire, and/or to check the tensional state of the concrete cross-section and to obtain the actual tension in the cables, since the actual permanent loads are known, and it is possible to estimate the losses.

The X-ray diffraction technique is classically employed as NDT to determine residual stresses in metals; it can investigate a very shallow region (10 μm) and can be applied to assess stresses in the wire. From a practical point of view, it estimates the inter-plane distance between planes of the crystal lattice and, assuming linear elastic distortion and knowing the inter-plane distance at zero stress, the acting stress can be derived. The saw-cut method, on the other hand, is based on a very simple principle: by isolating a concrete area and by recording its deformation, assuming a linear relation between stresses and strain, and knowing the Elastic Modulus, it is possible to obtain the acting stress. The tests can be carried out on-site, but normally it is not possible to employ strain gauges with a measuring base major of 30 cm, since the cuts would have become too deep. These tests are usually carried out in the mid-span section of the simply-supported beam since the tensional state there is the simplest (i.e. no shear under uniformly distributed load).

3 THE CASE OF STUDY

The viaduct is along the highway Turin-Savona in Savona Province. It is a one-way viaduct with 14 spans for a total length of around 600 m. Single spans have variable lengths of 45, 34, and 40 m; the large part (11 on 14) presents 45 m spans. Each deck is composed of 4 PT simply supported beams and 4 reinforced concrete (RC) cross members equidistant from each other, 14.16 m apart; the two extremes' members are at the heads of the beams. The 13 piers have a RC frame structure of variable height. The beam cross-section has a variable shape, tapering from the head to the mid-span cross-section and with a constant height equal to 2,40 m (Figure 1).

From the original documentation, the cables' layout for each type of beam and information about the mechanical properties of the materials used are known; however, there was no data on the initial prestressing force. The inspections focused on the 45 m beams, being the most common ones. The results of the in-situ experimental tests are presented below, distinguishing them according to their purpose.

Figure 1. Cross section of the viaduct.

3.1 Identification of cables' layout

The tests for determining cables' trace were carried out on 7 beams belonging to 3 different spans; each beam was examined in all areas where it was possible to perform the test, excluding consequently the head areas of the beam, due to the massive presence of ordinary steel and the large concrete cover, and the areas where the cables lie within the bulb. The GPR technique was adopted, and comparison between the design trace and as derived from the in-situ tests was performed (Figure 2). The results obtained on all beams were similar.

Figure 2. On site trace of two beams and comparison with the design.

Figure 3 summarizes the errors achieved for all measuring locations and tested beams: the average error was of 3.28 cm, but this error is probably due to how the measurements were carried out on-site and the errors in the cable deployment during construction rather than a systematic error of the instrument. The shape of the histogram is quite like a Gaussian distribution with average of 3.28 cm and a standard deviation of 3.37 cm. The associated coefficient of variation is about 1, therefore the variability of the results is huge. However, considering the present application, the probable error of ± 3.4 cm is negligible, considering that the height of a PT beam is usually within 1.75÷2.50 m. The results of the tests state the efficacy of the GPR measurements, even if a larger sample would be desirable.

Figure 3. Distribution of the GPR error.

3.2 Tests for identification of voids

Tests for the identification of voids are performed, as said, by combining NDT with endoscopic tests (SDT). The choice was to have a comparison between the results of NDT, which are inherently more uncertain, and those of SDT. Some direct essays are performed in all areas that cannot be detected either through UTs or endoscopies. The tests were performed on the same 7 beams inspected by GPR, since the trace of the cable is known; for each beam 2 cables were investigated in the areas considered as riskiest i.e. (Trejo et al., 2009): the beam head, the change of curvature, and the mid-span intrados zone (Figure 4).

Figure 4. Location of the tests. In blue are the tested cables; the red line indicates the riskiest zones.

The UT tests were performed in all detectable areas of the cables: it was not possible to test the intrados region, due to the strong presence of ordinary steel, and the beam head, due to the thicker concrete cover resulting from the tapering. The tests were executed by choosing a pitch of 10 cm and positioning the instrument in the transverse direction of the cable.

The calibration was performed by imposing the shear wave velocity, which is estimated by the relation $c_s t = \sqrt{(E/\rho \cdot 1/(2 \cdot (1 - \nu)))} = \sqrt{(G/\rho)}$ (Krautkrämer & Krautkrämer, 1990) and assuming a certain density (ρ) and shear modulus (G). The goodness of these assumptions was then verified by performing some scans in areas where no cables were present, calculating the estimated thickness of the beam, knowing the time t required for the wave to return, and comparing it with the actual thickness of the beam. Other important input parameters (analog and digital gain) were chosen by performing scans in areas with two or more cables where voids were less likely to be present, so that the displayed scan was not completely saturated. Both linear (Figure 5a) and matrix (Figure 5b) scans were performed: linear scan means that the 16 dry-point contact sensor of the instruments works in groups composed of 4 sensors; matrix scans means that each sensor works by itself (ACS Group, 2021). The presence of voids is considered probable when the visualized output is strongly saturated, for instance as happen for the scans (a) and (b) in Figure 5. The duct is considered fully grouted when is visualized as in Figure 5c.

Figure 5. Outputs of some UTs. a) is a linear UT which shows a probable void defect and b) show the same area but the test was performed through the matrix mode. The UT in c) shows a cable probably fully grouted.

The endoscopies were performed by drilling holes with a diameter of 20 mm both in areas warned as “defective” by the UTs and in random areas of the cables. Some outputs of the endoscopies are reported in Figure 6: 6.a show a fully grouted duct, while 6.b shows the presence of a void within the duct and the concrete matrix, and 6.c a not grouted duct. On a total of 56 endoscopies, 26 were executed in random areas of the cables and 30 in the areas warned by UTs. 63% of the tests in the warned areas reported the presence of voids; however, some of these voids are not located inside the duct but outside of it. The tests in random areas reported voids in 23% of the cases. No oxidized or corroded wires were found. These results prove that it is desirable to employ more than one NDT/SDT to investigate a structure.

Figure 6. The endoscopy in a. shows a fully grouted duct, the one in b. a void between the duct and the concrete matrix, the one in c. an ungrouted duct.

3.3 Tests for the definition of actual prestressing tension

The tests were carried out on 3 of the 7 beams inspected with the previous methodologies.

The X-Ray Diffraction (XRD) tests were performed in the intrados area of the beams at mid-span region, being here easier to locate the instrument; on each beam at least 4 measurements on the same cable were executed. The average value of acting tension ranges from 569 to 686 MPa depending on the tendon (Table 1). It can be noticed that both on the same cable and on the same wire consistent deviations of maximum 110 MPa (beam 3 of span 3) were observed, probably due to the variability in residual stresses induced by the operation of stressing (Carfagno et al., 1995). By assuming an initial stress in the cables equal to the 65% of the ultimate tensile stress of the steel (i.e. 1570 MPa) and by estimating the friction and the long-term losses (resulting equal to the 22% of the initial tension), it was obtained an acting tension of 776 MPa. Therefore, the XRD measurements seem to indicate major losses, around the 27%, or the presence of compressive residual stresses deriving from the manufacturing processes (Carfagno et al., 1995). The results obtained are aligned to other recent applications of the XRD (Zanini et al., 2022).

Table 1. XRD measurements.

Span	Beam	Wire	Measure 1	Measure 2	Measure 3	Mean	CoV
			[MPa]	[MPa]	[MPa]	[MPa]	
3	1	A	631	/	/	648	7%
		B	685	/	/		
		C	688	588	/		
3	3	A	708	742	726	686	6%
		B	704	678	/		
		C	634	665	630		
6	3	A	550	525	/	569	6%
		B	611	559	601		

In addition, the saw-cut method was used for the estimation of the tension acting through the concrete. The test was carried out in the mid-span cross-section of the 3 selected beams. These sections were chosen due to the supposed simpler tensional state in the simply supported static scheme (no shear influence). Three measuring points in the single beam (Figure 7b) were selected. The test was carried out by posing strain gauges of 30 mm base of measure in the longitudinal direction and by performing two cuts in the transversal direction. The choice of these measuring bases comes from the necessity to not deepen the cuts more than 30-40 mm. Figure 7c shows the comparison between the measurements and the ideal behavior. It was necessary to discard all the data of the E2 point, as un-reliable values were obtained. In general, the on-site results are very far from the theoretical ones assuming an elastic and linear behavior of

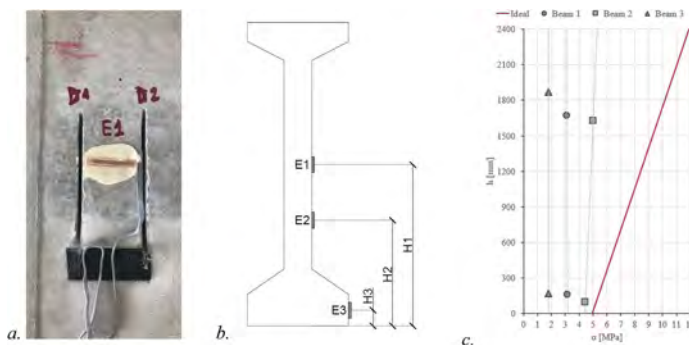

Figure 7. Execution of the saw-cut test: *a.* configuration of the cuts, *b.* location of measurements and *c.* comparison between theoretical acting tension (red) and experimental ones.

the material. It can be noticed that E3 measuring points are more reliable than the others, but still not enough to be employed in the assessment of the stress state.

4 SIMULATION OF DAMAGE SCENARIOS AND CORRESPONDING PERFORMANCE

By performing inspections according to the methodologies described above, information concerning the cables' layout, the possible presence of voids related to the activation of corrosion phenomena and an estimation of the tensional state of the beam can be derived. Since voids in the ducts could lead to a favourable environment for deterioration, it is worth to investigate the possible presence of these phenomena by the estimation of the width of the cracks. During the present campaign, no corrosion of the cables was ever found; since not a reasonably large number of endoscopies were performed and since the UTs investigated only the presence of voids, it would be reasonable to search for the condition in which cracking started to occur. For this reason, a series of damage scenarios will be considered, and the relative width of the cracks accordingly computed. The dimensions of the beam, the ordinary reinforcement, the mechanical properties of materials and the PT cables were known by the design documentation; only permanent loads were considered. Since the dimensions of the beam were verified on-site, the self-weight was considered in its actual value, while the weight of the road surfacing was considered in its characteristic upper value. Damage scenarios account for the loss of a certain amount of cross-sectional area of one or more cables are selected; in this case, corrosion was assumed to affect the lower cables, as this condition is more feasible since these cables present lower cover. Table 2 shows the considered damage scenarios, the value of the associated decompression (M_{dec}) and cracking moment (M_{crack}), the ratio between this last and the design value of acting moment (M_{sd}/M_{crack}), and the width of the cracks (w_k). The acting moment is equal to 10'608 kNm. It can be noticed that the loss of cross section in cable 1 or 2 (see Figure 8) leads to a serious situation in comparison to the loss of cross section in cable 3 or 4, as biaxial bending occurs. These results show that the presence of serious corrosion in the cables (or alternatively the loss of prestressing) can be easily visualized by cracks of considerable width. In some cases (scenario a., d., e., g. in Table 2) the cracking moment is higher than the acting moment. However, it is important to notice that for each of the considered damage scenarios, the safety at the ULS is still verified (M_{sd}/M_{rd} in Table 2). The calculations were performed adopting a rectangle parabola constitutive law for the concrete and an elastic-perfectly plastic behavior for both reinforcing and prestressing steels.

Table 2. Damage scenarios.

Damage scenario	M_{dec}	M_{crack}	M_{sd}	w_k	M_{sd}
	[kNm]	[kNm]	M_{crack}	[mm]	M_{rd}
a. Loss of 30% section in cable 1 or 2	9'185	10'900	0.97	-	0.69
b. Loss of 50% section in cable 1 or 2	8'440	10'140	1.05	0.44	0.70
c. Loss of 100% section in cable 1 or 2	6'595	8'250	1.29	0.47	0.71
d. Loss of 30% section in cable 3 or 4	9'658	11'380	0.93	-	0.69
e. Loss of 50% section in cable 3 or 4	9'225	10'950	0.97	-	0.70
f. Loss of 100% section in cable 3 or 4	8'146	9'830	1.08	0.48	0.71
g. Loss of 30% section in cable 1 and 2	9'258	10'975	0.97	-	0.70
h. Loss of 50% section in cable 1 and 2	8'558	10'260	1.03	0.48	0.71
i. Loss of 30% section in cable 1, 2, 3, 4	8'207	9'900	1.07	0.50	0.72
l. Loss of 50% section in cable 1, 2, 3, 4	6'806	8'465	1.25	0.53	0.76

Figure 8. Bulb's cross section.

5 CONCLUSION

The current research can be considered the starting point of a more articulated project aiming to define a reliable methodology for the inspection of PT bridges and to translate the results of these inspections in numerical terms for the evaluation of the residual capacity and remaining service life. Several NDTs were selected and adopted on a case-study bridge located in Italy. As

visible, several tests are promising: for instance, the GPR is very effective in the location of the cables and the XRD method is able to give a very reliable value of the acting tension through the PT cables. The UTs work quite well but results are affected by a big issue: it is impossible to know if the inspected void is inside or outside the duct; moreover, by an on-site test campaign it is not possible to know where voids effectively are and, therefore, there are no sufficient data to estimate the sensitivity of the UT tests. At the moment, results provided by the saw-cut method needs to be improved, but in any case, it is desirable to extend the samples for each test's methodology and carry out tests in controlled conditions, such as the laboratory, to quantify their effectiveness and accuracy. On the other hand, it is necessary to assess how the results of the tests may affect the overall structural performance. In the present work, the proposal has been to transpose the presence of corrosion/oxidation in the loss of the cables' cross-section and the equivalent prestressing loss and ultimate capacity. Only the width of the cracks is preliminarily computed in correspondence with a hypothesized damage condition. These preliminary results show how serious damage is often associated with a considerable width of the cracks that can be easily assessed by visual inspection. By having an idea about the expected loss of cross-section on the tendons, it would be possible to estimate the corresponding loss of performance of the single beam and, therefore, the related effect on the span and the whole structure.

Non-destructive and partially destructive test locations in RC structures: A combined spatial optimisation and Bayesian updating approach

S. Karmakar & S. Ghosh

Structural Safety, Risk & Reliability (SSRR) Lab, Department of Civil Engineering, Indian Institute of Technology Bombay, Mumbai, India

D. Saha

Bhabha Atomic Research Centre, Mumbai, India

Infrastructure Risk Management (IRM), Mumbai, India

ABSTRACT: Non-destructive (NDT) and partially destructive (PDT) tests are conducted for assessing present health of reinforced concrete structures. An improved understanding from this is possible by the judicious fusion of NDT and PDT results. Though international standards provide guidelines for NDT/PDT, a scientific approach for the selection of NDT/PDT locations is missing from literature. The selection of location is particularly critical for PDT, because of their limited number, additional distress to the structure and higher costs. Quantitative decision criteria for maximising the information collected through NDT/PDT, while incorporating constraints of cost, accessibility, functional restrictions and criticality of locations can be very useful. The proposed approach attempts to capture the actual spatial variability of concrete strength through judicious choice of NDT locations, executed under multiple constraints. This is subsequently augmented with Bayesian updating for the selection of PDT locations, based on the prior knowledge of deterioration and NDT results. The proposed approach is demonstrated with case studies.

1 THE CHALLENGE OF SELECTING NDT AND PDT LOCATIONS

Reinforced concrete structures – nearing the end of design life, requiring functional modifications, showing potential distresses, or demanding re-qualification as per latest codes – need to be scientifically evaluated to decide upon their repair, rehabilitation, retrofitting or demolition. The present-day characteristic compressive strength of concrete in the structure is one of the crucial elements in this decision-making. Where underestimation of strength can lead to unnecessary costly repairs, overestimation may compromise safety and lead to unforeseen losses.

Though some of the past research works on NDT and PDT had identified that the selection of test locations is a challenge (Faroz, Ghosh, & Faroz 2023), till today, no standardised method has been developed that a practising engineer can follow specially for NDT. Many of the practical projects (Pfister, Tundo, & Luprano 2014; Alwash, Breyse, & Sbartaï 2017) have carried out selection of NDT locations primarily based on experience and/or ease of testing. Sometimes core tests too are performed without using NDT test results (Dauji & Karmakar 2022), that might lead to gross mis-representations of concrete properties. Of the various approaches tried so far, experience-based approaches (Dauji & Karmakar 2022) may involve bias, site feasibility-based approaches (Faroz, Ghosh, & Faroz 2023) may not be truly representative, and uniform random distribution of test locations (Pfister, Tundo, & Luprano 2014) can be good only when conducted in large numbers. The major limitation of such applications is an improper representation of the in-situ spatial variability of the concrete strength and consequent underestimation of associated uncertainty (McCann & Forde 2001). Codes, standards, and

guidelines (FEMA 2000; CEN 2005; BSI 2019) generally suggest a combined application of NDT and PDT to overcome the limitations of each, and advise selecting locations for PDT based on NDT results. The same philosophy has been implemented by some researchers (Pfister, Tundo, & Luprano 2014; Alwash, Breyse, & Sbartaï 2017; Saleh, Tarawneh, Dwairi, & AlHamaydeh 2022) using various techniques, such as, proportional stratified random sampling, and guided/conditioned coring which uses NDT test results to arrive at PDT locations.

The research gaps existing today in literature would include: (i) non-inclusion of domain knowledge in identifying the possible zones of concrete homogeneity across a structure (Breyse 2012; Breyse & Luis 2014; BSI 2019); (ii) not performing a thorough statistical analysis of NDT and core sample distribution across different elements in the structure (Pfister, Tundo, & Luprano 2014); and (iii) not including cost as one of the criteria for selection of location (Sbartaï, Alwash, Breyse, Romão, & Luprano 2021; Faroz, Ghosh, & Faroz 2023). The ideal objective for optimisation of selection of NDT/PDT locations, therefore, is to capture the true variability of concrete strength and to extract maximum information on its distribution with cost consideration.

This article proposes a step-wise procedure for the selection of NDT, PDT locations for existing reinforced concrete buildings first; then it demonstrates the proposed approach with a real-life case studies. This proposed method is expected to result in a better statistical inference of the structural condition from NDT, by enhancing the spatial variability captured using domain knowledge. Further, a process of selection of PDT locations based on Bayesian updating, using the combination of NDT results and prior knowledge of similar buildings, is also presented in this work.

2 FRAMEWORK FOR THE SELECTION OF NDT LOCATIONS

2.1 Methodology for the selection of NDT locations

2.1.1 Global importance fraction (\mathcal{G}_i) to define immediate effects of failure

This particular fraction is applicable for different types of members (slab, beam, column, etc.). The objective of defining this parameter is to quantify the immediate possible effects (not cascading effects) of failure of each structural member as elaborated here:

- Effect of a slab failure: Adjacent 4 slabs (for internal slabs), adjacent 3 slabs (for peripheral slabs), adjacent 2 slabs (for corner slabs).
- Effect of a beam failure: 8 elements for internal beams (2 beams + columns of 2 floors at two ends + 2 slabs), 7 elements for peripheral beams (2 beams + columns of 2 floors at two ends + 1 slab), 6 elements for corner beams (1 beam + columns of 2 floors at two ends + 1 slab).
- Effect of a column failure: 10 elements for internal columns wall (below and above column + 4 slabs + 4 beams), 7 elements for peripheral columns (below and above column + 2 slabs + 3 beams), 5 elements for corner columns (below and above column + 1 slab + 2 beams).

A beam failure would result in a column failure when its failure converts a short column to a long column and demand exceeds capacity. Therefore, only a 50% contribution is taken in these cases. Hence, considering internal elements, failure of 1 slab will affect 4 structural elements; failure of 1 beam will affect $(2+2 \times 2 \times 0.5+2) = 6$ structural elements; and failure of 1 column will affect $(2+4+4) = 10$ structural elements. The ratio of effects of failure of different internal elements failures (slab : beam : column) thereby becomes 4 : 6 : 10, which is normalised to make the sum unity, to arrive at global importance fractions. Thus, $\mathcal{G}_i = 0.20, 0.30$ and 0.50 for (internal) slabs, beams and columns, respectively. Similarly, for others $3 : 5 : 7 = 0.20 : 0.33 : 0.47$ (peripheral), and $2 : 4 : 5 = 0.18 : 0.36 : 0.46$ (external). Here, $i = 1, \dots, m$ counts the member types (for example, $m = 3$ for structures comprising of beam, column and slab).

2.1.2 Local importance factors (\mathcal{L}_{ijk})

This factor is applicable for subcategories of a member type for a floor. Depending on the functionality and exposure conditions of each structural members, first a factor I_{ik} is obtained for each individual elements all across the building. This I_{ik} is obtained by multiplying \mathcal{I}_{ik} (Equation 1) which depends on the influence area, L_{ik} i.e., the load applied, and \mathcal{E}_{ik} which is

the exposure factor that quantifies the effect of exposure to deteriorating environment as shown in Equation 2. However, this leaves a scope of further refinement in the future with more controlling factors.

$$I_{ik} = \mathcal{I}_{ik} L_{ik} \mathcal{E}_{ik} \quad (1)$$

$$\mathcal{E}_{ik} = 1 + \frac{\text{Number of exposed surfaces to the environment, or in moisture zones}}{\text{Number of available surfaces}} \quad (2)$$

Here, $k = 1, \dots, f$ counts the number of floors. The whole range of I_{ik} is divided into n subcategories for each member types, with equal intervals of I_{ik} values. For each of the n subcategories, the average of all I_{ik} values, $\mathcal{I}_{m_{ijk}}$ is obtained. Here, $j = 1, \dots, n$ counts the member subcategories. The value of n may be 3 to 5 depending upon the size of building. Afterwards, the local importance factor is calculated by normalising these $\mathcal{I}_{m_{ijk}}$ values:

$$\mathcal{L}_{ijk} = \frac{\mathcal{I}_{m_{ijk}}}{\min_{i,j,k \in \text{all}} \{ \mathcal{I}_{m_{ijk}} \}} \quad (3)$$

2.1.3 Member-wise floor importance fraction (\mathcal{M}_{ijk})

In this step global importance fraction (\mathcal{G}_i), local importance factors (\mathcal{L}_{ijk}) are combined to obtain member-wise floor importance fraction (\mathcal{M}_{ijk}) to be used for multi constraint problem for optimisation of spatial variability. Member-wise floor importance fractions \mathcal{M}_{ijk} , is defined as the floor-wise fractions for each subcategory of members in different floors as given in Equation 4.

$$\mathcal{M}_{ijk} = \frac{\mathcal{G}_i N_{ijk} \mathcal{L}_{ijk}}{\sum_{i=1}^m \sum_{j=1}^n \sum_{k=1}^f \mathcal{G}_i N_{ijk} \mathcal{L}_{ijk}} \quad (4)$$

Where, N_{ijk} is total numbers of elements in each subcategory.

2.1.4 Multi-constraint problem and solution algorithm

The constraints for the given problem are:

1. The total number of NDTs (N) for the building is considered to be limited by budget:

$$N = \sum_{i=1}^m \sum_{j=1}^n \sum_{k=1}^f \mathcal{N}_{ijk} \quad (5)$$

2. The number of test samples for each floor is proportional to the sum of $\mathcal{G}_i \times \mathcal{L}_{ijk}$ of all elements.
3. The number of samples for each subcategory across all floors is proportional to the sum of ($\mathcal{G}_i \times \mathcal{L}_{ijk}$) of the that subcategory across all floors.

In Equation 4, member-wise floor importance fractions \mathcal{M}_{ijk} are obtained for each sub-category, member type, and floor. The challenge is to arrive at whole numbers (\mathcal{N}_{ijk}) from these fractions (\mathcal{M}_{ijk}), so that the constraints are satisfied. The systematic approach is proposed as follows:

1. Multiply all \mathcal{M}_{ijk} with the overall sample size (N) to obtain \mathcal{S}_{ijk} :

$$\mathcal{S}_{ijk} = N \times \mathcal{M}_{ijk} \quad (6)$$

2. Round off \mathcal{S}_{ijk} to the nearest integer value:

$$\mathcal{I}_{R_{ijk}} = \text{round}[\mathcal{S}_{ijk}] \quad (7)$$

where $\text{round}[\cdot]$ represents the nearest integer value.

3. The problem is to solve (fmn) unknowns with available ($f + mn$) number of equations.
4. Find the following summations:

$$C_{IR_{ij}} = \sum_{k=1}^f \mathcal{I}_{R_{ijk}} \text{ and } C_{IR_k} = \sum_{i=1}^m \sum_{j=1}^n \mathcal{I}_{R_{ijk}} \quad (8)$$

5. Round off after carrying out the summations as given below:

$$\mathcal{S}_{C_{ij}} = \text{round} \left[\sum_{k=1}^f \mathcal{S}_{ijk} \right] \text{ and } \mathcal{S}_{R_k} = \text{round} \left[\sum_{i=1}^m \sum_{j=1}^n \mathcal{S}_{ijk} \right] \quad (9)$$

6. Find the sum of all rounded off values (\mathcal{C}_{SC} and \mathcal{C}_{SR}):

$$\mathcal{C}_{SC} = \sum_{i=1}^m \sum_{j=1}^n \mathcal{S}_{C_{ij}} \text{ and } \mathcal{C}_{SR} = \sum_{k=1}^f \mathcal{S}_{R_k} \quad (10)$$

7. Ideally, \mathcal{C}_{SC} and \mathcal{C}_{SR} should be equal to the actual sample size (N). But in most practical cases it will vary due to rounding off operations. In such cases, some adjustments are necessary. If \mathcal{C}_{SC} and/or \mathcal{C}_{SR} are less than actual sample size (N), the sample needs to be added (in integers) with $\mathcal{S}_{C_{ij}}$ and \mathcal{S}_{R_k} values, based on the following priority.

- i. Groups with lower value of $\mathcal{S}_{C_{ij}}$ or \mathcal{S}_{R_k} (including zero),
- ii. If $\mathcal{S}_{C_{ij}}$ or \mathcal{S}_{R_k} values are the same for two groups, the groups with the higher fractional values $\left(\left[\sum_{k=1}^f \mathcal{S}_{ijk} \right], \left[\sum_{i=1}^m \sum_{j=1}^n \mathcal{S}_{ijk} \right] \right)$.

If \mathcal{C}_{SC} and/or \mathcal{C}_{SR} are greater than the actual sample size, additional sample needs to be removed (in integers) based on priority list given below:

- i. Groups with higher value of $\mathcal{S}_{C_{ij}}$ or \mathcal{S}_{R_k}
- ii. If $\mathcal{S}_{C_{ij}}$ or \mathcal{S}_{R_k} values are the same for two groups, the groups with the lower fractional values $\left(\left[\sum_{k=1}^f \mathcal{S}_{ijk} \right], \left[\sum_{i=1}^m \sum_{j=1}^n \mathcal{S}_{ijk} \right] \right)$.

This step will update the $\mathcal{S}_{C_{ij}}$ values to $\mathcal{M}_{SC_{ij}}$ and \mathcal{S}_{R_k} values to \mathcal{M}_{SR_k} .

8. Find the difference \mathcal{D}_{ij} of updated values of $\mathcal{M}_{SC_{ij}}$ (Step 7) and $\mathcal{C}_{IR_{ij}}$ (Step 4).

$$\mathcal{D}_{ij} = \mathcal{M}_{SC_{ij}} - \mathcal{C}_{IR_{ij}} \quad (11)$$

9. Follow an iterative process until all \mathcal{D}_{ij} becomes 0 as enumerated below:

- i. Due to the rounding off operations, some $\mathcal{I}_{R_{ijk}}$ would become zero and some will remain zero in case \mathcal{S}_{ijk} equals to zero. Hence, at first mark $\mathcal{I}_{R_{ijk}}$ which corresponds to \mathcal{S}_{ijk} equal to zero, called forbidden locations. These elements will not participate in subsequent steps.
- ii. Exchange $\mathcal{I}_{R_{ijk}}$ in between (ij)s corresponding to maximum positive and minimum negative values of \mathcal{D}_{ij} . These operations will be done $\min[\max(\mathcal{D}_{ij}), |\min(\mathcal{D}_{ij})|]$ times. The selection of (k)s for exchange of $\mathcal{I}_{R_{ijk}}$ will be determined by random number generation to avoid any bias in the choice.
- iii. Iterate this process until all the differences carry same sign or zero. In the iterations, if multiple $\max(\mathcal{D}_{ij})$ or $|\min(\mathcal{D}_{ij})|$ is encountered, one of these shall be selected through random number generation. After this step $\mathcal{C}_{IR_{ij}}$ and \mathcal{C}_{IR_k} will also get updated. Find the difference \mathcal{D}_k of updated values.

$$\mathcal{D}_k = \mathcal{M}_{SR_k} - \mathcal{C}_{IR_k} \quad (12)$$

- iv. After arriving to the same final sign of all \mathcal{D}_{ij} or exceptional cases as mentioned in the previous point, addition or deletion shall be done only in those cells where $\mathcal{D}_k \neq 0$ and $|\mathcal{D}_k|$ reduces with alteration. At the end of this step, all \mathcal{D}_{ij} and \mathcal{D}_k will become zero. This will update few/all $\mathcal{I}_{R_{ijk}}$ to the final desired \mathcal{N}_{ijk} .

It is worth mentioning that above mentioned method can give multiple solutions due to the process of random number generation. However, solutions will be devoid of bias in overall due to application of domain knowledge, step wise solution with random selection in conflicting cases.

2.2 Execute survey for site feasibility

A field survey should be conducted to identify feasible locations for NDT, for each sub-category of elements. It is suggested that the number of such locations should be at least five times the required numbers for each sub-category, to avoid bias in the optimisation process.

2.3 Mathematical optimisation for spatial variability with member wise floor importance and site constraints

Samples from nearby locations tend to be more alike than ones farther apart (Warrick & Myers 1987). Using this concept, it is assumed here that the optimal selection of locations – for capturing maximum information on spatial variability and distribution of concrete strength – should contain the farthest among feasible NDT locations. This should also be satisfying \mathcal{N}_{ijk} in various sub-categories. An optimisation method for capturing maximum spatial variability is developed in this study based on this, by maximising minimum distance between sampling locations.

1. All distances between the locations derived from site feasibility study are calculated.
2. For each floor, the sampling location(s) yielding the minimum distance is/are iteratively eliminated provided options are still available for selection of \mathcal{N}_{ijk} in each sub-categories from truncated set of available choices for each subcategory that was initially derived from site feasibility study in Section 2.2. Otherwise, the location/s are retained in the selection.
3. The set of locations obtained in the end would be the optimal set of NDT locations for capturing maximum spatial variability under given constraints.

3 FRAMEWORK FOR THE SELECTION OF PDT LOCATIONS

Prior knowledge on the structure and/or other structures with similar background has not been considered so far in improving PDT locations. This can be especially useful in case of clusters of buildings with similar features (age, design considerations, environmental exposure, construction, soil, and maintenance strategies). This can be used for defining prior distribution of NDT parameters. Using likelihood function obtained from rebound hammer (RH) tests on structure, Bayesian updating is employed on prior distribution of parameters, to obtain posterior distribution.

3.1 Methodology for selection of PDT locations

The likelihood function (\mathcal{L}) of RH values is assumed to be lognormally distributed:

$$\mathcal{L}(R | \mu_{R_m}, \sigma_{R_p}) = \prod_{t=1}^{N_t} \frac{1}{R_t \sigma_{R_p} \sqrt{2\pi}} \exp \left[-\frac{(\ln R_t - \mu_{R_m})^2}{2\sigma_{R_p}^2} \right] \quad (13)$$

where, R is the result of RH test on the building with counter t , μ_{R_m} = mean value of natural logarithm of a RH population m , σ_{R_p} = standard deviation of natural logarithm of a RH population p , N_t = total number of RH tests carried out for the present building. The prior distributions of μ_{R_m} and σ_{R_p} are a derivation of knowledge from surrounding buildings. In the absence of any significant correlation between the prior parameters, the bi-variate joint distribution of mean and standard deviation can be obtained by simply multiplying the individual probabilities. Using likelihood (Equation 13) and prior, posterior distribution of RH parameters is obtained:

$$\mathbb{P}(\mu_{R_m}, \sigma_{R_p} | R) = \frac{\mathcal{L}(R | \mu_{R_m}, \sigma_{R_p}) \mathbb{P}(\mu_{R_m}, \sigma_{R_p})}{\sum_{m=1}^{p_1} \sum_{p=1}^{q_1} \mathcal{L}(\mathcal{R} | \mu_{R_\downarrow}, \sigma_{R_\downarrow}) \mathbb{P}(\mu_{R_\downarrow}, \sigma_{R_\downarrow})} \quad (14)$$

where, p_1 and q_1 are the number of subgroups in prior mean and standard deviation distribution. The posterior predictive distribution of \bar{R} is then obtained using likelihood function (Equation 13) and posterior distribution of RH parameter (Equation 14). Afterwards, the core samples of each cluster/identified groups are divided according to the fractional weightage in approximate proportion to the posterior predictive distribution.

$$\mathbb{P}(\tilde{R}/R) = \sum_{m=1}^{p1} \sum_{p=1}^{q1} \frac{1}{\tilde{R}\sigma_{R_p}\sqrt{2\pi}} \exp\left[-\frac{(\ln\tilde{R} - \mu_{R_m})^2}{2\sigma_{R_p}^2}\right] \mathbb{P}(\mu_{R_m}, \sigma_{R_p} | R) \quad (15)$$

4 DEMONSTRATION ON TWO MULTI-STOREY RC BUILDINGS

4.1 Building description

Buildings considered for selection of NDT and PDT locations are G+13 storey commercial and G+2 storey residential building, located on coast of Arabian Sea, India. To set up the prior for PDT case study, NDT data are acquired from adjacent buildings having similar environmental exposure, design grade of concrete and reinforcement, subsoil, seismic zone, and age group.

4.2 Test results for the selection of NDT locations

The office building has two typical floor plans: (a) ground to 9th (Area: 510 m²/ floor) and (b) above 9th (Area: 360 m²/ floor). The pre-specified number of NDT locations are divided as per varying plan area: 200 (ground to 9th floors) and 60 (floors above). The structural members are column, beam (primary and secondary) and slab; each of which are subdivided using local importance factors (shown in Figure 1b for ground to 9th floors) into three subcategories. Hence, total of nine subcategories are used, three each for columns (C1, C2, C3), beams (B1, B2, B3), and slabs (S1, S2, S3). The bar charts of different groups with respect to frequency and local importance factors (\mathcal{S}_{ijk}) are shown in Figure 1 for one typical case (applicable for ground to 9th floor).

Figure 1. (a) Frequency and (b) local importance factor of each subcategory from ground to ninth floor.

Number of samples in each subcategory (\mathcal{S}_{ijk} and \mathcal{N}_{ijk}) is shown in Figure 2. Possible locations for NDT of each subcategory are obtained by site survey and proposed optimisation is performed to finalise NDT locations. Distribution of NDT locations in ground floor is presented in Figure 3.

Figure 2. (a) \mathcal{S}_{ijk} (Fractional) and (b) \mathcal{N}_{ijk} (Integer) for each floor (0th to 13th) and different subcategory.

4.3 Test results for the selection of PDT locations

This work proposes an additional measure prior applying conditioned/guided coring approach adopted in various past publications (Pfister, Tundo, & Luprano 2014; Alwash, Breyse, & Sbartaï

2017; Faroz, Ghosh, & Faroz 2023). This novel modification is achieved by employing observed RH data-set as likelihood for updating prior RH parameters (shown in Figure 4a) to posterior predictive distribution (shown in Figure 4b). The posterior predictive distribution of RH parameters is found using Equations 13-15. Inclusion of likelihood in prior knowledge reduces the associated uncertainty of the RH parameters i.e., lesser spread of RH parameters as shown in Figure 4(b).

For the fractional weightage of different ranges of RH values, the prior predictive distribution, obtained test results and posterior predictive distribution are computed, and are presented in Figure 5. The slight unevenness of the observed data is moderated with prior predictive distribution (Figure 5a) to obtain a smooth posterior predictive distribution (Figure 5b). This posterior predictive distribution can later be used as a guiding criterion in the conditioned/guided coring.

4.3.1 Multi-constraint problem and optimisation of sampling location

Within the limited scope of this paper, selection of PDT locations is implemented on the overall building RH data using proportional stratified random sampling (Pfister, Tundo, & Luprano 2014). Same approach can be integrated with the other conditioned/guided coring applications. At first, the total number of samples should be divided into columns and beams, based on their global importance fractions (since coring from slabs is generally not recommended), in proportion to the posterior predictive distribution, i.e. Figure 5(b). Next, a random selection needs to be applied, following a stratified pattern with respect to floor and member type. The selection criteria will follow a way such that any new sample should not be from same floor or same type of subcategory until a complete cycle of floor and subcategory is incorporated. However in optimisation part the only difference over here is that the Euclidean distance needs to be calculated in the 3-D space, in contrast to the earlier 2-D plans used in NDT location optimisation.

Figure 3. Proposed locations for NDT on Ground floor.

Figure 5. (a) Prior predictive, (b) Posterior predictive distribution of RH value.

5 CONCLUSIONS

The prevalent methods for the selection of NDT and PDT locations have inherent limitations as exemplified in the relevant literature. This study proposes the selection of such test locations with the following additions: (i) application of domain knowledge (NDT) with a multi-constraint solution and (ii) the use of prior knowledge from similar buildings (PDT). For a limited number of test locations, proposed optimisation methodology is another novelty of the paper. Further, additional aspects such as the nature of an element, type of a member, and the importance of a member – so far not considered in NDT/PDT testing plan – are incorporated in the approach. The proposed practicable methodology is demonstrated through two sample case studies, wherein the objective of capturing the true spatial variability of concrete strength from a given number of tests is achieved. Future works in this direction should be oriented towards the evaluation of the proposed approach in comparison with existing approaches from the perspective of robustness.

ABSTRACT: For a highway operator, such as ASFiNAG, bridges are very important assets. Despite all regular maintenance measures, these structures are strongly subjected to ageing and degradation, because of their exposure. Thus, leading to high maintenance expenditures. The optimal time for rehabilitation is therefore a decisive factor in the cost and measure planning of an infrastructure operator.

To find this optimal point in time and condition, it is important to have a simple index-based method for declaring an accurate condition status. Often the input for the method is gained in the course of regular bridge inspections.

The aim of this paper is to determine condition and degradation (condition indices) by using objective indicators, like humidity, electrical resistivity, and corrosion potential. For the purpose of objectivity and the demand of an exact determination of the condition state, an overall performance index (CDI) is derived from the condition indices by using an analytic hierarchy process (AHP). The challenge of assessing corrosion relevant data – especially when doing this in an automated process – is the influence of many factors on the measurement values in unknown extent (e.g. concrete humidity on corrosion potentials), which doesn't allow an explicit, fixed interpretation as it can be done with e.g. concrete strength data.

Hence, this assessment methodology is Fuzzy-Logic (FL), which treats and combines input data in not clear-cut borderlines to choose an optimal maintenance measure. A case study will proof the method to deal with lack of knowledge and uncertainty in this fuzzy decision process.

1 INTRODUCTION

A large number of components of road infrastructure are exposed to increased degradation due to various damaging effects. Exposure of concrete surfaces to chlorides is a major factor and driver of degradation. In many cases, the amount at the rebar level is the determining indicator of deterioration here. Degradation of the reinforcement in the concrete is triggered at a threshold level of chlorides that the concrete can no longer absorb. Over time, other indicators of degradation develop, such as cracking, visual appearance of the concrete surface, or a drop in the electrochemical potential of the reinforcement.

The aim of the paper is to show those examinations that were used to provide an objective assessment of the degradation of the reinforced concrete member. The results of the survey provide information about the condition of the object. All common indicators of degradation that can be recorded visually or simply non-destructively are addressed and assigned to a four-part damage class. The classification of the degradation indicators into damage classes is based on relevant standards and guidelines as well as on published literature.

Finally, the classified degradation indicators are transferred into an overall Condition index (CDI) by using the AHP process. This index serves as an input parameter for the Fuzzy logic decision algorithm to propose the optimal maintenance measure.

2 METHODOLOGY

Condition assessments are mostly regulated by national standards or internal guidelines. Primarily, condition surveys are performed on a visual basis. This procedure is informative, fast and, when performed by experienced engineers, sufficiently accurate.

Nevertheless, the obtained data are discrete in time and covers only a small section of possible data for condition assessment. Condition surveys are mostly governed by national standards or internal guidelines. Nowadays Europe-wide efforts are undertaken in standardization of indicators obtained during principal inspections, through a visual examination, a non-destructive test or a temporary or permanent monitoring system (Casas & Matos, 2017). It should be noted that currently the majority of condition assessments are based purely on visual inspections. At the same time, this means that damage tends to be detected too late, because it is not sufficiently apparent by visual inspection, and thus the danger of systematically underestimating the condition is present. An objective condition assessment with easy-to-handle preliminary inspection techniques should support in this case and help to reduce the gap between visual assessment and actual condition.

Prerequisite for a successful and sustainable repair of reinforced concrete structures is an exact knowledge of the condition based on a detailed visual assessment of the components, as well as results of performed material tests. All preliminary examinations together have the goal of showing as complete and exact a picture as possible of the current condition of the existing structure. In addition, it should be possible to use the condition analysis to predict future development in terms of a forecast of an optimal time for maintenance.

The scope of the condition analysis must always keep in mind the overall objective. In addition, the actual condition state also plays a major role, e.g., in the selection of suitable condition surveys methods.

There are many different Non-Destructive Testing (NDT) methods used to identify and evaluate the deterioration of reinforced concrete. However, there is no single NDT method capable of identifying all aspects of reinforced concrete deterioration. For this reason, a multimodal NDT approach is a more effective one in terms of condition assessment. A multimodal approach provides a more complete condition assessment because it can identify different deterioration states simultaneously (see Figure 1).

Figure 1 shows the efficiency of condition survey techniques as a function of the condition state. For example, a determined investigation for a specific problem, such as half-cell potential mapping, does not provide more accurate information about the state of preservation until parts of the reinforcement are already affected by corrosion and the concrete components can be therefore already in the damage phase. Furthermore, the figure shows an important insight for the engineer, that with single visual condition assessment, damage is detected very late. Therefore, it is of enormous importance to know when and how accurate a possible degradation can be detected.

The examination techniques mentioned in Figure 3.1 are established procedures and allow one to obtain acceptable good and quantitatively sufficient results with sufficient monetary expenditure. It is always important that the procedures enable and support the increase of knowledge of the overall objective of the condition analysis.

As already mentioned, it is difficult to determine the true dimension of damage only based on visual appearance of the concrete component. Nevertheless, different condition survey techniques are available depending on the stage of degradation (see Figure 1).

2.1 *Indicators for corrosion*

The condition, which is initially determined mainly visually, as well as the development of damage due to corrosion over time, is serving as the basis for decisions regarding the time and intensity of repair. A simple and objective method for assessing the condition of concrete structures is of decisive economic interest.

Figure 1. Effectiveness of different condition survey methods for condition assessment depending on the state of degradation based on (Pailes & Gucunski, 2015).

Based on all available results from preliminary examinations, the condition of the structural element should be determined simply and objectively. The primary basis in the procedure for objectifying and standardizing the results of condition assessment is a thorough and, above all, complete inspection, which thus makes it possible to take further steps towards classification and indexing of the results obtained. The indicators obtained individually from the various preliminary inspections are of varying degrees of importance for degradation. Therefore, the indicators were subjected to weighting via an analytical hierarchy process (AHP) before being synthesized into a condition index.

Additionally, the results of condition assessments are often not clearly interpretable, as they also contain a subjective perspective. This results in unclear decisions regarding the maintenance strategy. Therefore, a fuzzy logic expert system is introduced which can deal with this vague decision space.

Table 1. Indicator for degradation and their levels.

Degradation Ind.	Akr.	Unit	Degradation indicator level			
			1	2	3	4
			Negligible	Low	Moderate	High
Visual appearance	Vis	[mm]	< 1	≥ 1 - 4	≥ 4 - 10	≥ 10
Carbonation depth	X _{CO}	[mm]	0% C	≤ 75% C	> 75% C	≥ C
Chloride content	X _{Cl}	[m%]	≤ 0,2	0,2 - 0,6	0,6 - 1,0	> 1,0
Concrete resistivity	ρ	[Ωm]	> 1000	500 - 1000	100 - 500	< 100
Corrosion potential ¹	E _{corr}	[mV]	> -200	-200 - -350	-350 - -500	< -500
Corrosion state	KG	[-]	0 < 1	≥ 1 - 2	≥ 2 - 3	≥ 3 - 4

¹ using Cu/CuSO₄ reference electrode C means thickness of the concrete cover

2.2 Condition index

For the determination of a condition index, all available results from preliminary investigations at the evaluation time, such as carbonation depth and chloride content at the reinforcement level, are divided into classes. From these, information is obtained that can provide

information on the current state, respectively the intensity of the damage due to corrosion. The index is divided into four classes as follows:

1. = no damage and negligible or no corrosion,
2. = minor damage and low corrosion,
3. = moderate damage and moderate corrosion,
4. = high damage and high corrosion.

The corrosion damage index (CDI) is obtained by first transferring measured values to Corrosion indicator levels, see Table 1. These scenarios represent common evaluation approaches which have to be proven and possibly up dated in practical use. The mean of the corrosion indicator levels results in the “Corrosion Damage Index”:

$$CDI_{Mean} = \sum_i^n \frac{Degradation\ indicator\ level_i}{n} \quad (1)$$

here n is the number of corrosion indicators used, according to Table 1.

The mean value is calculated for simplification purposes. In principle, it is possible to assign more importance to individual indicators.

A weighting can be based on the type of measurement on the one hand and on the significance of the indicator on the other. The indicators carbonation, visual appearance, chloride content at reinforcement level and cracks are all indicators that provide indirect information about the degradation, whereas potential, corrosion rate or cross-section loss of the rebar represent direct measured values related to the corrosion of the reinforcement and may therefore weighted stronger. A method for determining the weights, the analytical hierarchy process (AHP) (Saaty, 1977). The calculation of the condition index when weighted indicators are used is as follows:

$$CDI_{AHP} = \sum_i^n Degradation\ indicator\ level_i \cdot w_i \quad (2)$$

where w_i is the weighting factor for the particular degradation indicator used.

The method enables transparent traceability of how prioritization was calculated and, thus, strengthens the understanding and acceptance in decision making. Thus, a comprehensible and expert-based weighting is achieved. The approach of the method is to simplify the problem by breaking it down into a hierarchical system and to form a systematic procedure to structure and solve the decision processes. Which indicators are used in particular and how they are ranked and prioritized can be seen in Table 2. Therefore, the corrosion indicator chloride content is two times more important than the corrosion potential (X_{CI}) and seven times more influential than the carbonation depth (X_{CO}). This additional information is processed in the AHP algorithm and derives the weighting in percent, which is given in the last column of Table 2 labeled as priority.

Table 2. Weights of the degradation indicators to determine the condition index

Degradation indicator DI	Rank	Importance						w_i [%]
		1	2	3	4	5	6	
Chloride content	1	1	3	4	5	7	8	43,7
Corrosion potential	2	1/2	1	2	3	6	7	23,9
Concrete resistivity	3	1/3	1/2	1	2	5	6	15,7
Corrosion state	4	1/4	1/3	1/2	1	4	5	10,3
Carbonation depth	5	1/7	1/6	1/5	1/4	1	2	3,8
Visual appearance	6	1/8	1/7	1/6	1/5	1/2	1	2,7

The CDI is thus a measure of the direct quantifiable damage due to corrosion the reinforcement has undergone, combined with the expected corrosion progress. The result is therefore a measure that provides information about damage already caused and describes the current status of the degradation. The level of the index (CDI) shows the extent of the damage that has already occurred. The higher the damage index, the greater the damage and extent of the degradation. By using AHP

the decision problem is decomposed into a hierarchy of more easily comprehensible sub-problems, which can be analyzed independently. Once the hierarchy is built, the process consists of systematically evaluate the elements and determine their interrelations and by comparing them to each other with respect to their impact on an element above them in the hierarchy. In making the comparisons, concrete data about the elements can be used to enhance the judgments about the elements' relative meaning and importance. The AHP converts these evaluations to numerical values that can be processed and compared over the entire range of the proposed problem. Finally, a numerical weight or priority is derived for each element of the hierarchy, allowing diverse and often incommensurable elements to be compared in a rational and consistent way. After incorporating these judgments this yields to a set of overall priorities for the hierarchy. With every kind of pairwise comparison, inconsistencies can also occur. For the examination of these inconsistencies a so called Consistency Ratio (CR) is used, where $CR < 10\%$ is considered to be acceptable. For the examination of these inconsistencies a so called Consistency Ratio (CR) is used, where $CR < 10\%$ is considered to be acceptable (Saaty, 1990).

2.3 Fuzzy-logic decision support system

It is indeed difficult to perform a quantitative evaluation of the effectiveness of repairs. This problem has many sources. They include environmental influences, time pressure during implementation, lack of root cause analysis, price wars among repair companies and poor execution quality.

It is not possible to evaluate the effectiveness of repair procedures quantitatively. Complex tests on site and in the laboratory are required for realization.

It is more appropriate to use an expert system so that knowledge can be made available to experts. A rule-based expert system (RES) models an expert who can handle the system instead of the system to be operated. This makes the expert knowledge accessible to non-experts, who can thus make decisions with the help of the RES. Furthermore, the conception of a RES enables the knowledge of the experts, which is intuitive and empirical, to be readable and processable by computers.

Fuzzy RES are based on qualitative (fuzzy) expert statements and thus on (fuzzy) stored qualitative knowledge. In addition to the use of linguistic variables and operators, an essential concept is the method of defuzzification. In this paper, it is shown how the effectiveness of individual repair measures can be estimated as a function of the damage classes or corrosion indicators using the fuzzy logic approach.

The simplest form of a fuzzy logic application is a fuzzy controller. This takes input, then performs calculations and finally provides an output value. Fuzzy sets were first applied by (Zadeh, 1965). The following steps must be gone through:

- Setting the input and output values as linguistic variables,
- Definition of the fuzzy sets of input and output values,
- Converting the input values into fuzzy values (fuzzyfication),
- Formulation of the rules and store in the knowledge base,
- Applying the rules to the fuzzy values (inference),
- Convert obtained statements into numerical form (defuzzyfication).

Figure 2 illustrates the basic structure of a fuzzy logic expert system with focus of the presented problem.

Figure 2. Illustration of the fuzzy logic process to determine the effectiveness of repair measure based on the condition index (CDI = 1.5).

3 FIELD STUDY

The survey was undertaken on a retaining wall situated in Vienna at the Austrian motorway network of ASFiNAG. The retaining wall is 3.80 m beside the motorway lane. The wall is 133 m long and between 0.5 m and 5.90 m of height. It is retaining a slope before an overpass. Taking into account that the surveyed structure is 38 years old, the evaluation of the conditions shows already degradation phenomena, like delamination, cracks and particularly corrosion of the reinforcement. The preliminary survey shows a mean carbonation depth of 2.4 cm and chloride contamination over 1 % Chloride per mass binder up to approximately 4 cm in the concrete surface (see Figure 3).

4 CONCLUSIONS

The paper presented a methodology to assess the condition of concrete components. The condition is determined from real and therefore objective values which are suitable to indicate degradation. The obtained data is mainly derived from condition surveys and may also monitoring data, like humidity, electrical resistivity, and corrosion potential.

The demand of an exact as possible determination of the condition state is a key mission for the asset management to decide which maintenance measure is the best for a certain condition at certain time. This is considered by using objective indicators (degradation indices) to derive an overall performance index. This condition indicator (CDI) is handled through an analytic hierarchy process (AHP) for the sake of objectivity and comprehensibility.

The AHP was utilized in this paper to develop a useful tool for determining the corrosion damage condition of a reinforced concrete bridge component based on different corrosion indicators. AHP method was used to help determine weight factors for different indicators relative to the determination of the final corrosion condition. AHP method can reduce the influence of certain expert's mistakes in the judgment by using pairwise comparison method. A final and more accurate CDI value can be obtained.

The condition index has been transformed into a fuzzy logic system. An overview of the whole fuzzy logic process for determining the effectiveness of repairs based on the condition index CDI was given. A simple expert-based decision rule regime was used to determine the effectiveness of individual repair principles.

At first, membership functions of the sharp input, here condition index, and output variables, here theoretical effectiveness of repair, are conceived. Fuzzy ranges of values are created. These values are related in the inference via a rule database, which was designed empirically and based on expert knowledge. After defuzzification, the effectiveness of the respective maintenance principle is the output to the corresponding condition index CDI.

In Figure 3.h) it can be seen that the effectiveness of a certain maintenance measure is not completely ineffective or fully effective in any of the cases. The developed decision algorithm can reliably represent the state of knowledge of experts in the field of repair of reinforced concrete structures. The structure of the system is deliberately kept simple and the reconstruction of the decisions is also clearly comprehensible.

In addition, the fuzzy logic expert system can be extended with respect to the degradation indicators forming the condition index. Furthermore, the developed system is machine-readable, therefore simultaneously applicable to a collective of reinforced concrete components or even entire infrastructure networks.

The methodology was evaluated, proofed, and demonstrated within the case study. If enough data from the condition assessment is available, it can provide a more accurate condition overall and so serve for more profound input for the Fuzzy Logic expert system to choose an optimal repair measure.

The strict rely on only visual inspection data for condition assessment to manage repair measures is considered as critical by the authors.

The paper presents a comprehensive methodology for structural monitoring with the aim of showing how directly usable results from monitoring can be, obtained in the long term for service life prognosis, asset management and maintenance with acceptable effort.

In addition, with the application of this approach on a larger, representative building stock, the perspective of an even more reliable service life prognosis will take place. Therefore, the data already acquired, but also future data, can be described as valuables. In the future better forecasts will be possible based on more precise condition assessments. An important point is that uncertainties on both the impact and the resistance side can be concretized or reduced through dense NDT in time and space, or monitoring.

5 OUTLOOK

The transfer of damage to reinforced concrete components into damage classes can be extended to include indicators for freeze-thaw attack or sulfate attack. Also, such damage classifications can be applied to other materials, such as steel by extension. The application of the degradation indicators allows an objective representation of the state and contributes to the homogenization of the data.

With this more accurate data, at the structure level, the fuzzy logic algorithm can serve as a decision support tool in choosing the optimal repair method. In addition, the fuzzy logic expert system can be extended with regard to the degradation indicators forming the condition index. In addition, the developed system is also applicable to a collective of components, structures or even entire infrastructure networks.

At the network level, the fuzzy logic algorithm can provide more accurate results when calculating the budget requirements of future maintenance activities. This allows to take full advantage of the optimal rehabilitation at the optimal time and so effectiveness of financial resources.

ABSTRACT: Chloride ingress is one of the most important causes of reinforcement corrosion. To assess the risk of chloride-induced corrosion, a frequently used technique is to measure the concrete cover and chloride profile in order to map the chloride ingress process and associated risk for depassivation of the rebars. Based on the results of the analysis, a range of different repair solutions can be proposed, among which a repair mortar applied to the concrete surface to increase the quality and thickness of the concrete cover, such to lower the risk of forthcoming depassivation. Unfortunately, modelling of the migration process of chlorides after such an intervention becomes more complex as two different materials with varying diffusion coefficients are combined. Here, a novel framework is proposed in order to determine the minimal thickness of the repair mortar applied to the surface, ensuring that the probability of depassivation stays below a predefined threshold.

1 INTRODUCTION

Chloride migration in reinforced concrete is one of the main reasons why reinforcement starts to corrode. When chlorides penetrate the concrete, the chloride concentration at the reinforcement level rises to the point where it may exceed a critical chloride concentration and the steel is depassivated, i.e. it may start to corrode. Fortunately, extensive research has been done in the past and consensus has been achieved regarding the modelling of the time to corrosion initiation, considering uncracked concrete structures subjected to chloride ingress (fib Bulletin 34, 2006). In case of performance-based design of new structures, generally the required concrete cover is determined as to ensure the probability of depassivation stays below 10% throughout the structure's lifetime (CROW 2018). However, for existing structures a different threshold might be appropriate due to the limited remaining lifetime and considering the corrosion propagation phase. To make sure this threshold is not exceeded during the structure's remaining or extended lifetime, a repair intervention might be needed.

A possible intervention could be to apply an additional repair mortar layer on top of the concrete surface. The effect of this compact mortar layer is twofold: (1) it will slow down the migration of new chlorides into the concrete, and (2) part of the chlorides in the already contaminated concrete can diffuse into the mortar layer. Solving the differential equation for two materials with different diffusion coefficients has been done in the past, when studying the so-called skin-effect (Andrade, 1997). However, in order to take into account the previously diffused chlorides which have migrated into the concrete substrate before the application of the repair mortar, the differential equation is numerically solved by discretizing in time and space using the finite difference method.

This numerical approximation is complex and impractical for practicing engineers and hence an objective way to determine an appropriate repair mortar strategy is still lacking. In this work, a framework is proposed for the development of easy-to-use nomograms to determine the required thickness for a repair mortar overlay for a specific situation. The influence of several input parameters on the proposed repair strategy is investigated first, in order to select the main parameters to be used in the nomograms.

2 MODELLING THE MIGRATION PROCESS OF CHLORIDES INTO CONCRETE

2.1 Modelling diffusion of chlorides

The one-dimensional transport of chlorides through the concrete substrate is described by the diffusion law (Saetta 1993, Crank 1979):

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} D \frac{\partial C}{\partial x} \quad (1)$$

where C [m%*cement*] is the chloride concentration at time t and location x and D [mm²/s] is the diffusion coefficient of the substrate material. Considering that chlorides are migrating through a single material with a time-invariant diffusion coefficient, no initial chlorides were present in the substrate and a constant chloride concentration is maintained at the surface, the solution of the differential equation becomes:

$$C(x, t) = C_s \left[1 - \operatorname{erf} \left(\frac{x}{2\sqrt{Dt}} \right) \right] \quad (2)$$

where C_s [m%*cement*] is the surface chloride concentration which follows from the environmental conditions, and $\operatorname{erf}(x)$ the Gauss error function. When the diffusion coefficient and surface concentration are known, this equation allows to determine the chloride concentration at any time and location. However, in case a repair mortar is applied to the concrete surface, a new material with a different diffusion coefficient is introduced. Consequently, the diffusion coefficient in equation (1) varies with the depth of the substrate, and the single material solution given by equation (2) does not apply anymore. To solve the chloride migration problem, the differential equation can be solved numerically. In the work of Petcherdchoo (2018), the following numerical scheme is proposed based on the finite-difference principle of Crank-Nicolson (William, 2007):

$$\frac{c_{i,j+1} - c_{i,j}}{\Delta t} = \frac{1}{2} \left(\frac{D_{i+\frac{1}{2}}(c_{i+1,j+1} - c_{i,j+1}) - D_{i-\frac{1}{2}}(c_{i,j+1} - c_{i-1,j+1})}{(\Delta x)^2} + \frac{D_{i+\frac{1}{2}}(c_{i+1,j} - c_{i,j}) - D_{i-\frac{1}{2}}(c_{i,j} - c_{i-1,j})}{(\Delta x)^2} \right) \quad (3)$$

where $c_{i,j}$ is the chloride concentration at mesh point i and timestep j . Diffusion coefficients $D_{i+\frac{1}{2}}$ and $D_{i-\frac{1}{2}}$ are located in between two mesh points and determined by taking the average of the diffusion coefficients of their neighbours.

2.2 Time-dependent diffusion coefficient

Conflicting with the assumptions previously made, the diffusion coefficient and chloride concentration at the surface may change over time (Andrade, 2011). First of all, the diffusion coefficient changes due to a change in the porosity of the concrete as it ages, and binding of the chlorides to the substrate material instead of migrating further. Secondly, the surface chloride concentration is in reality not constant due to the varying exposure conditions. These

Figure 1. Apparent diffusion coefficient over time.

effects are taken into account by defining an averaged diffusion coefficient over the period considered, the so-called apparent diffusion coefficient D_{app} , defined in the *fib* Model Code for Service Life Design (2006):

$$D_{app}(t) = k_e \cdot D_{RCM,0} \cdot k_t \cdot \left[\frac{t_0}{t} \right]^a \quad (4)$$

where k_t [-] is the transfer variable which is equal to 1 by default and a [-] the ageing exponent describing the time-dependent behaviour of the diffusion coefficient. k_e [-] is the environmental transfer variable considering the outside temperature's influence. This value is assumed to be equal to 1 in the subsequent analyses, i.e. the temperature of the concrete element under consideration is equal to a reference temperature of 20°C. $D_{RCM,0}$ is the diffusion coefficient at a reference time t_0 of 28 days measured by the Rapid Chloride Migration (RCM) method.

Equation (4) is based on multiple diffusion measurements of the same concrete substrate over time. However, when applying a repair mortar to the concrete surface, the time-dependent processes influencing the diffusion coefficient, such as the ageing of concrete, might be altered. Figure 1 shows the evolution of the diffusion coefficient D_{app} over time for different values of the ageing exponent, indicating that the diffusion coefficient more or less stabilizes after a period of 20 to 30 years. In most practical cases, an intervention is required only for existing structures with a considerable age and thus the application of the repair mortar will not alter the time-dependent behaviour of the concrete diffusion coefficient much. Hence, the use of the apparent diffusion coefficient D_{app} in combination with equation (3) to simulate the progression of chlorides through the concrete substrate and mortar layer is appropriate. About the time-dependent behaviour of repair mortars, little research has been executed and in this work the diffusion coefficient of the repair mortar is assumed to be described by equation (4) as well.

2.3 Mesh properties and incremental time step

To numerically approximate the multi-material diffusion process by means of equation (3), a discretization in time and space is required. Therefore, the mesh point size Δx , depth of 1D space x_{limit} and incremental time step Δt , need to be determined. Increasing Δx and Δt and decreasing x_{limit} reduces the computation time, but at the expense of numerical accuracy and therefore an appropriate choice should be made. First of all, based on the recommendations of Petcherdchoo (2018), Δx is taken equal to 1 mm. Secondly, the considered depth x_{limit} of 1D space should be large enough to ensure that the assumption $C(x=+\infty; t)=0$ is satisfied. Here, the value for x_{limit} is determined based on the analysis of a single material diffusion process, where the analytical solution of equation (2) can be compared to the numerical solution according to equation (3). The results are shown in Figure 2 for an extreme set of parameters compared to the values included in *fib* Bulletin 76 (2015) ($C_s = 2$ m% cement,

$D = 50 \text{ mm}^2/\text{y}$, $t = 150 \text{ y}$, $\Delta t = 0.1 \text{ y}$ and $\Delta x = 1 \text{ mm}$). It appears that $x_{limit} = 200$ and 300 mm lead to an acceptable prediction of the chloride concentration at the level of the reinforcement, typically located around 20 to 70 mm from the boundary. Therefore, x_{limit} is chosen equal to 300 mm.

Figure 2. Influence of depth of 1D space on the numerical approximation of the diffusion process.

Finally, Δt is an important parameter because it has a significant influence on the computation time. This is because the chloride concentration needs to be iteratively determined for every time step, compared to the spatial characteristics which can be vectorized. In the work of Petcherdchoo (2018), Δt is chosen equal to 0.08 y (1 month) to ensure a smooth transition of the chlorides into the two-material substrate. In Figure 3, the problem statement as described previously is solved for different values of Δt , considering the application of a repair mortar of 20 mm after 50 years. The graphs represent the results at respectively 5, 20 and 50 years after application of the repair mortar. It is clear that the smaller Δt , the more smooth the chloride migration process is simulated and especially for larger values, the chloride concentration at the boundary between the concrete and the repair mortar is not well simulated. However, the chloride concentration at the level of the reinforcement, which is typically around 20 to 70 mm from the original surface (+20 mm to mortar surface), seems to be predicted well by all values of Δt . To increase the efficiency of the algorithm and still maintain a reasonable approximation of the chloride concentration at the materials' interface, the value of Δt is set equal to 1y in this work.

3 FRAMEWORK FOR DETERMINATION OF THE REPAIR STRATEGY FOR REPAIR MORTAR OVERLAY

3.1 Description of the general framework

The framework which is developed in this contribution allows to assemble practical nomograms which indicate the appropriate repair mortar solution for a set of input parameters. In the *fib* Model Code for Service Life Design (2006) and *fib* Bulletin 76 (2015), the probabilistic characteristics of the parameters describing the diffusion process have been characterised. For a given concrete composition and mortar type (diffusion coefficients of both materials), exposure condition (chloride concentration) and concrete cover, it is possible to derive nomograms that indicate the most appropriate repair strategy (usefulness of repair mortar overlay and its thickness), taking into account a maximum threshold for the probability of depassivation and age of the structure.

Using Latin Hypercube Sampling (Ollson 2003), first the probability of depassivation P_{dep,t_0} at the time of intervention t_0 is determined. If P_{dep,t_0} already exceeds the threshold probability P_{lim} , a repair mortar overlay solution is not advised and a more drastic repair strategy is needed, e.g. removing and repairing the contaminated concrete. If P_{dep,t_0} did not

Figure 3. Influence of the incremental time step on the numerical approximation of the diffusion process.

exceed P_{lim} yet, the probability of depassivation $P_{dep,t1}$ at the end of the structure's intended lifetime t_1 is determined. In case $P_{dep,t1}$ is still below P_{lim} , no repair mortar is needed at all. If $P_{dep,t0}$ is below P_{lim} and $P_{dep,t1}$ is above P_{lim} , a repair mortar overlay solution might be possible and the repair mortar thickness is increased step by step by 5 mm until $P_{dep,t1}$ is below P_{lim} . The maximum repair mortar thickness is considered to be 50 mm.

3.2 Reference nomogram

Consider a concrete composed of fly-ash cement combined with a water/cement ratio of 0.4 located in environmental class XD2 (wet, rarely dry). Based on this information, further to that of a polymer-cement based (PCC) repair mortar, the input parameters and probabilistic characteristics are given in Table 1. Note that the parameters that were defined in literature as normally distributed are defined as lognormally distributed in order to exclude negative values. The characteristics of the repair mortar correspond to a commercially available repair mortar. Due to the absence of probabilistic information about the properties of the repair mortar, the ageing exponent a_m is considered deterministic and the coefficient of variation of the diffusion coefficient $D_{RCM,0,m}$ is considered to be equivalent to the corresponding value of the original concrete, and hence $V_{RCM,0,m}$ is considered equal to 0.2. The calculation is done for different ages of mortar application (between 20 to 70 years) and concrete covers (between 30 and 60 mm). Furthermore, the desired remaining lifetime is considered to be 50 years, the probability of depassivation threshold is 10% and 10 000 Latin Hypercube Samples are used.

The resulting nomogram is given in Figure 4, where three different regions are visualized: a region where no repair mortar overlay is needed (green), a region where a repair mortar overlay could be applied (blue) and a region where no repair mortar overlay solution is possible (red), either due to the probability of depassivation being already exceeded at the time of intervention or the need for an excessive mortar overlay thickness.

Within the region where a repair mortar overlay could be applied, the required thickness of the repair mortar layer increases by 5 mm in a stepwise manner indicated by the dotted lines, starting from 0 mm at the most right boundary. For example, for the reference nomogram in Figure 4, a mean concrete cover of 40 mm combined with a time of application of 40 years gives a required repair mortar layer thickness of 10 mm to prevent the probability of depassivation from going over the threshold of 10%.

The region where a repair mortar can be applied is rather narrow, indicating that a repair mortar overlay solution would only be feasible in a limited amount of cases. Also, the largest thickness of repair mortar needed is 20 mm. This indicates that in situations where the threshold would be exceeded (yet where depassivation of the reinforcement was not yet reached at time of intervention), a relatively thin layer of additional repair mortar can be enough to stay below the required threshold probability.

Table 1. Probabilistic distribution of parameters influencing the migration of chlorides.

Variable	Distribution	μ	V	σ	a^*	b^{**}
Ageing exponent concrete $a_c[-]$	Beta	0.6	0.2	0.12	0	1
Ageing exponent mortar $a_m[-]$	Deterministic	0.5	/	/	/	/
Diffusion coefficient concrete $D_{RCM,0,c}[10^{-12}m^2/s]$	Lognormal	5.6	0.2	1.12	/	/
Diffusion coefficient mortar $D_{RCM,0,m}[10^{-12}m^2/s]$	Lognormal	1.27	0.2	0.25	/	/
Concrete cover $c[mm]$	Lognormal	Varying	σ/μ	8	/	/
Surface concentration $C_s[m\%cement]$	Lognormal	3	0.75	2.25	/	/
Critical concentration $C_{crit}[m\%cement]$	Beta	0.6	0.25	0.15	0.2	2.0

a^* : lower bound of Beta distribution
 b^{**} : upper bound of Beta distribution

4 INFLUENCE OF PARAMETERS ON NOMOGRAMS

To derive nomograms for different diffusion coefficients, surface concentrations etc., it is important to consider the influence of these parameters on the proposed repair mortar overlay solution. The influence of the mean value of four parameters from the reference nomogram in Figure 4 will be investigated: the ageing exponent and diffusion coefficient of the concrete, the surface concentration and the remaining lifetime. The uncertainty of the characteristics of the repair mortar is not varied as currently information on these properties is rather scarce and should be investigated more in-depth in further work. The results are given in Figure 5, where only the indicated variable is changed compared to the reference nomogram, while the other value remain as indicated in Table 1.

It can be seen that the nomograms change significantly compared to the reference case, which indicates the importance of each of the varied parameters. Moreover, increasing the desired remaining lifetime increases the feasibility of a repair mortar overlay strategy.

Figure 4. Reference nomogram.

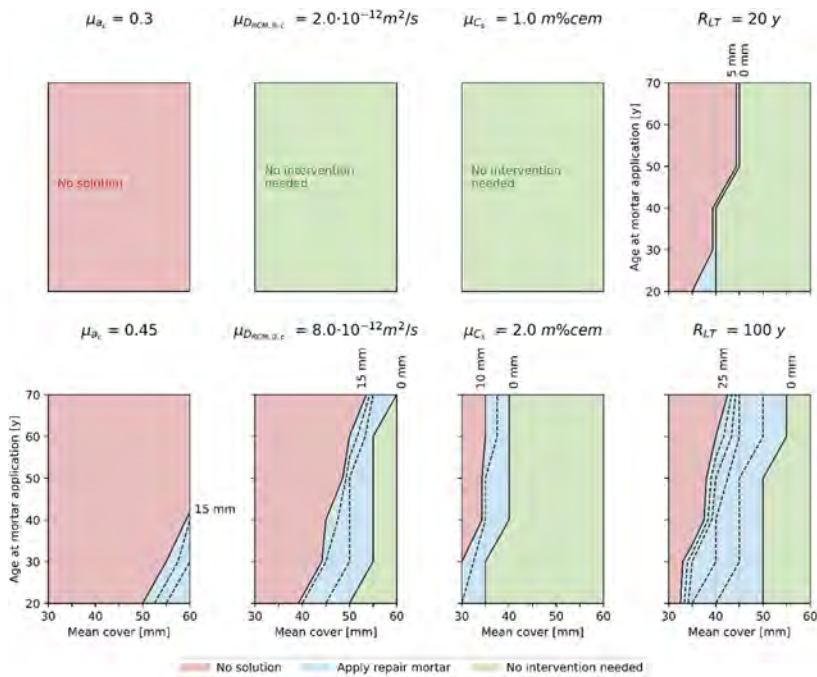

Figure 5. Influence several parameters on nomogram.

5 CONCLUSIONS AND FURTHER WORK

In this work, a framework was proposed to determine the minimal thickness of repair mortar overlay that needs to be applied to the concrete surface to slow down the chloride ingress and make sure the probability of depassivation stays below a certain predefined threshold. This framework can be used to construct easy-to-use nomograms for different types of concrete compositions and environmental conditions, using the probabilistic characteristics defined in the fib Model Code for Service Life Design (2006) and fib Bulletin 76 (2015). Generally, only a limited repair mortar thickness is required to make sure the threshold of depassivation probability is not exceeded. However, the required thickness of the mortar overlay increases when the desired remaining lifetime increases.

In order to generate different nomograms, it is important to determine the parameters which have a significant influence on the final repair solution. It was found that the mean values of the ageing exponent, diffusion coefficient, surface concentration and remaining intended lifetime significantly influence the resulting nomograms. However, it is important to note that the influence of the properties of the repair mortar has not been considered here and possibly has also a large influence on the final nomograms. Further work includes investigating the influence of the repair mortar properties and also the influence of the uncertainty on the parameters involved.

ABSTRACT: Reinforced Concrete is one of the most widely used composite materials in the modern construction industry, but corrosion has become a significant problem worldwide, resulting in exceptionally high maintenance costs. To maintain structural integrity and safety, robust non-destructive techniques are required. Ultrasonic-guided wave (UGW) based monitoring has proven to be sensitive to a wide range of flaws, since they can propagate for long distances to inspect larger areas. Corrosion causes delamination between the reinforcing steel and concrete interface, which affects the wave propagation characteristics. In this study, we aimed at detecting early corrosion in steel-reinforced concrete by relying on UGW. Hence, UGW propagation in steel bars embedded in concrete and the inspection of leaked energy from one bar to another through propagating in the concrete medium was investigated. Since natural corrosion is a slow process, an accelerated corrosion setup was used to induce artificial corrosion using the impressed voltage approach.

1 INTRODUCTION

Reinforced Concrete (RC) is one of the most widely used composite materials in the modern construction due to its robustness, availability, relatively low cost, ease of casting and fire resistance. The actual cause of concrete failure is rarely visible, where only symptoms are visible due to accumulated internal stresses. These stresses may end up in many types of failure that can trigger partial or full collapse of the structure. One of these failures could be due to the stresses generated as a result of rust accumulation since corrosion not only reduces the strength of the reinforcement, but its by-product, iron oxide, expands where this expansion causes stresses in the surrounding concrete, which eventually leads to cracking, delamination, spalling, and may reach a complete loss of serviceability (Sharma et al., 2018).

One of the major contributors to the corrosion of steel reinforcement is chloride attack as a result of the use of chloride-contaminated components, or diffusion into the concrete from the surrounding environment, particularly in coastal regions with high chloride concentrations (Sharma et al., 2018, Luković et al., 2017). Chloride attack is special because it acts primarily on corroding the steel reinforcement, and the surrounding concrete is only damaged because of the corrosion process (Luković et al., 2017).

Non-destructive testing (NDT) is the process of evaluating components, materials, or systems without affecting their serviceability. However, even if they involve invasive procedures, non-destructive testing techniques are those that do not compromise a component's future usefulness (Ivanchev, 2022). To avoid being late in corrosion detection, the initiation of corrosion should be recognized as early as possible to select appropriate protective measures to control subsequent deterioration (Gjørv, 2011). Hence, structural health monitoring (SHM) has been intensively

investigated in recent years because of its feasibility and importance in early non-destructive monitoring and damage detection, where the literature reported a variety of techniques that were suitably employed for monitoring and assessment of concrete health (Tan et al., 2016). Structural and civil engineers used different nondestructive techniques to monitor and assess concrete structures. One of the most promising active techniques for monitoring corrosion-related damage in reinforcing bars has been ultrasonic guided wave (UGW) monitoring (Su and Ye, 2009). This approach makes use of ultrasonic waves that travel over an extended structure while being directed by its boundaries and then observing waves transmission. The steel bar embedded in concrete serves as a waveguide, aiding in the transmission of wave packet where the transmitted wave properties will vary when the bar deteriorates due to corrosion (Sharma et al., 2015). The modes propagating a cylindrical structure are the longitudinal, torsional, and flexural modes, labeled with L, T, and F, respectively and they are frequency dependent modes (Su and Ye, 2009).

Some of the studies reported the use of UGW as a method for corrosion detection where the delamination was studied using both low frequency (100 kHz) and high frequency (1 MHz) signals. It was concluded that the low frequency fundamental mode excited at 100 kHz was less attenuative and it is a surface sensitive mode capable of detecting corrosion's debonding action. However, the $L(0, 7)$ mode at 1 MHz is a core sensitive with low attenuation and minimal leakage into the surrounding concrete (Luković et al., 2017). Moreover, the UGW technique was adopted to monitor the damage evolution due to corrosion of 20 mm steel rebar embedded in concrete. Based on the dispersion curves, the $L(0, 1)$ mode was selected at an excitation frequency of 40 kHz where in this study, the amplitude of first wave packet was only observed where it showed a gradual decrease as the corrosion process proceeded (Li et al., 2014). Another study investigated the effect of debonding levels between steel bar and concrete on the transmitted wave using a 120 kHz excitation frequency and a five-cycle sinusoidal wave (Miller et al., 2013). Before pouring concrete, PVC pipes were wrapped around the steel to simulate delamination. $L(0, 1)$ is the first wave in the received signal since it has the highest velocity, so the first peak was studied for different delamination lengths. Wave propagation was examined along the rebar with and without simulated corrosion introduced by partial removal of the concrete surrounding the rebar (Mustapha et al., 2014). The time reversal of wave signal was experimentally used to detect damage in rebar without relying on previous benchmark signals, which are typically impacted by external factors. The signals were generated using piezoelectric ceramics at one end of the rebar, received from the other end, time-reversed in the time domain, and then resent to be captured by the original piezoelectric ceramic. It was concluded that the time reversal process can detect damage of different lengths in rebar embedded in reinforced concrete since the damage size will ultimately modify the actuated signal.

This work focuses on the investigation of UGW propagation in steel bars embedded in concrete and the inspection of leakage behavior of the guided waves where the waves will be captured and monitored from different bars when actuating at a single bar. Also, it aims at active monitoring and early detection and propagation of corrosion of steel reinforcement embedded in concrete using UGW technique. To verify the proposed approach, an impressed voltage technique was used for accelerating corrosion of steel reinforcement in RC specimen. The response of the specimens will be monitored to detect the wave characteristics and correlate it with corrosion phases.

2 METHODOLOGY

2.1 Reinforced concrete specimen preparation

In this experiment two test specimens were first prepared using ordinary Portland cement (P.O 42.5), water, coarse aggregates, standard sand, and reinforcing steel. The water to cement ratio was 0.5 and the mix proportion of concrete is presented in Table 1. Each of the specimens prepared was of 400 mm long, 400 mm wide and 200 mm high and reinforced with five deformed rebar of 10 mm diameter and 600 mm length of which 400 mm centered embedded length in concrete and 100 mm was outstretched outside the concrete from each side. The properties of the steel bar are shown in Table 1. Before preparing the specimen, the reinforcing bars were cleaned, then fresh concrete was poured into the molds and cured for two days before demolding the specimen, then subsequently put in a normal curing chamber for 28 days. Concrete cylinders have been tested after 7 and 28 days

Figure 1. Reinforced concrete specimen detailing; (a) Top view, (b) Side view.

Table 1. Concrete and steel properties used.

Concrete Mix	Water	Cement	Fine Aggregates	Coarse Aggregates	
Proportions (kg/m ³)	200	400	700	1150	
Steel bar	Diameter	Length	Density	Young's modulus	Poisson ratio
properties	10 mm	600 mm	7850 kg/m ³	210 GPa	0.28

respectively and the average final compressive strength is 21 and 24.8 MPa, respectively. Specimen detailed dimensions are presented in Figure 1.

2.2 UGW monitoring setup

To facilitate the attachments of PZTs, both ends of the steel rebars were smoothed. The rectangular PZTs (PI Ceramics, Lederhose, Germany) 20 mm x 5 mm x 1 mm were then glued 550 mm apart on both ends of the rebar where one end PZT will serve as an actuator and the other end PZT will serve as a sensor. A typical ultrasonic testing setup for ultrasonic guided wave monitoring is used consisting of a Keysight 33500B signal generator, where the wave packet is produced, an EPA-104 Piezo System Inc voltage amplifier, and a keysight Inc. InfiniiVision DSO-X-3024A oscilloscope, which enables the data collection from the PZTs. The experimental setup with the generation and acquisition systems are shown in Figure 2 with the actuators and sensors connected to the amplifier and oscilloscope devices, respectively. The input signal is a five-cycle sine pulse in a Hanning window. The voltage peak-peak was set to about 200 volts.

Figure 2. Experimental setup of the concrete specimen.

In the set-up, the change in the transmitted signal compared to a healthy signal due to the degradation of the steel bars resulting from the corrosion was monitored. Moreover, the steel

rebar may be considered as a smooth cylinder when the diameter to length ratio is less than 0.4, which is the case in this experiment where the diameter to length ratio is 0.018 where the effect of ribs is neglected (Ervin et al., 2006).

3 RESULTS AND DISCUSSION

3.1 Excitation frequency and wave mode selection

The responses to various excitation frequencies were studied varying from 25 kHz to 150 kHz. The work suggests that the optimum results with the clearer waveforms of the first longitudinal mode and highest amplitude values were obtained with an excitation frequency of 75 kHz.

3.2 Wave analysis in a healthy concrete

3.2.1 UGW through the steel bars embedded in concrete

Figure 3 represents the sensor numberings and distribution over the bars. In this section, the guided wave through the rebar will be investigated on a healthy concrete.

Figure 3. Sensor distribution and specimen main parts allocation.

So, actuation was conducted the rebar subjected to corrosion where PZT attached at one end of the rebar will serve as an actuator and the PZT attached to the other end will serve as a sensor so the waves will be guided within the steel bar boundaries. Thus, PZT2 will act as an actuator and PZT7 will acts as a sensor.

Figure 4. Waveforms actuated and sensed along bar2 embedded in a healthy concrete at 75 kHz.

Figure 4 represents the results of guided wave and its envelope showing the actuated and received signals where amplitudes are normalized for better visualization of actuated and received signal on the same graph. The signals of the UGW propagation in steel surrounded by concrete were quite complicated, as shown Figure 4, but the signals of the first received

wave packet were very significant. The guided wave's reflection and refraction at the steel rebar's end and in the steel rebar's contact with the concrete cause the modes to change which increases the complexity of the received waves, so low amplitude wave packets noticed will be attributed to boundary reflections.

In this research, the first wave packet was explored by evaluating the velocity and amplitude that are main features of the signals, so the collected data will serve as a benchmark. Based on the literature, the predominant mode propagating may be attributed to the longitudinal mode $L(0, 1)$.

3.2.2 Wave leakage investigation

Guided-wave structures may experience wave leakage throughout propagation. Wave leakage is highly influenced by a variety of factors such as structural geometry, fill materials, surrounding conditions, and simulation frequency. The leaky behavior of GWs will be explored in this part, where PZT2 attached to the bar subjected to corrosion, will be an actuator and PZT6, PZT9, and PZT10 from the facing side will be sensors (see Figure 3). Once the wave is sent, it will propagate through the exposed part of the steel in side 1 shown in Figure 3 then at the steel-concrete interface, part of the wave will leak into the surrounding concrete where it will propagate in the concrete and then at the concrete-steel interface part of the wave will be guided again through the exposed part of the steel from side 2.

3.2.2.1 Actuating by PZT2 and receiving by PZT6

The received wave packets are complicated, with no clearly separable modes; this might be attributable to the fact that concrete is a heterogeneous material made up of randomly distributed aggregates of various sizes and shapes. Peaks were selected visually, and the amplitude and velocity of these peaks were determined as shown in Figure 5. The peaks were referred to mode1, mode2, and mode3 since the wave is propagating through different mediums (steel and concrete) and different body sections (cylindrical and rectangular). However, since we are exploring the leakage behavior, the amplitude the dominant mode propagating through the rebar will be monitored which corresponds to the highest peak shown in Figure 5.

Figure 5. Actuated and received waveforms at 75 kHz (PZT6).

3.2.2.2 Actuating by PZT2 and receiving by PZT9

Similar results were shown in Figure 6 with clearer wave packets. It is shown here that the highest peak corresponds to the dominant mode propagated along the rebar. The amplitude of this peak which is 6.34% of the amplitude received by PZT7 with a velocity of 2375 m/s.

3.2.2.3 Actuating by PZT2 and receiving by PZT10

The wave captured by PZT10 is presented in Figure 7. Although the wave is propagating larger distance in the concrete, the dominant mode guided along the rebar is still appearing and the dominant mode with the highest amplitude. Since one mode with the highest peak was detected by all sensors, this will allow the monitoring of corrosion effect by monitoring this dominant mode.

Figure 6. Actuated and received waveforms at 75 kHz (PZT9).

Figure 7. Actuated and received waveforms at 75 kHz (PZT10).

3.3 Effect of corrosion on UGW

The ultrasonic pulse transmission signals were recorded on a regular basis in the RC specimen undergoing corrosion. Despite the complexity of the signals received, L(0, 1) mode signals were highly significant, and amplitude fluctuation was clearly detectable throughout various corrosion days. The corrosion phases will be related to amplitude variation; an increase or decrease in amplitudes will correspond to one of the corrosion phases that are corrosion initiation following the entry of chloride solution, corrosion propagation and rust accumulation, and finally diameter reduction as progression takes place.

3.3.1 UGW through the steel bars during different phases of corrosion

The changes in amplitude for the waves guided in bar 2 subjected to corrosion are presented in Figure 8. Since corrosion was started at bar 2, a change in amplitude was noticed in rebar 2 at day 3, where a drop of 37.02% of the initial amplitude was detected and was attributed to the corrosion

Figure 8. Variation in the amplitude of the dominant mode in bar2 with the progress of corrosion.

initiation. So, the start of corrosion results in an increase in the rebar's diameter where the initiation of corrosion is indicated by the reduced amplitude due to the increase in bonding strength between the concrete and steel, thus increasing the energy released to the surrounding concrete.

The amplitude gradually decreases until it started to increase at day 9 (Figure 8). The rise in signal is due to debonding of the rebar from the surrounding concrete due to rust buildup and formation of internal cracks that will weaken the bonding between concrete and steel which leads to the reduction in the energy leakage, indicating that the progression phase is detected. The specimen was left in the corrosion setup for further days so that the visible changes may be correlated with received waves signals. In this phase, there is a decrease in amplitude referring to the diameter reduction after corrosion progression and it continued to decrease until day 23.

3.3.2 Wave leakage during different phases of corrosion

The initiation and evolution of flaws in steel and concrete will be reflected by UGW since the wave is propagating in both mediums between the sending and receiving points, making the received signal more complicated. However, as indicated in previous sections, monitoring the leakage of L (0, 1) will reveal the presence of defects or changes in the RC specimen.

3.3.2.1 Actuating by PZT2 and receiving by PZT6

According to Figure 9, the amplitude of the received waves was decreasing between day 1 and 9 then it showed a slight increase between day 11 and 17 where a sharp increase started to appear after day 17 after the beginning of diameter reduction phase of bar2 which started at day 15.

Figure 9. Amplitude variation of the dominant mode received by PZT6 with the progress of corrosion.

3.3.2.2 Actuating by PZT2 and receiving by PZT9

Starting day 11, no signals were received by PZT9. This could be attributed to an internal major crack along the path of the wave.

Figure 10. Amplitude variation of the dominant mode received by PZT10 with the progress of corrosion.

3.3.2.3 Actuating by PZT2 and receiving by PZT10

The amplitude of L (0, 1) was monitored from PZT10 signals. The amplitude showed a continuous decrease with a slight increase at day 17. From Figure 10, it is shown that the amplitude is highly affected by the stresses generated due to corrosion initiation and progression. However, at day 17 the increase in amplitude was very small compared to the jump in amplitude captured by PZT6. This could be referred to two reasons. One of them is the large distance covered by the wave in concrete medium which is a dispersive material for wave propagation so waves will lose its energy while propagating. Another reason may be the formation of the internal crack along the path of wave to PZT9 which may affect the strength of the received signals by PZT10.

4 CONCLUSIONS

In this work, it was shown that ultrasonic guided waves can identify corrosion phases and detecting corrosion of steel bars embedded in concrete before symptoms appearance. The assessment of guided wave propagation in steel bars embedded in healthy concrete has been examined. Following that, the impressed voltage technique was used to accelerate the corrosion of the steel bars, as corrosion is normally slow and takes a long time. Also, the leakage behavior of UGW was investigated on a healthy concrete and during different phases of corrosion. Because corrosion activity was the only variable in the experiment, the change in the collected UGW amplitudes of the dominant mode attributed to the first longitudinal mode L (0, 1) in the corroding and adjacent bars over the exposure time is assigned to corrosion activity.

UGW demonstrated a high sensitivity to the initiation and propagation of corrosion even when monitored away from the source of corrosion, and the proposed methodology is a potential NDT technique for use in RC members.

ABSTRACT: For the assessment of the condition of a large structure suffering reinforcement corrosion, it is necessary first to have a strategy for the inspection for collecting the appropriate parameters for appraisal of its present condition and the prediction of its residual life. In present communication very briefly the procedure followed for identifying the corroding zones of a football stadium will be described and how the efficacy of corrosion inhibitors has been evaluated for their repair. In each selected zone the corrosion rate was measured through the Polarization Resistance technique using a modulated confinement to delimit the polarized area.

1 INTRODUCTION

Corrosion of reinforcement is the most common deterioration mechanism that unfortunately shortens the service life of structural concrete. Reinforcement corrosion impairs the structural capacity by reducing the steel cross section and inducing cover cracking. When the corrosion is visible through the identification of rust spots or cracks/spalling appear, inspections are necessary to characterize the condition and the level of corrosion. Numerous administrations and owners have issued maintenance rules (ACI 222R, JSJC no.17), which consider procedures and guidance to perform such inspections when the reinforcement corrosion has started. However, in spite the corrosion rate is a key parameter to characterize the present condition and to predict the evolution of the corrosion process (Andrade et al.1978, Contecvet 2001), this parameter is neither measured or used. The lack of the key parameter related to the deterioration rate evolution limits very much the possibility to quantify the structural consequences of the corrosion.

In present paper the procedure is presented to quantify the level of corrosion and the measurement of the corrosion rate in the case of a football stadium and additionally also for evaluating the efficacy of corrosion inhibitors (Berke 1987, Page et al. 2000) that were selected as the least invasive method to stop the corrosion process. Their efficiency including the economic cost is out of the scope of the present study. The main first interest of the owners is the incorporation of an auxiliary structure, hanging on the beams to carry all the cabling allowing the new technologies transmission. This new structure will be metallic but its weight plus that of the cables and instruments demanded a structural recalculation.

2 EXPERIMENTAL

The structure is around 50 years old. It is framed structure with columns and beams as Figure 1 shows. The bleachers of the stadium are exposed to the atmosphere and rain (Figure 2) because most of them are not covered. The aim of the inspection was focused on identifying if the structural elements to support the new auxiliary structure are corroding and if so, which is their level of degradation. Additionally, the aim was to inspect all the main structural elements and the bleachers.

Figure 1. Aspect of the bottom parts of the bleachers. Figure 2. The bleachers are exposed to rain.

The procedure of inspection and reporting was:

1. Visual observations
2. Grouping the elements and zones in lots by: a) structural function, b) apparent degradation level and c) exposure class.
3. Performing of corrosion rate measurements in each lot
4. Analysis of results and issuing of first step Report

The grouping in lots was made after the visual inspection. It was decided to make the groups by structural elements in; columns, beams and slabs, all placed in the interior protected from rain. Another lot was the bleachers that are exposed to rain. As an example, only the tests performed in the cores drilled from the columns will be commented. Figure 3 shows where the selected columns were located. The test types were: compression strength, ultrasound velocity, porosity, density, cover depth, carbonation depth and chloride profile. Besides the drilled cores were, corrosion measurements were performed to obtain the corrosion potential, resistivity and corrosion rate.

Figure 3. Zones where the cores were drilled in several places of the stadium.

The measurement of the corrosion rate was made using the Polarization Resistance (R_p) technique following (Andrade et al. 1978, Andrade et al. 2004, Feliu et al. 1990) using the portable corrosimeter Gecor10 which used a modulated confinement of the current applied in

order to delimit the area of the bar that is polarized. Thus, R_p and I_{corr} are obtained from the equations (Andrade et al. 1978):

$$R_p = \left[\left(\frac{\Delta E}{\Delta i} \right)_{\Delta E \rightarrow 0} - R_{oh} \right] \quad \text{and} \quad I_{corr} = \frac{B}{R_{ps}}$$

Where Δi is the galvanostatic pulse applied, ΔE is the shift in potential produced, R_{oh} is the ohmic drop produced by the concrete, B is a constant with an averaged value of 26 mV and R_{ps} is the value of the Polarization resistance multiplied by the polarized area. The units are: R_p [Kohm], R_{ps} [Kohm·cm²] and I_{corr} [μ A/cm²]. The measurement was made through a corrosion meter with a modulated confinement of the current (Figures 4 and 5).

Figure 4. Measuring the corrosion in a column.

Figure 5. Corrosion-meter to measure in large elements by means of the modulated confinement of the current.

2.1 Inhibitor efficacy

After the assessment of the condition of the concrete elements, corrosion inhibitors were applied in selected zones for comparing their effects. The steps of the phase of studying the efficacy of corrosion inhibitors were:

1. Selection of zones where the trial with inhibitors was to be performed
2. Measurement of corrosion rates in each trial zone before application
3. Application of inhibitors by the different producers. Survey of the works
4. Post application measurement of corrosion rates in each trial zone
5. Analysis of the results and comparison of efficacy
6. Issuing of definitive Report with the categorization of inhibitor efficacy (only technical comparison)

For the trial 5 different commercial inhibitors were selected. Two zones were also selected having a similar corrosion level (Figure 6): one was a wall and the other a beam. In both a grid was made (see Figure 6) for the different inhibitor suppliers.

In each of the zones of the grid a different inhibitor was applied by each supplier with their own operator and methodology (Figure 7). The corrosion rate was measured before and after the application in all the zones treated. Figure 7 shows some examples of preparation of the surface before the application of each inhibitor and two different manners of application with a spray and a roller.

3 RESULTS

From the first visual inspection it could be realized that the different types of defects were very slight and superficial taking into account the age of the structure. Thus, some delamination in the bottom of the columns (Figure 8) or in some slabs as well as some leaking places (Figure 9) from the bleachers were localized.

Figure 6. Aspect of the two selected zones for the trials and the grid made for each inhibitor.

Figure 7. Examples of preparation of the surface before the application of each inhibitor and two different manners of application with a spray and a roller.

The results of the tests in the columns are given in Table 1. In general, the strength is relatively low, typical of the age when the stadium was built coherent with the high values of porosity, however the ultrasound velocity is relatively high and the density is also above 2.1 g/cm^3 . The carbonation depth was deeper than the cover depth of the bar and there is a certain content of superficial chlorides because the stadium is located in a town besides the sea, but with negligible concentration of chlorides at the rebar level.

The values of the Polarization resistance technique enabled to have the corrosion potential, ohmic resistance and corrosion rate (Table2). From them it was possible to identify that, in spite the carbonation front was deeper than the position of the bar, the corrosion rates were relatively low because the columns were not affected by the rain, except in two places, as shown in Figure 10 (in red color), where the values recorded were shown along the sketch of the stadium. The green captions mean corrosion rates below $0.1 \mu\text{A/cm}^2$ indicative of negligible corrosion following (5) and the red color captions mean corrosion rates above such threshold value.

3.1 Inhibitor efficacy

For the repair, the treatment by corrosion inhibitors was selected as the corrosion level and rate (shown in Table 2) (5) was small enough for not having produced cover cracking or spalling except in few places of the stadium.

Figure 8. Delamination in the bottom of a column.

Figure 9. Leaking places underneath the bleachers.

Table 1. Results of the tests performed in the cores drilled from the columns.

	Column 96B	Column 85B	Column 75C	Column 67A	Column 52B	Column 44B	Column 30A	Column 26A
Compression strength (MPa)	19.0	-	23.7	-	14.9	-	20.1	-

Chloride conc at rebar level (%)	0.08	-	<0.08	-	<0.08	-	0.16	-
Corrosion Potential (E _{corr} - mV)	137	-755	3.4/71	-	45	187	-227	151
Resistivity (KOhm-cm)	670	0	769/454	-	835	912	155	387
Corrosion rate (I _{corr} - μA/cm ²)	0,04	0,08	0,03	0,01	0,04	0,04	0,003	0,30

Table 2. Levels of corrosion rates and condition of the bar (5).

Corrosion level	μA/cm ²	μm/year	Rebar condition
Negligible	< 0.1	< 1	Passive
Low	0.1 – 0.5	1 – 5	Depassivated, low humidity concrete
Moderate	0.5 – 1	5 – 10	Active corrosion, medium humidity
High	1 - 10	10-100	Large areas corroding in wet concrete
Very high	>10	>1000	Very corroded all around

To compare the several corrosion inhibitors available in the market, it was decided to make a pre-application trial. As soon as the trial zones were selected, the corrosion measurements were also made in each of the zones where the inhibitors will be applied. The previous level is shown in Figure 11. The letter F means the number given to the particular supplier. Five different inhibitors were applied. The color of each supplier indicates the level of corrosion prior the application.

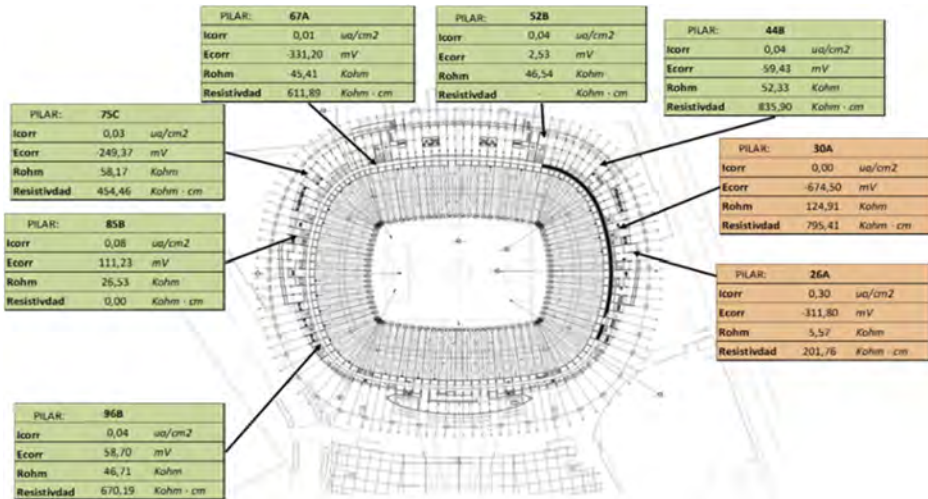

Figure 10. Values of the corrosion parameters measured in the columns in different zones of the stadium.

Element	ZONE				
	A	B	C	D	E
G3.1	F2	F1	F3	F5	F4
G3.2	F1	F2	F3	F4	F5
G3.3	F3	F4	F5	F1	F2
G3.4	F1	F2	F3	F4	F5
G2.1	F4	F5	F1	F2	F1
G2.1	F2	F3	F4	F5	F3

Legend

	not measured
	high corrosion
	moderate corrosion
	no corrosion

Figure 11. Levels of corrosion found in the trial sites before application of inhibitors.

The criteria for comparing the efficacy were based on the decrease of the corrosion rate and with less importance, as well the shift in the values of corrosion potential and electrical resistance in each of the zones treated. Table 3 shows the relative weight from 1 to 4 given.

Table 3. Criteria based on the corrosion rate for comparing efficacy of inhibitors.

Decrease of corrosion rates	1	2	3	4
Achieving values below $< 0,10 \mu\text{A}/\text{cm}^2$.	Any zone has achieved a lowering in the corrosion rate	Less than half of the points	More than half of the points	All points have achieved passivity

Figure 12 shows the weight achieved by each of the measurement points grouped by type of element. Figure 13 shows the results by inhibitor supplier (F1 to F5). From this Figure 13 it is possible to deduce that there was an element in which any of the inhibitors in that particular place were good enough, as the weight reached by them was very low. In the rest of places several inhibitors were effective.

With this technical information, and the cost of each inhibitor treatment, the designer of the repair technique selected the best option for the different zones of the stadium.

Figure 12. Relative weight by element treated.

Figure 13. Relative weight by type of inhibitor (1 is the worst and 4 the best efficacy).

4 DISCUSSION

There are numerous structures all around the world that are inspected because they are corroding due to the progressive aging and contamination of concrete. In these inspections, in spite corrosion is the main reason of the damage its level and rate is not measured. Just corrosion is noticed and reported but its level is not accounted for. This lack of quantification is an important goal for the correct link between the corrosion level of the bars and the loss in structural performance. It is essential that in naturally corroding elements the degree of corrosion is measured in order to have a database for the future improvements of the methods to assess corroding elements. For the measurement of the corrosion degree two main techniques are available: the direct measurement of the loss in bar cross section through a capiler and the electrochemical measurement of the corrosion rate with approprita corrosio-meters (3,6). The first gives the accumulated corrosion (P_{corr}) until the time of the inspection, while the electrochemical measurement informs on the instantaneous rate (I_{corr}) that needs to be integrated back from the moment that corrosion could have started. The extrapolation back is made using the carbonation depth (7) which informs on the time of initiation and then enables to know the number of years since when the corrosion started on the bar surface.

For the comparison of the efficacy of the inhibitors (the efficiency is taking into account the cost as well) a pre-application trial was performed because this repair method is not yet

well established and there were doubts on the time after application needed by the product to show its inhibitor effect and also on the long term duration of it. For that long term effect it was suggested to measure again after 5 years for the continuity verification of the inhibiting ability.

5 CONCLUSIONS

The main aim and conclusion of the work was to show the advantages for a quick and reliable assessment of the degree and rate of corrosion by using electrochemical techniques and direct visual inspection of the bar aspect.

This practice is seldom used in the numerous inspections made in the world in corroding structures where the corrosion is noticed but not accounted for and even less a link to the relative loss of structural performance.

A systematic recording of both corrosion loss (P_{corr}) and corrosion rate (I_{corr}) are needed for the statistical link between the material and the structural degradation.

Net-zero and lightweight steel technologies for the construction sector: Overview and case studies in Italy

M.M. Sesana

DICATAM Department, Fondazione Promozione Acciaio Commissione Sostenibilità, University of Brescia, Brescia, Italy

ABSTRACT: The construction industry is responsible for approximately 25% of global emissions, about a third of which are associated with the construction process, being a voracious steel consumer, accounting to 50% of global demand. Given these impacts, there is an urgent need for the construction steel chain to define a realistic decarbonization path. In this context, the paper focuses on a promising technology, the Light-weight Steel Frame (LSF), providing an overview coupled with real applications. LSF and drywall techniques have been shown around the world to result in cost-effective and sustainable buildings under different aspects: fast in construction, seismically resistant, high levels of thermal and acoustic performance, energy efficient, and aesthetic value. The publication also addresses a review of the latest regulations and methodologies for sustainability and carbon neutrality assessment, to clarify challenges and contributions that the steel company can provide to the construction sector in terms of sustainability and circularity.

1 INTRODUCTION

From houses to bridges, hospitals, and skyscrapers, the construction industry is responsible for approximately 37 percent of CO₂ global emissions, about a third of which are associated with the construction process, and for around 34% of total energy consumption (United Nations 2022). Therefore, the reduction of energy consumption and the use of energy from renewable sources in the building sector constitute important measures needed to reduce the European Union's energy dependency and to reach carbon neutrality by 2050, as defined in the European Green Deal, in 2019 (European Commission 2021a). To achieve this ambitious goal, it is urgent to drastically reduce harmful emissions in the construction sector, improve its efficiency and complete its circular transition, which is still struggling to become a consolidated and stable mechanism. For this change to take place, however, it must be conceived not only as an environmental or economic project but as a new cultural project for Europe, capable of triggering a real systemic change with its aesthetics, combining design and sustainability. Sustainable construction is a relatively new subject with which many of those involved in planning and construction are not familiar. It has been covered in numerous publications, but a limited number of them present specific measures for implementing sustainability in the steel building and construction industry.

Light Steel Frame (LSF) solutions are becoming increasingly popular in construction practice in response to the need to work on a heterogeneous and energy-intensive building stock and to meet the new demands of the construction market in a flexible, versatile, industrialized, and sustainable manner. Off-site industrialization, reduced construction time and costs, and aesthetic and performance quality are the strengths of cold-formed profile solutions for the building industry. These technologies provide flexible and aesthetically expressive constructions both from a morphological-architectural point of view and in terms of room adaptability, allowing the design of tailor-made solutions that meet people's needs. This publication aims to review the latest regulations and methodologies for sustainability and carbon neutrality assessment, to clarify

challenges, opportunities, and prominent contributions that the steel company can provide to the construction sector in terms of sustainability and circularity, thanks to lightweight steel technologies.

After the introduction in section one, the second section sets the scene by discussing the latest regulations and standards for the construction sector in Europe and also providing an overview of methods and tools to assess and evaluate sustainability in buildings. Section 3 presents the steel industry's reply to the European New Green Deal, with a focus on LSF solutions as a suitable construction technology to reach the current energy efficiency requirements and targets of the construction sector. Section 4 presents the results of applied research on case studies realized in LSF to verify the level of implementation into the practice of this technology, with a focus on an Italian residential case study. Finally, Section 5 provides conclusions and inputs for improvements and further works in order to complete the framework of challenges and opportunities of the steel construction industry to reach the carbon neutrality target and to realize sustainable buildings.

2 SUSTAINABILITY AND CARBON NEUTRALITY FOR CONSTRUCTION SECTOR

2.1 *Regulations and standards for certification and assessment*

Energy production and consumption significantly impact climate change due to their contribution to atmospheric emissions of CO₂ resulting from fossil fuels. Decarbonization and sustainability have been since decades the key points of the European regulation frameworks, in particular, the reduction of energy demand in buildings through the adoption of an energy efficiency policy is a key pillar of the European Union (EU) climate and energy strategy.

In the European Union (EU), energy production and use is responsible for 80% of all GHG emissions, accounting for about 40% of EU's final energy and 36% of CO₂ emissions, buildings are associated with a significant untapped energy saving potential due to outdated construction practices, use of inefficient systems or appliances and lack of effective technical control systems, even if there are already in the market various passive and active solutions that can limit this energy waste in buildings. (Camarasa et al. 2019).

In the EU, buildings have been an integral part of the EU energy and climate policy for several years. Energy efficiency policies for buildings can take the form of regulatory or control instruments, building codes, consumer information campaigns, and economic or financial incentives.

The "SAVE" Directive (93/76/EEC) of 1993 represents the first major EU policy on energy efficiency. The Directive required the Member States to draw up and implement programs to improve energy efficiency, with the aim to limit CO₂ emissions and to promote the rational use of energy. Since 2000 the Commission has published several Energy Efficiency Action Plans laying out its strategic vision and proposing actions such as new policies or strengthened existing measures. In 2006 the European Commission published its second Energy Efficiency Action Plan (Fawcett et al. 2019) with the scope to control and reduce energy demand and to take targeted action on consumption and supply with the intention to save 20% of the annual consumption of primary energy by 2020 compared to baseline energy consumption forecasts for 2020. This objective corresponded to achieving approximately a 1.5% saving per year up to 2020.

The first cohesive European legal act on energy policy in buildings was the Energy Performance of Buildings Directive (EPBD, 2002/91/EC) which introduced a joint energy performance calculation methodology for buildings. Since its adoption, the EPBD has been closely connected with the EU climate targets and has been aligned to reflect their progressive evolution. In this context, the core aim of the directive – to systematically enhance the energy performance of buildings and to increase the level of renovations – has remained unchanged since its introduction.

In 2009 the European Commission presented the recast of the EPBD (2010/31/EC, EPBD Recast) with the aim to strengthen some original EPBD provisions and capture additional energy savings and introduced for the first time the concept of nearly zero energy building (NZEB), defined as a building of very high energy performance, where the nearly zero or very low amount of energy required should be covered to a very significant extent by energy from renewable sources produced on-site or nearby.

Later, a targeted revision of the EPBD (2018/844/EU, EPBD) was launched as part of the clean energy for all Europeans package and adopted in 2018 (European Parliament 2018). This new

Directive came into force introducing targeted amendments to the previous EPBD version aimed at accelerating the cost-effective renovation of existing buildings, with the aim of a decarbonized building stock by cutting its net CO₂ emissions by at least 55% by 2030, compared to the 1990 levels, and to become climate neutral by 2050. To reach these goals, the EU then adopted a new strategic agenda for 2019-2024, including the European Green Deal (EGD), a package of strategic initiatives. The EGD is the environmental plan of the European Union divided into 116 points, in which all the Member States (MS) declare their commitment to undertake urgent and ambitious interventions to tackle climate change and environmental challenges to limit global warming to 1.5°C and further biodiversity losses. The main objective of this ambitious climate regulation is the achievement of the legally binding national target of achieving zero emissions by 2050, as well as the 2030 interim target of a 55% reduction in emissions compared to levels of 1990. The EGD is not limited to outlining environmental policy but rather uses environmental protection as a pretext to define and promote attention to a wide range of sectors: from transport to construction and from agriculture to industry (European Commission 2019b).

In this framework, the EU Commission launched in October 2020 the Renovation Wave initiative with the intention to double the European renovation rate of buildings by 2030 and to maintain it in the following years. This strategy highlights several points of intervention with a precise timeline to make existing buildings energy efficient by reducing the consumption of energy and resources, with the use of circular economy approaches, low environmental impact strategies to improve the quality of indoor environmental and air quality, and the buildings' comfort for end users and it can be summarized in the following four main priorities: (i) decarbonization of heating and cooling systems; (ii) tackling energy poverty and inefficiency; (iii) renovation of public buildings such as schools, hospitals and offices; (iv) application of holistic approach throughout the building lifecycle, from project design and financing to completion and subsequent maintenance.

The Renovation Wave strategy aims to reach the target of doubling up the renovation rate of the built environment by 2030, applying existing measures such as energy performance certificates, long-term strategies, financial incentives, and technological innovations but also introducing some new instruments, such as mandatory minimum energy performance standards and the development of a roadmap to 2050 to reduce carbon emissions throughout the buildings' life cycle. In December 2021, the Commission has proposed to align the rules for the energy performance of buildings with the European Green Deal and decarbonize the EU's building stock by 2050 (European Parliament 2021). To achieve this, it is necessary to promote a rapid energy conversion of the building stock, favoring deep renovations and transformation into "nearly zero energy buildings" (nZEB). In the same year, the EC launched, as part of the Green New Deal package, also the New European Bauhaus, to foster spaces for discussion and experimentation around the theme of physical spaces, a creative and interdisciplinary movement to rethink European cities, making them more functional and accessible to all. The program of the new European Bauhaus is divided into three phases: collective design, realization, and dissemination. The first design phase ended in June 2021 with the identification of the first five sites where the program has to be applied, representing the beginning of the second phase of realization. The aim is to make methods and solutions available to designers and the community that can be shared and replicated on a large scale. From January 2023, the third and final phase of Bauhaus will begin, in which space will be given to disseminating and sharing good practices to as wide an audience as possible, including outside Europe.

At the Italian level, the Italy Tomorrow Plan (Piano Nazionale di Ripresa e Resilienza - PNRR) approved in April 2021, foresees reforms and investments to be implemented in the span of the next five years in key sectors. The plan is developed around three strategic axes shared at the European level: digitalization and innovation, ecological transition, and social inclusion, and is divided into 16 components, grouped into 6 missions. Relevance has been set for the construction sector in Component 3 (Energy Efficiency and Renovation of Buildings) of Mission 2 (Green Revolution and Ecological Transition) with which energy efficiency can be strengthened by increasing the efficiency of buildings, which suffers from a building stock more than 60% of which is over 45 years old, both in public and private Italian buildings. The measures included in the PNRR aim to provide a boost to the economy and employment and to promote social resilience by improving comfort, energy saving, and seismic risk prevention of buildings (Sesana 2022a).

2.2 Methodologies and tools framework

Besides the regulations, also the tools for the analysis of the sustainability levels of buildings play a fundamental role in their application, as it required particular care to align them. An overview of such instruments is presented in this section, to better understand the methodologies currently in use and the new initiatives with high potential to support the carbon neutrality goal.

The implementation of the regulations outlined in the previous section, especially in relation to buildings, led to the need to define energy-environmental assessment and certification systems as an essential method to improve energy efficiency, minimize energy consumption and enable greater transparency regarding energy use. To provide a complete overview of such methodologies and tools, this subsection focuses on compulsory tools, as required by current regulations, and those that are voluntary or in the process of being defined, for sustainable nZEB design with practical indications and recent updates for their use.

Over the years, the EPBD has employed a diverse set of policy tools, but the most well-known mandatory one for buildings is the energy performance certificate (EPC). The EPC was introduced at the European level by Directive 2010/31/EU and the recent EPBD 2018/844 strengthened the certification system for existing buildings with the inclusion of a mandatory recommendations report listing improvement measures and their priorities (European Parliament 2010).

The Italian version of the EPC, the so-called *Attestato di Prestazione Energetica* (APE), is considered mainly as an informative document that certifies the energy performance of a building using a rating scale from A4 to G, which provides general recommendations for energy efficiency improvements. If properly drafted, the APE certification could become a powerful market tool for creating demand for energy efficiency in buildings by providing recommendations for cost-effective, time- and cost-optimized improvements (Sesana 2022a).

Complementary to the EPC and structured according to a long-term renovation roadmap outlining intervention measures for the improvement of energy performance based on quality criteria, the Building Renovation Passport (BRP) was introduced for the first time in the revision of Directive 2018/844/EU (Toth et al 2022). The purpose of this tool was then detailed in the Renovation Wave strategy, as a support tool for owners and investors to better understand and plan interventions, providing a clear roadmap for gradual renovation over the lifetime of a building. According to this, the Building Passport can be described as a repository of relevant building-related information covering the physicality, management, financing, valuation and ownership of buildings with the structure defined by two key elements: a data archive part, usually called a logbook, and a renovation roadmap for identifying the actions to be implemented for a deep renovation in terms of time, cost and building technologies to be used.

Alongside experiences with building passports, there have also been initiatives related to establishing digital passports for single material or products in general (Digital Product Passport, DPP). The implementation of such tool could facilitate tracking and tracing materials and compiling information in one unique database. It is supposed to deliver information on the origin, composition, repair, and dismantling options of a product, as well as on its handling at the end of its service life. However, there are several open questions regarding the DPP's final design and its implementation. For instance, any future DPP information requirements should be ideally designed in a way that manufacturers, which are the most important source of product information, and other stakeholders perceive them as an advantage and not as an additional burden, to create business models and intrinsic motivation. Therefore, implementation options for digital product passports need to be evaluated to allow a circular flow of materials through the active engagement of all the actors involved (Sesana 2022a).

An important contribution to the issue of tools and methodologies for construction in the field of efficiency and sustainability has been made by the voluntary environmental assessment and certification developed worldwide over the past twenty years with different approaches: some with prerequisites to gain optional credits in relation to the specific context, others with prescriptive approach or performance-based requirements according to building types. As a result, it can be difficult and time-consuming in terms of time and quality to determine which standards, certifications, and assessment programs are most reliable and applicable to a particular building being various per building types or goals' project. For this reason, the EC within the EGD initiative

launched a common framework for assessing the sustainability performance of buildings: Level(S) (European Commission 2019), with the aim to create a common approach based on the integration of current certification tools with a whole life cycle approach. This system relies on existing standards and circularity principles using a limited number of indicators to measure the effects of carbon, materials, water, health, and comfort. Although Level(s) is not a certification scheme, its simple structure aims to facilitate existing schemes to use the same language and facilitate assessment methods and data comparison between projects (Ferrari et al 2022).

3 THE STEEL INDUSTRY REPLIES TO THE EUROPEAN NEW GREEN DEAL

Steel is one of the most important engineering and construction materials. However, the industry now needs to cope with the pressure to reduce its carbon footprint from both environmental and economic perspectives. Currently, the steel industry is among the three biggest producers of carbon dioxide, with emissions being produced by a limited number of locations; steel plants are therefore a good candidate for decarbonization.

For this reason, the European steel industry has set itself the main goal of investing in research and development to rethink its production processes and achieve substantial reductions in emissions to remain competitive and contribute to the achievement of carbon neutrality by 2050.

Steel is a sustainable material, and in some cases, the most sustainable choice, since it is a circular material, being reusable and recyclable repeatedly and allowing a long service life.

In response to the EGD, the more feasible option for the steel sector is to move to a much more circular system by 2050, replacing 30 Mt of the current 92 Mt of primary steel production with secondary production and reducing emissions by 57 Mt CO₂ per year by mid-century to meet the targets (EUROFER 2021).

Conceiving steel management as much as possible from a perspective of sustainability and circularity means intervening in the process of production, use, and end-of-life of this material whose properties allow theoretically infinite recycling. However, given this characteristic, a complementary path to increase the level of sustainability of the material is to optimize its use, minimize processing waste, or facilitate the recovery of components to be sent for recycling. It is necessary to rethink on one hand the technologies in use in Europe to produce steel, but at the same time also to encourage the use of scrap, instead of producing a virgin product, with a circular approach. It follows, however, that the efforts required to implement these changes must be supported by all sectors that use steel either as a base material or as a component of other products. The annual volumes recorded in 2019 of the steel demand are distributed percentage-wise between construction and infrastructure (42% of demand), followed by the transportation sector (31%), machinery (16%), and finally a range of other steel products (11%).

Although recycling steel for production not from virgin material is advantageous, particularly in terms of preserving materials and reducing the extraction of raw materials, there is another lower-impact option that is gaining popularity not only in research but also in practice: the reuse of the steel materials and components themselves. From this perspective, the built environment can thus be seen as a veritable bank of materials including the stored energy and carbon emissions in building materials, components, and structures. Their targeted separation and recovery during demolition can avoid the passage of more than 70% of materials from landfills in addition to contributing to the circular economy goals should such materials, components, or structures be reused in new construction. Compared to other recycling options, therefore, it offers additional environmental and economic benefits but often requires higher initial investment costs. Recent research conducted on the technical feasibility of this type of reuse in both quantitative and qualitative terms has confirmed the possibility of achieving the goals that the steel industry has set for itself but has also identified the barriers that currently limit the spread of this practice.

In the case of steel-based structural steelwork and building components, reuse avoids the negative impacts associated with scrap recycling in steel production. Avoided scrap can come from individual fabricated components or entire steel assemblies or steel parts separated by composite elements (McKinsey Global Institute 2022). The market for recycled steel building products is still small because the effort associated with their reconditioning and CE marking often makes the process more expensive than recycling the materials. In addition, reusing

individual structural steel components is more difficult because they are generally optimized and manufactured for a specific building project. Therefore, most successful reuse projects are whole building relocations, repairs and renovations or extensions of steel structures, or on-site reuse. The overall benefit of building steel reuse depends on the widespread adoption of this approach in design and construction practices by all stakeholders in the building process. Designers should understand how to incorporate reclaimed materials into new design applications and how to optimize their designs for deconstruction and reuse, while manufacturers should consider reclaimed steelwork as a possible source of materials. Of course, there are also some technical challenges associated with this issue that would require the integrated design to avoid increased deconstruction costs and time.

3.1 *Light steel frame solutions*

The importance of steel in the building construction industry derives from the combination of lightness and loadbearing capacity but also from factors like prefabrication, fast construction time, and 'dry' building site. These aspects, in addition to their lightness and performance, make steel a sustainable building material with great potential for the future. In the last 20 years, Light Steel Frame used as a structural material have become a widely used solution for residential and industrial buildings, especially due to the main advantages that offer in comparison with traditional building materials (Martins et al 2013). The lightness of the system implies the use of less material, facilitates the transportation phase to the construction site, and offers benefits in terms of time construction phase by offering preassembled solutions and demonstrating their great potentialities in terms of circularity. All the main advantages that the technology offers, make LSF the main competitor for traditional structural construction systems (Abou Hamad et al 2019).

In Italy, prefabrication and dry construction are a long tradition in commercial, industrial and public construction, but have been less frequently applied to residential construction, however, recently the benefits of this building technique have opened many interesting opportunities for application in residential buildings. The dry construction system is based on the prefabrication and mechanical assembly of several functional layers made up of elements that are supplied to the worksite certified and ready to be assembled on a light and resistant framework made of steel, wood, and reinforced concrete. In the past, the idea of prefabrication was associated with a limited catalog of building components to combine to form a complete building, characterized by modular rigidity. This aspect was thus seen as a limitation to customization and design creativity and as the reason for the simplicity and seriality of low architectural and technological quality buildings.

Nowadays prefabrication foresees elements manufactured with the precision of industrial production for beams, pillars, uprights, cross-pieces, walls, floors, roofs, unique works or works that can be repeated on a large scale and the architecture/industry nexus, which felt impossible for a long time, has found a real possibility for development. Moreover, the LFS can provide a high level of adaptability to different architectural solutions; high energy and acoustic performance and safety in case of earthquake and fire; industrialization of the system, and the lightness of dry solutions combined with the great durability of steel constructions.

In literature, the LSF is defined as a construction system based on structures composed of cold-formed steel elements, produced by cold-forming or press-bending thin steel sheets (Lawson 1999). The intrinsic characteristics of the construction system, make it competitive compared to traditional systems, this is because the LSF represents a clear point of contact between construction and industry, through the standardization of products, processes, and design. the purely industrial approach of this construction system has proven effective in terms of economic advantages and sustainable performance: compared to traditional construction techniques, the most obvious advantage of LSF is the lightness of the system.

It is estimated that the weight of an LSF building can weigh up to ten times less than a building made with traditional techniques. The physical properties of cold-formed steel make it an exceptionally sustainable material: resilient, durable, and adaptable, steel allows it to operate in a wide range of buildings and environments. For example, its ductility, strength, and lightweight make it a suitable material for construction in windy and seismic locations. The ability to treat steel

against corrosion phenomena, for example with zinc coating, provides the material with durability properties that exceed even one hundred years. Steel also does not emit volatile organic compounds and is 100% recyclable, a feature that significantly reduces life cycle costs.

The advantages of the LSF system are not limited to the peculiarities of the production technique and the material; but benefits vary depending on the project site, the complexity of the work, and the quality of the result. In recent years there has been a progressive increase in the number of catalog solutions offered by companies producing cold-formed profiles, and their diffusion is increasing not only for new constructions but also for renovations (Sesana 2022b).

4 AN ITALIAN RESIDENTIAL CASE STUDY WITH LIGHT STEEL FRAME SYSTEM

A study was conducted in 2021, in collaboration with Fondazione Promozione Acciaio (FPA), Italian promotion and communication entity of steel in construction, on a selection of recent mostly residential case studies, mainly located in Italy and some outside the European Union, meeting the above-mentioned regulations and methodologies with LSF solutions.

In this section, one case study in Italy, as representative of the study, is presented as a proof of concept of the LSF feasibility construction and to underline its potentialities in terms of efficiency and sustainability for buildings.

Figure 1. Graphical summary of the main data of the residential case study realized in LSF in Italy.

Slash House is the name of the high-energy-efficient residential building realized in 2019 in Godiasco Salice Terme (PV).

The main data about the location, the climatic context, the year of construction, and geometry are summarized in the first line of the graphical summary (Figure 1), while in the second row, there are represented both the envelope performance in terms of thermal transmittance for wall, roof, and window and the main KPIs for energy (Primary energy and Renewable energy produced on-site). The load-bearing structure is separate from the curtain wall structure: thus the insulating capacity of the walls, curtain wall, and windows and doors was optimized. For the walls, a drywall construction system constituted by C profiles in LSF was used with an outer cladding of reinforced concrete slabs and an inner cladding of gypsum plasterboards. The high-performance envelope is completed with the installation of triple-glazed windows, including the curtain wall, with Argon gas in the double-glazing units and selective low-emissivity treatment. Strategies for optimizing envelope performance include flat roofs with hanging greenery that provide excellent performance in both summer and winter due to the inertia provided by the soil.

In order to achieve nearly zero energy consumption, the system plant foresees efficient summer-winter air conditioning, both in the generation and distribution of heating or cooling fluid, supplemented by mechanical ventilation with heat recovery.

The air-conditioning system is an air-to-air heat pump with internal splits, supplemented by a controlled mechanical ventilation system with total heat recovery and all of the house and system is managed by automatic control.

The house is not connected to the gas grid; electricity is produced by the photovoltaic system composed by 24 modules of about 6 kW, integrated in the roof.

The house, with a total non-renewable primary energy requirement of 44.85 kWh/m² per year, reached an energy performance class of A4 and reach its target of nearly-zero energy building covering the overall energy demand with the renewable energy produced on-site.

5 CONCLUSIONS

The paper presents an overview of the major role of the steel construction sector in making sustainable and efficient buildings for the future and reducing the environmental impact of the construction sector in order to achieve the European goal of climate neutrality by 2050.

From the analysis of the presented work, it emerged that despite the effort of the steel industry to adapt their products and building systems to the European goal of carbon neutrality, there is an urgent to identify: (i) the most suitable methodology to design net-zero energy buildings; (ii) commons tools to manage, share and calculate data in a digitalized way; (iii) a common data framework to evaluate the energy performance of the building using the LCA methods.

The LSF solutions implemented in the case study represent a valuable solution to reach the NEB goals thanks to the described potentialities and advantages in comparison with traditional solutions. The LSF systems in fact offer more flexibility compared, for example, to concrete and brick walls and are, therefore, less sensitive to dynamic stress and it is also suited to earthquake-proof designs. The “dry” and “light” aspects, therefore, seem to address all the requirements of modern living, from design to comfort, taking their place in the environment with a light footprint.

Life-cycle assessment of light steel frame buildings: A systematic literature review

G. Marrone & M. Imperadori

Architecture, Built Environment and Construction Engineering Department, Politecnico di Milano, Milan, Italy

M.M. Sesana

DICATAM Department, University of Brescia, Brescia, Italy

ABSTRACT: Light Steel Frame structures (LSF) have become one of the main competitors of traditional construction systems. The optimized material use, its lightness, and the timesaving in the construction phase, show the potential of this technology to reduce environmental impacts. The purpose of this study is to review and analyse the current literature on the application of the Life Cycle Assessment (LCA) methodology to LSF buildings and identify related gaps. A systematic literature review has been performed to query Web of Science and Scopus databases, highlighting methods, limitations, trends, and tools used to address LCA applied to LSF buildings. Although many efforts have been made to evaluate LSF buildings in comparison with other construction solutions, a gap persists in performing whole LCA. Considering the potential disassembly and reuse offered by LSF and the recyclability of steel, there is a need for future research focusing beyond the end-of-life stage.

1 INTRODUCTION

Climate breakdown, resource scarcity, ecological collapse, as well as economic uncertainties make the next years crucial to shape the conversion to a carbon-neutral construction sector. Considering the increasing number of net-zero energy buildings and the consequent optimization of the operational energy emissions, within the next years, the building's embodied energy is likely to become fundamental towards the accomplishment of sustainability goals (Gervásio *et al.* 2010).

The European Green Deal (European Commission 2020) aims to eliminate greenhouse gas emissions through the introduction of circular economy principles in energy-intensive industries (i.e. steel, cement) enhancing the secondary use of materials, components and products (European Commission 2014). In this context, the steel industry plays an important role, since the largest amount of steel produced worldwide is used in construction, material efficiency is necessary. In reducing embodied energy, weight plays an important role (Mateus *et al.* 2013). Therefore, new lightweight building systems such as Light Steel Frame (LSF) have emerged as a promising solution for low-rise buildings.

In the last 20 years, there has been growing interest in LSF both for residential and industrial applications due to the main advantages offered compared to traditional construction techniques (Grubb *et al.* 1999, Abouhamad and Abu-Hamd 2019). LSF is an offsite construction system which relies on the optimization of the shape in favour of the lightness, thus facilitating the transportation and construction phases. Furthermore, the possibility to preassemble the profiles in panels and volumes offers construction time benefits. Moreover, as a dry construction system, it also has a great potential for circularity and recyclability.

Even though there is a general understanding of the cause-and-effect link between a building's environmental performance and its energy needs, the same link is not immediate for embodied

energy. Hence, is necessary to provide benchmarking values also for the embodied energy (Gervasio *et al.* 2018). In recent years, many researchers have focused on building performance calculation within a life-cycle perspective, investigating and comparing different types of buildings, construction materials, and techniques. Life Cycle Assessment (LCA) is a quantitative approach to measure and analyse products and processes' environmental impacts. According to ISO 14040/44:2006, the LCA methodology usually consists of four main steps: (i) goal and scope definition, (ii) life cycle inventory (LCI), (iii) life cycle impact assessment (LCIA), (iv) interpretation of results. EN15978 regulates the application of LCA in construction works considering environmental, economic, and social aspects of sustainability.

Besides some review articles have been published concerning LCA applied to LSF buildings, they usually followed the traditional review approach. Therefore, a shared and recognized methodology to perform the review is needed. Considering the growing reputation of offsite construction systems and particularly LSF both in the scientific community and in the construction market as a reliable system in terms of environmental impacts and sustainability assessment (Smith and Quale 2017, Buzatu *et al.* 2020, Tavares, Soares, *et al.* 2021, Thirunavukkarasu *et al.* 2021) the purpose of this work is to give an overview and interpretation of the existent literature.

Through a systematic literature review, the studies on LCA methodology applied to LSF buildings are investigated, understanding methods, highlighting limitations, tools, and trends, thereby enabling practitioners and researchers to gain knowledge on the already researched areas and identifying existent literature gaps. The paper is organized as follows: the second section presents the research questions and the process followed for the systematic literature review. The third section introduces the review of the selected works, highlighting the methodological choices in performing LCA. The paper concludes with a discussion of the main findings in the fourth section, identifying literature gaps and suggesting future research directions.

2 METHODOLOGY

This study contributes to the existing literature by synthesising previous scientific works about the application of LCA methodology to LSF buildings through a systematic literature review. Xiao and Watson (2019) recognise the need to perform a systematic literature review to find the current state and gaps of the topic through the breadth and deep analysis of the existing high-quality literature. In this paper, the systematic review follows the methodology found in the literature, which consists of four main steps: the definition of the scope and research questions, the definition of inclusion and exclusion criteria and a synthesis of the findings.

Once the scope of the work has been defined, the authors designed three research questions: 'What are the methodological choices made to perform an LCA of LSF buildings?' and 'What is the environmental performance of LSF buildings?', 'What promising opportunities for future research can be identified?'. To answer the research questions, the authors queried two frequently used databases – Scopus and Web of Science. To gather and analyze a significant and high-quality sample of papers, different spelling (i.e. cold-formed" OR "coldformed" OR "cold formed") and different terms (i.e. cold formed, light steel frame, light gauge) have been used. The search string and the inclusion and exclusion criteria are shown in Table 1.

Table 1. Construction of the search string and criteria used for the articles' selection.

Search string	Inclusion criteria	Exclusion criteria
<ul style="list-style-type: none"> – Keywords: ("cold-formed" OR "cold-formed" OR "cold formed" OR "light steel" OR "LSF" OR "light gauge") – AND ("Life cycle" OR "LCA" OR "Environmental impact") – Search in: title, abstract, keywords – Document type: articles and review articles (Peer-reviewed) 	<ul style="list-style-type: none"> – Articles/review articles investigating the building sector – Articles/review articles investigating environmental LCA of LSF buildings 	<ul style="list-style-type: none"> – Full text not available – Articles not published in peer-reviewed journals – Articles not written in English

The databases' query was executed on 18 December 2022. The literature identification process retrieved 49 articles from SCOPUS and 42 articles from Web of Science, a total of 91 articles. After removing 34 duplicate articles, 57 articles remained for the abstract screening phase.

Through the abstract reading, the relevance of each article within the search objectives has been evaluated with the inclusion and exclusion criteria. Accordingly, 28 articles were out of scope and related to other disciplines (i.e. metallurgy, chemistry, structural engineering) thus leaving 31 articles for full-text analysis. Once the full-text reading has been completed, the criteria have been applied again: 3 articles were not readable, while 10 articles were investigating LSF buildings but environmental LCA. Since the 10 articles don't meet the criteria, they were not included in the deep review. The remaining 18 articles were analysed to identify the methodological choices made in performing LCA on LSF buildings, considering the first three phases of LCA according to ISO 14040/44:2006. A schematization of the methodology used to narrow down the number of articles from 91 to the final sample of the 18 deeply reviewed papers is presented in Figure 1.

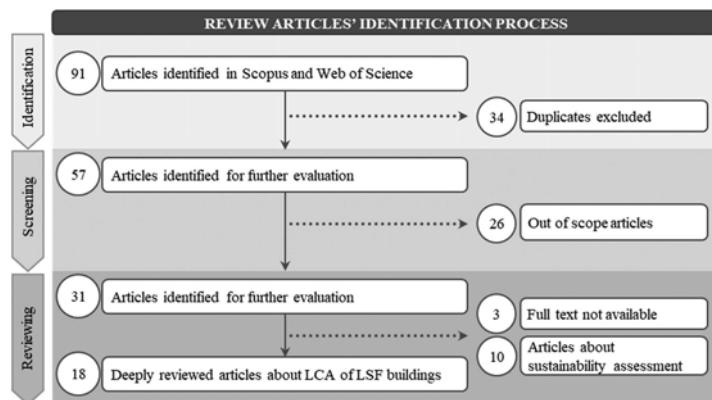

Figure 1. Flow chart for the identification of the reviewed articles according to inclusion/exclusion criteria.

The papers have been analysed to identify methodological choices in performing LCA on LSF buildings to enable researchers and practitioners to gain insights into previously researched areas and identify research gaps. The data have been collected in a comprehensive table divided according to the first three steps of the LCA.

3 LIFE CYCLE ASSESSMENT OF LIGHT STEEL FRAME BUILDINGS

With the rapid growth of LCA studies in the building sector, also review papers have been published to summarize the progress. Although, the review articles published concerning LCA applied to LSF buildings follow a traditional reviewing approach. In this section, the results of the systematic literature review of the 28 identified articles are presented to address the search objectives. Among the 28 reviewed articles, 18 works are related to the application of environmental LCA to LSF buildings; the remaining articles are not concerning the specific topic, although they are considered relevant for the reviewed literature body. Within these 10 works identified, Soares et al. (2017) published a traditional literature review highlighting key advantages and drawbacks of LSF in terms of energy efficiency and thermal performance. Many studies focused on Life Cycle Energy Assessment, Gervásio et al. (2010) published a parametric study on different insulation levels of a residential LSF building, confronting operational and embodied energy. The study highlighted that in 16 years the operational energy can overcome the embodied one. On the same page, Santos et al. (2014), focused on the LSF operational energy by optimization of thermal bridges and improvement of thermal inertia, thus addressing "life-cycle design". Other works focused on the calculation of Life Cycle Cost or the adoption of multidimensional methods, acting on the life cycle's risks (Zeynalian et al. 2013, Çelik and Kamali 2018, Abouhamad and Abu-Hamd 2019, Sen et al. 2021, Noorzai et al. 2022). Also considering the structural performances, Lu (2016) and Usefi et al. (2021) addressed the sustainability assessment of LSF.

Considering the 18 articles related to the application of LCA to LSF buildings, the analysis follows the first three main steps of the methodology suggested by ISO 14040/44:2006. The main methodological choices described in the reviewed papers in performing LCA have been synthesized in Table 2. First, the goal and scope definition is presented, highlighting the type of building, the type of study performed, the lifespan, the geographical location, the functional equivalent/unit and the system boundaries. Then, the tools and databases used to create the inventory of input and output flows (LCI) have been highlighted: we found that there isn't a harmonized inventory data collection methodology. Lastly, the choices about the environmental impact assessment (LCIA) are reported. According to this structure, the results are presented in the following paragraph.

3.1 Goal and scope definition in the reviewed literature

Within the body of reviewed literature, two types of studies have been identified (i) a baseline study (non-comparative) used to assess individual project performances, (ii) a comparative study to compare the environmental performances of different construction systems. On one hand, some methodological choices are shared across the literature, but many others are different and need to be deepened. There is a general agreement on the selection of 50 years lifespan of the building, only one study proposes 90 years. Among the 18 works, the residential building is the most investigated. Considering the building locations, many areas of the world have been covered. Some studies addressed the buildings' environmental impacts in different scenarios and locations (Tavares *et al.* 2019, Tavares, Gregory, *et al.* 2021).

In performing LCA, the definition of the life cycle stages included in the system boundaries is fundamental and can affect the results. According to EN15978, the life cycle stages are: (i) product stage (A1-A3), which includes the provision of materials, products and energy; (ii) construction (A4-A5), which includes transport to the building site and installation; (iii) use (B1-B7) includes also maintenance, repair, replacement, refurbishment and operational energy and water use; (iv) end-of-life (EoL)(C1-C4), includes deconstruction/demolition, transport to waste processing and disposal; (v) benefits and loads beyond the system boundaries (D), this module allows to take into account the net impacts and benefits of reuse, recovery or recycling after demolition.

Considering the non-comparative approach, both a whole case study building and a single component have been analysed. Both Tuca *et al.* (2012) and Zygomalas and Baniotopoulos (2014) focused on a whole building, one calculating the impact of the maintenance process and the other highlighting the type of environmental impact caused by LSF, which mainly affects natural resources and human health. In the last years, Liu *et al.* (2022) addressed a new demountable and modular LSF wall, highlighting the environmental impact advantages of a reusable module. Highlighting the benefits associated with recycling and reuse, Abouhamad and Abu-Hamd (2020) included in the analysis also the module D, finding that Global Warming Potential (GWP) is reduced by 15.4% while the embodied primary energy is reduced by 6.22%, accordingly, the environmental impacts of LSF are considerably lower than conventional construction systems. Using the same case study building, Abouhamad and Abu-Hamd (2021) proposed a new framework to facilitate the decision-making process in selecting sustainable design alternatives.

Recycled steel is used in the production of new steel thus, the relevance of module D in steel buildings is confirmed by many comparative studies. Vitale *et al.* (2018) calculated that LSF has a better environmental performance than reinforced concrete and brick wall buildings, considering the profiles' recovery the performance can increase up to 24%. On the same page, Dani *et al.* (2022) published a comparative study in New Zealand between LSF and timber frame buildings. Using a cradle-to-cradle approach, the authors showed that when module D is considered, LSF has lower emissions: the difference is 1.69 kg CO₂ eq/m²/year.

Many comparative studies showed the environmental advantages of timber frames in different applications and locations when module D is excluded (Gong *et al.* 2012, Rodrigues and Freire 2014, Crafford *et al.* 2017, Li *et al.* 2021). Broadly speaking, the literature agrees on the better environmental performance of LSF among traditional construction systems. For example, some studies highlighted the environmental advantages of LSF when compared to masonry buildings (Iuorio *et al.* 2019, Bianchi *et al.* 2021, de Oliveira Rezende *et al.* 2022).

Table 2. Analysis and synthesis of the reviewed literature.

Also, the comparison between hot-rolled steel and LSF in a portal frame of industrial buildings performed by Johnston et al. (2018) highlighted the better economic and environmental performances of LSF, which allows 33% of steel savings.

Besides the comparison with different construction materials, the potential of LSF as a prefabricated construction system has been addressed by Tavares, Soares, et al. (2021): prefabricated construction has a lower environmental impact (except for abiotic depletion for LSF) compared to conventional construction systems. The comparative studies analysed, in summary, show that LSF represents a good alternative to traditional construction systems.

3.2 *Life cycle inventory in the reviewed literature*

The uncertainty of LCA results occurs also when the inventory phase is performed because of the missing foreground data. Addressing the LCI phase, it must be highlighted the complexity of the data collection of the material flows through the system boundaries. Most of the studies gathered data with the help of well-known databases, such as EcoInvent or databases already included in the LCA tools used to perform the analysis. In some contributions also Environmental Product Declarations (EPDs) have been used as a data source.

Many studies contributed to the LCA literature through primary data collection directly from manufacturers. In performing an LCA, different calculation tools are used to address the environmental impacts. From the literature, it can be observed that in the first publications, the main tool used is SimaPro while in the last years, the increasing sensitivity on the topic allowed the spread of new simplified tools specialized in building applications, often connected with BIM instruments.

3.3 *Life cycle impact assessment in the reviewed literature*

In all the studies analysed, the environmental impacts calculated and considered are different. Among others, the entire body of reviewed literature focused on the calculation of the GWP. Although, as many parametric studies highlighted, when performing an LCA it is appropriate to give a complete overview of the performances in all the impact categories, especially in comparative studies. Highlighting a better or worst performance between different materials considering only one specific environmental impact category can lead to misleading conclusions.

4 CONCLUSIONS

This systematic literature review has provided an overview of the key methodological choices made by researchers in performing environmental LCA on LSF buildings. In this section, some observations on the reviewed literature are made and research gaps are identified, thus providing guidelines for future research that can contribute to the progress of the scientific debate on the topic. The following propositions mirror the main conclusions of our analysis:

- The review has shown that there is a lot of effort invested in comparative studies. Although, they are not performed considering the same boundary conditions (i.e. different building layouts). In some cases, critical information in goal and scope definition is completely absent;
- The results obtained by different studies are not comparable because they have been conducted with different methodologies, also considering the location. Concerning this, there is a need to develop georeferenced and structured data related to the specific construction system;
- The calculations may vary significantly depending on the data collection, geographical location, scope, and methodology used. These items should not be used to compare results between buildings out of the same scope;
- The comparative studies aim to demonstrate the better environmental performance of a construction technology compared to another. In doing so, some fundamental features of LSF such as recyclability and durability are often not considered;
- In comparative studies, different assets of the system boundaries lead to different results. According to the potential recyclability, further developments are needed to assess the LCA of LSF buildings with a cradle-to-cradle approach which also considers module

- D. The potential recyclability of structural elements is fundamental in net-zero buildings since they contain up to 60% of the total embodied energy (Berggren *et al.* 2013). Therefore, the cradle-to-gate analysis should be revised considering also the new European policies on the minimum recycled content;
- Further experimental studies with realistic data and coherent methods are needed to implement and develop reliable and georeferenced benchmarking in different scenarios.

Considering the above, generical statements about the use of specific materials based on not harmonized methodologies and not related to a specific scenario should be revised. Nonetheless, the construction market, asks the scientific community for guidance and comparisons between different construction materials using the right KPIs. In response to this need, the authors are investigating an embryonic project (ARCADIA - ENEA) developed at the Italian level on some material supply chains focused also on the construction of a materials database. In conclusion, the authors want to turn the reader's attention to three main future research directions, LSF durability, its potential use in recladding applications and the need to perform the whole LCA.

Steel durability is rarely considered in comparative studies, especially when steel is compared to wood. In this regard, the authors consider it fundamental to deepen the LCA of LSF through the exploration of different end-of-life scenarios considering that the lifespan of steel is higher than the building's one. The matrix of the scenarios should be recalibrated with meticulous work of sensitivity analysis.

According to the authors' experience, future research in the application of LCA to LSF buildings can be done considering the potential application in buildings' recladding. The authors believe that the application in this context could highlight the LSF benefits among other solutions. Lastly, few studies addressed the potential of LSF also in terms of economic sustainability. Given the advantages of this construction technology, further research is suggested in developing multicriterial methods to perform a whole LCA of LSF, addressing all the various aspects of sustainability.

ABSTRACT: To date, most of the efforts to reduce the environmental impact of the construction sector were mainly focused on operational carbon. However, due to the decarbonization of the energy sector, embodied carbon has been recognized as the dominant climate impact driver. In response, countries are currently accelerating their efforts to comply with climate change commitments and regulations, pressure grows for the construction sector to reduce its impact rapidly. Life-cycle assessment (LCA) of buildings is an important tool in this process. Building LCA is a science-based methodology for quantifying the lifetime environmental impacts of buildings. It is used to measure and reduce the embodied, operational, and whole-life carbon of buildings. This paper presents the comparative results of a building LCA of a structure in Luxembourg. The work presented here compares three structural systems: a steel frame, a prefabricated reinforced concrete frame, and a timber frame.

1 INTRODUCTION

The building and construction sector is responsible for around 40% of global carbon emissions and if improvement is not made in short term this impact will probably double in the next 20 years (Khan S.A, 2022). Sustainability of the built environment and the need to stem the climate crisis are topics that have gained great popularity thanks to many public awareness actions. In response to this grow of attention, several countries have aligned their policy to meet the goals of the Paris agreement, encouraging and supporting environmental policies at various levels. Recently, the European Green Deal set a goal to achieve zero net emission by 2050, a key sector is the building construction and renovation. This sector has become more efficient in terms of energy consumption, but a lot is still needed for reducing overall emissions. Some European countries have introduced policies to reduce whole-life carbon emissions from buildings and construction. While a common EU policy on whole-life carbon is still in the making, Denmark, the Netherlands, and France have introduced CO_{2eq} limits for a large share of new buildings, while Finland and Sweden have plans to do so. Germany, the UK, and Switzerland have life cycle assessment requirements for certain public buildings; Belgium is planning similar requirements.

In a building, part of emissions is coming from the so-called “embodied carbon”, associated with materials and all the construction process during the whole life cycle. The carbon emission of a building can be grouped in different stage of its lifetime, from the material extraction until the end of life (EOL), considering the material processing and component manufacturing, the construction and assembly, the operation and service, and all the emission related to transport (i.e., from manufacturing to site). Given the need to rapidly decarbonise the energy

supply chain, embodied carbon will soon be the main source of emissions in the built environment, and for this reason, the topic is attracting considerable attention.

Reducing the carbon embedded in a structure involves evaluating each design choice using a whole life-cycle approach and seeking to minimize upfront carbon impacts (e.g., low carbon materials), as well as taking steps to avoid future embodied carbon during the end of life (e.g., circularity). Low carbon solutions do not only rely on selecting low embodied carbon materials, but also on an efficient structural design where engineers and architects play an important role.

To assess the carbon emissions of a building, a procedure called LCA (Life Cycle Assessment), is generally used. This procedure is a science-based and standardized (AEN/CTN 198, ISO 14044) methodology for quantifying and reporting on environmental impacts. It can be used to give insights on how to reduce the carbon emissions of buildings over their life cycle: before the use of the building, during the use of the building and the EOL of the building. Even if an LCA can be performed at any stage of the design processes, LCA performed at the earliest possible can maximise the optimization of the solution (Hauke B., 2016). Emissions from materials and products must be addressed by LCAs to ensure that the buildings designed and built today are optimized for minimizing emission over lifetime. This involves evaluating each design choice using a whole life-cycle approach seeking to minimize upfront carbon impacts (e.g., efficient design, low carbon materials), as well as taking steps to avoid future embodied carbon during the end- of-life. Low carbon solutions do not only rely on selecting low embodied carbon products and materials, but also on an efficient structural design where engineers and architects play an important role. A proper and optimized design positively influences the overall sustainability of the project, for example, reducing the material quantity by selecting a proper structural grid and using high strength materials can have a significant impact on global emissions. There are additional choices that can further improve a building's carbon footprint like the reuse of existing elements and low carbon materials.

1.1 *Life Cycle Assessment (LCA)*

LCA is a scientific and quantitative method for determining and assessing environmentally relevant processes. It was first developed for assessing products, but it is also used today to assess industrial processes, services, behavioural patterns, and complete buildings. Buildings have different life-cycle stages such as: product, construction, use, end-of-life, and benefits beyond the system boundary. These stages correspond to specific standardized modules (from A1 to D). The LCA procedure is defined by the ISO norm 14,040 series (ISO 2006a; ISO 2006b) and the steps to follow are: goal and scope definition, life cycle inventory analysis (LCI), life cycle impact assessment (LCIA), and interpretation of the results. At the building level, the EN 15978 (2011) *Sustainability of construction works - Assessment of environmental performance of buildings - Calculation method*, provides calculation rules for the assessment of the environmental performance of new and existing buildings based on a life cycle approach. It is intended to support the decision-making process and documentation of the assessment of the environmental performance of a building. LCA assesses several environmental impact categories, with Global Warming Potential (GWP) being the most widely recognized. When only GWP is measured, the assessment is known as a carbon footprint. During LCA, emissions are converted into environmental impacts potentials. The impacts are expressed in quantities of a substance that can cause environmental harm, such as greenhouse gas emissions, and known as midpoint indicators. They do not represent the actual harm, known as endpoint indicators, for example sea level rise. The Building LCA is based on the following stages (Figure 1): (modules A1-A3), construction process (modules A4-A5), end-of-life (module C), and the benefits and loads beyond the system boundary (module D).

1.2 *Objective of the work*

This paper presents the comparative results of a building LCA of a typical office building located in Luxembourg with 50 years of service life. Three structural systems are compared:

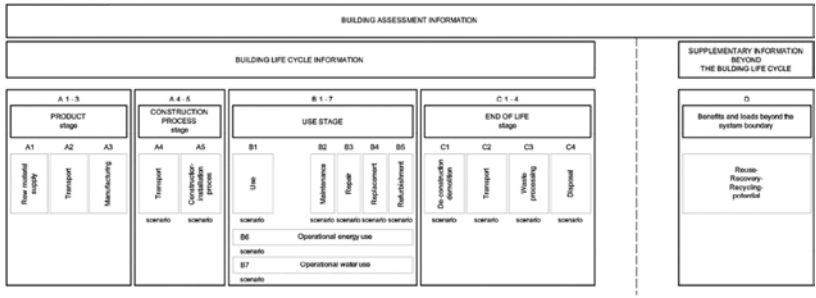

Figure 1. Display of modular information for the different stages of the building assessment.

a steel frame, a prefabricated reinforced concrete frame, and a timber frame. To ensure that the structural alternatives were functional equivalent, the same life-cycle scenario and assumptions are used in this work. To assess the impact of all the material and product used in the comparison environmental product declarations (EPDs) published according to the EN 15804+A1 and the EN 15978 are used. LCA studies are performed using the commercial software One Click LCA*. The Building LCAs, presented in this work, have as final objective the comparison and the potential benefits of different materials for the building structural frame application. This building LCA focuses on the following modules: A1-A5, B4, C3-4, D.

2 STUDIED EXAMPLE

2.1 Generalities of the office building

This paper presents the comparative results of a building LCA of a typical 9-storey office building located in Luxembourg (2018) with 50 years of service life. To define a representative office building for the Luxemburgish construction context, a market analysis was performed by the company TBC. The selected office building type was configured in an “L” shape (Figure 2) and the most significant dimensions are listed in Table 1.

Table 1. Significant office building dimensions.

Building depth [m]	13,60
Building length [m]	78,15
Superstructure the number of levels	R+8
Infrastructure number of levels	2
Free height on the ground floor [m]	3,5
Free height on the intermediate floors [m]	2,7

Figure 2. Typical floor layout.

2.2 Structural options

Three structural systems are compared: a steel concrete composite frame, a prefabricated reinforced concrete frame, and a timber frame. Two grid options were adopted based on the best performance of the different structural options and materials: 8,1m by 13m (clear span) for the steel concrete composite steel option, 8,1m by 5m +8m (with intermediate columns) for the prefabricated reinforced concrete option, and finally 5,4m by 5m + 8m (with intermediate columns) for the timber options (Figure 3a, b and c). All the structural options assessed were designed and verified according to the Eurocode's rules by independent design offices. Also, Table 2 shows a summary of the structural options analysed in this work.

Table 2. Structural options.

Reinforced concrete

Floor	CLT GL24h panel 5,4m span

Figure 3. Structural options: a. Reinforced concrete; b. Composite; c. Timber.

2.3 Goal and scope definition

The first step of the analysis consists in choosing a functional unit and defining a level of detail. All the modules that can be included in a LCA are shown in Figure 1. The goal of the present building LCA is to quantify the environmental performance of equivalent structural options, composed of different materials, of an office building located in Luxembourg. This comparative study can support the different construction chain players (e.g.: engineers, architects, real estate developers, etc.) in the decision-making process by providing comparisons of the environmental performance of different design options and by indicating the potential for environmental performance improvement. As mentioned above, this building LCA focuses on the following modules: A1-A5, B4, C3-4, D.

2.3.1 Product Stage A1-A2

These modules are covering resource extraction (A1), transport of the resourced (A2) the manufacturing process, and completion of the finished products at the factory gate (A3). Material and product quantities were extracted from construction drawings, bills of quantities, and BIM models as delivered by designers. Net quantities were used in this work.

2.3.2 Construction Process Stage (A4-A5)

Transportation of building materials and products from the factory to the construction site (A4), and the actual construction/assembly on-site (A5). Transportation scenarios from One

Click LCA were used and represent regionally typical transportation distances and methods. Wastage quantities were estimated by default values of One Click LCA based on different materials and accounted for in module A5.

2.3.3 Use stage – Replacement (B4)

Due to the purpose of the building LCA, the only relevant life-cycle stage during the use of the building was module B4. Service life determines how long the product is used before being replaced. Values for the different products and materials were taken from the respective EPDs.

2.3.4 End of life stage (C3-C4)

Waste processing (C3) relates to structural elements and building materials that can be reused, recycled, or used otherwise (e.g., for energy recovery) (C3), and Disposal (C4) relates to structural elements and building materials that must be disposed/landfilled (C4) life-cycle stages were considered in the building LCA analysis. Table 3 presents the end-of-life (EOL) scenarios adopted for the different materials:

Table 3. EOL assumptions.

Material	Landfill %	Re-use %	Recycling %	Incineration with energy recovery %	Source
Structural steel	1	11	88		EPD
Steel reinforcement bars	10		90		EPD
Reinforced concrete	25		75		BETie
Timber scenario 1				100	One Click LCA
Timber scenario 2	100				EPD

The EOL assumptions are taken from the considered EPDs and One Click LCA’s database (see Table 3). They reproduce the current practices for deconstruction and treatment of the Construction Demolition Waste (CDW) of the location where the building is situated. Since the EPD used for wood elements declares several EOL scenarios, two are proposed: landfilling and incineration with energy recovery since often timber CDW is subjected to different practices. It is assumed that the amount of CO₂ absorbed during the photosynthesis and stored within wood during its life cycle is equal to that released at the EOL and thus there is no net impact on emissions. This assumption is commonly adopted for wood-based products in LCA (Morris F., 2021), however, a focus on biogenic carbon is presented in the next chapter.

2.3.5 Benefits and loads beyond the system boundary (D)

Based on decisions taken at the EOL, potential benefits related to the substitution of primary resources are accounted for. Module D is considered in the building LCA analysis characterizing it as a cradle-to-cradle LCA. For the end-of-life scenario Timber scenario 1, where the energy recovered by incineration is substituted in the energy mix, the District Heat, Luxembourg profile IEA2019 was selected.

2.4 Life cycle inventory

The life cycle inventory (LCI) is composed of construction environmental product declarations (EPDs) published according to the EN 15804+A1 and the EN 15978. EPDs provide quantified information on environmental impacts and aspects of products and services for use in a building LCA. The main EPDs and environmental data used in the building LCA are presented in Table 4 together with their embodied carbon impacts (A1-A3) in terms of their functional unit (FU).

Table 4. EPDs and environmental data.

Data source	Material	FU	GWP [kg CO ₂ eq./FU]
EPD XCarb™ Recycled and renewably produced Structural steel sections and merchant bars ArcelorMittal Europe	Structural steel sections	kg	0,33
EPD Structural steel sections in HISTAR grades ArcelorMittal	Structural steel sections	kg	0,52
EPD XCarb™ Reinforcing steel in bars ArcelorMittal Europe	Steel reinforcement bars	kg	0,3

3 RESULTS AND DISCUSSION

The Building LCA presented focuses on global warming potential (GWP) to describe the environmental impact. For the office building designed in composite steel structural solution, two building LCA analyses were made. The first is referred to as “Steel Composite usual AM’s structural steel” to highlight the environmental results of ArcelorMittal’s electric arc furnace (EAF) process of structural steel making. The second is referred to as “Steel Composite XCarb®” to highlight the benefits achieved using 100% recycled steel (scrap) and 100% renewable energy during the process of steel-making. Results of all the analysed options are plotted in terms of the total gross floor area (GFA) of the office building for the two wood EOL scenarios: 100% incineration with energy recovery (Figure 4a) and 100% landfilling respectively (Figure 4b). Similarly, Figure 5 (a, b) show results of the GWP by GFA highlighting the contribution of each structural building part.

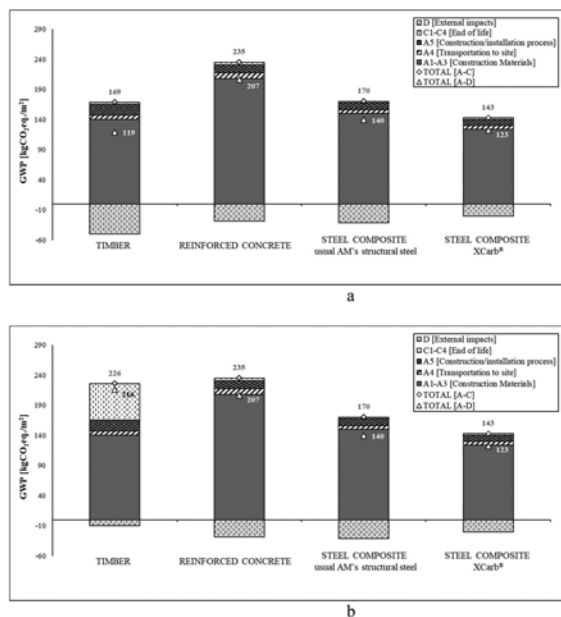

Figure 4. GWP [kgCO₂eq./m²] results by life cycle stages, 100% wood incineration with energy recovery (a); 100% wood landfilling (b).

Figure 5. GWP [kgCO₂eq./m²] results by structural building parts, 100% wood incineration (a) and 100% wood landfilling (b).

3.1 Results & comparison

Regardless of the structural option, the product life-cycle stage (A1-A3) is the most contributing to the GWP. In terms of CO₂_{eq} emissions, the steel frame outperforms the reinforced concrete frame by reducing by 32% the overall GWP for the usual structural steel scenario (Figure 4). A greater reduction is achieved using XCarb® steel frame scenario where the overall GWP can be reduced by up to 41%. The timber frame when compared to the steel frame scenarios: usual structural steel and the XCarb®, is outperformed by 43% for the 100% landfill EOL scenario and performs equally for the 100% incineration with energy recovery, EOL scenario.

For all the structural options, the building part that contributes the most to the overall GWP is the floors (Figure 5). Steel composite floors outperform prefabricated reinforced concrete hollow core slabs by 37% and 42% for the usual structural steel and XCarb® steel frame scenarios respectively. It is seen that for the timber option, the floors are greatly impacted by the choice of EOL scenarios: 82 kgCO₂_{eq}/m² and 45 kgCO₂_{eq}/m² for the 100% landfill and 100% incineration with energy recovery scenarios respectively. Timber EOL has an important influence on the overall GWP, this will be discussed further in the next paragraph.

3.2 Focus on biogenic carbon

To understand the difference between the scenarios considered in this work for the timber option it is important to recognize the role played by Biogenic carbon. All the biological materials accumulate during their life carbon dioxide subtracted to the atmosphere (process known as sequestration). This carbon is released back to the atmosphere in form of biogenic CO₂, CO and CH₄ because of the oxidation and/or reduction of biomass by means of its transformation or degradation (e.g., combustion, digestion, composting, landfilling) (Hoxha E., 2020). Methane is a gas that contributes to the GWP, it causes 25 times more warming over 100 years compared to 1kg of CO₂, and so methane has a GWP of 25 (Forster P., 2007).

In the 100% landfill scenario for wood EOL, it is assumed that the landfill is a large modern Type 3 facility with CH₄ collection. The methane uptake partially substitutes natural gas in heat production as a benefit in module D. The non-collected CH₄ is released and accounted for GWP in module C. This explains the variation of results of the timber frame option

between both EOL scenarios. It also explains the reason why the timber frame module C, for the 100% landfill EOL assumption is the highest compared to the other structural options. According to the current practices, most of the wood (58%) is being landfilled in its EOL.

When it is assumed the 100% incineration with energy recovery scenario, the energy created in the combustion process is harnessed for electricity generation. In consequence, the life-cycle stage module D represents the benefit of avoiding energy production and not the benefit of avoiding raw material extraction (the harvesting of virgin wood) to produce timber structural elements. According to the current practices of wood as a CDW, just the minority (6%) is being incinerated with energy recovery in its EOL. When accounting for biogenic carbon, neglecting some phase of the LCA can lead to a misleading result (Hoxha E., 2020), for example if only modules A are considered in the LCA only the positive effect if the biogenic carbon is included without including the release at end of life.

4 CONCLUSIONS

The purpose of this building LCA application is two-fold: to quantify the environmental performance of equivalent structural options with materials and, based on the first, to guide the different construction chain players the decision-making process of different structural design options.

In this study, an R+8 multi-story office building representative of the Luxembourgish market with an RSL of 50 years is analysed. Three structural systems are considered: a steel frame, a prefabricated reinforced concrete frame, and a timber frame. A cradle-to-cradle Building LCA is performed to quantify the overall GWP of each building's structural system.

The steel frame outperforms the reinforced concrete frame reducing by 32% the overall GWP for the usual AM's structural steel scenario. For the XCarb® steel frame scenario, the overall GWP can be further reduced by 41%. The overall GWP of the timber frame is very sensitive to the wood EOL assumptions. When compared to the XCarb® steel frame scenario, the timber frame with the EOL assumption: 100% incineration with energy recovery, performs equivalently concerning the overall GWP. On the other hand, when 100% landfilled, the timber frame is outperformed by the XCarb® steel frame scenario by 43%. To conclude, steel frame option profits from a high-recycled material content, greatly reducing the embodied carbon from steel products. In addition, XCarb® environmental performance is enhanced using 100% renewable energy in steel production, lowering, even more, the embodied carbon.

Optimised steel structures for a low carbon future

M. D'Antimo

Steligen[®] ArcelorMittal, Milan, Italy

ABSTRACT: The construction sector is responsible for a considerable share of global CO₂ emissions. With the growing trend of the world population and the world's building stock, the share of emissions of the built environment is bound to increase dramatically in the coming years. Embodied carbon of structural materials will be soon the major source of emissions in constructions. The most promising construction material to help reducing building emissions and enhancing circularity is certainly steel. Even if the steel industry has the stigma of being among the highest-emitting industries, the carbon footprint of its manufacturing process is rapidly decreasing, and today low carbon steel products are cutting emissions faster than before. In this work the decarbonization journey of the steel industry will be addressed and simplified embodied carbon calculations will be presented and discussed for different material solutions in structural applications.

1 INTRODUCTION

1.1 *The Climate crisis*

The construction industry is the largest consumer of raw materials and the built environment alone accounts for about 25 and 40 percent of total carbon emissions in the world. The sector is also responsible for nearly 40% of raw material use annually and around 39% of the total primary energy use. In the coming years with the increase of world population will also increase the need to build/renovate structures and infrastructures; almost 75 percent of the infrastructure that will exist in 2050 has yet to be built, in fact, the world's building stock is expected to double by 2060, this will add 100-200 gigatons of embodied carbon coming only from construction materials. In this framework, the construction industry is only expected to expand, and with it the associated emissions, however, this will provide a significant opportunity to improve its efficiency and transition toward a low-carbon future (Carbon Pricing Leadership Coalition, 2018).

Embodied carbon of structural materials will be soon the major source of emissions in constructions. Operational carbon, which today is the major source of buildings emissions, is expected to decrease in time thanks to the ongoing decarbonisation strategies of the energy sector. The journey towards decarbonization of construction materials must speed up to reach the carbon neutrality targets. The most promising construction material in terms of low emissions and increasing circularity is steel.

Although the steel industry has the stigma of being among the highest-emitting industries (about 7% of global carbon dioxide emissions), the carbon footprint of its manufacturing process has decreased by 37 percent per ton since 1990 (Carbon Pricing Leadership Coalition, 2018), and today new low carbon alternatives are cutting emissions faster than before. The circularity of steel, enhanced by the possibility to upcycle, unlike other materials, and its low carbon alternatives have encouraged its use in ambitious projects driven by sustainability and facilitated higher ratings than would otherwise have been possible. The decarbonisation journey of production chains must go together with a change of paradigm in the way a project is conceived, design should be approached in a holistic way considering sustainability as an added value and not a burden. The first step is to approach an efficient design process, reducing the use of material by avoiding over-design, reducing impact of renovation and maintenance, allowing easy reversion of spaces, and only at the end of this process select low carbon alternatives for the traditional materials.

The increase in popularity of environmental issues has certainly led to a growth in awareness but it has also led to an exponential increase in often contradictory information. It is

more and more difficult to understand what can be practically done in design to reduce the emissions of construction in general. Starting from this consideration, this work tries to give a brief and surely non-exhaustive overview on decarbonization journey of the steel production and ultimately to present an easy way to estimate the embodied carbon of structural elements.

1.2 *Sustainability in construction and materials*

Materials and technologies play a fundamental role in cultural and social transformation, not only for technological development, but also in urbanization and in stemming the climate crisis.

Manufacturers and construction industry have engaged to reach net zero carbon within 2050, in line with the European and international strategic objectives. In response to the growing demand for green, sustainable, and low-carbon constructions, the industry is making efforts to address emissions of construction materials. Investors increasingly require the industry to meet standards of energy efficiency and sustainability (RE 2020 in France, LETI Guide in England, CAM in Italy...), green building rating systems (like LEED and BREEAM), responsible resource management, together with resilience and high-performance requirements for buildings and infrastructure. In this framework the journey towards decarbonisation of construction industry must speed up to meet the Paris Agreements.

To date the only scientific way to compare structural solutions in term of sustainability is the standardized methodology called LCA “life cycle assessment”. This technique is used for assessing the potential environmental impacts associated with a product or a service not only related to construction world. LCA is an objective method to evaluate and quantify the environmental loads, and potential impacts along the entire life cycle, from the acquisition of raw materials to the end of life (“from the cradle to the grave”) and beyond (“cradle to cradle”). The tool can be used at different “scales”: for the single product (steel, cement, etc.), for a solution (steel beam, composite flooring) or for a building, a group of buildings or even a city. Designers can use LCA to choose between alternative solutions, while manufacturers use LCA to define the impact of a product, in both cases, it is a useful tool to address and reduce the environmental impacts.

The relevance of the LCA technique lies mainly in its approach which consists of evaluating all the phases of a production process as related and dependent. The use of the LCA method is defined and regulated by the technical committee CEN TC 350 (in particular, EN 15978: Sustainability of construction works – Assessment of environmental performance of buildings – Calculation method). Several indicators are used in the assessment, but the current focus is on the Global Warming Potential (GWP), which expresses the contribution of a gas to the greenhouse effect in relation to the effect of CO₂, whose reference potential is equal to 1. It is expressed in units of CO_{2e}, where the “e” stands for equivalent.

LCA also breaks down the impacts into stages and modules that represent the magnitude of the impacts throughout each life stage – see Figure 1. An important aspect of carrying out an LCA is to define the goal and scope, and which boundaries are included in the analysis, for example, the analysis can be “cradle to gate”, “cradle to practical completion” or “cradle to cradle” (i.e., including module D) (Swann, 2021).

These aspects are crucial when different products or structural solutions are compared, the give comprehensive information to select a more sustainable option. If all the stages of the LCA are not included, the comparison could be inconsistent and therefore misleading. It is worth emphasising that conclusions reached on a cradle to gate analysis could be different to those on a cradle to grave or cradle to cradle. At European level, LCA supports the development of Environmental Labelling schemes, which provide information about a product or service in terms of its overall environmental benefits, such as the recyclability of its packaging, or the absence of noxious ingredients. Three type of labels exists: Type I (ecolabel), Type II (Ricoh Recycle Label) and Type III (EPD- Environmental Product Declaration). Type III environmental declarations (EPD), quantify the environmental information for the life cycle of a product and represent the most reliable and transparent data to develop an LCA assessment at the scale of the building (GBC Italy, 2019). To ensure consistency and to compare functionally equivalent products or services, these are classified into well-defined groups following a specific Product Category Rules (PCR), manufacturers must comply with it when conducting LCA for EPD evaluation. For construction products the reference, updated to 2020 is the EN 15804+A2.

Figure 1. BS EN 15978 Life cycle stages LCA stages.

Reducing embodied carbon in a project is not a linear process often there are no general rules and assumptions that apply in all cases.

Designers should be able to compare in a simple but coherent way different solutions and environmental impacts, with the aim of choosing the most appropriate one for their project. Reducing emission implies first to use less material, refurbish instead of built, use a life cycle approach, minimize upfront embodied carbon (lean construction, low carbon materials, low carbon process, etc.), but also thinking about end of life. This last point is quite crucial in modern design, and answer to the question: what will happen to a building behind its life span? Building must be flexible, have a low embodied carbon (including renovation and maintenance), allow for adaptation and reconversion of spaces, include circular materials, and account for demountability, etc.

The approach to sustainable design and life cycle thinking is a complex process and it has to involve all the actors of the construction process: producers, and their engagement in decarbonization; investor, designer, and construction companies, with the need of having more sustainable option and a clear path to include sustainability in their daily practice.

2 STEELMAKING AND SUSTAINABILITY

Referring to building emissions, the highest impact on the emissions is given by the energy consumption (operation carbon), followed by construction process and materials and their production processes (embodied carbon). However, the energetic impact, which seems to be predominant today, can be reduced designing energy efficient buildings with well-designed insulation, efficient HVAC systems, photovoltaic roofing, etc. Additionally, considering the effort of the energy supply in shifting to clean energy, one can assume that this impact will decrease in the next 30 years.

Briefly, energy efficiency and clean production will drastically reduce operational carbon. On the contrary, the material impact remains unchanged and over time will be the major source of CO₂ emissions in the construction sector (D'Antimo, 2022). In this section the emissions of the steel industry will be addressed and the ongoing decarbonisation path will be presented.

2.1 Steel circularity

As stated, steel is a key material for technological evolution and in the circular economy. Many advances are currently taking place in the steel industry, increasing the rate of recycling (and potential reuse), implementation of decarbonization strategies (ArcelorMittal, 2021), industry standards and certification programs, such as ResponsibleSteel, improved productivity and efficiency of process (from energy efficiency to increased use of scrap).

Steel recycling is a well-established and efficient practice with capture rates as high as 99% at end of life (Figure 2) and steel production from scrap is already a mature steelmaking process. However, the predicted increase in global steel demand, means a transition to

steelmaking entirely based on scrap will not be possible for some time and so there will still be a need for primary steelmaking, and an urgent need to decarbonise the primary production too. The circularity of steel, enchanted by the possibility to upcycle, unlike other materials, and its low carbon alternatives have encouraged the use of this material in ambitious projects driven by sustainability and helped them to obtain better ratings in green certifications.

Steel is a perfect material to help designer in their approach to a more sustainably way of designing constructions and reducing usage of material. For example, approximately 75% of modern steels have been developed in the past 20 years. This means that, if the Eiffel Tower were to be rebuilt today, with the new steel types, it could be built with one-third of the steel that was originally used. This is true not only in construction but in all the sectors where steel is a key material, modern cars are built with new steels that are stronger and up to 35% lighter than in the past (WBCSD, 2003).

Over the past decades, technology, knowledge, and research have led to a more efficient use and exploitation of steel and materials in general. In a nutshell, this means that the first rule to cut emissions is to use is to “use less stuff”. If manufacturers are engaged in the decarbonization process to reduce the carbon footprint of production, designers have an important role to play in the transition. It is no longer enough to simply design efficiently, it is also necessary for designers to understand and engage with the supply chain and be aware of the latest developments and the available alternatives with lower embodied carbon, if they are to successfully deliver low impact buildings.

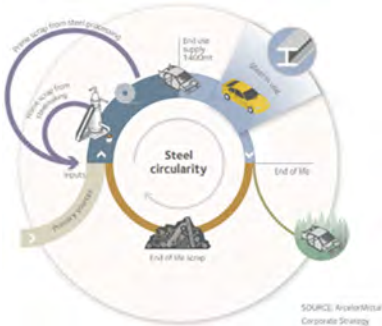

Figure 2. Steel circularity from (ArcelorMittal, 2020).

2.2 Decarbonization of the steel industry

There are currently three main technologies to produce steel:

- Primary steel making or Blast Furnace – Basic Oxygen furnace route (BF-BOF), where carbon coke is used to reduce the iron ore to make iron, the direct CO₂ emissions are the result of this chemical reaction in the furnace (Table 1). After iron is produced steel can be made in a Basic oxygen furnace by injecting oxygen.
- Secondary steel making from scrap (with Electric Arc Furnaces), where emissions are coming from the used electricity.
- Direct Reduced Iron (DRI) where a sponge iron is produced from the direct reduction of iron ore (in the form of lumps, pellets, or fines) into iron using reducing gasses (CO and H₂) derived from natural gas (CH₄). Then the sponge iron is melted in an electric arc furnace. The two reducing gasses, carbon monoxide and hydrogen, contribute to the reduction process in roughly equal amounts, resulting in respective emissions of CO₂ and H₂O. This illustrates one of the potential transition pathways to carbon neutral steelmaking, 100% hydrogen reduction using hydrogen from the electrolysis of water using 100% renewables (Swann et al, 2021).

3As presented in Table 1, different steel production routes have different sources of emissions and therefore require completely different technological efforts and decarbonization strategies to reach emission reduction targets. EAF steel is already relatively low in carbon.

Table 1. Steelmaking routes and emissions.

Blast Furnace (BF/BOF)	Direct Reduced Iron (DRI)	(c) Electric Arc furnace (EAF)
		
Source of CO ₂ e: Coke and electricity	Source of CO ₂ e: CH ₄ and electricity	Source of CO ₂ e: Electricity

When the feedstock is 100% scrap, the main source of emissions are those indirect emissions due to electricity generation. Over time, as the proportion of renewable electricity in the grid mix increases, the impacts of scrap-EAF steel will reduce.

Different strategies are needed for the primary steelmaking journey toward carbon neutral steel. Among these, green hydrogen can be used to completely replace the use of natural gas in DRI-EAF manufacture bringing the process close to carbon neutrality. Green hydrogen can only be produced with clean energy and the infrastructure to support this shift is not yet ready, however, the steel industry is already moving in this direction (ArcelorMittal, 2021). To summarise, the strategies being implemented for the decarbonisation of the steel supply chain are based on five major millstones: (i) Steelmaking transformation, from coal to natural gas as a precursor to green hydrogen DRI; (ii) Energy transformation (including green hydrogen, circular forms of carbon and carbon capture usage and storage technologies); (iii) Increased use of scrap; (iv) Sourcing clean electricity; and (v) Offsetting residual emissions.

3 EMBODIED CARBON ASSESSMENTS

3.1 *Build with less embodied carbon*

A structure built today needs to reduce its environmental impact as much as possible, in the next 50 years there will be many changes that the planet and the construction world will have to face. The approach to sustainable design and life cycle thinking is a complex process and involves all the actors of the construction process, producers, and their engagement in decarbonization, investor, designer, and construction companies. Reducing emission also means investing more in renovation more than new buildings, design using a life cycle approach, minimizing upfront embodied carbon (lean construction, low carbon materials, low carbon process, etc.), but also thinking about end of life. This last point is crucial in modern design, buildings must be flexible, reduce the embodied carbon for renovation and maintenance, adaptation and reconversion of spaces, circularity of materials, including demountability of the whole structure or some elements. More holistically, flexibility and end of life are an old-new way to approach construction. Flexibility in design and space allows for better utilization of the building potential and can be realized using long spans to create clear spaces that can easily accommodate change of use, allowing for demountable solutions, which allow possible reuse of elements and ensuring a life of the structure far behind the service life. A project and its impacts must always be analysed using a life cycle approach, otherwise there is a risk of missing all the benefits that some sustainable choices bring to the design. For example, the benefits of reducing the weight of structural elements does not only bring a direct benefit (less material = less CO₂) but also many indirect benefits. Among these, less impact due to transportation of materials (therefore less CO₂ from transport and less cost), less weight in the foundations (therefore less material, less excavations, lower cost in construction), lower impact of the construction site (in terms of duration, size, and cost), etc. This simple example explains how without considering the whole picture (LCA) it is not possible to make informed choices and compare solutions or alternatives in terms of sustainability. A project and its impacts must always be analysed using a whole life cycle approach, this is the principle on which the LCA approach is based.

3.2 Reducing embodied carbon of a beam element

Embodied carbon is important through the entire design process. To calculate it, the quantity of material is multiplied by carbon factor (in kgCO₂ per kg of material), as shown below:

$$\text{Embodied carbon (EC)} = \text{quantity} \times \text{carbon factor} \quad (1)$$

The carbon factor varies for the different LCA modules. The quantities, especially in early-stage evaluation or feasibility study, might be approximate. However, it is still a good way to assess impact (Orr et al, 2020). In this work, only emissions covering the production processes [A1-A3] (cradle to gate) are considered for the comparison of five alternative column solutions of a tall building. The column type (CT) elements compared are subjected to the same design assumptions, same length (4m) and, although it is a theoretical exercise, the methodology can be used for different cases and structural solutions. The column types compared, are as follows:

1. CT1: Circular reinforced concrete Φ 850 c40/50
2. CT2: Circular steel hollow section 508/30
3. CT3: Open welded profile (400 x 287)
4. CT4: Hot-rolled profile (HD 400 x 287- Histar®)
5. CT5: Hot-rolled & low carbon steel profile (HD 400 x 287- XCarb® recycled and renewably produced)

To estimate the value of equation (1), embodied carbon factors (ECF) from relevant EPD can be used or other equivalent sources. Attention must be paid in the calculation because the same materials, from different manufacturers, can have different environmental impacts. For example, the A1-A3 factor for structural steel section varies from 2.45 (British steel EPD) to 0.33 (ArcelorMittal XCarb® recycled and renewably produced EPD for sections and merchant bars). In Table 2 the EPD used in this work are reported with the ECF for [A1-A3], which, when multiplied by the material quantity gives an estimate of the embodied carbon.

Table 2. Used EPD and values.

EPD	Producer/publisher	Units	ECF [A1-A3]
Concrete	ICEv3-[C40/50-100% OPC	tCO ₂ e/m ³	0.42
Reinforcing steel bar	ArcelorMittal/IBU	tCO ₂ e/ t	1.23
Tubular	ArcelorMittal/IBU	tCO ₂ e/ t	2.27
Steel plate	ArcelorMittal/IBU	tCO ₂ e/ t	2.6
Steel profile	ArcelorMittal/IBU	tCO ₂ e/ t	0.524
Low carbon (XCarb®)	ArcelorMittal/IBU	tCO ₂ e/ t	0.333

For example, for CT1 the calculation according to (1) accounting for the contribution of the concrete and the steel rebars is as follows:

$$EC_{\text{concrete}} + EC_{\text{RBars}} = 0.42 \text{ tCO}_2\text{e/m}^3 \times 0.57 \text{ m}^2 + 0.135 \text{ t/m} \times 1.23 \text{ t CO}_2\text{e/ t} = 405 \text{ kgCO}_2\text{e/m} \quad (2)$$

While for CT4, a hot rolled steel profile with high strength steel S460 (HISTAR®), the embodied carbon is as follows:

$$EC = 0.287 \text{ kg/m} \times 0.524 \text{ t CO}_2\text{e/ t steel} = 151 \text{ kgCO}_2\text{e/m} \quad (3)$$

To make comparison easy, the embodied carbon in this case is expressed in kg per m of column. Quantities can be representative of the functional unit considered, however, when confronting different functional units, the coherence of results must be ensured. All the inputs and the results for the analysed cases are reported in Table 3.

In the reference project, the initial studied solutions were CT1 and CT2 (BF/BOF production) with an associated embodied carbon of 405 kgCO₂e/m and 807 kgCO₂e/m. However, to

Table 3. EC Results.

Case #	CT1	CT2	CT3	CT4	CT5
Dimensions	Φ 850	CHS 508/ 30	400 x 287	HD 400 x 287	HD 400 x 287
Material	Concrete/Rebars	S355	S460	S460 Histar [®]	S460 XCarb [®]
Quantity	0.57m ² /135 kg/m	354 kg/m	287 kg/m	287 kg/m	287 kg/m
EC	405 kgCO ₂ e/m	807 kgCO ₂ e/m	746 kgCO ₂ e/m	151 kgCO ₂ e/m	95 kgCO ₂ e/m

optimize the design, an open rolled profile in high-strength steel was proposed (CT4), which led to a considerable reduction in weight and dimensions and to a reduction of 80% in embodied carbon compared to CT2. To optimize further, an alternative low carbon material is added (case CT5) and a total reduction of 651 kgCO₂e/m (87%) can be obtained. For comparative purposes also CT1 and CT3 (welded profile) are presented in the Table 3.

3.3 Flooring

Following the same approach presented in the previous paragraph, different flooring solutions are compared estimating the EC associated with each solution. For the sake of brevity, the compared solutions are schematically presented in Table 4: (a) flat slab, (b) flooring composed of a cellular or smart beam and steel composite deck and (c) a slim floor beam (SFB) with additive steel floor.

For each element of the solution, an EPD or equivalent database (namely [13] for the concrete) have been used to establish a relevant ECF and summed to obtain the total embodied carbon.

Contrary to the previous column comparison, here the functional unit is expressed in m² (and not in m) thus the EC will be expressed in kgCO₂e/m². Two scenarios are considered: ordinary steel elements which give the EC (1) value and low-emission steel from the XCarb[®] family which returns the EC (2) value of the solution (b) and (c), nothing changes for (a).

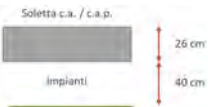

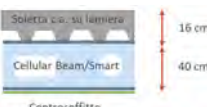

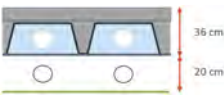

For the sake of consistency, reinforcing rebars are the same in all solutions (EPD: Arcelor-Mittal with an ECF of 1.23 tCO₂e/t) For case (a) cellular or smart beams with steel deck, using equation (1) for all the elements comprising the flooring solution, it is possible to obtain the embodied carbon following the procedure presented in the previous paragraph and more details can be found in (D'Antimo et al., 2022). Using low carbon steel, case EC (2), for solutions (b) and (c) can bring a reduction of about 30-33% of the embodied carbon. Comparing the same cases with the flat slab option where rebars are kept the same (EC of 139.5 kgCO₂e/m² is constant) embodied factor can be reduced of 55 % passing from (a) to (b) while the reduction is 41% passing from (a) to solution (c).

4 CONCLUSIONS

This work provides a brief overview of the decarbonization pathways of the steel industry, some considerations on the future of the construction industry and its emissions are examined. The main purpose of the work is to provide easy way to assess embodied carbon in projects at early stage, and how to effectively compare different solutions in terms of sustainability. A project or a solution must always be analysed using a life cycle approach, and the usual conception of a structure might be revised. The first step is to adapt instead of building (renovate); the second step is checking the design process to reduce the material and the primary resources used; paying attention to use the right material in the right place; at this stage low carbon alternatives can help further reducing the emissions. The conception of a structure must go behind the end of life, including possible scenarios (dismountability, reuse of space, reconversion), this can be achieved with flexible, clear spaces that are easy to convert, and using demountable solutions with circular materials.

Using a life cycle approach together with low carbon specifications can drastically reduce the carbon footprint of the built environment and help to meet sustainability targets. Low carbon alternatives and a more conscious choice of material sourcing have been proven to reduce the embodied carbon emissions, but this reduction can be even greater if coupled with an efficient lean design of high-performance buildings.

The contribution of low carbon steel to the decarbonization of the building sector

H. Gervasio & L. Simões da Silva

ISISE, University of Coimbra, Coimbra, Portugal

M. D'Antimo

Stelligence ArcelorMittal, Milano, Italy

ABSTRACT: The building sector is responsible for about 40% of carbon emissions, in which about 11% are related to embodied carbon emissions. Therefore, buildings play an important role to the carbon neutrality of the construction sector, and the use of low-carbon materials is an added-value towards this goal. This paper aims to highlight the contribution of low-carbon steel buildings to the reduction of embodied carbon emissions in the building sector. The study entails a comparative life cycle assessment of a steel building using standard carbon steel and a building made of low-carbon steel. The comparative analysis entails the complete life cycle of the building, from the construction stage to the recycling stage, including Module D. As expected, the results show that the low-carbon steel has a lower impact in the production stage when compared with the standard steel. However, in the end-of-life stage, the result is the opposite as the net credits allocated in Module D are in this case a burden. Nevertheless, in terms of the whole LCA result, the life cycle result of the low-carbon steel is about 24% lower when compared with the standard carbon steel.

1 INTRODUCTION

The increase of atmospheric CO₂ and other greenhouse gases, mainly as result of anthropic activities, induced an increase in global air temperature (about 1°C compared to the preindustrial era) (IPCC, 2021), and has been leading to climate changes. These changes, which are effecting the entire planet, are unequivocal according to the United Nations Intergovernmental Panel on Climate Change (IPCC, 2021).

Across EU there is a broad agreement that decarbonization of the economy to net-zero by 2050 is required to avoid an increase of global temperature by more than 1.5°C or 2°C, above pre-industrial levels, complying with the Paris Agreement (UNFCCC, 2015).

However, decarbonization of the EU economy requires the engagement of all economic sectors, and the construction sector must play its role towards climate-neutrality. In fact, the construction sector has a huge contribution towards the increase in carbon emissions: the building sector alone is responsibility for about 40% of carbon emissions, in which about 11% are related to embodied carbon emissions (Worldgbc, 2019). Therefore, the construction sector is a priority under the umbrella of the European Green Deal (COM(2019) 640) and related initiatives, such as the Circular Economy Action Plan (COM(2020) 98), the Industrial Strategy for Europe (COM(2020) 102), the Renovation Wave for Europe (COM(2020) 662) and the New European Bauhaus (COM(2021) 573).

The steel industry is very energy intensive and therefore, it is also responsible for a significant share of carbon emissions. Nevertheless, over the years, different strategies have been implemented in order to reduce the consumption of energy for steel production, and consequently reduce carbon emissions.

In this context, this paper aims to highlight one of such strategies, the production of low-carbon steels and its contribution to the reduction of embodied carbon emissions in the building sector. The analysis will be carried out based on a comparative life cycle assessment of a steel structure. The paper is organized into the following sections. After this introductory section, in Section 2, a brief overview is provided on the main strategies for the decarbonization of the building sector, given emphasis on the production of steel for the construction sector, and its application to buildings. Then the adopted approach for life cycle analysis is described in Section 3, focusing on the modelling of steel production and end-of-life stages. In Section 4, this approach is applied in the comparative life cycle analysis between a steel structure of a building using standard carbon steel and the same structure made of low-carbon steel. The comparative analysis entails the complete life cycle of the structure, from the construction stage to the recycling stage, thus allowing to discuss the adopted allocation approach for Module D, which takes into account the use of recycled material in the production of steel and the recycling of steel at the end-of-life of the structure. Final conclusions are drawn by the end of the paper, in Section 5.

2 DECARBONIZATION OF BUILDINGS

Despite the investments in the energy efficiency of buildings, the energy consumption and related carbon emissions of the building sector have increased after the post-pandemic crisis. In 2021, the emissions of CO₂ related to the consumption of energy increased about 5% in relation to 2020 (UNEP, 2022). Unfortunately, this means that the gap between the climate performance of the building sector and the decarbonization target is widening.

Moreover, with the world economic grow, the global consumption of raw materials may double by 2060 (OECD, 2019). To reduce overall emissions, the building and construction sector should keep investing in energy and material efficiency, promoting materials' circularity and materials with low embodied carbon. For instance, the implementation of material efficiency strategies, such as the use of recycling materials, may reduce greenhouse gas emissions of residential buildings by over 80% in 2060 (UNEP, 2022).

Steel is one of the most popular construction materials in the world. The steel industry has a strategic importance to the EU economy, employing about 330000 people and creating around 29 billion euros of added value (Somers, 2021). At the same time, the production of steel is very energy intensive, being responsible for about 5% of CO₂ emissions at the EU level and 7% at the global level (IEA, 2020).

The emission of CO₂ from the production of steel has a wide variability as it depends on the production route. Steel is produced mainly from two distinct routes: the blast furnace or blast oxygen furnace (BF/BOF), and the electric arc furnace (EAF). The former is known as the primary (integrated) route, in which iron ore is reduced by coke and injection of coal to achieve the required (high) temperature. On the other hand, in the EAF, steel is produced mainly by melting recycled steel scrap, and therefore it is usually known as the secondary route. In the latter case, the process is almost fully electrified, and the emission of CO₂ is much smaller when compared with the BF/BOF route. To illustrate this, Figure 1 provides the values of Global Warming Potential (GWP) and Primary Energy (PE) for the production of 1 kg of steel products, with different inputs of steel scrap in the production stage. It is noted that data displayed in Figure 1 is global generic data from GaBi database (Thinkstep, 2017).

The production of steel in 2020 is illustrated in Figure 2, by country and respective steelmaking process. China is one of the main steel producers, and in 2020 it was responsible for about 45% of the world's steel (Somers, 2021). This steel was produced mainly through the BOF route.

On the other hand, in Europe, the production of steel is more balanced, although the BOF route has a slightly higher share than the EAF route. It is noted that another route is indicated in Figure 2 for Ukraine and Russia. This other route, the open hearth furnace (OHF), is an older and less efficient process to produce steel.

Although not as popular as the two previous routes, an alternative way to produce steel is through the Direct Reduced Iron (DRI) process. In this case, iron ore is directly reduced in its

Figure 1. GWP and PE in the production of 1 kg of different steel products (Gervásio and Dimova, 2018).

Figure 2. Stages considered in the analysis [extracted from Somers (2021)].

solid state to produce sponge iron, which in turn is melted and refined into steel, often with the addition of scrap in a EAF. The reduction gases in this process are hydrogen and carbon monoxide generated from natural gas or coal, thus avoiding the use of a blast furnace. Steel produced through this route accounts for a minor share (around 5%) (WorldSteel, 2019). However, this production route is currently increasing.

To be in line with EU's climate targets, new low-carbon technologies have to be adopted and/or developed within the near future.

From the above, one important lever for decarbonization of the steel industry is to maximize the recycling of steel, although virgin material will still be required. Other strategies currently being exploited by the steel industry to cut CO₂ emissions, although with completely levels of development, include the replacement of fossil fuels by low-carbon energies, carbon capture and storage, the use of hydrogen to reduce iron-ore (Hydrogen DRI), among others. These latter solutions are beyond the scope of this paper, and in the following, the focus is given to the production of low carbon steel, made through the EAF route and relying on the use of renewable energy.

3 METHODOLOGY FOR LCA

3.1 General framework

The adopted model for the Life Cycle Assessment (LCA) of buildings is based on the standardized framework for LCA developed by CEN TC 350 for the sustainability assessment of construction works (Gervásio and Dimova, 2018). Two main standards will be herein addressed: EN 15804:2012 for the assessment at the product level and EN 15978:2011 for the assessment at the building level. This model was implemented into GaBi (Thinkstep, 2017), a professional software for LCA.

The model takes into account the complete life cycle of the building, from the product stage to the end-of-life stage. According to the above standards, a modular concept is considered for the definition of the system boundaries of the LCA. In this case, the potential impacts occurring at each stage are allocated to a different module, as illustrated in Figure 3.

In the following case study, all modules were taken into account except Modules A4 to A5 and B1 to B7. It is considered that these modules do not depend on the structural system of the building and therefore, they are not considered in the scope of the analysis.

In the following paragraphs, a brief description of the most relevant modules is provided.

Product stage			Process stage		Use stage							End-of-life stage				
A1	A2	A3	A4	A4	B1	B2	B3	B4	B5	B6	B7	C1	C2	C3	C4	D
Raw material supply	Transport	Manufacturing	Transport	Construction	Use	Maintenance	Repair	Replacement	Refurbishment	Operational energy use	Operational water use	Deconstruction	Transport	Waste processing	Disposal	Reuse-recycling-recover
x	x	x	-	-	-	-	-	-	-	-	-	x	x	x	x	x

Figure 3. Stages considered in the analysis.

Modules A1 to A3 – Include the production of all buildings materials that are used in the foundations and structure of the building, until the gate of the factory. Data for these modules is usually provided from the Bill of Materials (BoM) of the building.

Module C1 – C4 – These modules include all relevant data from decommission of the structural system of the building to the stage in which the end-of-waste state is reached by all the structural materials. This includes the use of equipment and machinery for the deconstruction of the building structure, sorting of materials and transport of the resulting materials to their final destination. This data should be based on scenarios.

Module D – This module allocates net benefits due to the reuse, recycling and recover of materials. Data for this module should be based on scenarios taking into account the average available technology, current practices and current rates of recycling, reuse and recover of materials.

Since the case study herein provided is focused on a steel structure, in the following subsection a brief description is provided for the life cycle of steel products.

3.2 Life cycle of steel products

As previously indicated, steel is usually produced either by BF/BOF or EAF. The main difference between these two routes is the percentage of scrap introduced into the steelmaking process. In the BOF route the input of scrap may be up to 35%, while in the EAF route the input is close to 100% (WorldSteel, 2017).

After the steel making process, the downstream processes of casting and rolling are the same, independently of the upstream route. According to the WorldSteel (2017), all products can be produced through both routes, depending on the plant in which they are produced.

Hence, the life cycle of steel products has to consider both possibilities as illustrated in Figure 4. In addition, since there might be an input of steel scrap (in the production stage) and an output of scrap in the end-of-life (steel sent for recycling or reuse), an appropriate allocation procedure has to be adopted to cope with the credits due to the input and output of steel scrap.

The adopted allocation procedure is based on the model developed by WorldSteel (2017). In this case, Module D is given by:

$$Module\ D = \sum_i (RR_i - S_i) (X_{EAF,i} - X_{BF,i}) Y_i \tag{1}$$

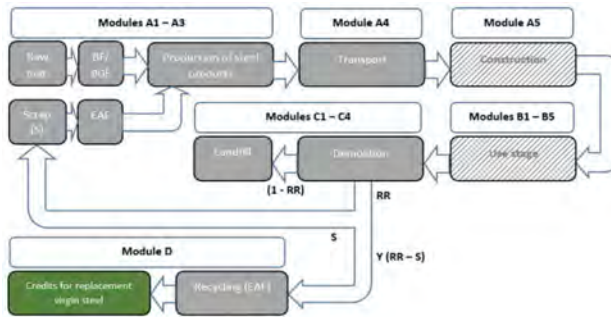

Figure 4. Model for life cycle analysis of steel (Gervasio and Dimova, 2018).

Where, RR is the recovering and recycling rate at the end-of-life stage; S is the recycled content in the production stage; $(X_{EAF,i} - X_{BF,i})$ represents the ‘potential savings’ achieved through recycling (or reuse) relative to primary (BF/BOF) production; and Y is a yield factor representing the efficiency of the steelmaking process.

It is noted that according to expression (1), Module D takes into account only ‘net flows’, given by the difference between output and input flows.

For example, the production of 1 tonne of steel sections, from GaBi database, has a scrap input (S) of 731 kg. Assuming that the recycling rate (RR) at the end-of-life stage is 80%, then the credit allocated in module D corresponds to $800 - 731 = 69$ kg of steel. In this case, Module D has a negative sign, and the complete life cycle of steel sections is given by the values indicated in Table 1:

Table 1. GWP for 1 tonne of steel from a generic database.

Modules A1-A3	Module D	Total LCA
1653 kg CO ₂ eq	-163 kg CO ₂ eq	1480 kg CO ₂ eq

It is worth noting that when the amount of steel leaving the system (scrap to be recycled) is lower than the amount of steel entering the system (scrap input), then the value in Module D is positive, and in this case it represents a burden.

4 COMPARATIVE LIFE CYCLE ASSESSMENT

4.1 Goals of the case study

This case study aims to demonstrate the contribution of low carbon steels in the life cycle analysis of steel buildings. Hence, a comparative life cycle analysis is carried out using two steels with the same grade (S355) but with different values of embodied carbon.

The analysis is focused on a demonstration building to be built in the framework of the project DREAMERS (2021 – 2025), and based on the results of a previous research project: FREEDAM - *Free from damage steel connections* (2015 – 2018).

As the goal of the analysis is to compare different types of steel, the analysis is limited to the load-bearing structure of the building, as all other components would be the same independently of the material of the structure. Further details of the case study are provided in the following sub-section.

4.2 Description of the case study

The demonstration building developed in DREAMERS aims to show the applicability and the increased seismic performance achievable by using innovative friction connections. Hence, the case study hereby presented is focused on a seismic resilient two-storey building, with about 800 m², which is currently being built in the University Campus of Salerno, Italy. It is noted that the following life cycle analysis was carried out based on the preliminary design of the building, considering a total of 93.7 tonnes of steel S355JR.

The building is characterized by a 15 m x 25 m plan, and 2 storeys with a total height of about 10 m. The building will be used for offices and classrooms, and therefore it offers wide internal spaces that allow flexible use of the areas as lecture rooms or open space offices.

The load-bearing structure of the building is composed of twelve columns made with HEB 500 profiles and slim composite floors (CoSFB), with HE300A+500x25 beams, developed by Arcelor Mittal, as illustrated in Figure 5.

Figure 5. Floor layout of the structure of the building [DREAMERS (2021 – 2025)].

This free from damage structure will be equipped with beam-to-column friction joints, developed in FREEDAM project, which are made by friction pads coated by friction material located in the middle of a vertical sliding plates connected by high strength bolts to the bottom flange of the beams (Latour et al., 2022). These joints are assumed to be installed in both buildings so that the structural performance of both buildings may be assumed to be equivalent.

4.3 Life cycle analysis of the building structure

The life cycle analysis herein provided is based on the model previously described. In this case, the environmental data for steel production was retrieved from Environmental Product Declarations (EPD) available online from the platform IBU (<https://ibu-epd.com/>), all the remaining data was from GaBi database. In both cases, the LCA was carried out according to EN 15804:2012.

Two different analysis were carried out: the first analysis took into account a steel produced through the two main routes and a standard energy mix; while, the second analysis takes into account a low carbon steel produced from recycled material and renewable energy. The former analysis is hereafter denominated with standard carbon steel.

Hence, the first analysis took into account a steel produced in both the integrated route BOF (26%) and the electric arc furnace (EAF) route (74%) (bauforumstahl, 2018). The analysis took into account modules A1-A3, C1-C4 and D, and the results are illustrated in Figure 6. The end-of-life scenario assumed 11% reuse, 88% recycling and 1% landfill. The calculation of module D followed the procedure described above.

On the other hand, using a low-carbon steel, considering the production from the EAF (100%) with 100% renewable energy (Arcelor, 2021). In this case, the analysis took into account modules A1-A3, C1-C4 and D. The end-of-life scenario and the allocation procedure considered for

module D are the ones considered for the standard carbon steel. The results of this analysis are compared with the results of the previous one in Figure 6, in terms of Global Warming Potential (in kg CO₂ eq./ton). It is noted that the scenarios considered for modules C1-C4 were the same for both analysis and therefore, the results are not indicated in Figure 6.

Figure 6. Comparative LCA of both steel structures.

As expected, in the case of steel production (modules A1 – A3) the value of the low carbon is much lower than the value of the standard steel (about 2/3 lower). On the other side, in module D the value of the low carbon steel is positive, thus representing a burden (i.e. the net balance between the output and input is negative); while, in the case of the standard steel the result is negative, as the output of scrap is higher than the input. Nevertheless, in terms of the whole LCA result, the life cycle result is about 24% lower when compared with the value obtained by the standard carbon steel.

5 CONCLUSIONS

Despite the investments over time in energy and material efficiency of buildings, the emissions of CO₂ are still rising, widening the gap between the climate performance of buildings and the decarbonization target. Steel is one of the most popular construction materials in the world, but its production is also very energy demanding, thus having an important contribution towards carbon emissions.

To be in line with EU's climate targets, low-carbon materials and technologies have to be considered. Hence, this paper highlighted the contribution of low-carbon steel buildings to the reduction of embodied carbon emissions in the building sector. The study entailed a comparative life cycle assessment of a steel building using standard carbon steel and a building made of low-carbon steel. The results of the life cycle analysis, in terms of Global Warming Potential, showed that the use of the low-carbon steel allowed to reduce in about 24% the value obtained with the other carbon steel.

ABSTRACT: Concrete industry is responsible for 8% of CO₂ emissions (primarily related to cement production) and for about 20 billion tons of natural aggregate consumption. On the other side, it is worth noticing that around 35% of waste generated in Europe is Construction and Demolition Waste (CDW). To reduce the amount of waste generated and prevent raw material consumption, coarse recycled concrete aggregates (CRCA) are a smart solution that can replace natural aggregates without affecting mechanical performance significantly. Furthermore, incineration of municipal solid waste (MSW) is a good option to reduce the volume of waste and generate electric energy in the process. However, this process produces ash that needs to be disposed of, and usually includes heavy metals and toxic organic components. A feasible way to treat ash is vitrification, which allows using it as supplementary cementitious material (SCM) without risks to humans and the environment. In this research, CRCA and vitrified ash from municipal solid waste incineration (MSWI) were used as coarse aggregate (25 and 50%) and cement (10%) replacement, respectively, and then an experimental analysis of fresh state properties and mechanical performance of the developed eco-concretes is presented.

1 INTRODUCTION

Concrete is the second most-used material by mass just after water, with an estimated annual production of 30 billion tons (Monteiro et al., 2020). This massive amount of concrete requires large quantities of components, resulting in particular in 4.17 billion tons of cement used in 2020 (Cembureau, 2021), and converting cement into the largest manufactured product by mass (Scrivener et al., 2018).

The use of by-products created with different types of waste is a viable solution to reduce environmental impact and greenhouse gas emissions in concrete production. According to Eurostat (European Commission, 2020), 798 Mt of construction and demolition waste (CDW) were produced only in Europe. Almost 100% of this waste can be reused in the construction sector as raw material for new elements. Concrete and masonry wastes are the best components that can be used as recycled aggregates to reduce the amount of natural resources exploited in the construction sector, and also reduce energy consumption and waste disposal (Kisku et al., 2017). Several Authors tested concrete with coarse and fine recycled aggregates to check if strength and durability properties were significantly affected. Among others, Hassan et al. (2021) tested full recycled aggregate concrete, analysing coarse and fine fractions alone and together. All mixes had compressive and tensile strength losses, up to 40% in case of full substitution of aggregates by recycled concrete. However, test results by Vinay Kumar

et al. (2018) showed that concrete with recycled aggregates could be even stronger than natural aggregate concrete. This behaviour is depending on the amount of old mortar attached to recycled aggregates. In particular, Duan & Poon (2014) pointed out that voids and cracks in old cement paste can cause more absorption and a weak granular skeleton.

Furthermore, to reduce CO₂ emissions, the use of supplementary cementitious materials (SCM) is the most common option to reduce both the Portland cement consumption and waste generated in some valorization activities. Municipal solid waste (MSW) has increased significantly during the last decades. One common strategy adopted to treat this waste while generating energy is incineration. However, in this thermal process, combustion residues are generated, namely bottom and fly ash, which usually contains toxic compounds for human health and the environment, mainly consisting of heavy metals and toxic organic components. Moreover, the presence of dangerous compounds, such as soluble salts, which could worsen the performance of cementitious materials makes the use of ash without any treatment not advisable. A possible way to treat ash so to make it chemically inert is vitrification. In this way, MSW incineration ash can be used safely as SCM, because of its pozzolanic activity, as highlighted in previous research in the literature (Saccani et al., 2005), (Ferraris et al., 2009), (Sharifikolouei et al., 2020).

In the present study, concrete containing coarse recycled concrete aggregates (CRCA) and municipal solid waste incineration (MSWI) vitrified bottom ash as partial cement replacement was tested. The combined use into concrete of these two kind of waste was never explored before. After raw materials characterization, concrete containing 25% and 50% CDW as aggregate replacement and 10% MSWI vitrified ash as cement replacement was cast and cured in water. Fresh state (slump, fresh density) and hardened state (compressive and flexural strength and fracture energy) were evaluated to determine if these types of concrete could be used as structural material.

2 MATERIALS AND METHODS

2.1 *Materials*

The natural aggregates used were divided into two fractions: river sand (RS) and natural gravel (NG). All materials had around 70-80% SiO₂, containing also low contents of Al₂O₃, CaO, and Fe₂O₃. Recycled concrete aggregates were supplied by ARAPLASA, a CDW management plant located in the Spanish province of Cáceres. This recycled gravel (RG), which consisted only of crushed concrete, was characterised by almost the same particle size distribution of natural gravel.

Municipal solid waste incineration (MSWI) ash used in this experimental campaign came from a plant located in the North of Italy. To apply vitrification, this ash was subjected to temperature increase by starting at 1100°C and then reaching 1450°C (Ferraris et al., 2009). This thermal treatment aims to convert ash into a stable and homogeneous glassy solid material by melt quenching (Colombo et al., 2003) and also to incorporate heavy metals in a stable form inside the glass matrix, combusting, by the way, toxic organic components as dioxins. In this study, after vitrification, the glassy material was ground to obtain powder for cement replacement, with a maximum particle size of 70 µm. Portland cement chosen was CEM II/A-LL 42.5 R according to EN 197-1:2011 standard. Finally, to obtain good workability while maintaining a low w/c ratio, a superplasticizer (Mapei Dynamon Xtend W202R) was used.

2.2 *Mix design*

The six different mixes studied were batched as summarized in Table 1. Reference concrete (RC) contained 100% natural aggregate and no cement replacement, while five different mixes were defined by considering two replacement levels for coarse aggregate and one for cement. In more detail, two mixes (C25 and C50) were obtained by replacing natural aggregates with 25% and 50% of recycled gravel, respectively; one mix (V), by replacing 10% of cement with MSWI vitrified ash and finally, two mixes (VC25 and VC50) were studied with both aggregate and cement replacement. For RC mix, cement, sand, gravel, and water were used in the proportion of 1:2.75:1.375:0.5 by weight. For eco-concrete, the percentage of replacement of natural gravel was computed by volume, while MSWI vitrified ash partially replaced cement by mass.

It is worth noticing that the amount of aggregates (natural and recycled) and water reported in Table 1, refers to the saturated-surface-dry (SSD) condition for the aggregates, so indicating the effective water of the mix. During mixing, all the aggregates were used in dry state, so properly adjusting the amount of required water by considering aggregate absorption (i.e. 0.79%, 0.86%, 5.40%, for RS, NG and RG, respectively).

Table 1. Mix batching.

Concrete components kg/m ³							
Mix	River Sand RS	Natural Gravel NG	Recycled Gravel RG	Cement C	MSWI Vitrified Ash	Water W	Superplasticizer SP
RC	1138.98	567.34	0.00	400.00	0.00	200.00	2.60
C25	1138.98	425.51	134.31	400.00	0.00	200.00	2.60
C50	1138.98	283.67	268.63	400.00	0.00	200.00	2.60
V	1138.98	567.34	0.00	360.00	40.00	200.00	2.34
VC25	1138.98	425.51	134.31	360.00	40.00	200.00	2.34
VC50	1138.98	283.67	268.63	360.00	40.00	200.00	2.34

2.3 Experimental campaign

All mixes were cast using a drum-type mixer following the same procedure. i) dry aggregates were poured inside the mixer with the inner drum surface wet; ii) ~50% of required water was added and mixed for 3-4 minutes; iii) binders (cement and ash) and ~25% of water were added and mixed for about 2-3 minutes; iv) remaining water and superplasticizer were poured and mixed for 3 minutes until concrete components were homogeneous. In all cases, no segregation and bleeding problems were found.

To obtain the same consistence class, defined as S5 according to EN 206:2013, superplasticizer content was modified in the mixes with vitrified ash, reducing the content from 0.65% of cement weight, for RC, C25 and C50 mix, to 0.585% for V, VC25 and VC50 mix.

For each mix, 2 different types of moulds were used for casting according to EN 12390-1:2021: 100 x 100 x 100 mm cubes for compressive strength and fresh density tests and 100 x 100 x 400 mm prisms for three-point bending test and fracture energy. Then, the specimens were cured in water at 20°C ±2°C until testing.

3 RESULTS

3.1 Aggregate characterization

Figure 1 reports particle size distributions of aggregates (river sand, natural and recycled gravel), which were tested according to EN 933-1:2012. Fines content resulted in any case low, because all natural aggregates were washed. In the case of recycled gravel, fines content was below 1.5% according to the standards. Comparing natural to recycled gravel, particle size distribution was almost the same, even if recycled aggregates had sharp edges while natural gravel had smooth edges.

In case of recycled gravel, classification test for the constituents according to EN 933-11:2009 was performed. Results are listed in Table 2. Composition of recycled gravel was almost concrete and unbound particles (Rc+Ru), that must be over 95% to classify this type of aggregate as concrete aggregate.

Coarse aggregate properties are listed in Table 3. Density of recycled gravel was lower than that of natural gravel, with a 10% decrease. Furthermore, water absorption of recycled gravel was nearly 6.2 times higher compared with that of natural gravel. The remaining properties were similar, so this kind of RG can be used in partial replacement of NG in the ratio allowed by the standards for structural concrete. The lower density and higher absorption of recycled

gravel were caused by the attached mortar from old concrete. This old mortar had a lot of voids and cracks, allowing water to enter the pores and increase absorption.

Figure 1. Grading curves.

Table 2. Classification of recycled gravel constituents.

Type	Code	Amount wt%
Concrete, concrete products, mortar	Rc	38.28
Unbound mortar, natural stone	Ru	59.90
Masonry	Rb	0.73
Asphalt	Ra	0.00
Floating particles	FL	0.03
Other (metal, plaster)	X	0.06
Other + Glass	X+Rg	0.06

Table 3. Coarse aggregate properties.

Type	Density Mg/m ³	Absorption wt%	Flakiness index wt%	Water-soluble chlorides wt%	Acid-soluble sulfates wt%	Total sulfates wt%
NG	2.64	0.86	<15	0.0013	<0.2	<1
RG	2.37	5.40	16.08	<0.01	<0.002	<0.001

3.2 Fresh concrete properties

Slump values of all mixes are listed in Table 4. All the values, obtained by following EN 12350-2:2020 standard, were very similar, and equivalent to a S5 consistency according to EN 206:2013, as expected. These findings confirm that recycled aggregates have no influence on workability if the effective w/c ratio is constant. Moreover, C, C25 and C50 mix also had the same SP content.

The experimental data are consistent with the results reported by other Authors replacing up to 100% of coarse (Zhang et al., 2022) or up to 50% of fine natural aggregates with recycled concrete aggregates (Plaza et al., 2021).

On the contrary, it was observed that MSWI vitrified ash increased slump values if w/c ratio and SP content were kept constant. So, in this study, to adjust workability and work with the same consistency in all mixes, SP content was modified for all mixes which included MSWI vitrified ash, resulting in a low amount of SP for mix V, VC25 and VC50 (Table 1). This behaviour was already described by Sirico et. al. (2022) using the same type of vitrified waste material.

Figure 2 plots fresh density obtained for all the mixes, divided into two groups: i) mixes where only CEM II/A-LL 42.5 R is used (denoted as V0, and including RC, C25 and C50 mix,

with a RG percentage equal to 0%, 25% and 50%, respectively) and ii) mixes where MSWI vitrified ash was used as partial (10%) cement replacement (denoted as V10, and including V, VC25 and VC50 mix, with a RG percentage equal to 0%, 25% and 50%, respectively). Density, which was measured according to EN 12350-6:2020, was observed to decline with the increasing of recycled aggregates content, with a linear relationship ($R^2 > 0.99$) between replacement ratio and density. The lower density of recycled aggregates caused a decrease in density, but differences were lower than 2% in all the cases. Xiao et. al. (2005) found slightly higher losses (between 2.4 and 5%) using the same types of aggregates. For MSWI, there was no significative difference by keeping constant the content of recycled aggregates.

Table 4. Slump values obtained for all the concrete mixes.

Mix	RC	C25	C50	V	VC25	VC50
Slump (cm)	22.50	23.25	24.00	23.50	23.00	23.50

Figure 2. Fresh density for mixes without (V0) and with (V10) vitrified ash.

3.3 Hardened concrete properties

3.3.1 Compressive strength

Compressive strength values for all mixes at 7 and 28 days were measured according to EN 12390-3:2020, by means of a testing machine METROCOM PV P30. The results, which represent the mean values obtained on three cubes, together with the related standard deviations, are plotted in Figure 3.

As can be noted, 7-day compressive strength was lower in mixes including MSWI ash (V10), inducing variations between 8.54% (V mix) to 17.53% (VC50 mix). However, at 28 days strength was slightly higher compared with RC mix (0.32% for V mix) or presented comparable values to the corresponding mix without vitrified ash (the maximum reduction, which was registered for VC25 with respect to C25, is less than 3.5%). By comparing 7 and 28 day-strength, it can be argued that MSWI vitrified ash has pozzolanic activity, improving long-term strength by sealing pores due to CaCO_3 obtained by pozzolanic reaction. These results confirm the trend already recognized in literature (Saccani et al., 2005), (Ferraris et al., 2009), (Sharifikolouei et al., 2020).

7 and 28 day-strength was higher for 25% replacement ratio of recycled aggregates (0.78% and 3.45% variation for 7 and 28 days). For 50% replacement, compressive strength decreased by 8.93% at 7 days and 6.49% at 28 days. Chang et al. (2022) observed similar behaviour at 7 days for C25 and similar losses for C50 at 28 days. A higher volume of macropores induced a loss in load transfer capacity due to the presence of mortar in recycled aggregates (Pedro et al., 2017).

3.3.2 Flexural strength and fracture energy

Flexural strength $f_{ct,flex}$ and fracture energy G_f were evaluated by performing three-point bending tests on notched specimens according to the Japan Concrete Institute Standard

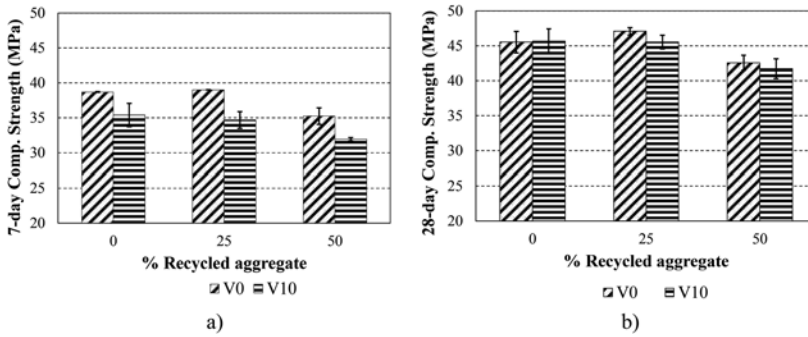

Figure 3. Compressive strength for mixes without (V0) and with (V10) vitrified ash including an increasing percentage of recycled aggregates at: a) 7 days; b) 28 days.

JCI-S-001-2003, which enables to get the load F – Crack mouth Opening Displacement ($CMOD$) curve. The notch was cut in the middle of each beam at the bottom, after 28 days of curing, and its height d and thickness t were equal to 30 mm and 5 mm, respectively. The tests were performed by using an INSTRON 8862 machine, under $CMOD$ control.

Flexural strength, which represents an indirect measure of the tensile strength of the material starting from the peak load of F – $CMOD$ curve (F_{max}), was computed as:

$$f_{ct,flex} = F_{max} \frac{3S}{2B(D-d)^2} \quad (1)$$

where D and B are the height and the width of the cross section (equal to 100 mm), and S is the span (equal to 300 mm).

Fracture energy G_f , a parameter that describes the ability of the material to resist fracture, and related to the area W_0 under the P – $CMOD$ curve, was evaluated as:

$$G_f = \frac{0.75W_0 + W_1}{B(D-d)} \quad (2)$$

where W_1 takes into account the work done by the deadweight of specimen and testing equipment.

The results in terms of $f_{ct,flex}$ and G_f , which were evaluated as the mean values obtained on three specimens for each mix, together with the related standard deviations, are shown in Figure 4.

Considering the standard deviations of the different mixes, it can be stated that the replacement of 10% cement with vitrified ash does not significantly modify the flexural behaviour of concrete in terms of both flexural strength and fracture energy, as already stated by Sirico et al. (2022). This effect is due to the pozzolanic reaction that MSWI vitrified ash develops in combination with Portland cement, as already recognized in this work for compressive strength.

However, concrete with recycled aggregates showed higher values for flexural strength, with similar values for 25% and 50% of replacement. This behaviour is not the most common, but some Authors found similar strength when good quality recycled aggregates are used (Kenai et al., 2002). Furthermore, Jayasuriya et al. (2021) analysed statistically more than 2200 data and found that flexural strength can be from 0.5% higher to 9.3% lower in concrete including partial or total replacement of recycled aggregates.

4 CONCLUSIONS

This work presents the results of an extensive experimental program concerning the development of eco-concrete incorporating recycled concrete aggregates (CRCA) and vitrified municipal solid waste from incineration (MSWI) ash, used as partial replacement of natural aggregates and cement, respectively. The novelty of this study concerns both this use of MSWI vitrified ash as SCM, which was scarcely explored in previous research, and the combined use of these two kind of waste into concrete, which was never been explored before.

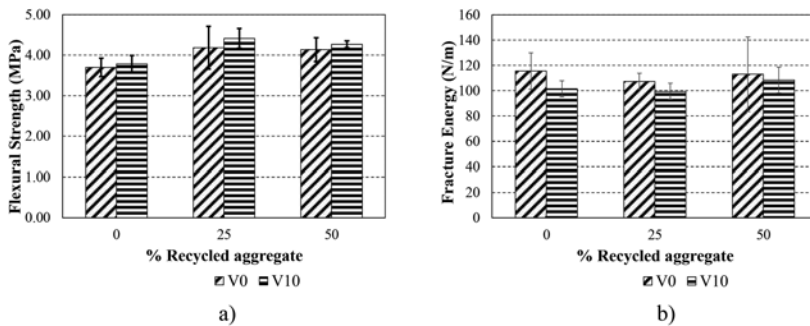

Figure 4. Results for mixes without (V0) and with (V10) vitrified ash including an increasing percentage of recycled aggregates in terms of: a) flexural strength; b) fracture energy.

By analysing the physical and mechanical behaviour of the developed eco-concrete, it can be concluded that the partial substitution of natural gravel and cement with these two types of waste can be successfully adopted for concrete production. These replacements indeed do not cause a significant worsening of the main properties of concrete, but provide undeniable environmental benefits in terms of saving natural resources and reducing CO₂ emissions. Based on the experimental results, the following conclusions can be asserted:

- CRCA have lower density and higher absorption than natural aggregates, but, especially for a replacement up to 25%, all the main physical and mechanical properties of concrete are not negatively affected.
- Recycled concrete aggregates have no influence in workability, whereas MSWI vitrified ash increases slump values.
- Fresh density is not significantly affected by the presence of CRCA or MSWI vitrified ash. More in detail, fresh density is slightly lower when recycled aggregate replacement ratio increases, but in all cases, losses were below 2%.
- Compressive strength is negatively affected by MSWI vitrified ash at 7 days but at 28 days, thanks to its pozzolanic activity, this effect disappears, so obtaining almost the same values as reference. Replacing 25% natural aggregates with CRCA does not worsen the compressive behaviour both at 7 and 28 days, while 50% replacement leads to a reduction equal to 6.49% at 28 days.
- Flexural and fracture energy are not negatively affected by both CRCA or MSWI vitrified ash.

ACKNOWLEDGEMENTS

This research was granted by University of Parma through the action “Bando di Ateneo 2021 per la ricerca” co-funded by MUR-Italian Ministry of Universities and Research - D.M. 737/2021 - PNR - PNRR - NextGenerationEU. Moreover, this study benefitted from the Spanish Ministry of Universities mobility grant (ETS22/00702) awarded in connection with pre-doctoral university professor scholarship FPU19/06704, under which Pablo Plaza Caballero participated in the research at the University of Parma.

Authors gratefully acknowledge Cementirossi SpA and Mapei SpA for providing cement and superplasticizer for concrete preparation.

ABSTRACT: This work aims at the experimental investigation of cementitious materials that incorporate recycled waste, in order to boost the transition of the building industry towards a sustainable path and for the development of a circular economy. More in detail, vitrified beads, which represent the by-products obtained by an innovative industrial plant that produces low-cost energy (steam and electricity), are used as partial aggregate replacement in mortars. Vitrified beads are inserted into the mixes in two different forms: “as they are”, i.e. without any pre-treatment, and after grinding, by replacing in both cases 15% of natural aggregates. The performance of the cementitious mortars with vitrified beads is assessed both on fresh and hardened samples, by means of density and consistence measurements, as well as by performing compressive and three-point bending tests. The obtained experimental results show that this by-product could be a promising waste to be recycled into construction cementitious materials.

1 INTRODUCTION

Nowadays, due to global urbanization, the demand for concrete, and in general for cementitious materials, is increasing, with a level of production reaching more than 30 billion tons each year (Monteiro et al. 2017). This results in high environmental impacts, especially in terms of carbon dioxide emissions (CO₂) and consumption of raw materials. For this reason, in the last years, there has been an increased focus on mitigation strategies, including the use of recycled materials as substitutes for non-renewable resources. The aim is to reduce the environmental impact of the concrete industry and decrease the amount of waste to be disposed of in landfills, so promoting a circular economy. Depending on the chemical composition, the recycled waste can be inserted in the formulation of cementitious materials as filler, cement replacement, or aggregate replacement. Limiting the attention to this latter case, different kinds of industrial by-products or waste have been studied during the last decades; among others, plastics (Saikia & De Brito 2012), glass (Shi & Zheng 2007), fly (Shanmugasundaram et al. 2010) and bottom (Kim et al. 2021) ash, granulated blast furnace (Sandanayake et al. 2020) or steel (Anastasiou et al. 2014) slag, biomass (Thomas et al. 2021), construction and demolition waste (Tam et al. 2018).

The use of waste materials for the concrete industry follows the new trends promoted by the European Green Deal related to sustainability and circular economy, as well as the European actions of Green Public Procurement (GPP). At national level, within GPP policy, the Minimum Environmental Criteria (CAM), which represent mandatory environmental requirements for public procurement in Italy, prescribe that at least 5% by weight of dried product, for both cast-in-situ and precast concrete, should be represented by recycled materials. However, finding suitable recycled materials, which do not compromise the performance of concrete and can be considered safe for the human health and the environment, is still often not easy for concrete producers.

Focusing the attention on ash derived from power plants, furnaces or incinerators, different treatments were proposed in the literature to assure its safety, before inserting it as fine aggregate replacement in cementitious materials. Among them, Revasol process (Aubert et al. 2004), stabilization by a cement-lime process (Collivignarelli & Sorlini 2002), sintering process (Mangialardi 2001), or vitrification process (Sharifikolouei et al. 2019, Ferraris et al. 2009) can be cited. This latter represents a thermal treatment allowing obtaining a glassy solid material with a strongly reduced metal content and organic components compared to the original ash, since the toxic products are volatilized or remain trapped in a stable form.

Few works in the literature have investigated the use of the vitrified product as aggregate replacement. Sharifikolouei et al. (2019) found that the replacement of sand up to 20% in mortars can be adopted without compromising excessively the strength. Ferraris et al. (2009) stated that a sand replacement of more than 25% in mortars leads to unsatisfactory results, whereas the replacement of coarse aggregates (4-10 mm and 10-20 mm) up to 50% replacement by volume allows maintaining almost the same compressive strength as reference concrete with only natural aggregates.

Within the context of finding waste materials suitable for the building industry, in this work the use into concrete of an industrial by-product represented by vitrified beads is investigated. The beads were at first chemically analyzed to check their safety, and then used as partial aggregate replacement in mortars, as a first step for analyzing concrete. Vitrified beads, in which incombustible ash are fixed in a glassy structure, represents a kind of waste coming from an industrial plant that produces energy. The aim of the experimental program was to check the feasibility of developing an eco-concrete that incorporates the vitrified beads: i) without any treatment, ii) after grinding, in both cases as replacement of fine aggregates. The influence of the use of vitrified beads on main properties of the developed mortars were explored in the present study in terms of valuation of density, workability, compressive strength, flexural strength, and fracture energy.

2 MATERIALS AND METHODS

2.1 *Vitrified beads*

The vitrified beads used in this experimental campaign are by-products obtained from an innovative industrial plant that produces low-cost energy (steam and electricity) by using low-rank fuels, such as municipal solid waste, industrial waste, heavy oils, flare gas, pet coke, and poor carbon. In more detail, the plant is based on the “ISOTHERM®” technology, and the process can be summarized as follows. The material to be treated, which in the present research was represented by municipal waste, is introduced into the reactor in the form of a slurry suspension, together with technical oxygen (title 88-94%). In the reactor, slightly under pressure and at a uniform temperature between 1300 and 1500°C, the “ISOTHERM®” process takes place, in a completely different way from traditional combustion. No flame forms and the oxidation reactions of the material occur homogeneously throughout the entire reactor chamber, in a predictable and controllable manner, with a production of only CO₂ and water vapor. In the reactor, the incombustible fraction present in the material to be treated is brought to molten state. Then, it is collected and discharged on the bottom of the reactor, by pouring it into a current of water that causes its instantaneous solidification into inert pearls with a glassy structure, i.e. the vitrified beads.

These beads, which fix incombustible fraction in a glassy structure, are totally amorphous, carbon-free, and do not release unburnt pyrolytic compounds or metals, so being perfectly compatible with the production of building materials, without posing risks to the health and safety of people and environment, as demonstrated by the leaching analysis performed according to EN 12457-2:2004 and EN ISO 11885:2009. The results are reported in Table 1. For this reason, the vitrified beads are respective of the “end of waste” regulation for the reuse of by-products. XRF (X-ray fluorescence) was performed on the vitrified beads, highlighting the presence of oxygen (O), silicon (Si), calcium (Ca), aluminium (Al) in quantities greater than 40%, 25%, 10% and 5%, respectively. Moreover, the amount of chlorine (Cl) and sulphur (S), which can be harmful for cementitious composites, is less than 0.05%. The vitrified beads were used without any treatment (Figure 1a), or after grinding (Figure 1b), as partial replacement of fine aggregates in mortars.

Table 1. Analytical results of the leaching test (in mg/l).

Sb	As	Ba	Cd	Cr	Mo	Ni	Pb	Cu	Se	Zn
<0.003	<0.001	0.002	<0.001	0.005	0.003	<0.01	<0.01	0.002	<0.003	<0.01

Figure 1. Vitrified beads: a) as obtained from the plant; b) after grinding (roll crushing) process.

2.2 Preparation of specimens

To study of the effect of vitrified beads on concrete, mortar mixes were defined with the aim of reproducing a typical concrete for precast elements, by using the “method of concrete equivalent mortar” (MBE), which was originally developed by the Technical Laboratory of Italcementi France (Schwartzentruber & Catherine 2000) and adapted on purpose for this study, on the basis of previous research (Sirico et al. 2020). MBE was adopted to realize tests on mortars, so saving materials (since the smaller size of specimens), but at the same time performing reliable tests able to approximate the behaviour of concrete. Hence, aggregates with maximum diameter of 6 mm were adopted and their quantity with respect to the other components of the mix was adjusted based on MBE. More in detail, this method implies using the same water/cement ratio and the same sand (or very fine gravel) of the reference concrete, while excluding the amount of gravel.

The grain size distribution of natural aggregates used in this study is reported in Figure 2, while the amount of all the components needed for casting are reported in Table 2. All the mixes were prepared by using cement II A-LL 42.5 R, and with a water/cement ratio of 0.45. Moreover, a superplasticizer, Mapei Dynamon Xtend W202R, was used to reach the desired consistency. It is worth noticing that the amount of aggregates and vitrified beads reported in Table 2, refers to the saturated-surface-dry (SSD) condition for them; hence, the amount of water in Table 2 refers to the effective water of the mix. The absorption of natural aggregates and vitrified beads was equal to 0.80% and 0.35%, whereas density was equal to 2.7 g/cm³ and 2.6 g/cm³, respectively.

Table 2. Mix design (in g).

Mix	Cement	Water	Aggregates	Vitrified beads “as they are”	Vitrified beads “grounded”	Superplasticizer
R	391	176	1315	-	-	3.46
V	391	176	1116	196	-	3.46
GV	391	176	1116	-	196	3.46

Vitrified beads were inserted “as they are” (V mix), so without any pre-treatment, and also after grinding (GV mix), in order to highlight the influence both of the waste material and the pre-treatment with respect to the properties of the reference mix (R). R mix contained 100% natural aggregates, while both V and GV mixes contained 15% of vitrified beads, by computing this percentage of replacement by volume of natural aggregates. Vitrified beads “as they are” or grounded were substituted to the corresponding sieve part of natural aggregates, so to obtain about the same size distribution curve for all the mixes, as can be seen in Figure 2.

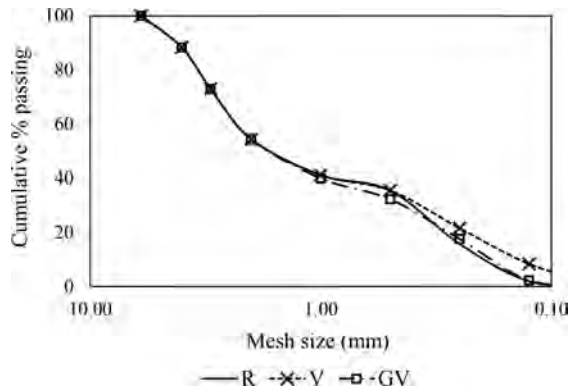

Figure 2. Comparison between the three mixes in terms of grading curves.

All the mixes were cast by using a fully automatic mortar mixer. At first, the bowl was wet, then all the aggregates (natural/vitrified beads) and half of the total water were added and mixed for 120 s at low speed. After 90 s of stop, cement was added and the components were mixed for 60 s at low speed, and then the remaining water and the superplasticizer were added. After 60 s of mixing at high speed, the mixer was stopped for other 90 s, while the edge of the bowl was scraped, and finally, the components were mixed at high speed for 30 s. Then, the admixtures were cast into 40 mm × 40 mm × 160 mm prisms, and compacted by means of a jolting table, by applying 60 jolts per minute for each layer, as described in EN 196-1 (2016). Polythene sheets were put on the molds for the next 24 hours until demolding, and then the specimens were cured in water at 20°C ± 2°C until the day of testing (i.e. 28 days after casting).

2.3 Experimental set-up and methods

Properties at both fresh and hardened state of mortars were analyzed, by means of density and consistence measurements, as well as by performing compressive and three-point bending tests.

Bulk density of fresh mortars was obtained by following EN 1015-6 (2007) standard; whereas consistence was measured as the mean diameter of the test sample, in the two perpendicular directions, placed on a flow table, after shaking the flow table 15 times at a constant rate of about one shot per second, according to EN 1015-3 (2007).

For the measure of flexural strength, each 40 mm × 40 mm × 160 mm prism was subjected to three-point bending, over a net span S of 120 mm. Before testing, a notch a , which was equal to 0.3 times the depth d of the sample, was made at the middle of the specimen by following JCI-S-001 (2003) standard. Three-point bending tests were performed under Crack Mouth Opening Displacement (CMOD) control by using an Instron 8862 machine, by following JCI-S-001 (2003) standard. CMOD was acquired by a clip-gage mounted across the notch, while the load was measured through a load cell with a capacity of 100 kN. Flexural tensile strength $f_{ct,fl}$ was determined as:

$$f_{ct,fl} = 1.5 \frac{P_{max} S}{b(d-a)^2} \quad (1)$$

where b is the width of the cross section and P_{max} represents the peak load of P - CMOD curve.

By performing three-point bending tests, it is also possible to evaluate the fracture energy G_f , since it is related to the ratio between the area W_0 under the load-CMOD curve and the area of the nominal ligament A_{lig} by also taking into account the work done by the deadweight of specimen and loading equipment W_1 . The equation proposed in the JCI-S-001 (2003) standard is adopted herein:

$$G_f = \frac{0.75 W_0 + W_1}{A_{lig}} \quad (2)$$

where $A_{lig} = b(d-a)$.

Compression tests were then performed on the two halves of the broken prisms, previously subjected to three-point bending test (3PBT), by using an Instron 5882 testing machine working under loading control with a loading rate of 2400 N/s, according to EN 196-1 (2016).

3 RESULTS

3.1 Properties on fresh state

As regards bulk density, as expected, no significant differences are recorded for the mixes with vitrified beads (V and GV) compared to the control one (R), as shown in Figure 3a. The density of natural aggregates and vitrified beads presents indeed almost the same values (i.e. 2.7 g/cm³ and 2.6 g/cm³, respectively).

Consistence values, obtained by using the same w/c ratio and superplasticizer (SP) content for all the mixes, are reported in Figure 3b. Since the experimental values for all mixes are between 140 and 200 mm, the mortars can be considered of plastic consistency. By examining Figure 3b, it can be stated that the presence of vitrified ash without pre-treatment (V mix) does not change the consistency of mortar, whereas the use of the grounded material (GV mix) causes a reduction of 19% in the obtained value.

Figure 3. Comparison between the three mixes in terms of: a) bulk density; b) consistency (by flow table).

3.2 28-day mechanical properties

As concern the flexural behaviour, Figure 4 reports the results of three-point bending tests. It can be seen that the replacement of 15% natural aggregates with vitrified beads, grounded or not, does not lead to a significant difference with respect to control, since the same flexural behaviour in terms of stress σ – CMOD, can be recognized for all the admixtures.

Figure 4. Stress σ – CMOD curves as obtained from three-point bending tests for: a) reference mix (R); b) mix with vitrified beads without pre-treatment (V); c) mix with grounded vitrified beads (GV).

More in detail, the average values in terms of flexural strengths and fracture energy computed on three specimens for each mix, as well as the corresponding standard deviations, are reported in Figure 5. Flexural strengths in Figure 5a are analysed by ANOVA statistical test, by adopting a level of significance of 5%, which implies a 95% probability of the use of vitrified beads being significant. Since $F_{\text{calculated}}$ is less than F_{critical} , the null hypothesis is accepted,

which means that there is no statistically significant effect among the averages of the considered mixes. The same ANOVA analysis is performed also on the results of fracture energy reported in Figure 5b, so confirming that there is no statistically significant variation in fracture energy values when vitrified beads are used as partial aggregate replacement.

Figure 5. Comparison between the three mixes in terms of average: a) flexural strength, and b) fracture energy, together with the corresponding standard deviations.

Figures 6a and b report the images of one-half of the broken prism for mix V and GV, after three-point bending test. As can be seen, the vitrified beads are well distributed along the whole height of the sample, so confirming at hardened state the high homogeneity of the mixture, which was seen also during mixing, without any segregation or bleeding.

Figure 6. Broken specimens from 3PBT: a) V mix with vitrified beads without any treatment; b) GV mix with grounded vitrified beads.

Each of the two halves of the prisms broken under flexure were then tested under compression. Figure 7 reports the average compressive strength computed on the six resulting specimens for each mix, together with the corresponding standard deviations. As can be seen, the replacement of 15% fine aggregates with the vitrified beads, without pre-treatment or after grinding, does not worsen the compressive behaviour. The ANOVA analysis confirms indeed that there is no significant variation between the experimental values of the three mixes.

Figure 7. Comparison between the three mixes in terms of average compressive strength together with the corresponding standard deviations.

4 CONCLUSIONS

In this work, the mechanical behavior of mortars that incorporated vitrified beads was experimentally investigated, so to assess if the use of this by-product coming from an innovative industrial plant that produces low-cost energy, could be promising for the development of eco-friendly and sustainable cementitious materials.

The vitrified beads were included in the mixes both “as they are” and grounded. The substitution of 15% aggregates by volume with vitrified beads without pre-treatment enables reducing the environmental impact of mortars (by saving natural resources), without diminishing their physical and mechanical performance. 28-day compression strength resulted slightly enhanced, while the observed flexural behavior was almost the same then that of the reference mortar. Similarly, the use of grounded vitrified beads leads to the same mechanical properties as reference, but a significant reduction of flowability was observed. Since in this case also an additional energy consumption is needed for grinding, it can be argued that the more favorable option for the use of these vitrified beads into concrete is without any pre-treatment.

So, based on the experimental results, it can be concluded that this vitrified material without pre-treatment seems an excellent substitute for fine aggregates, since its use allowed maintaining unaltered all the analyzed properties of the mortars: density, consistence, compressive and flexural behavior. Given the promising results obtained from this first experimentation, the use of this by-product into concrete could be further explored, also by considering increasing percentages of aggregate substitution. Moreover, in order to better clarify the actual environmental benefits related to the recycling of this material, the study should be completed by a Life Cycle Assessment analysis able to quantify the overall sustainability of this eco-concrete.

ABSTRACT: The use of recycled materials in concrete members has gained a significant attraction in the last years. In this context, the possibility of including metallurgical slags in concrete has been explored by several research works, among them it is worth citing the ones carried out in the last 15 years by the research groups of the University of Padova, University of Burgos and University of Basque Country. In this contribution, a review of the main features of Electric Arc Furnace slag (EAF) concrete is made, focusing on the improvements observed in the properties of this concrete compared to the reference realized with natural aggregates only. Furthermore, two examples of real-scale applications in reinforced concrete (RC) structures are shown. Lastly, a life cycle analysis (LCA) has been applied to one of the above-mentioned cases, demonstrating the gains in terms of reduced environmental impacts that can be achieved using this material.

1 INTRODUCTION

During the last years, many efforts have been made to develop sustainable concretes containing recycled materials, thanks to the policies related to the sustainable development goals (SDGs) asked by United Nations. The possibility of using industrial waste as aggregate in concrete has been widely studied. Some research groups primarily studied Basic Oxygen Furnace (BOF) slags and Blast Furnace (BF) slags (Douglas et al. 1997, Jelidi & Bouslama 2015, Reddy et al. 2006). In Italy and Spain, however, the production of steel occurs mainly in Electric Arc Furnaces (EAF), and thus EAF slag is much more abundant than the others. Particularly, EAF slag is formed during the refining process of the molten steel bath, thanks to the addition of some materials such as limestone, lime and fluorspar. Nowadays, about 40% of global steel production is carried out properly in EAF plants, and every year, more than 10 million tons of this slag are produced all over Europe, with some peaks in North-Eastern Italy and in Northern Spain. Recall indeed that from one ton of steel produced in an EAF, approximately 100–150 kg of electric arc furnace slag is obtained.

For this reason, a consistent literature was provided by authors from these two regions, to find suitable recycling potentials for this material. Among the others, the contributions from University of Padova in Italy and University of Burgos and Basque Country in Spain are worth mentioning, both for their consistency and abundance of experimental data.

In the past, the partial and total substitution of natural aggregates with EAF slags was investigated by the authors. Since aggregates represent about 70% of total concrete volume, they significantly affect the properties of the fresh and hardened conglomerate. As an indicative data, the permanent growing of raw material consumption is principally due to building industry according to OECD (OECD 2018). At the end of 2021, US construction aggregate

producers closed the year with shipments totaling 1.54 billion tons of crushed rock and 1 billion tons of sand and gravel (Concrete News 2022). According to the principle of circular economy, the possibility to employ EAF slags in concrete allows to reduce raw material consumption and the amount of slag to be disposed of.

Several research works have been developed to test both mechanical properties and durability of concrete containing EAF slag. In most cases, EAF concrete shows similar, and even superior, mechanical properties than Natural Aggregate Concrete (NAC). Promising results were obtained about the adoption of this concrete for structural applications, as observed testing different real-scale elements, such as RC beams under flexure-shear (Faleschini & Pellegrino 2013), RC beam-columns joints under cyclic reversed lateral loading with flexural-shear failure (Faleschini et al. 2017a,b). Some recent results highlighted that, both under gravity loads (Zanini 2019) and seismic solicitation (Faleschini et al. 2019), the use of EAF concrete allows attaining the same, or even higher structural reliability than NAC. Additionally, even in the production of self-compacting concrete (Santamaria et al. 2020) and high-strength concrete (Faleschini et al. 2015), EAF slag seems to be employable in substitution of natural aggregates.

To better understand which are the main features that characterize EAF concrete, a first review of the main outcomes from more than 15 years of past research studies are shown here. Then, two examples of real-scale applications of EAF concrete in reinforced concrete (RC) structures are presented. Lastly, the environmental performance of this kind of concrete is discussed, through the application of a life cycle analysis (LCA) to one of the above-mentioned cases.

2 EAF SLAG PROPERTIES

The properties of EAF slag, and in turns, those of EAF concrete, depend on multiple variables that can be summarized as: the type of furnace, the type of steel to be produced, the type of additions, the operating conditions of the furnace, the management operations carried out during and after the slag cooling. Focusing on the EAF-C type only, i.e., the slag produced from carbon steel production, and on the most common type of cooling processes (based on slow air-cooling) and slag treatments (weathering and crushing, sieving, magnetic separation), it can be said that typically this material is reused as an aggregate for bituminous and hydraulically bound mixtures (Kumar & Varma 2021) or for cement-based materials (Lee et al. 2019). This slag type appears as a dark grey/black rock (Figure 1), sometimes with some white spots (associated to the presence of limited quantity of free CaO, when the slag is not properly weathered), and it has a crystalline nature.

Figure 1. EAF slag particles (coarse fraction).

The above-mentioned variables may influence significantly the physical, chemical and micro-structural properties of the slag: in fact, non-negligible differences may be found when comparing slags obtained from different facilities. For instance, Santamaria et al. (2017) compared two slag

types, one coming from Zerocento Srl, a company located in Italy, and from Hormor-Zestoa in Spain, demonstrating that the two slags have different compositions (e.g. the iron oxides content varied more than 10%). Different phases were observed through the X-Ray Diffraction (in the former case, the most abundant phases were wustite, larnite, ghelenite and magnetite, whereas in the latter wustite, ghelenite and kristenite), and also the physical properties differed. Particularly, the Spanish slag was characterized by a higher porosity and lower density compared to the Italian one, with a difference, for this last property, of more than 10%. Additionally, the treatment operations may affect significantly the expansion potential of a slag: dimensional stability is a feature of paramount importance for a safe use in concrete materials, and it should be limited below 0.5% according to some recent indications (Santamaria et al. 2018). The same authors highlighted how the pretreatment operations, and specifically cooling and weathering type and duration, have a significant impact to reduce slag swelling potential.

A dataset collected by some of the authors (Pellegrino & Faleschini 2016), continuously updated during time, allows to provide the range of variations of some main features of the EAF-C slag type, that can be summarized as shown in Table 1. Data refer to average values from aggregates having both fine (0-4 mm) and coarse (> 4 mm) particle size.

Table 1. Range of variations of the physical properties of EAF slag from carbon steel production.

Property	Unit	Average Value
Density	kg/m ³	2840 – 4020
Bulk density	kg/m ³	1480 – 1900
Water absorption	%	0.1 – 10.0
Volumetric expansion	%	0.1 – 3.5
Pore dimensions	mm	0.2 – 8000
Porosity	%	2 – 42
Los Angeles Loss	%	10 – 35
Crushing Value	%	10 – 22
Shape Index	%	1 – 10
Flakiness Index	%	1 - 10

3 EAF SLAG CONCRETE PROPERTIES

EAF slag has been used to cast both concretes with normal strength (NSC) and ordinary features, but, as already mentioned, also high strength concrete (HSC) and self-compacting mixes (SCC) could be achieved using this material as an alternative aggregate. Here the effects of aggregates partial or total substitution on NSC are discussed only for sake of brevity, recalling that the introduction of the EAF slag in a mix affects the properties both in the fresh and hardened states.

EAF concrete is generally characterized by a worse workability than NAC, and the decrease of this property is proportional to the amount of the substitution. In general, the highest deterioration of the slump value is observed when also the fine fraction of the aggregates is substituted. The reasons of this low performance at the fresh state depend on the particles shape, which is typically very angular due to the crushing process (Pellegrino et al. 2013), and this has an impact on both the viscosity and yielding stress characterizing the flow of a viscoplastic fluid. Further, some slags are characterized also by high water absorption, thus altering the water demand of the mix. However, the adoption of water reducing admixtures (fluidifying, plasticizers, air entrainers) is able to limit this effect and to allow to cast EAF concrete mixes with comparable fluidity of NAC.

In terms of density, EAF concretes exhibit higher values of this property, but the increase depends significantly on the slag density itself, and on the slag replacement ratio. As discussed in Section 2, depending on the slag type, this property may vary a lot. EAF concretes density may vary between 2500 and 3100 kg/m³, and even more. However, in general terms, an EAF concrete can be seen as a high-density concrete, and thanks to this feature, several works attempted to investigate its ability to shield the radiations, obtaining successful results (Papachristoforou & Papayianni

2018, Pomaro et al. 2019). Accordingly, EAF concrete can be used as a sustainable alternative to concretes made with barite, limonite, hematite, etc.

Concerning the mechanical strength, the main parameters that are investigated in literature are compressive, tensile and flexural strength, other than the strength gain in time. All the three main strength properties are generally positively influenced by the addition of the slag, especially when it is used in the coarse fraction. The beneficial effect associated to the EAF slag use is linked to several co-causes, among which is worth mentioning the high strength of the slag itself (recall that the composition is made by iron oxides in large amount), the good bond with the cementitious matrix thanks to the slag shape, and lastly, a good interfacial transition zone (ITZ) quality (Arribas et al. 2015). The strength enhancement depends also on the slag type: in fact, when porous slags are used, this beneficial effect is less visible. However, in average, Faleschini et al. (2019) estimated that the average increase is about 35-40% on the compressive strength value. Concerning the latter feature, i.e., the strength development in time, this is not influenced by the slag use in the concrete mix.

The elastic modulus of EAF concrete is also affected, but also in this case two main cases may be observed, depending on the slag porosity: when low-porosity slags are adopted, the elastic modulus increases even by 30% compared to that of NAC; instead, for porous slags, such increase is much more limited, and, in some cases, even less stiff concretes may be obtained compared to their natural counterparts.

In terms of durability-related properties, the number of available experimental evidences decrease significantly in literature, which however are sufficient to depict a trend of the expected behavior of this kind of concrete in the longtime. In fact, similarly to what already observed for the mechanical strength and elastic properties, properties such as water absorption, chlorides penetration, freezing/thawing and wetting/drying resistance are all affected depending on the slag features, and particularly, on its porosity. Better behavior is displayed by those concretes made with non-porous EAF slag, with improvements in the above properties until 10-20%, whereas when porous slags are used, generally no enhancement (but either, no deterioration) is obtained. A special mention has to be done about two properties: carbonation and high temperature resistance. For the former property, non-conclusive results are available in literature: some authors reported a better behavior of EAF mixes (Andrade et al. 2021, Sosa et al. 2022), some others an increase of the carbonation depth that could reach six times higher than that observed in NAC (González-Ortega et al. 2019). The latter property is instead investigated in Beaucour et al. (2020): EAF concrete is more stable with regard to linear expansion and contraction, it does not display appreciable signs of aggregates spalling even when the heating rate is more critical, and its strength loss at high temperatures (until 600°C) is more limited than in NAC.

Table 2 provides a brief summary of the effects of EAF slag introduction in concrete, in qualitative terms when no quantitative average indications can be provided. Recall that these data refer to average values considering both the most and least porous slags that may be found in the market.

Table 2. Average variations of EAF concrete properties compared to those of NAC.

Property	Unit	Average Variation (%)	Average Effect
Workability	mm	-	Slightly decrease
Density	kg/m ³	+ 15% (up to + 30%)	Increase
Compressive strength	MPa	+ 20% (up to + 30%)	Increase
Tensile strength	MPa	+ 15% (up to + 30%)	Increase
Flexural strength	MPa	+ 15% (up to + 30%)	Increase
Strength gain in time	MPa	-	Not affected
Secant Elastic Modulus	GPa	+ 15% (up to + 40%)	Increase
Water absorption	%	-	Decrease
Carbonation depth	mm	-	Increase or decrease
Chlorides penetration	mm	-	Decrease
Freezing/thawing resistance	-	-	Slightly increase
Wetting/drying resistance	-	-	Slightly increase
High temperature resistance	-	-	Increase

4 EAF SLAG CONCRETE: APPLICATIONS IN REAL SCALE STRUCTURES

Here, two applications in real structures of EAF slag concretes are shown, one from the Spanish and one from the Italian context. The first case-study deals with the construction of the Kubik building, owned by Tecnia, and located in Zamudio, in the Basque Country (Figure 2). The building, with an overall surface of 500 m² distributed in an underground floor, a ground floor and up to two story, was inaugurated in 2010 and currently it is in its full operation. The main walls and the foundations of this building were casted with two different concrete mixes including large amounts of EAF slag (Chica et al. 2011). For instance, to cast the foundation slabs, about 150 m³ of EAF concrete were used: the mix was based on a limestone cement with rapid strength development, a relatively low w/c ratio, whereas the 80% of the coarse aggregates and 100% of the fine ones were made by EAF particles. The overall recycled constituents of this mix reached about 76% on the total compounds. The average compressive strength of the concrete at 28 days of curing was 47 MPa and 53 MPa for the walls and the foundation slabs, respectively.

Figure 2. Kubik building from Tecnia (courtesy of Prof. Manuel Manso, University of Burgos).

The second case-study deals with the rehabilitation works of a military infrastructure (owned by the North Atlantic Treaty Organization - NATO) located in Vicenza, Italy, where Heidelberg Cement Groups casted about 11455 m³ of EAF concrete for varying structures. The works were carried out in 2009. Among them, they produced concretes characterized by different strength classes, varying from $f_c = 10$ to 32 MPa, which were employed both in non-structural elements and for the foundation elements, including the slabs and piles. The mix design, in this case, includes a slag cement with rapid strength development, and the overall content of EAF slag was about 10% on the overall constituents of the mixes (Zecchini 2019).

5 ENVIRONMENTAL FOOTPRINT OF EAF CONCRETE

The most common tool to assess the environmental impacts associated to a product is the Life Cycle Assessment (LCA), which is a methodology for quantifying environmental impacts and burdens associated with an item over its entire life (ISO 14040, 2006). LCA is often applied even in the field of construction materials and more generally, in civil engineering (Knoeri et al. 2013, Faleschini et al. 2014), to quantify and compare different scenarios related to the adoption of one material (i.e., the natural) or another (i.e., in the present case, the EAF slag concrete). Depending on the system boundaries, the analysis is carried with a cradle-to-gate or cradle-to-cradle approach: in the former case, the analysis simply stops when the material is released in the market, whereas in the latter it integrates all the life phases of the structure, i.e., material manufacture,

construction, maintenance and operation, and lastly the end of life, with its alternative solutions being dismantling and landfilling or materials recovery and recycling.

Here, LCA is carried out with reference to the first case-study, i.e., the casting of the RC slab of the Kubik building, comparing the current scenario to that of having adopted natural aggregates only. LCA is made by four mandatory phases: (i) the goal and scope definition; (ii) the inventory analysis (LCI); (iii) the impact assessment (LCIA); and finally (iv) the interpretation. The simplified procedure followed here assumes that first only the aggregates' impacts are analyzed; once the aggregate emissions estimation has been performed, the assessment of the environmental impacts of the experimental concrete mixes of NAC and EAF concrete is carried out. This means that in this case, only the impacts related to production of the materials are considered, thus neglecting both transportation and manufacturing of concrete, which are assumed to be similar both in case of NAC and EAF concrete.

Concerning the first step, the aim of the study is to define the environmental emissions of the products "1 slab made with NAC" and "1 slab made with EAF concrete", and compare the main results together. For this scope, it is necessary to define the system boundaries related to the aggregates production, with a cradle-to-gate approach, where the major processes included are the extraction of raw materials, manufacturing and transportation. Concerning the EAF slag, particularly, the "zero burden assumption" (Ekvall et al. 2007) is adopted, meaning that the slag does not carry any of the steel production upstream burdens into the waste-management system. This choice is due to the fact that still in most cases the slag is not considered as a product, but for a steel-plant, it is considered a waste only. The choice is also supported by the enormous difference in the final price to the market of 1 ton of steel and 1 ton of slag (economic principle).

All the supporting data are taken from Faleschini et al. (2014), where an exhaustive analysis was already carried out using inventory data collected from real plants of natural aggregates extraction and slag management. Particularly, in that work, the Life Cycle Inventory (LCI) phase was carried out to collect the data for each unit process, quantifying all relevant input and output elements of the products systems, both for NA and EAF slag. Cement impacts are still taken from the same publication, whereas the impacts related to the admixtures are not considered due to the small amount of them in the mixes. The impacts related to the steel reinforcement are instead neglected, assuming that the same reinforcement details are used both for the project with EAF concrete and NAC, given the same strength class of the two mixes.

The impact assessment is carried out following a problem-oriented methodology, thus allowing to calculate the environmental impacts associated with climate change, eutrophication, acidification, human toxicity, eco-toxicity, etc. In order to evaluate the environmental burdens for the systems of NA and EAF slag, the evaluation procedure is performed in all the production phases, and it is based on the basic categories of CML 2002 Method (Guinée et al. 2002). A limited set of mid-point indicators will be shown here for sake of brevity, which are Global Warming Potential (kg CO₂ eq.), Acidification (kg SO₂ eq.) and Eutrophication (kg PO₄ eq.).

The interpretation phase follows with a comparison of the two identified scenarios, i.e., the production of 1 slab made with 150 m³ of NAC and 1 slab made with 150 m³ of EAF concrete. Particularly, two mix designs are considered, that correspond both to the same strength class with $f_{ck} = 30$ MPa. The two mixes are shown in Table 3, whereas the calculated impacts are shown in Table 4 for each of the analyzed impact categories.

Table 3. Mix details (in kg/m³).

Compound	NAC	EAF concrete
Cement II-B-M(V-L-S) 42.5R	400	385
Natural sand	723	-
Natural Coarse Aggregate	1085	271
EAF Slag Sand	-	958
EAF slag Coarse Aggregate	-	1091
Water	172	173
Admixtures (%)	0.6	1.2

Table 4. Total environmental emissions for the analyzed categories, for 1 slab of RC with 150 m³.

Compound	NAC	EAF concrete	Saved Emissions
Climate change (kg CO ₂ eq.)	23597	21795	- 8%
Acidification (kg SO ₂ eq.)	78.8	71.2	- 10%
Eutrophication (kg PO ₄ eq.)	8.2	7.8	- 5.3%

6 CONCLUSIONS

The following conclusions can be drawn from this study:

- EAF slag is a very hard, black, stony-like recycled material coming from steelmaking industry as by-product; its properties depend on multiple variables, but generally it is characterized by lower porosity and higher density compared to NA.
- The concrete containing EAF slag shows similar mechanical properties, or even better, compared to traditional counterparts in terms of compressive, tensile and flexural strength. In terms of durability, the properties are typically enhanced, too.
- Real-structures applications confirmed that EAF concrete can be suitably used without compromising the serviceability, functionality and the behavior at the ultimate state.
- Casting a RC element with EAF concrete, instead with NAC with the same strength class, allows to reduce the environmental emissions in terms of CO₂, SO₂ and PO₄.

Sustainable design of lightened reinforced concrete flat slabs in coastal environment

A.J. Sánchez-Garrido, I.J. Navarro & V. Yepes
Universitat Politècnica de València, Valencia, Spain

ABSTRACT: The construction industry has a significant impact on the environment, particularly in the residential building sector, due to high resource consumption. To reduce environmental impact in the construction, service, and end-of-life phases of buildings, scholars prioritize adopting Modern Methods of Construction (MMC) to optimize material consumption and minimize the life cycle impact of buildings. This study assesses the sustainability of reinforced concrete flat slabs using a hollow structural body system, especially in environments that trigger concrete corrosion. The analysis focuses on seven design alternatives for a beachfront hotel structure, using the VIKOR technique to aggregate five sustainability criteria. The most cost-effective and environmentally beneficial option is using 10% silica fume concrete, which reduces life-cycle costs by 87% and impacts the base design by 67%. However, considering economic and environmental sustainability criteria led to better sustainable designs, such as a more extensive concrete cover for bottom reinforcing bars resulting in a 46% better sustainability index.

1 INTRODUCTION

Around half of the non-renewable resources consumed by humanity come from the construction industry, making it one of the less sustainable sectors in the world (Yepes & Lopez, 2021). If this trend continues, energy efficiency and the transition to renewable energy will no longer be enough. Against this alarming backdrop, the newly established European Green Deal aims to overcome the challenges posed by climate change by, among other objectives, the firm intention of achieving no net greenhouse gas emissions by 2050. The fact that one-third of the investments from the NextGenerationEU Recovery Plan are intended to finance the European Green Deal shows the commitment of the European Commission to achieve climate neutrality. This is only one of the many initiatives slowly trying to materialize the Sustainable Development Goals established in 2015.

In this context, the search for sustainable buildings and other infrastructures arises as a critical requirement to achieve the abovementioned carbon-neutral horizon we aspire to (Lei et al., 2021; Chan et al., 2022). Recently, research has been conducted on the sustainability assessment of several infrastructures (Navarro et al., 2020), building structures (Sánchez-Garrido et al., 2022b) or constructive elements (Pons et al., 2018; Balasbaneh & Marsono, 2020). A conclusion that is recurrently reached in recent research is that the impacts related to the maintenance of buildings and other types of structures play an essential role in the life cycle-related sustainability performance of the designs. Consequently, more and more studies focus on optimizing maintenance activities (Frangopol et al. (2017); García-Segura et al., 2017) or analyzing different material alternatives to increase the durability of conventional designs (Biondini & Frangopol, 2017; Navarro et al., 2018), trying

to reach conclusions on the best practices to achieve sustainable structures and buildings along their service lives.

Such impacts are particularly relevant in aggressive environments, where the maintenance demands can be significant. Such is the case for coastal regions, where concrete structures are affected by chlorides (Petcherdchoo, 2015). Consequently, studies on the performance of different design alternatives in such scenarios are essential to achieve both durable and sustainable solutions.

The present communication aims to evaluate the life cycle impacts of seven improved design alternatives on a particular type of MMC, namely “Unidome” slabs. MMCs are postulated as economically preferable alternatives to conventional construction methods and a powerful way to reduce life cycle environmental impacts by optimizing material consumption. These alternatives are intended to increase the durability of the base design, thereby reducing maintenance requirements over the life cycle of use and maintenance of the structural solution. Several economic and environmental criteria are considered to evaluate each design’s sustainability.

2 MATERIALS AND METHODS

2.1 *Goal and scope definition*

This work aims to analyze the sustainable performance of different alternatives based on the reference design for the structure of a hotel building located on the coast of Chiclana, Cadiz (Spain). The reference design (hereafter REF) comprises a module of rooms between expansion joints that, with three floors and repeated longitudinally, represents more than 80% of the built area of the hotel. Structurally, the module consists of a mat foundation and three slab levels (Figure 1), designed with an innovative MMC. The system consists of reinforced concrete flat slabs lightened with hollow structural bodies (hereafter referred to as “Unidome slabs”).

One of the attacks that most affect the durability of concrete is the penetration of chlorides from seawater, with varying degrees of severity. The design alternatives considered base their durability strategy on extending the service life of the concrete structure. For this purpose, different response mechanisms against chloride-induced corrosion are used, such as improving the resistance of the concrete to external aggressions, its thickness, the inhibitory protection, or the type of steel. Six alternative designs are analyzed here, along with the REF design, for comparison. Three design options are based on reducing the permeability of concrete. One way is to modify the base mix using cement with 10% silica fume (hereafter, SF-C) or adding admixtures such as 20% fly ash (hereafter, FA-A). Another way is to achieve a very compact and well-vibrated concrete by reducing the water-to-cement ratio from 0.60 in the base mix to 0.50 (W/C alternative). The duration of the protective effect of the concrete on the reinforcement can be extended over time by increasing, at most, the concrete cover from 3 cm in the baseline option to 4.5 cm (CC45 alternative). Applying a hydrophobic corrosion inhibitor impregnation (HCII) to protect the exposed surface of the slabs is also a suitable option. Using corrosion-resistant steels is also an excellent way to increase corrosion durability. In our case, we replaced conventional carbon steel reinforcing bars with galvanized steel reinforcing bars (GSR). Stainless steel is not valued because its cost for building construction is so high that, except in very justified cases, it is economically unsustainable.

In order to compare the life cycle impact assessment, it is necessary to base it on the same functional unit, according to ISO 14040. This analysis considers 1 m² built based on a hotel module composed of three levels of rooms and 2132 m² built of structure and foundations. To assess the impacts derived from both construction and maintenance activities, a “gate to gate” approach has been considered. Construction and maintenance activities are included for a nominal service life of 50 years, as required by national codes (Fomento, 2008).

Figure 1. 3D model of the baseline (REF) structure.

2.2 Reliability-based maintenance requirements

A deterioration model will be chosen to determine the impact of maintenance on each of the design alternatives to be compared. A durability model has been chosen for chloride corrosion processes versus carbonation since the former is a much faster attack in a marine exposure environment such as the one in question. Concrete deterioration begins when chloride ions penetrate the concrete cover and reach the reinforcing bars at a concentration capable of triggering the steel corrosion process. This concentration is known as the critical chloride content (C_{cr}), whose reach time depends on the properties of the concrete cover. Under normal conditions, a value of 0.6% of the weight of cement is adopted according to the Spanish concrete code. The propagation stage is completed when an unacceptable steel section loss occurs, or cracks appear in the concrete cover. A two-dimensional version of the Fickian model suggested in Fib Bulletin 34 (2006), subsequently refined by Navarro et al. (2019), to evaluate the progression in chloride concentration in concrete as a function of time is used. The chloride concentration C at any time t (in years) and any depth (in mm) in the x and y directions of the analyzed cross-section can be calculated as:

$$C(x, y, t) = C_s \left[1 - \operatorname{erf} \frac{x}{2\sqrt{D_{0,x} \cdot \left(\frac{t}{t_0}\right)^\alpha \cdot t}} \cdot \operatorname{erf} \frac{y}{2\sqrt{D_{0,y} \cdot \left(\frac{t}{t_0}\right)^\alpha \cdot t}} \right] \quad (1)$$

where C_s = surface chloride concentration (wt%/binder); $\operatorname{erf}(\cdot)$ = the Gaussian error function; D_0 ($\times 10^{-12}$ m²/s) is the chloride diffusion coefficient (mm²/year); α = age factor, assumed 0.5 according to the Spanish codes; $t_0 = 0.0767$ years (28 days).

Table 1 shows the value of the parameters used to characterize the measures analyzed and the maintenance cycles required during the structure's service life (50 years) according to the durability obtained for each alternative. After each maintenance cycle, the structure is assumed to recover its original state (Stewart et al., 2004).

Table 1. Characterization of the durability of the preventive alternatives studied.

2.3 Impact assessment

Two sets of criteria have been considered to assess the impacts generated along the life cycle of each of the design alternatives under study. The first set, containing economy-related criteria, includes two impacts: the costs associated with the construction of the above-described functional unit and the costs associated with the use and maintenance life cycle stage.

The second set of criteria includes the three endpoint assessment criteria associated with the environmental assessment methodology called ReCiPe: damage to human health, ecosystems, and resource availability. ReCiPe methodology converts the emissions of any activity into 18 so-called midpoint indicators, which include impacts such as an increase in various types of diseases (respiratory, cancer, and others), damage to different types of species (terrestrial marine and freshwater), and also the effects of the increasing scarcity of natural resources. These midpoint impacts are then adequately grouped and converted into the abovementioned endpoint indicators. On the one hand, the damage to human health is measured in DALYs, which stands for Disability-Adjusted Life Years. This metric takes into consideration the living years which are lost due to premature death or due to illnesses of different types.

The damage to ecosystems is measured in PDF, which stands for Potentially Disappeared Fraction. It evaluates the species that are potentially lost yearly due to the effects of anthropogenic activities occupying or converting their habitats. In addition, the PAF is also considered to evaluate the impacts on the ecosystems, which stands for Potentially Affected Fraction. This metric measures the percentage of species exposed to unbearable toxic substances. The last assessment criterion is related to the contribution of each of the alternatives under study to the scarcity of natural resources. According to the ReCiPe assessment methodology, this impact considers the energy surplus required to extract mineral resources or fossil fuels.

Finally, the subjective weightings of each criterion are determined using the Analytic Network Process (ANP) through a group of experts (Sánchez-Garrido et al., 2022c). Once the relevance is assigned to each criterion, a distance-based MCDM technique, namely VIKOR, is applied to find the design alternative with the maintenance interval that maximizes the sustainability of the structure's life cycle.

2.4 Inventory analysis

The material quantities associated with each alternative will be defined to evaluate the above impacts. The costs are summarized in Table 2 and include materials, labor, equipment and machinery, and direct ancillary costs. The material costs assumed in this analysis have been collected from specific and recognized Spanish construction databases developed by "CYPE Ingenieros", updated to 2022, and specific supplier data.

Table 2. Construction and repair costs considered in LCCA.

Parameters of design alternatives	Cost	Unit
Mat foundation 60 cm (25 Mpa) + steel 60 Kg/m ³	196.22	€/m ³
Concrete slab 25cm (25 Mpa) + steel 104 Kg/m ³	116.76	€/m ³

3 RESULTS AND DISCUSSION

3.1 LCCA results

Figure 2 reproduces the results obtained in the life cycle economic assessment for the seven design options analyzed. It includes the costs associated with construction per square meter of structure and those related to maintenance over 50 years. Repair costs are calculated based on the reactive maintenance cycles required for each alternative, depending on the strategy adopted to extend the structure's service life.

The lower construction cost is attributed to the REF option because it is the baseline option that does not incorporate any preventive strategy. This economic reading will be distorted if the whole life cycle is not considered. By incorporating the maintenance phase, the total cost becomes a ruin by requiring 25 repairs in 50 years. However, designs such as W/C and CC45, with minimum increases of 6% over the reference cost, achieve a drastic reduction in repair frequency and, therefore, the maintenance cost of 68% and 75%, respectively.

Finally, the design option based on silica fume cement (SF-C) resulted in the lowest life-cycle costs, followed by adding fly ash (FA-A) and galvanized reinforcing bars. Their results represent cost reductions of 87%, 80%, and 79%, respectively, over the total economic impact associated with the reference design.

Figure 2. Results of the Life Cycle Cost Assessment (LCCA).

3.2 LCA results

The impacts resulting from the environmental life cycle assessment of the six alternative designs are presented in Figure 3. The endpoint approach has been adopted with three oriented damage indicators: human health, ecosystems, and availability of natural resources. The graphs highlight the most relevant environmental impacts affecting human health, followed by resource depletion, which is very similar in all the alternatives analyzed, except in the case of the REF, which is disproportionate. The options with silica fume (SF-C) and fly ash (FA-A) added to the concrete mix provide the best environmental performance by reducing REF impacts by 67% and 60%, respectively. In general, it is concluded that the greater the durability of the preventive maintenance strategy, the lower the frequency of reactive maintenance, which will reduce the resulting impact on the environment.

3.3 LCCA-LCA sustainability assessment

The relevance of each criterion was obtained through an expert seminar to evaluate the sustainability of each design presented. Table 4 shows the weights assigned by the group to each of the five impact categories defined.

From the obtained crisp weights, the VIKOR technique (Sánchez-Garrido et al., 2022a) is applied to aggregate the five different impact categories into a single sustainability score ($0 \leq Q_j \leq 1$) for each design option to be compared. In this case, Q_j is better the closer to 0. Figure 4 shows the results for each design alternative, considering the interval in years leading to the

Figure 3. Results of the Life Cycle Assessment (LCA).

Table 4. Results of the weighting of criteria.

Criteria	Definition	Weight
C1	Construction Costs	0.1971
C2	Service life Costs	0.1529
C3	Human health impact	0.3059
C4	Ecosystem impact	0.0986
C5	Resources	0.2455

first maintenance and, therefore, to the repair of the cover concrete to prevent the propagation of corrosion in the reinforcement.

From a sustainability standpoint, the optimal preventive maintenance design is CC45, with an overall score of 98.3%, followed closely by FA-A with 97.6% and HCII with 95.7%. It is worth noting that the SF-C alternative, which was the best in the LCA and LCA, obtained an intermediate performance in the final sustainability evaluation, with a discrete 67.1%. On the other hand, design strategies that did not stand out in the individual evaluations have turned out to have superior performance when aggregated into a sustainability score. This has been the case for the CC45 and HCII alternatives, first and third in the ranking, with virtually equal maintenance intervals. Only FA-A, second in the ranking, has performed well economically and environmentally.

Figure 4. Results of the Sustainability Life Cycle Assessment.

4 CONCLUSIONS

The present communication shows the different durability performances over the life cycle of a concrete structure, based on MMC, exposed to aggressive environments. Several alternatives are evaluated that base the durability strategy on using different base concrete mixes, increasing the bottom cover of the slab with corrosion inhibitor impregnation, and substituting the type of reinforcing steel.

From the results, the evaluation of economic and environmental impacts by a one-dimensional life cycle analysis does not guarantee that a design is optimal from a sustainability point of view. Sustainability is a complex issue that tries to solve a multi-criteria decision-making problem, so it must be approached from a holistic perspective, simultaneously considering all the dimensions involved in the evaluation associated with the design of the structure.

Exploratory analysis of the impact of natural hazards on road infrastructure in the Philippines

M. Adarne, A. Amir & M. Henry

Shibaura Institute of Technology, Kotou-ku, Tokyo, Japan

ABSTRACT: The Philippines is in the Golden age of Infrastructure development, where roads and bridges are currently being constructed to interconnect the cities and provinces. However, these infrastructures are susceptible to the adverse effects of climate change, as the Philippines ranked 8th on the risk index among the countries with the highest exposure to disaster. Natural hazards may temporarily or permanently interrupt the normal operation of road infrastructures resulting in the need to adopt a sustainable risk management approach for road networks exposed to natural disasters. The research aimed to find the impact of natural hazards in the shape of damages to the road network by performing statistical analysis on the natural hazards data of the year 2021. The results may help in understanding and visualizing risks and damages to road networks under natural hazards and provide effective safety management practices when a disaster occurs.

1 INTRODUCTION

Infrastructure can be the deciding factor in determining whether or not the situation becomes a disaster when extreme natural hazards occur (World Risk Report, 2016). Road infrastructure is an integral part of the country's economy and is most prone to these hazards. Natural hazards may temporarily or permanently interrupt the normal operation of road infrastructures; however, they provide access to quickly supply relief aids to affected communities but if they become the first affected by the disaster, the entire region can be cut off.

In recent years, the Philippines has been focusing on infrastructure development in which roads and bridges are being constructed to overcome the limitations provided by its outdated and inadequate infrastructure. The country has started the "Build Build Build" Program in which roads and bridges are being constructed to interconnect the country's cities and provinces (Malindog-Uy, 2020). However, at the same time, these infrastructures are prone to natural disasters and calamities as the Philippines ranked 8th on the risk index with a score of 21.39 and placed 9th among countries with the highest exposure to disaster (World Risk Report, 2021). The country faces a variety of natural hazards, including geophysical disturbances like earthquakes and volcanic eruptions, meteorological and hydrological events like typhoons and floods, and slow-onset disasters like droughts that affect the infrastructure (Iuchi et. al., 2019), specifically the transport infrastructure to larger extent and resulting in damages and significantly affecting the economy and livelihoods of the country. Unlike the development of a proper scheduled plan for the timely completion of these infrastructures, natural disasters and ensuing damage to these infrastructures cannot be planned for in the same way. However, it is possible to prepare in advance for such events to some extent through the development of a mitigation plan (Shibayama, 2017). With the evolution of data analytics, it is now possible to analyze historical data in terms of understanding the impact of past events or past patterns, and by conceptualizing what transpired, a future mitigation strategy can be developed. May Haggag et. al. employed data analytics and machine learning techniques on the disaster data of New York state to investigate the relationship between different climate-induced disasters and infrastructure performance and then developed the performance prediction framework for the infrastructure (Haggag et. al., 2021). Similarly, the database of high-impact weather events that

occurred in Greece was developed, and a descriptive impact analysis was performed for the period 2001-2011 (Papagiannaki et. al., 2013).

In this study, data on natural disasters that caused damage to infrastructure in the Philippines in the year 2021 obtained from the Bureau of Maintenance (BOM), Department of Public Works and Highways (DPWH) were analyzed. First, the occurrences of natural hazards in the different regions at different times were examined. Then the damages that occurred to road infrastructures in different regions in the Philippines were studied. Finally, the combined effect of disasters on the road infrastructure was studied by performing an Odds Ratio (OR) analysis to obtain an idea of the relative impact a natural event may have on road infrastructure as compared to other natural disasters. The study can be utilized in the future for the development of mitigation planning by sorting out the critical structure based on natural disasters.

2 RESEARCH METHODOLOGY

2.1 Research data

The data was collected from DPWH which included 1,305 damage events of various disaster types that occurred in the country in 2021. The BOM, DPWH gathered information from District offices that report data immediately after the occurrence of natural disasters. The condition of the structure prior to the natural disaster is usually not determined, however, the damages that occurred due to the natural disaster are collected and reported. Five variables were used in the study, i.e., year of occurrence, types of natural disasters, region of the affected area, types of infrastructures, and types of damages. Data cleaning was done, and it was observed that 936 damage events are associated with transportation infrastructures such as roads and bridges, with 64% and 8% of the total damages, respectively. The remaining 369 damage events are associated with flood control and public building infrastructures, with 21% and 7% of the total damages, respectively, as shown in Figure 1. Damages related to transportation infrastructure were classified into road and bridge damage groups based on the type of infrastructure affected by natural disasters. The damages to the roads and bridges were subsequently subdivided into three groups based on the importance and traffic conditions during repairs. In addition, the data were grouped by affected regions and month of occurrence to determine the distribution of damages and affected areas during natural disasters.

2.2 Natural disaster

The data obtained from the department consisted of various natural disasters that occurred in the year 2021 and caused damages to infrastructures. It was observed that among nine natural disasters that caused damage to infrastructures, eight disasters were related to damage to the transportation infrastructure (roads and bridges). The percentage of damage caused by each natural disaster is depicted in Figure 2. It was found that typhoons caused the majority of road and bridge infrastructure damages (42%), followed by tropical storms (41% and 15%, respectively).

Figure 1. Total number of damages to infrastructure the year 2021.

Figure 2. Percentage of Natural disasters cause in damages.

2.3 Roads and bridges damages

The data consisted of 138 types of damages to roads and bridges in 2021 caused by natural disasters, with a total of 936 incidents of damage to roads and bridges. Figure 3 shows the

percentage of damages to the transportation infrastructures in the year 2021. Roads were the most affected by disasters as they got the highest percentage of damages as compared to the bridge infrastructure in 2021. Similarly, 50% of damages were received by the road structures group, which shows that they were most impacted during the climatic events in the year 2021, followed by road protection structures and road-associated structures.

Figure 3. Corrosion Damage States (CDSs) probabilities for structural components over the structural lifetime.

2.4 Odds Ratio (OR) analysis

Odds Ratio (OR), a statistical analysis that was done to measure the strength of the association between natural disasters and infrastructure damage. OR Analysis measures the probability that an outcome (infrastructure damage) will occur given a specific exposure (natural disaster). It can determine if a certain exposure is a risk factor for a certain outcome and compare the size of different risk factors for that outcome. (Szumilas, 2010). The OR can be defined as the ratio between the odds values where odds are the probability that an event will occur divided by the probability that the event will not occur, as shown by the formula.

$$OR = \frac{\text{odds that an outcome occur in particular exposure}}{\text{odds that an outcome occur in the absence of exposure}} \quad (1)$$

where $OR=1$, exposure does not affect the odds; $OR>1$, exposure associated with higher odds of an outcome; $OR<1$, exposure associated with lower odds of an outcome

In this research, the exposure is the natural disaster that caused damages to transport infrastructures in the year 2021, while the outcome was the damages that occurred during the natural disaster. Hence, the OR was performed to find the probability that infrastructure damage will occur in the presence of a specific disaster.

3 RESULTS AND DISCUSSION

3.1 Region and month of disaster occurrence

Table 1 shows the total natural disaster events that affected transportation infrastructure in 2021 per region by disaster type, as well as the percentage of individual natural events in each region that affected roads and bridges. Typhoon has caused the highest number of infrastructure damages among the eight natural disasters, with 393 occurrences, followed by tropical storms with 383 occurrences, and southwest monsoon with 129 occurrences. In addition, typhoons caused infrastructure damage in most regions, with region VII being one of the worst affected areas.

Table 1 also depicts that the Cordillera Administrative Region (CAR) has the highest incidence of infrastructure-damaging events compared to other regions, with 53.8% of damaging events attributed to tropical storms and 53.5% attributed to the southwest monsoon. CAR might possibly be experiencing these infrastructure-damaging events because the region has two distinct seasons, the dry season from November to April and the wet season for the rest of the year. But from the last few years, the regions also experienced the effect of climate

change due to which sometimes there is no dry season but there is maximum rainfall in November and December (Philippine Statistic Authority 2020) thus causing a greater number of events of infrastructure damage. According to Hugen et al., the typhoon events seem to indicate a gradual shift towards the end of the year, such that the number of typhoons in the rainy season, which run from June to November, has decreased while the number of typhoons in December has increased in the Philippines (Hugen et al., 2006).

Table 2 indicates the month-wise infrastructure damages caused by different natural disasters. Typhoons caused the most infrastructure damage in the month of December (91.6%), followed by September (8.4%). According to Philippine Atmospheric, Geophysical, and Astronomical Services Administration (PAG-ASA), the agency for assessing and forecasting weather in the Philippines, the peak season of typhoons is from July through October, when nearly 70% of the typhoon develop (Department of Science and Technology 2022), however, by analyzing the data, it was observed that the typhoons in the month of December were more disastrous to the road and bridges infrastructure.

Figure 4 shows the percentage of damaged roads and bridges across the country, with CAR experiencing the highest level of road damage (32.25%) compared to other regions, while Region VII experienced the highest level of bridge damage (38.5%), which also the highest percent of bridge damage compared to other regions.

Figure 4. Percentage of road and bridge damages per region.

3.2 Types of damage caused by natural disasters.

The percentage of infrastructure damages (roads and bridges) caused by natural events in each region is shown in Table 3. It was observed that CAR and region VII experienced the highest portion of total damages, as shown in Figure 4. Among the road damages and bridge damages groups, the road group experienced more numbers of damages, with a total of 581 damages to the road structure, and 39.6% of total road structure damages occurred in CAR. Whereas the bridge protection work was worst affected by natural disasters in a bridge damages group, with a total of 46 incidents causing damages to bridge structures and 45.7% of these damages occurred in Region VII. CAR is susceptible to more damage may be due to its geophysical and astrological condition, mountainous topography comprised of towering peaks, plateaus, and intermittent valleys, and 71 percent of the region’s land area has slopes of 30 degrees or more. The soil characteristics of this area also contributed to the greater numbers of damages, as it consists of various types of soil, primarily mountain soil and clay loam. The most common type of soil degradation is soil erosion. According to the Department of Environmental and National Resources (DENR), 36 percent of the region’s land area is susceptible to moderate erosion, and most of the region’s land area is susceptible to slight erosion (36%) (Philippine Statistic Authority 2020). In Region VII, the potential for damage may be due to the presence of major islands, one smaller island, and several outlying islands. The Visayan Sea borders to the north, the Camotes Sea and Camiguin Channel to the east, Negros Island to the west, and the Mindanao Sea to the south. The interior of the provinces of Region VII is dominated by highlands, with narrow strips of arable land lining the coast, and most of the province’s land area is hilly and mountainous (62% of total land), while the remainder is flat and rolling (32% of land) (Arkipelago, 2016).

Table 4 indicates the month-wise natural disasters that caused damage to the roads and bridges infrastructure. It was observed that most of the infrastructure damaging events occurred in the months of July, October, and December, with the maximum number of damages in the month of December as shown in Figure 5. Among various infrastructure damages in the year 2021, the maximum number of road structures were damaged in October, whereas the majority of bridge protection structures were affected in December due to natural disasters.

3.3 Odds Ratio (OR) analysis

After analyzing the disasters and damages separately, OR analysis was conducted on the data to determine the likelihood of the association between infrastructure damages and natural disaster events. Table 5 shows the result of the OR analysis. The zero and no values in the table are due to the minimal exposure or outcome that cannot be calculated.

Table 3. Percentage of infrastructure damages that occurred per region.

It was observed that tropical storms, typhoons, and continuous rains were the events that caused most of the damage to the transportation infrastructure in the year 2021. The results of OR analysis showed that when tropical storms occur, it is 28.5 % more likely to cause damage to road structures, 62% more likely to cause damage to road-associated structures, and 36.3% more likely to cause damage to road protection structures than any other types of natural disaster. Conversely, in the case of typhoons, it is 120.5% more likely to cause damage to bridge structures, 498.3% more likely to cause damage to bridge superstructures, and 103.5% more likely to cause damage to bridge protection works than any other type of natural event.

However, continuous rainfall was found to be associated with damage to both roads and bridges. The analysis revealed that if it is continuous rainfall, it is 583.2% more likely to cause road structure damages and 385% more likely to cause bridge substructure damages than any other natural disaster.

Figure 5. Percentage of road and bridge damage per month.

Table 5. Odds Ratio Analysis results show the relative risk of damages to the infrastructure in case of natural disasters that cause damages to road infrastructure.

Natural Disaster		Road Damages			Bridge Damages

4 CONCLUSION

Considering the significant adverse effect of natural events on transportation infrastructures, the current work aimed to 1) specify the region-wise disasters that are prone to transportation infrastructure, 2) categorize the damages of road and bridge infrastructure due to natural events, and 3) to find the impact of each natural disasters on road and bridge infrastructure in different regions. The results of the analysis of the disaster showed that CAR and Region VII were the most affected regions in the case of road and bridge infrastructure damages, thus, raising the need to give special attention to the transport infrastructure in these regions.

However, most of the transport infrastructure damaging events occurred in the months of September, October, and December due to tropical storms and typhoons therefore, the concerned departments need to take this into consideration during the development of a mitigation plan. The results of the odds ratio analysis concluded that typhoons caused maximum numbers of damage to bridges while tropical storms were found to be most devastating for roads. However, continuous rains were found to cause damage to both roads and bridges. Therefore, road authorities need to consider these disasters during the designing stage of roads and bridges to reduce the effect of disasters on the transport infrastructure.

Conclusively, the work tries to indicate awareness and knowledge of transportation infrastructure damages in case of natural disasters. However, the research needs to extend to more previous years' data in order to study the complete pattern of damages to transportation infrastructure during natural disasters, which may enable to develop the mitigation plan for the transportation infrastructure.

ACKNOWLEDGEMENT

The Authors would like to thank the Japan International Cooperation Agency (JICA) for their support through the Road Asset Management Platform (RAMP), the Shibaura Institute of Technology (SIT) for providing the environment for the research, the Department of Public Works and Highways Philippines (DPWH), for sharing the data and information needed, and the Unified Project Management Office (UPMO), DPWH for their warm support.

Prediction of R.C. bridge deterioration under changing environmental conditions

F. Landi & P. Croce

Department of Civil and Industrial Engineering, University of Pisa, Italy

F. Marsili & S. Kessler

Helmut-Schmidt-University/University of the Federal Armed Forces Hamburg, Hamburg, Germany

ABSTRACT: Climate change affects the reliability and durability of r.c. structures both increasing the magnitude and the frequency of extreme events and accelerating the rate of degradation processes such as carbonation and corrosion. In the paper, bridge deterioration models are presented and discussed with the aim to extend their application to structures exposed to changing environmental conditions over their life cycle. The evaluation of transition probabilities in Markov and semi-Markov model, which is generally carried out by means of inspection data, is integrated with data derived by mechanistic-empirical models describing the deterioration of r.c. structures. Existing models for chloride induced corrosion, corrosion propagation and cracking are considered, introducing in the analysis the expected variations of temperature and atmospheric humidity. Results in terms of predicted deterioration curves are presented and discussed for a case study highlighting the influence of the expected changes in environmental conditions under different climate change scenarios.

1 INTRODUCTION

The degradation of structures and infrastructures is a major challenge for the coming decades with significant implications in terms of safety and costs (Stewart et al. 2012, Forzieri et al. 2018). Evaluating the performance and the remaining service life of aging bridges is of great concern to the asset owners and is the subject of several researches in civil engineering (van Noortwijk and Frangopol, 2004, Ellingwood, 2005, Thomas and Sobanjo, 2016). Numerous infrastructures are approaching the end of their design service life and at the same time a combination of environmental factors, operating conditions and delayed or ineffective maintenance accelerate deterioration (Ellingwood, 2005, Croce et al 2020).

In this context, specific attention should be devoted to the potential impact of climate change on the environment to which the structure is exposed. In fact, climate change will affect the reliability and durability of structures and infrastructures both increasing the magnitude and the frequency of extreme events and accelerating the rate of degradation processes such as carbonation and corrosion (Croce et al., 2019, Sousa et al., 2020).

Environmental conditions significantly influence the durability of r.c. structures, and the current increase of CO₂ concentrations, with the associated temperature and humidity variations increase degradation rate (Stewart et al. 2011, Sousa et al., 2020, Nasr et al. 2022, Zhang et al. 2022). For example, the rise of CO₂ concentration and the alternation of dry and wet conditions will increase the risk of carbonation-induced corrosion, while temperature increases directly affects corrosion rates due to the decrease of electrochemical resistances in the system.

In bridge maintenance management systems, the deterioration of reinforced concrete elements is generally predicted based on statistical models, such as Markov and semi-Markov

models, where transition probabilities are evaluated using the results of time-ordered visual inspections (Thomas and Sobanjo, 2016, Lethanh et al., 2017). However, scarce inspection data series complicate the evaluation of transition probabilities. In these situations, the infrastructure managers can rely only on expert opinion and mechanistic empirical models to predict the degradation (Mizutani et al., 2017). These models refer to a combination of a mechanistic model, which describes the physical behavior of the elements, and an empirical model, which is based on direct observations and measurements. A mechanistic empirical model is used in (Thomas and Sobanjo, 2016) to develop the transition probabilities for r.c. bridge elements affected by chloride-induced corrosion.

In the paper, the use of mechanistic empirical models is proposed to evaluate transition probabilities in a changing environment. The expected variations of climatic variables, such as temperature and relative humidity, are included in the implementation of the model for chloride-induced corrosion and their influence on transition probabilities and deterioration curves is assessed.

2 METHODOLOGY

The general methodology can be summarized in the following steps:

- Selection or development of mechanistic-empirical models, to describe the degradation of the investigated bridge elements;
- Definition of condition states for the bridge, associating them to chemical and physical parameters obtained from the mechanistic-empirical models;
- Simulation of condition indicators over time, considering uncertainties in the parameters of the mechanistic-empirical models and the expected variations of climate variables;
- Aggregation of condition states in each time interval and estimation of transition probabilities for the different condition states;
- Evaluation of expected condition and derivation of deterioration curves over time.

In the following sub-sections, details about each step of the procedure are provided.

2.1 Mechanistic-empirical model for chloride induced corrosion

The deterioration models of r.c. elements are mostly based on the outcomes of the DuraCrete project (DuraCrete, 2000), which formed the basis for the probabilistic durability design of r. c. structures and for several research in the field (Choe et al., 2008, Stewart et al., 2011, Thomas and Sobanjo, 2016, Nasr et al., 2022, Zhang et al. 2022). In this work, the initiation and propagation models proposed by DuraCrete are adopted as well, and the effect of climate change is quantifiable through time-dependent parameters.

Focusing on the deterioration of r.c. elements induced by chlorides, the first phase is the chloride penetration which is described by mechanistic-empirical models based on Fick's second law of diffusion. The chloride concentration C_{cl} at depth x at time t is obtained as:

$$C_{cl}(x, t) = C_s \left[1 - \operatorname{erf} \left(\frac{x}{2\sqrt{k_e k_t k_c f_t(t) f_{RH}(t) D_0 \left(\frac{t_0}{t}\right)^n t}} \right) \right] \quad (1)$$

Where C_s is the surface chloride concentration; k_e is the environmental factor; k_t is the test method factor; k_c is the execution parameter; D_0 is the empirical chloride diffusion coefficient; t_0 is the reference time in years, i.e. 0.0767 years corresponding to 28 days; n is the age factor; and $f_t(t)$ is the temperature effect on diffusion coefficient which can be obtained according to Stewart et al. (2011) by:

$$f_T(t) = \exp \left(\frac{E}{R} \left(\frac{1}{293} - \frac{1}{273 + T_{av}(t)} \right) \right) \text{ and } T_{av}(t) = \frac{\sum_{i=t_1+1}^t T(t)}{t - t_1} \quad (2)$$

with $E = 40$ kJ/mol is the activation energy of the diffusion process; $R = 8.314 \times 10^{-3}$ kJ/mol K is the gas constant; $T(t)$ is the average temperature for year t ; and t_1 is the year of construction. In a similar way, the influence of relative humidity on diffusion coefficient can be considered by means the coefficient $f_{RH}(t)$

$$f_{RH}(t) = \exp\left(1 - \frac{(100 - RH_{av}(t))^4}{(100 - 75)^4}\right)^{-1} \text{ and } RH_{av}(t) = \frac{\sum_{i=t_1+1}^t RH(t)}{t - t_1} \quad (3)$$

The surface chloride concentration depends on the exposure category of the structural element, i.e. submerged, splash, tidal, and atmospheric zone, and is described as a function of the water to cement ratio w/c and an error term ε_{cl} (DuraCrete, 2000, Choe et al., 2008)

$$C_s = A_{cl} \frac{w}{c} + \varepsilon_{cl} \quad (4)$$

where A_{cl} = regression coefficient associated to the exposure category.

Once the chloride concentration C_{cl} reaches critical values C_{cr} , corrosion of steel rebar is initiated. Corrosion of the reinforcement leads to the formation of corrosion products which occupies a larger volume than the original steel rebar, thus causing cracks in the concrete cover and eventually spalling. The crack width is evaluated according to the mechanistic-empirical model defined by the DuraCrete project (DuraCrete, 2000) as

$$w(t) = w_0 + b[p(t) - p_0] \quad (5)$$

where w_0 is the initial width of the visible crack in mm; b is the parameter which controls the propagation and depends on the position of the rebar in mm/ μ m; p_0 is the value of the corrosion penetration necessary to produce a crack in μ m; $p(t)$ is the corrosion penetration at time t in μ m. The corrosion penetration needed to open a crack p_0 can be derived from the following expression

$$p_0 = a_1 + a_2 \frac{x}{\phi} + a_3 f_{ct} \quad (6)$$

where a_1, a_2, a_3 are regression parameters; x is the concrete cover depth in mm; ϕ is the diameter of the steel rebar in mm; f_{ct} is the concrete tensile strength in N/mm². The corrosion penetration at time t , $p(t)$, is evaluated as

$$p(t) = i_{corr}(t) w_t (t - t_i) \quad (7)$$

Where w_t is the relative time of wetness; t_i is the time to corrosion initiation; $i_{corr}(t)$ is the corrosion rate at time t in mm/year, which depends on temperature and is estimated starting from the value at 20 °C ($i_{corr,20}$) as

$$i_{corr}(t) = i_{corr,20} [1 + K(T(t) - 20)] \quad (8)$$

in which K is the factor that describes the dependency of conductive with temperature T .

Reference values of the parameters in Equations (1) to (7) are provided in the final report of the DuraCrete project (DuraCrete, 2000) depending on the location and exposure zone of the structure, together with their probabilistic models which are summarized in Table 1.

2.2 Definition of bridge condition states

In bridge maintenance management systems, the condition states are mainly described qualitatively based on visual inspection and there is still little connection from these condition states and the structural behavior of the elements.

Table 1. Probabilistic models for the parameters of the mechanistic empirical model.

Parameter	Mean	St. Dev.	Distribution	Unit
x	x^c	10	LogNormal	[mm]
A_{cl} (atmospheric)	2.565	0.356	Normal	[%] relative to binder
ε_{cl} (atmospheric)	0	0.405	Normal	[%] relative to binder
k_e (atmospheric)	0.676	0.114	Gamma	[-]
A_{cl} (splash)	7.758	1.36	Normal	[%] relative to binder
ε_{cl} (splash)	0	1.05	Normal	[%] relative to binder
k_e (splash)	0.265	0.045	Gamma	[-]
k_t	0.832	0.024	Normal	[-]
k_c	1	-	Deterministic	[-]
D_0 ($w/c=0.5$)	473	43.2	Normal	[mm ² /year]
t_0	0.0767	-	Deterministic	[year]
n	0.3	0.12	Beta	[-]
w_0	0.05	0.005	Normal	[mm]
b	0.0086	0.0048	Normal	[mm/ μ m]
a_1	74.4	3.2	Normal	[μ m]
a_2	7.3	0.06	Normal	[μ m]
a_3	-17.4	5.7	Normal	[μ m/MPa]
f_{ct}	$0.53\sqrt{f_c}$	$0.08\sqrt{f_c}$	Normal	[MPa]
w_t	0.75	0.20	Normal	[-]
i_{corr}	0.03	0.02	Weibull	[mm/year]
$K(T > 20^\circ C)$	0.073	0.015	Normal	[-]
$K(T < 20^\circ C)$	0.025	0.005	Normal	[-]

A relationship between bridge condition states and the physical quantities described by the chloride induced corrosion model is here established. For the corrosion process, the condition states from CS1, where the structure is considered without any damage, to CS5 where the structure is severely damages, are generally used (Lethanh et al., 2017).

Examples of the relationship between condition states and analytical models for corrosion process can be found in Roelfstra et al. (2004) and Lethanh et al. (2017).

In this work, the definition proposed in Lethanh et al. (2017) is adopted with some slight modifications as reported in Table 2.

Table 2. Definition of bridge condition states based on the chloride content and crack width.

Condition state	Description	Criteria
1	New concrete contaminated	$0 \leq C_{cl}(x, t) < 0.24\%$
2	Increase in chloride content up to critical values	$0.24\% \leq C_{cl}(x, t) < 0.48\%$
3	Corrosion initiation, no visible cracks	$C_{cl}(x, t) > 0.48\% \cup w(t) < 0.25\text{mm}$
4	Visible cracks	$C_{cl}(x, t) > 0.48\% \cup 0.25\text{mm} \leq w(t) < 1\text{mm}$
5	Corrosion damage, severe cracks	$C_{cl}(x, t) > 0.48\% \cup w(t) > 1\text{mm}$

2.3 Generation of bridge condition indicators over time

The probabilistic models in Table 1 are adopted to perform Monte Carlo simulations and generate values of condition indicators, $C_{cl}(x, t)$ and $w(t)$, in each year t for a 100-year period according to the mechanistic-empirical model defined in Section 2.1.

In the simulations, the variation of climate parameters, annual temperature $T(t)$ and relative humidity $RH(t)$, are estimated considering an ensemble of climate projections provided by high-resolution Regional Climate Models (RCMs) based on different emission scenarios. Climate projections of temperature and relative humidity over several regional domains all over the world can be obtained from the Copernicus Data Store.

For Europe, the climate projections provided by the EURO-CORDEX initiative represents the most updated input for climate change impact studies (Jacob et al., 2014) and will be considered in this study. The data series cover the period 1951– 2100 and are split in two parts: a control period from 1951 until 2005 (Historical Experiment), and a future period depending on the emission scenario 2006–2100 (RCP Experiment).

Among the four available scenarios RCPs (van Vuuren et al., 2011), RCP4.5 and RCP8.5 are the most used in climate risk studies, and for them most climate projections are available. They correspond to medium and maximum concentration pathways, and they have been adopted in the present study as well. A probabilistic description of variations in temperatures and relative humidity is thus obtained enlarging the ensemble of climate projections by means of the use of weather generation techniques (Croce et al., 2021).

Once generated the time series of condition indicators, $C_c(x,t)$ and $w(t)$, condition states are evaluated according to the definitions in Table 2.

2.4 Evaluation of transition probabilities

The series of bridge condition indicators can be used to develop statistical models for bridge management. Markov and semi-Markov chain models can be set-up where changes from one state to another are evaluated in accordance with a set of transition probabilities defined analyzing the generated series of condition indicators.

Transition probabilities P_{ij} for the Markov process can be evaluated making use of the restricted least-squares transition probability estimator as illustrated in Lethanh et al.(2017), while for the semi-Markov, transition probabilities $P_{ij}(t)$ are estimated from the distribution of sojourn time in each condition state (Thomas and Sobanjo, 2016).

2.5 Expected bridge condition ratings and deterioration curves

Finally, the vector of bridge condition states at any time t , $CS(t)$, is predicted as the product of the estimated transition probability matrix $P_{ij}(t)$ and the initial condition vector $CS(t = 0)$

$$CS(t)^T = CS(t = 0)^T \times P_{ij}(t) \quad (9)$$

where $CS(t = 0)^T = [1 \ 0 \ 0 \ 0 \ 0]$ is a vector collecting the probability or proportion of the bridge to be in each state at time $t = 0$. Starting from the rating vector, $RATING^T = [1 \ 2 \ 3 \ 4 \ 5]$, the bridge expected condition state at any time t , $EXPCS(t)$, is evaluated by

$$EXPCS(t) = CS(t)^T \times RATING \quad (10)$$

3 RESULTS

The implementation of the presented methodology is demonstrated here focusing on a reinforced concrete bridge exposed to chloride-induced corrosion. For illustration purposes the following assumptions are made:

- the bridge is located in Italy, close to Pisa (lat. 43.6839, lon. 10.3927, alt.82 a.s.l.)
- the bridge was built in 2000
- a Portland cement with a water-cement ratio of 0.5 was used
- the curing time was 7 days
- two exposure category, atmospheric and splash zone, are considered for the element
- a concrete cover depth $x^c = 35$ mm is considered

First, climate data for the location of the bridge are collected considering historical observations at Pisa weather station, and an ensemble of climate projections provided by the EURO-CORDEX initiative (Jacob et al., 2014) for the historical experiment (period 1951-2005) and the two scenarios RCP4.5 and RCP8.5 (period 2006-2100).

The climate projections at the grid cell corresponding to the weather station are extracted and compared with the observations for the historical period. Changes in yearly average

temperatures are estimated from the analysis of climate model ensemble and then applied to the observations following the factor of change approach (Maraun, 2016). In Figure 1, the variations of annual temperature and relative humidity are shown for the period 2000-2100.

Figure 1. Expected variations of temperature (a) and relative humidity (b) according to different scenarios.

Significant changes are expected for temperature levels, with an average increase of 2.6°C (RCP4.5) and 4.5°C (RCP8.5) at the end of the century with respect to the period 1951-2000, while no clear trend is detected for relative humidity.

The analyses are then carried out considering three different scenarios: a stationary climate referring to the average temperature and relative humidity observed in the period 1951-2000 before the construction of the bridge, two changing climate conditions according to RCP4.5 and RCP8.5 concentration pathways.

Time series of condition indicators for chloride-induced corrosion, $C_{cl}(x,t)$ and $w(t)$, are generated implementing the mechanistic-empirical model described in previous section and adopting the probabilistic models in Table 1. Condition states are then defined according to the criteria established in Table 2 and transition probabilities are evaluated.

In Figure 2, the bridge expected condition states over time are shown for the investigated climate scenarios: stationary climate in black, RCP4.5 in red and RCP8.5 in blue.

Looking at the curves, it can be noticed that the impact of climate change becomes more and more relevant over time, thus affecting the time at which critical conditions are reached.

Figure 2. Expected condition ratings under stationary climate, (a) splash zone (b) atmospheric zone.

Moreover, for the investigated case study no significant differences are detected for the RCP4.5 and RCP8.5 scenario. For a structural element in splash zone, condition state 4 is expected to be reached after 58, 53, and 52 years under stationary climate, RCP4.5 and RCP8.5 respectively; while for a structural element in atmospheric zone, condition state 4 is expected to be reached after 93, 83, and 81 years.

The accelerated degradation due to climate change is confirmed by the results shown also in Figure 3 and 4, in which the predicted deterioration curves for atmospheric and splash zone are presented, respectively. Figures 3a and 4a refer to stationary climate conditions, while Figure 3b and 4b illustrate the deterioration curves corresponding to the RCP8.5 scenario but very similar results are obtained for the RCP4.5. In these Figures, the age of the bridge associated with a 50% probability to move to a worse condition state is highlighted by means of black dashed lines.

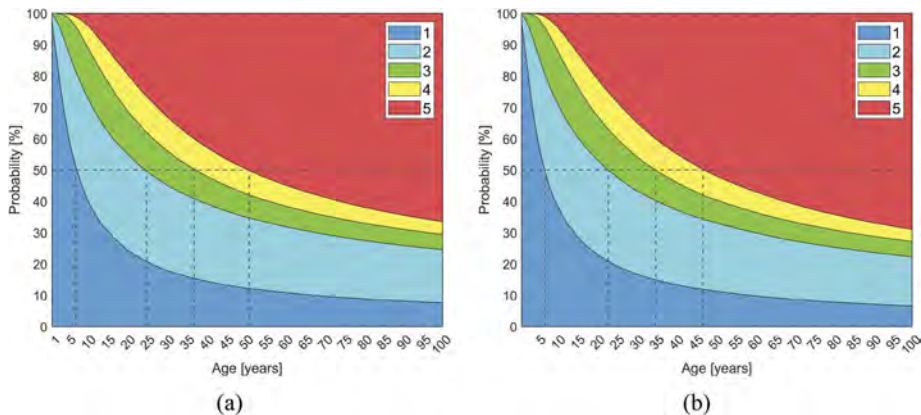

Figure 3. Deterioration curves for r.c. element in atmospheric zone: stationary climate (a) and RCP8.5 scenario (b).

Figure 4. Deterioration curves for r.c. element in splash zone: stationary climate (a) and RCP8.5 scenario (b).

4 CONCLUSION

A methodology to predict the deterioration of r.c. bridge elements affected by chloride induced corrosion is presented in the paper, considering the influence of changing environmental conditions over the life cycle.

The procedure, which is based on mechanistic empirical models, can support the prediction of bridge condition states in bridge management systems supplementing the information

collected during inspections and evaluate the acceleration of the corrosion processes due climate change as shown for a case study of r.c. bridge in Italy.

The procedure is general and can be applied to different degradation processes once the mechanistic-empirical model is established. However, it is important to notice that models for the prediction of corrosion initiation and propagation, although widely used in civil engineering community, are rough approximations, and still there is a need for improved models, allowing a better estimation of time-dependent effects and including improved knowledge about climate parameters such as temperature or humidity. Further studies will be thus devoted to improving the prediction of corrosion initiation and propagation as a function of time-dependent exposure climate.

Life-cycle assessment of R.C. bridge components based on cluster analysis and stochastic process

F. Marsili & S. Keßler

Helmut-Schmidt-University/University of the Federal Armed Forces, Hamburg, Germany

F. Landi

University of Pisa, Pisa, Italy

ABSTRACT: This article proposes an approach to assess the life-cycle of reinforced concrete bridge components by applying a cluster algorithm and a stochastic model for damage evolution. The k-means algorithm is used to identify families of bridge components that deteriorate at similar rates. A measure of performance, i.e., silhouette width, supports the choice of the optimal number of clusters. Once the cluster model is defined, a gamma process is fitted to the data on the evolution of the conditions that belong to each family. By simulating the gamma process, the cumulative distribution function of time to failure is calculated for each cluster of components. The procedure applies to reinforced concrete bridge components in Switzerland, whose inspection and maintenance data is collected in the KUBA-DB database. This approach ensures that the expected service life of bridge components can be predicted with limited uncertainty.

1 INTRODUCTION

The management of existing infrastructure and its maintenance is an increasingly topical and relevant issue for the well-being of our societies. While, on the one hand, and as a result of a period strongly marked by new construction, physical infrastructure assets are aging and increasingly in need of maintenance, on the other hand, investment in maintenance is insufficient and even declining. Keeping infrastructures in good condition is therefore a challenge, requiring highly advanced approaches that can significantly improve maintenance efficiency. Remaining useful life should be understood as the time remaining before the infrastructure reaches a critical condition and maintenance is required to ensure safety, serviceability, or durability. However, and despite the fact that physical assets are ageing, only in few cases the condition has been judged critical, so that little information is available concerning the time when a critical condition is reached.

With the scope to increase maintenance efficiency, many infrastructure operators have undertaken a digitization process, which has led to the development of digital systems for managing infrastructure and its maintenance. Condition databases collect the results of periodic visual inspections and special tests, which are represented by digital data of different types, such as images, and qualitative and quantitative information on the progress of degradation. An important information is the qualitative judgment issued at the end of each inspection which regards the criticality of damage, as well as the condition of the component and the object as a whole, which is also linked to the urgency of the maintenance intervention.

A maintenance intervention is deemed necessary when the safety, durability or serviceability of the component and therefore possibly also of the object are jeopardized by the deterioration process. The judgment is expressed through an increasing condition index: the more significant the damage, the higher the index. The condition index can thus be interpreted as a measure of damage accumulation. The objects whose information is contained in these databases were built in different periods and therefore have different ages. As a result, not all the objects have already reached a critical condition. In addition to that, the objects have different characteristics, which affect their

robustness against aging in different ways. Since the information relating to objects in satisfactory condition are predominant over those in critical condition, the database is affected by the well-known problem of data imbalance, and information about the time in which the critical condition is reached cannot be directly derived from the database in most of the cases.

The evaluation of the time in which the damage reaches a critical condition is subject to uncertainties that can significantly influence the maintenance planning and therefore must not be neglected. One way to consider the uncertainties affecting the prediction of the remaining service life is to model damage evolution through probabilistic models such as Markov process or gamma process (Frangopol et al., 2004). Markov process is currently the most commonly used approach in bridge maintenance models. However, it has some drawbacks: first, it does not provide any reliability estimation, making it also difficult to link life-cycle analysis to structural reliability assessment; secondly, it is a condition model suitable for incorporating information from visual inspections, but not for predicting the attainment of conditions that have not already been observed. This represents a major problem in the case of imbalance data such as condition data. Gamma processes have so far been less applied, but do not have these drawbacks. The gamma process is suitable to model gradual damage monotonically accumulating over time, such as wear, fatigue, corrosion, crack growth, erosion, consumption, creep, swell, a degrading health index (van Noortwijk, 2009), as in the case of damage affecting civil infrastructures and reinforced concrete bridges. A gamma process can be fitted to available degradation data and used to assess the probability of reaching a critical condition as a function of time. Gamma processes have been already used for modelling fatigue damage evolution (Guida and Penta, 2015), deterioration of coating systems (Nicolai et al., 2007), and corrosion in reinforced concrete structures (Zhang et al., 2023). Modelling the deterioration as a gamma process is also suitable when visual inspections are involved and summarized into a condition index, provided that the condition index can be interpreted as a measure of damage accumulation (Edirisinghe et al., 2013).

Although uncertainties are inevitable, it is necessary to assess the probability of reaching a critical condition and consequently to predict the remaining service life as precise as possible. In other words, it is necessary to identify groups of objects, or objects components, which show similarities in terms of condition evolution paths. Unsupervised learning techniques and cluster algorithms are data mining techniques suited for finding patterns in big data sets. A review of the application of these techniques to life-cycle assessment can be found in Ghoroghi et al. (2022). Cluster analyses have been already applied to identify spatial clusters of structurally deficient bridges (Amin et al., 2020), to identify damage patterns affecting bridges (Chang and Chi, 2019), to develop bridge deterioration models (Moscoso et al., 2022). Although a grouping of objects based on similar condition evolution paths has already been theorized and proposed by infrastructure operators (Marsili et al., 2018), this result has never been pursued in a completely empirical way, by applying cluster algorithms to condition databases for infrastructure management.

The objective of this paper is to assess the life-cycle of aging reinforced concrete (r.c.) bridge components by combining a cluster analysis with a stochastic process. The k-means algorithm is implemented to cluster bridge components with similar degradation paths. Once the families of bridge components with similar condition evolution have been identified, the gamma process is fitted to the data characterizing each cluster. This approach makes it possible to predict the service life of bridge component with higher precision and construct the cumulative distribution of time to reach an undesired condition, which can be referred to as time to failure, for each identified group of components. The paper is organized as follows: Section 2 gives some background information about the methods at the basis of the proposed approach, Section 3 presents the case study at which the procedure has been applied and Section 4 draws some conclusion.

2 METHODS

2.1 *Gamma process*

van Noortwijk (2009) presents a survey of gamma processes in maintenance. By following its presentation of gamma process, a random quantity X has a gamma distribution with shape parameter $v > 0$ and scale parameter $u > 0$ if its probability density function (PDF) is given by

$$\text{Ga}(x|v, u) = \frac{u^v}{\Gamma(v)} x^{v-1} \exp(-ux) I_{0,\infty}(x) \quad (1)$$

where $I_A(x) = 1$ for $x \in A$ and $I_A(x) = 0$ for $x \notin A$ and $\Gamma(a) = \int_{z=0}^{\infty} z^{a-1} e^{-z} dz$ is the gamma function for $a > 0$. Furthermore $v(t)$ is a non-decreasing, right continuous, real valued function for $t \geq 0$ with $v(0) = 0$. The gamma process with shape function $v(t) > 0$ and scale parameter $u > 0$ is a continuous time stochastic process $X(t), t \geq 0$ with the following properties:

- $X(0) = 0$ with probability one;
- $X(\tau) - X(t) \sim \text{Ga}(v(\tau) - v(t), u), t \in [0, \tau]$;
- $X(t)$ has independent increments.

$X(t)$ represents the deterioration at time $t, t \geq 0$. Its probability density function is given by

$$f_{X(t)}(x) = \text{Ga}(x|v(t), u) \quad (2)$$

in which

$$E(X(t)) = \frac{v(t)}{u}, \quad (3)$$

$$\text{Var}(X(t)) = \frac{v(t)}{u^2} \quad (4)$$

are the expectation and the variance, respectively.

Assuming H_0 as the initial value of the damage accumulation index, failure occurs when the damage accumulation index $H(t) = H_0 - X(t)$ reaches the critical level H_{crit} . The time at which failure occurs is especially called T_{crit} , which is also referred to as the first hitting time of the critical level H_{crit} . Then the cumulative distribution function (CDF) of time to failure can be written as

$$F(t) = \Pr\{T_{\text{crit}} \leq t\} = \Pr\{X(t) \geq H_{\text{crit}}\} = \int_{x=H_{\text{crit}}}^{\infty} f_{X(t)}(x) dx = \frac{\Gamma(v(t), uH_{\text{crit}})}{\Gamma(v(t))}, \quad (5)$$

where $\Gamma(a, x) = \int_{z=x}^{\infty} z^{a-1} e^{-z} dz$ is the incomplete gamma function for $x \geq 0$ and $a \geq 0$.

2.2 Parameter estimation for the gamma process

Let us assume to model the temporal variability in the deterioration with a gamma process. Empirical studies show that the expected deterioration at time t is often proportional to a power law

$$E(X(t)) = \frac{v(t)}{u} = \frac{ct^b}{u} \quad (6)$$

in which $c > 0$ and $b > 0$ are constant. The gamma process is called stationary if the expected deterioration is linear in time, i.e., when $b = 1$, and non-stationary when $b \neq 1$.

Let us consider a typical data set of inspection times $t_i, i = 1, \dots, n$, where $t_0 < t_1 < \dots < t_n$, and corresponding observations of the cumulative amounts of deterioration $x_i, i = 1, \dots, n$, where $0 = x_0 \leq x_1 \leq \dots \leq x_n$. The parameter b can be determined based on engineering experience or estimated from data, according to a least square method (Hu et al., 2022)

$$b = \frac{n \sum_{i=1}^n (\log t_i)(\log x_i) - (\sum_{i=1}^n \log t_i) (\sum_{i=1}^n \log x_i)}{n \sum_{i=1}^n (\log t_i)^2 - (\sum_{i=1}^n \log t_i)^2}. \quad (7)$$

The parameters c and u can be estimated according to different approaches such as method of maximum likelihood, method of moments, method of Bayesian statics. According to the method of moments (Hu et al., 2022)

$$c = \frac{x_n^2 \left[1 - \sum_{i=1}^n \left(\frac{\Delta t_i}{t_n} \right)^2 \right]}{t_n S_Y^2}, \quad (8)$$

$$u = \frac{x_n \left[1 - \sum_{i=1}^n \left(\frac{\Delta t_i}{t_n} \right)^2 \right]}{S_Y^2} \quad (9)$$

in which S_Y^2 is given by

$$S_Y^2 = \sum_{i=1}^n (\Delta x_i - \bar{Y} \Delta t_i)^2, \quad (10)$$

and

$$\bar{Y} = \frac{\sum_{i=1}^n \Delta x_i}{\sum_{i=1}^n \Delta t_i} = \frac{x_n}{t_n}. \quad (11)$$

2.3 The k-means algorithm

The k-means is one of the simplest and most efficient as well as most widely used partitional clustering algorithms. The algorithm starts by choosing K representative points as the initial centroids. Each point is then assigned to the closest centroid based on a proximity measure, usually the Euclidean distance metric. Once the clusters are formed, the centroids for each cluster are updated. The algorithm then iteratively repeats these two steps until a convergence criterion is met and the centroids do not change anymore. In particular, the objective function employed by k-means is the Sum of Squared Errors (SSE).

Given a set of m observation $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_m$ in which each observation is a d-dimensional real vector, k-means clustering aims to partition the m observations into $k \leq m$ sets $\mathbf{D} = \mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_k$ so as to minimize the SSE (Aggarwal and Reddy, 2014)

$$\underset{\mathbf{D}}{\operatorname{argmin}} = \sum_{k=1}^K \sum_{\mathbf{z}_j \in \mathbf{D}_k} \|\mathbf{z}_j - \mathbf{d}_k\|^2, \quad (12)$$

$$\mathbf{d}_k = \frac{\sum_{\mathbf{z}_j \in \mathbf{D}_k} \mathbf{z}_j}{|\mathbf{D}_k|}, \quad (13)$$

in which \mathbf{d}_k is the centroid of cluster \mathbf{D}_k and $|\mathbf{D}_k|$ is the size of \mathbf{D}_k .

The major factors that can impact the performance of the k-means algorithm are the following: 1) Choice of the initial centroids; 2) Estimation of the number of clusters K. Several methods are proposed in the literature to tackle these factors. In this work, the k-means++ algorithm is applied to select the initial centroids. According to this technique, the first cluster center is chosen uniformly at random from the data set. The next centroid is chosen randomly from the remaining data points with probability proportional to its distance from the point's closest existing cluster center. The problem of estimating the correct number of clusters is addressed by calculating the silhouette coefficient. This performance measure is based on the calculation of the intra- and inter-cluster distances. For a given point \mathbf{z}_j , first the average of the distances to all points in the same cluster is calculated. This value is set to e_j . Then for each cluster that does not contain \mathbf{z}_j , the average distance of \mathbf{z}_j to all the data points in each cluster is computed. This value is set to f_j . Using these two values the silhouette coefficient of a point is estimated. The average of all the silhouettes in the dataset is called the average silhouette width

$$P = \frac{\sum_{j=1}^m \frac{f_j - e_j}{\max(f_j, e_j)}}{m}, \quad (14)$$

and the larger its value, the higher the quality of clustering.

3 CASE STUDY

3.1 KUBA-DB

The Federal Roads Office (ASTRA) is the Swiss authority for road infrastructure management. In the context of the maintenance of ASTRA's engineering structures, inspection is of primary importance in order to detect damage at an early stage and to assess the current condition of the structure or the individual parts of the structure. Three different types of inspection can be carried out: primary, intermediate and special. The findings of primary and intermediate inspections are damage processes and information collected during the inspection is collected in the database KUBA-DB. A set of homogeneous damage processes within the same segment of the structural member and having the same effects on the functionality of the component forms a damage group. Each damage group is assigned to a condition class, which describes the condition of a relevant area of the structural element. Five condition classes have been defined, from "good condition" class to "alarming condition" class, with which a condition index from 1 to 5 is associated. Then, an assessment of the condition of the whole structural component is made, based on the damage groups and their effect on the safety and on the functionality of the component. This information is then aggregated at higher level to determine the condition of the whole object.

3.2 Description of the procedure

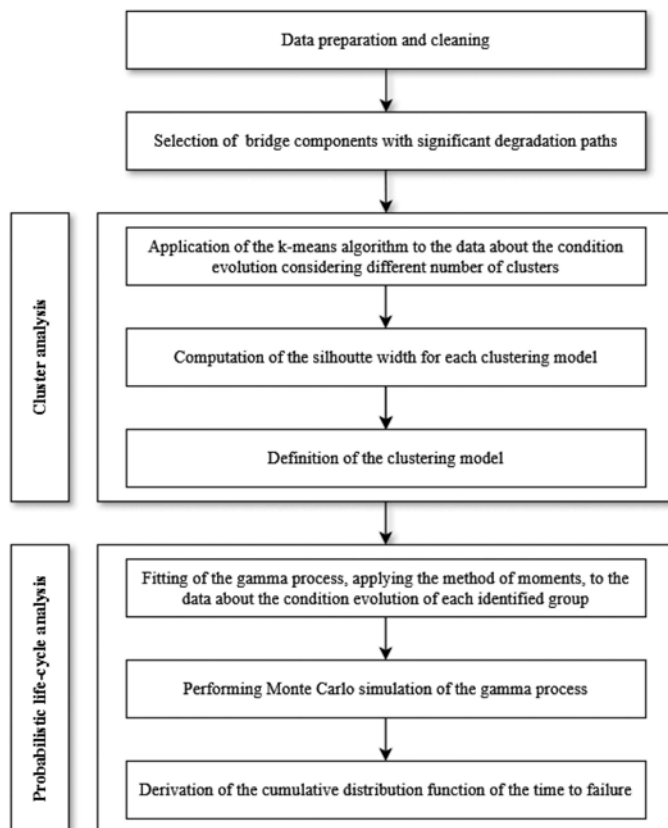

Figure 1. Flow chart summarizing the applied procedure.

Figure 1 summarizes the applied procedure for the analysis of the data. The first step is to prepare the data for analysis. In this step, data affected by inconsistencies due to human errors in their recording are removed, such as typing error. The data are cleaned and transformed into an appropriate format to perform the analysis. In a second step, the data for each structural component are selected, focusing on those structural components that show significant deterioration in their condition, i.e., those for which the condition index has experienced at least an increase from 1 to 2 and from 2 to 3. Such components are able to provide relevant information on the development of their condition, which will allow the fitting of a gamma process. Then, cluster analysis is performed, considering a variable number of clusters and calculating for each cluster model the performance measure. In general, it is possible to identify between two and three families of components that show similar condition development. More families can be identified only if a larger data set is available. The performance measure, i.e., silhouette width, supports the choice of the optimal number of clusters and is supplemented with a visual inspection of the identified clusters. Once the cluster model has been defined, a gamma process is fitted to the data belonging to each identified cluster. The parameters of the gamma process are determined based on Equations 7, 8, 9. Their definition allows a Monte Carlo simulation of the gamma process and the derivation of the mean time to failure as well as its CDF.

Figure 2. Results of k-means clustering for two and three centers.

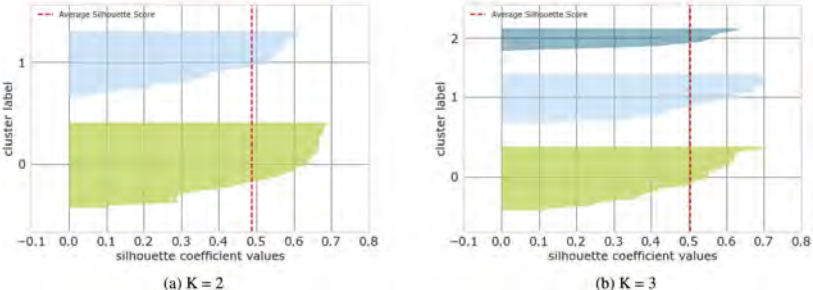

Figure 3. Silhouette plot of k-means clustering for 64 samples and two and three centers.

3.3 Results

For illustrative purposes, the results for a single component, namely the deck slab of reinforced concrete bridges, are reported. In a total of $m = 64$ cases, the condition of the deck slab deteriorate significantly over time, and the condition index increases from 1 up to 3.

The cluster analysis with the k-means algorithm is performed considering the evolution of the condition index over time of the selected elements. Figure 2 shows the clusters identified in the case where $K = 2$ and $K = 3$. For each cluster model the average silhouette width is calculated (Figure 3). Results reveal that the silhouette width of the model characterized by three clusters ($P(K = 3) = 0.505$) is higher than the silhouette width of the model characterized by

two clusters ($P(K = 2) = 0.488$). For this reason, the optimal number of clusters is three, and this model is assumed and considered in the subsequent analysis. The cluster analysis identifies three families of bridge deck slab that show markedly different condition evolution, which can be referred to as slow (cluster 1), normal (cluster 0) and fast (cluster 2). The next step is to fit the gamma process to the data characterizing each cluster, that is, to statistically estimate the parameters b , c , and u for each family of bridge deck slab. The results of the inspection, namely the condition index, must be first adjusted to obtain an index representing the accu-

Table 1. Estimated parameters of the gamma process and average time to failure resulting from its simulation for each cluster.

	b	u	c	Average time to failure (year)
Cluster 0	1.7027	1.3333	0.0069	52.4
Cluster 1	2.3245	1.3333	0.0004	60.2
Cluster 2	1.0930	1.3333	0.0935	43.6

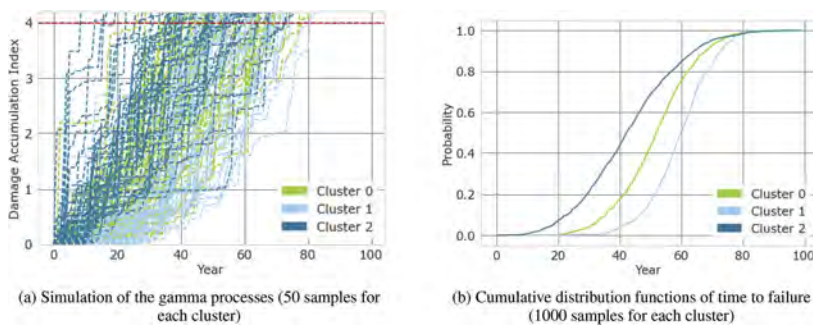

Figure 4. Probabilistic models for life-cycle assessment.

mulation of deterioration over time. Hence, the condition index is transformed into a damage accumulation index through the following equation

$$\text{Damageaccumulationindex} = \text{Conditionindex} - 1, \quad (15)$$

which is considered to fit the gamma process.

It is assumed that the critical damage accumulation level is 4, which corresponds to the condition index value 5, which is the critical value at which the component no longer fulfills a function (safety, serviceability, durability).

After that the parameters of the gamma process have been estimated (Table 1), a Monte Carlo simulation is performed (Figure 4). The Monte Carlo simulation allows the derivation of the average time to failure (Table 1) and the time to failure CDF for each identified cluster, which is shown in Figure 4. The CDF describes the trend of the failure probability as a function of time, which is directly related in statistical terms to the service life of the component. The average time to failure especially represents the expected service life of the component. Based on this result, it can be concluded that the group of components having a fast rate of deterioration has an expected service life of 43.6 years, the normal one of 52.4 years, and the slow one of 60.2 years.

4 CONCLUSIONS

The assessment of the remaining service life, understood as the service life before a degradation process reaches a critical level for which a maintenance intervention is deemed urgent, is an important step in improving the management of physical assets of infrastructure. Conscious of

this, this article proposes an approach to assess the life-cycle of reinforced concrete bridge components by applying an unsupervised learning technique and a stochastic process. A cluster analysis based on the k-means algorithm is applied to identify families of bridge components that degrade with similar rates. A gamma process is fitted to the data concerning the evolution of the degradation that characterizes each family. By simulating the gamma process, the average expected service life of each family of components can be estimated. The simulation also allows the estimation of the time-dependent probability of damage exceeding a threshold level, called the probability of failure. An application of this approach to the case of reinforced concrete bridges in Switzerland, whose inspection results are contained in the KUBA-DB database, is developed. In particular, condition data related to the deck slab of reinforced concrete bridges is analyzed with the described procedure. Results reveal that three families of components whose condition evolves in a similar way can be identified. A performance measure, namely the silhouette width, supports the choice of the optimal number of clusters. Finally, it can be said that through this approach the service life of components can be predicted with reduced uncertainties.

ACKNOWLEDGMENT

This research study is funded by the FFG project “ENDURE - Estimation of the remaining service life of bridges through the development and testing of hybrid models”, whose aim is to improve bridge life-cycle assessment analysing the infrastructure management databases of the D-A-CH countries.

ABSTRACT: Climate change is associated with significant variations of temperature, atmospheric humidity, and carbon dioxide concentration levels. These changes potentially produce a double negative effect on the safety and the life cycle of civil engineering structures: increased climatic actions and rate of material degradation. In fact, changes in these variables affect the service life of reinforced concrete and steel structures by acting on the rate of carbonation and corrosion. Corrosion has a detrimental effect especially on the seismic vulnerability influencing strength, ductility and affecting the dynamic response and consequently the failure of reinforced concrete structures. Particularly bridges, as structures directly exposed to the weather effects, are more susceptible to these phenomena. In this paper, a framework to quantitatively account for the effects of climate change on carbonation-induced corrosion is proposed, focusing on the loss of concrete passivity, and thus widespread corrosion. Different scenarios for the expected variations in CO₂ concentrations and temperature are analyzed and seismic risk indexes are evaluated through a real case study of bridge located in the province of Massa-Carrara (Italy).

1 INTRODUCTION

Corrosion has a detrimental impact on life cycle and on the seismic performance particularly of reinforced concrete structures. The effects of corrosion are more significant on strength than on ductility (Berto et al., 2012). Typically, reinforced concrete bridges, in which all the structural elements are exposed to the environmental conditions, are more prone to corrosion than steel bridges, where the possibility of inspection and maintenance are more effective, and buildings, where the structure is fully protected (Biondini et al. 2014).

Existing reinforced concrete bridges can be interested by damaging or collapse due to aging, design errors and usually the deterioration can be exacerbated by lack of maintenance and climate change impacts. The main failures are due to steel corrosion producing loss of prestress and a wide of brittle failure, especially diffused in the Gerber type bridges (Sassu et al. 2023).

Climate changes strickles existing structures and infrastructures with several effects. Rain-storms or tropical cyclones threaten the stability of bridges, particularly the one of reduced spans, producing erosion or additional actions (Sassu et al. 2017) (Puppio et al. 2021). Maintenance and visual inspections, joined with modern strategy of vulnerability assessment and refurbishment, are key action in the prevention of bridge failures (Mistretta et al. 2015) (Stochino et al 2018)(Pucci et al 2021)(Coni et al. 2021) (Hasa et al 2022).

The effects of climate change on civil engineering structures are now recognized and investigated into international context, considering different models and scenarios (Stewart et al., 2011) (Bastidas-Arteaga et al., 2013) (Croce et al., 2019). The Joint Research Center of the European Commission produced new international guidelines on the expected implications of climate changes on the corrosion of structures (Sousa et al., 2020). The report highlighted the impact of the increase of CO₂ levels and temperature levels on corrosion processes of r.c. structures thus calling for adaptation strategies guaranteeing that the corrosion damage probability will be not compromised from future climate.

The topic is of strategic concerns in Italy particularly considering the huge diffusion of r.c. bridges, the seismic exposure of the environments and the current state of maintenance. The paper proposes a method of investigation to consider the effects increase of temperature on seismic vulnerability of r.c. bridge and considering a real case of study in the province of Massa Carrara.

2 EFFECTS OF GLOBAL WARMING ON CORROSION RATE

The durability of reinforced concrete structures is affected by climate change mainly entailing the variations of three environmental parameters: temperature, relative humidity, and carbon dioxide (CO₂) concentration levels. In this work, the attention is focused on the impact of temperature increase on corrosion rate i_{corr} .

Future climate is predicted based on assumptions about future trends in socio-economic dynamics, future concentrations of greenhouse gasses, variations in land use and land cover. These assumptions lead to an increase in radiative forcing, i.e. the change in energy flux, in the year 2100 equal to 2.6, 4.5, 6.0 and 8.5 W/m² compared to the preindustrial era and define the so-called Representative Concentration Pathways (RCPs) (van Vuuren et al., 2011). The scenarios which are mostly considered in climate risk studies are RCP4.5 and RCP8.5, for which most climate projections are available. They correspond to medium and maximum pathways, and they have been adopted in the present study as well. Expected changes in climate parameters are thus estimated by the analysis of climate projections provided by high-resolution Regional Climate Models according to RCPs scenarios (Jacob et al., 2014). The limited number of climate projections can be then increased to provide a probabilistic description of temperature variations by means of the use of weather generation techniques such as that presented in (Croce et al., 2021). In Figure 1, the variations of yearly average temperature are shown for the location of the bridge, which will be investigated in the following sections, Massa in Italy (lon=10.141; lat=44.025).

Figure 1. Historical and future variation of yearly average temperature at Massa (Italy).

Temperature raises are associated with an increase of corrosion rate, which is generally described by the model developed by (DuraCrete, 2000):

$$i_{corr}(t) = i_{corr,20}[1 + K(T(t) - 20)] \quad (1)$$

where $i_{corr,20}$ is the corrosion rate at 20°C, which depends on the environmental exposure, and K is a factor can be assumed $K = 0.025 \text{ } ^\circ\text{C}^{-1}$ if $T(t) < 20 \text{ } ^\circ\text{C}$ and $K = 0.073 \text{ } ^\circ\text{C}^{-1}$ if $T(t) > 20 \text{ } ^\circ\text{C}$. Assuming $i_{corr,20} = 0.345, 0.172$, and $0.431 \text{ } \mu\text{A}/\text{cm}^2$, average values given in (Stewart et al., 2011) for exposure class C2 - Wet-rarely dry (unsheltered), C3 - Moderate humidity (sheltered), and C4 -Cyclic wet-dry (unsheltered), variation of corrosion rate i_{corr} with time are evaluated. Different outcomes, are obtained starting from the reference values $i_{corr,20}$ given in (DuraCrete, 2000) for slight, moderate, and high exposure: 0.1,1, and $5 \text{ } \mu\text{A}/\text{cm}^2$. Another model which is commonly used to describe temperature effects on corrosion rate is the one based on the Arrhenius Law (Pour-Ghaz et al., 2009):

$$i_{corr}(t) = i_{corr,20} \exp\left(\frac{E}{R} \left(\frac{1}{293} - \frac{1}{273 + T(t)}\right)\right) \quad (2)$$

where E is the activation energy of the diffusion process (40 kJ/mol) and R is the gas constant (8.314×10^{-3} kJ/mol K). In this case, the percentage of variations will be higher than the previous one, leading to increases up to 30% at the end of the century. Variation of corrosion rate i_{corr} with time are again evaluated considering the same reference values of $i_{corr,20}$ given in (Stewart et al., 2011) and (DuraCrete, 2000).

3 STRUCTURAL MODELLING AND ANALYSIS METHOD

To evaluate the corrosion effects due to carbonation on the seismic performance of existing RC bridges, the approach proposed by (Crespi et al., 2022) has been considered, based on the implementation of simplified 3D Finite Element Models (FEMs) using MIDAS Civil commercial software. The piers, the pier caps and the deck have been modelled with beam elements, while the elastomeric bearings have been schematized through elastic links having rotational and translational stiffnesses calculated according to EN 1337-3:2005. To guarantee the connection between the beam elements and the elastic links, a series of rigid links have been applied (Crespi et al., 2022). The abutments have been considered as perfect restrains and the non-structural elements have been implemented in the FEM as uniform distributed beam loads (Zucca et al., 2023).

To obtain the correct dynamic behavior of the bridge, the reduction of the bending stiffness of the piers due to the concrete cracking has been introduced through specific scale factors applied to the concrete gross-section elastic stiffness of each pier, calculated starting from the moment-curvature ($M-\chi$) diagrams of the gross-section of the piers according to EN 1998-3:2005. On the contrary, the stiffness of the deck is not scaled (Chen & Duan, 2000) and the traffic load has been neglected according to as reported in (Decreto Ministeriale, 2018).

Two different failure mechanisms are taken into consideration for each pier: the ductile and the brittle collapse mechanism. In particular, the ductile collapse mechanism is related to the moment-curvature diagram of the cross-section of the pier, and it is characterized by an initial elastic branch followed by a large strain hardening plastic trend while the brittle failure mechanism presents a linear load-displacement trend until reaching the ultimate shear resistance. The ductile collapse mechanism is regulated by the rotational capacity of the plastic hinge while the brittle collapse mechanism depends on the shear strength of the monitored structural element.

The non-linear behavior of the concrete and of the of the steel reinforcement bars has been considered using, respectively, Kent and Park model (Kent & Park, 1971) and Park Strain Hardening constitutive law (Park & Paulay, 1975). The two different verification criteria considered in this work are the following: for the ductile mechanism the achievement of $\frac{3}{4}$ of the ultimate rotation θ_u while for the brittle failure mechanism the achievement of the shear resistance of the monitored structural element, calculated considering the cyclic shear resistance reported in EN 1998-2, 2005. The corrosion effects due to carbonation have been considered in the FEM through a simplified analytical model related to the progressive reduction of the steel reinforcements diameter and where the penetration law in a generic concrete volume follows a parabolic trend:

$$s = k \cdot t^n \quad (3)$$

where s = thickness of the carbonated layer of concrete; k = penetration rate coefficient; and t = time. For existing RC bridges built around 1970's, it is possible to assume the parameter n equal to 2 because they were realized using normal compacted concrete (Saetta & Vitaliani, 2004).

As mentioned before, the existing RC bridges considered in this work were built around the 1970's and they have been designed without considering the seismic action. For this reason, the proposed approach directly considers the influence of the steel reinforcements area reduction on the seismic capacity of the bridges, according to Equations 4 and 5

$$d(t) = d_0 - 2P(t) = d_0 - 2i_{corr}k(t-t_1) \quad (4)$$

$$A_{s(t)} = \frac{\pi [d_0 - 2i_{corr}(t-t_i)]^2}{4} \quad (5)$$

Equation 4 considers the variation of the diameter of the steel reinforcement d as a function of the corroded thickness $P(t)$ while Equation 5 is related to the variation of cross-section area $A_{s(t)}$.

As mentioned in previous Sections, three different corrosion scenarios have been considered: slight, moderate and high. For these scenarios two different assumptions were made for the evaluation of i_{corr} value. In the first assumption, the value of i_{corr} has been obtained considering the average values given in (Stewart et al., 2011) which indicates values of i_{corr} equal to 0.172, 0.345, and $0.431 \mu\text{A}/\text{cm}^2$, respectively for slight, moderate and high corrosion level. In the second case, the values of i_{corr} have been calculated according to as reported in (DuraCrete, 2020) that is 0.1, 1 and $5 \mu\text{A}/\text{cm}^2$ respectively for slight, moderate and high corrosion scenario.

The reduction of the steel reinforcements diameter has been evaluated considering the difference between the initial steel reinforcements diameter d_0 and the actual one $d(t)$. The following values of the other parameters are taken into consideration: water/cement ratio (w/c) = 0.6, the compressive strength of the concrete $f_{ck} = 28 \text{ MPa}$, the penetration rate coefficient $k = 0.0116$ and the steel rebar ultimate deformation $\varepsilon_{u,0} = 9 \%$ are considered as constant for the different corrosion levels analysed. The initiation time t_i is assumed constant and equal to 13.5 years as in (Berto et al., 2009), disregarding the effect of climate change, especially the increase of CO_2 levels and temperatures, on the diffusion process. In this work, the corrosion effects are evaluated at different times (construction time and after 13.5, 50, 75 and 100 years of bridge service life) to obtain the variation of the seismic performance of the bridge over time. To evaluate the seismic behaviour of the bridges, multi-modal pushover approach has been chosen considering the Capacity Spectrum Method (CSM) for the determination of the performance point (ATC-40, 1996). Several capacity curves have been obtained and for each of them, corresponding to a vibration mode shape with a participating mass greater than 1% and a modal loading profile, the performance point is calculated considering the relevant seismic demand spectrum. For each vibration mode, the internal actions acting on the monitored structural element have been determined in correspondence to the performance point obtained by the intersection of the capacity curve and the demand spectrum in ADRS plane. The internal actions obtained for each capacity curve are combined through the complete quadratic combination (CQC) rule, for the safety verification purposes. Further detail about modelling can be found in (Zucca et al., 2023).

4 CASE STUDY

The procedure described in previous Section has been applied to a one existing RC bridge located in the province of Massa-Carrara and built around the 1970's. The main seismic parameters which characterize the site are the following: soil type C and PGA equal to 0.156 g. The analyzed bridge is characterized by the presence of two adjacent and independent carriageways, consisting in a sequence of four simply supported 40.40 m spans. The planimetric and altimetric layout is rectilinear. The overall width of the roadway is equal to 9.86 m and each span is realized by a precast concrete girder of three longitudinal prestressed I beams and five transverse beams. The bridge deck consists in a 20 cm concrete slab. Each span is supported by 2 x 3 elastomeric bearings located into the hammer cap. The deck is supported by three hexagonal hollow RC piers characterized by a height ranging between 5.06 m and 15.51 m (Figure 2). Table 1 reports the main characteristics of the piers. The first three fundamental periods which characterize the dynamic behaviour are $T_1 = 2.73 \text{ s}$, $T_2 = 2.56 \text{ s}$ and $T_3 = 2.41 \text{ s}$.

Figure 2. The analyzed bridge.

Table 1. Piers main characteristics.

Piers [n°]	Cross-section dimensions [m]	Height [m]	Longitudinal steel reinforcement [-]	Transverse steel reinforcement [-]	Piers thickness [m]
1	4.0 x 2.5	5.06	148Ø14	Ø10/20	0.35
2	4.0 x 2.5	10.84	148Ø14	Ø10/20	0.35
3	4.0 x 2.5	15.51	148Ø14	Ø10/20	0.35

Tables 2 and 3 summarize the results of the corrosion effects on the steel reinforcements expressed in terms of diameter and area reductions as a function of the age of the bridge considering, respectively, the reference values of i_{corr} suggested by (Stewart et al., 2011) and (DuraCrete, 2020). It is important to highlight that the reduction of the steel rebar ultimate deformation $\epsilon_{u,0}$ has been calculated according to (Lee & Choo, 2009). On the contrary, considering the i_{corr} values suggested by (DuraCrete, 2020) significant steel reinforcements area reductions can be observed as early as 50 years after the construction of the structure for the high corrosion scenario characterized by $i_{corr} = 5 \mu\text{A}/\text{cm}^2$. Considering the high corrosion level, it is possible to notice that, after 100 years from the construction of the bridge the transverse steel reinforcements appear completely corroded. As a result a slight increase of the natural periods of the bridge can be observed especially for the first vibration modes.

To complete the evaluation of the seismic behaviour of the analysed bridge, multi-modal push-over analyses have been carried out considering an iterative process. Once the determination of the peak ground acceleration which leads to the collapse of the first structural elements (PGA_C) it is possible to calculate the risk indices which characterize the bridge for the different corrosion scenarios analysed through Equation 6, where PGA_D = design peak ground acceleration:

$$RI_{PGA} = \frac{PGA_C}{PGA_D} \quad (6)$$

Values of risk indices close or greater than one concern cases of safe bridges, whereas values smaller than one indicate structures with a high risk of seismic failure. Tables 4 and 5 summarize the values of the risk indices obtained for the investigated corrosion scenarios, i_{corr} determined as reported in (Stewart et al., 2011) and in (DuraCrete, 2020), and where X indicates the direction along the longitudinal axis of the bridge and Y the transverse direction.

The reduction of the risk indices is more evident considering the moderate and high corrosion scenarios characterized by i_{corr} values suggested by (DuraCrete, 2020). It is possible to notice that after 100 years from the construction of the bridge, taking into consideration a value of $i_{corr} = 5 \mu\text{A}/\text{cm}^2$, the reduction of the risk indices reaches 80% for the ductile collapse mechanism and exceeds 90% for the brittle collapse mechanism while for $i_{corr} = 1 \mu\text{A}/\text{cm}^2$ there is a significant reduction of the brittle failure mechanism risk index in Y direction which slightly exceeds 75%. Important reduction of the risk indices is also highlightable after 75 years of the construction of the structure.

Table 4. Risk indices values considering i_{corr} given in (Stewart et al., 2011).

Figure 3. Variation of seismic risk index with i_{corr} .

The results for moderate and high exposure in Y direction are summarized in Figure 3. The results presented above are obtained considering constant reference values of i_{corr} , and can be used to assess the impact of global warming on seismic risk when different i_{corr} values are expected as illustrated in Section 2. Looking at R_{lPGA} for brittle mechanism in Y direction, the range of values of i_{corr} for the location of the bridge predicted in section 2 for moderate and high exposure lead to the variation of seismic risk indexes highlighted by the shaded colored areas in Figure 3.

5 CONCLUSIONS

In this work a framework to considers the effects of the increase of temperature on the corrosion of steel reinforcement in r.c. structures are presented and applied to a case of study in the province of Massa Carrara (Italy). The analyses considered both extreme as well as verisimilar scenarios; the results are definitely affected by the limited availability of data for corrosion rate i_{corr} . In any case, the situation at 100 years of age appears deserving of attentions, even considering numerous uncertainties and the fact that the method should be subject to successive refinements.

In any case, it should be considered that as at today the investigate viaduct has already 50 years of service life and that projections to 100 years are to be referred to 2070. Since most of the national heritage is built in the 50-70s an improvement of the framework could be to consider the current state of corrosion for numerical analyses. This, coupled with experimental i_{corr} knowledge and specific to that area, allow an improvement in the reliability of the numerical analysis. Considering the corrosion scenarios characterized by i_{corr} values suggested by (Stewart et al., 2011), a significant reduction of the risk indices values occurs only in the case of high corrosion level ($i_{corr} = 0.431 \mu A/cm^2$) for the brittle collapse mechanism. The slight corrosion scenario does not lead to significant reductions of risk indices values for the considered collapse mechanisms due to the small reduction of the steel reinforcements area that characterizes such a corrosion level. Different conclusions can be drawn from the i_{corr} values suggested by (DuraCrete, 2000), where more significant reduction of the risk indices is obtained with reduction up to 80% for the ductile collapse mechanism and exceeds 90% for the brittle collapse mechanism. Further refinement of the method and the introduction of other kind of degradation due to the environmental actions are expected as subsequent development of the works.

ABSTRACT: Reinforced concrete precast industrial buildings can attain a performance enhancement and extend their nominal service life through seismic retrofitting strategies. This work investigates the behaviour of two seismic dissipation devices designed for retrofit of precast buildings, with the aim of testing their effectiveness in improving the seismic response of this construction system, as well as qualitatively assessing their life cycle environmental impact. With reference to a single-storey case study building, a comparative analysis of the seismic response of the structure before and after the retrofit with the two proposed devices was undertaken. Two numerical models of the building, with and without the retrofit, were created in OpenSees and subjected to nonlinear static analyses. The obtained results provided reassurance on the efficacy of the proposed solutions in improving the seismic performance of existing and new precast industrial buildings. Moreover, the potentials of environmental impact reduction of the proposed retrofitting solutions showed that they are attractive under a sustainable viewpoint as well.

1 INTRODUCTION

Italian reinforced concrete (RC) precast industrial buildings, especially those not specifically designed to resist seismic actions, suffered from extensive damage following the recent earthquakes that struck Italy (Abruzzo 2009, Emilia-Romagna 2012 and Central Italy 2016-2017). The seismic response of these buildings can be generally improved by imposing the dissipation of an appropriate amount of energy. In the last decade, a large body of literature has been devoted to the development and the application of dissipation devices that can be used for precast structures, to enhance their seismic performance and extend their nominal service life. The practical issues that have been considered include the possibility to use the devices for both existing and new precast structures, the possibility to examine the devices from close up, the replaceability after a seismic event, the dry installation without the use of mortar, and the compatibility with the techniques adopted for the construction of typical precast buildings, for instance in the case of structures with monolithic columns and pin-ended beams (Belleri et al. 2010). The devices typically employed for these structures can dissipate energy through friction or by hysteresis and be combined with elements having the function to increase the initial stiffness; in this way, they prevent or mitigate the second order effects and excessive displacements at the serviceability limit state, which often drive the design of flexible structures.

While several works in the current literature explored the feasibility of energy dissipative cladding panel connection systems, the focus in this work is on dissipation devices designed for beam-to-column connections of precast industrial buildings, as well as dissipative bracing systems. Several researchers to date proposed retrofitting solutions that are applicable to frictional beam-to-column connections (e.g. Santagati et al. 2012, Belleri et al. 2017, Magliulo et al. 2017, Hu et al. 2020, Belleri & Labò 2021, Bai et al. 2022), or that make use of dissipative braces (e.g. Dal Lago et al. 2021). However, despite the relevance of sustainability issues related to the reduction of economic and environmental impacts (in terms of earthquake-induced losses) allowed by the retrofit, the benefit of dissipation devices to the life cycle seismic performance of precast structures, as well as their own life cycle environmental impact, have not been fully investigated yet.

This paper aims to test the effectiveness of energy dissipation devices in improving the seismic response of precast industrial buildings, while also qualitatively assessing their environmental impact reduction potentials: the latter include the impact of each device life cycle phase, as well as the consequent reduction of earthquake-induced losses during the service life of the structure. With reference to a single-storey case study building, a comparative analysis was undertaken on the seismic response of the structure before and after the retrofit with two proposed dissipation devices, namely a friction rotation damper for beam-to-column connections and a bracing system with dissipative sacrificial elements. The advantages deriving from the use of such devices include not only the reduction of global lateral displacements and resisting forces in the main structural elements, and the increase of the building’s lateral strength, but also their replaceability after a seismic event. Two three-dimensional numerical models of the case study building, with and without the retrofit, were created in OpenSees (McKenna et al. 2000) and subjected to nonlinear static (pushover) analyses in both the main directions. In Section 5, for each life cycle phase of the employed devices, their potentials of impact reduction are explored using a Life Cycle Thinking (LCT) indicator, showing that the proposed retrofitting solutions are expected to be environment-friendly under a life cycle perspective.

2 CASE STUDY BUILDING AND ADOPTED DISSIPATION DEVICES

The case study considered for this endeavour, depicted in Figure 1, is a single-storey precast structure representative of the Italian construction period of the ‘70s, located in Naples and designed on the base of gravity loads only.

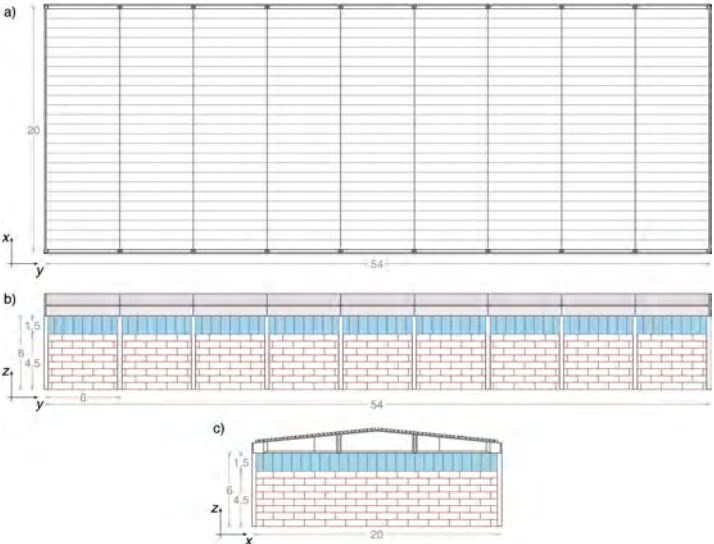

Figure 1. a) Top, b) side and c) frontal view of the case study building (Units: m).

The geometry consists of a single span with total plan size of $20 \times 54 \text{ m}^2$. The columns have a $0.35 \times 0.35 \text{ m}^2$ cross-section and a 6 m height. The prestressed main beams in the transverse (x) direction have a span length of 20 m and a double slope (10% inclination) with an I-section variable in both height and thickness. The secondary beams (or girders) in the longitudinal (y) direction are 6 m long with a tee cross-section. The connections of the main beams to the columns only rely on friction and are characterised by the presence of neoprene pads on the column top allowing for beam seating. On the other hand, the girders are fastened to the columns by steel dowels. The roof is composed of double-tee prestressed elements, rigidly jointed to the main beams by reinforcement stirrups protruding from the beams, additional steel bars between the elements and a finishing concrete casting. The external closure is present on all sides of the building and is constituted of masonry infill panels, creating a ribbon window of a 1.5 m height.

2.1 Dissipation devices

The first dissipation device considered herein is a friction rotation damper (see Figure 2), conceived to be applied at beam-to-column connections. The device is able to dissipate energy (thus increasing the system damping) through the friction generated by the relative rotation of steel plates with interposed brass discs. The interposition of brass discs, softer than the connected steel plates, guarantees smoothness during relative rotations (Belleri et al. 2017). The increase of the device activation moment is accomplished by incrementing the number of sliding surfaces (four in Figure 2b). The steel plates are fixed to the mounting frame by bolts placed in slotted holes, thus transferring the external tightening force to the brass discs. Cup springs are introduced on the main bolt for a better control of the tightening load acting on the brass discs. For each beam-to-column connection, the device works in a three-hinge scheme, where sliding surfaces are applied only at one hinge, whilst the remaining two hinges are left free to rotate. In the current study, this first retrofitting solution encompasses the use of the rotation damper coupled with steel profiles and passing holes hosting steel pins, which allow for relative rotations but prevent joint sliding. Also, given the presence of secondary beams, with no specific structural function, in the perimeter portal frames along the longitudinal direction, it was decided to install the rotation dampers only at the beam-to-column frictional connections in the ten portal frames that include the main beams, along the transverse direction. The size of the devices allows some clearance between them and the masonry infills, which are thus left intact.

Figure 2. a) Side and b) bottom view of the adopted friction rotation damper (Units: cm); c) Diagonal steel braces, with a close-up on the dissipative sacrificial elements.

The second dissipation solution adopted in this work entails the use of non-traditional diagonal steel braces, characterised by the inclusion of dissipative sacrificial elements, as well as the presence of a junction in the middle, which allows the upper and lower portions of the braces to be off-axis (Resilio system 2017). This system is able to channel the ingoing seismic energy towards predefined points in the vicinity of the junction, where the sacrificial elements are located (see Figure 2c): the latter are pushed in the nonlinear field and dissipate energy by hysteresis, thus preserving the rest of the structure. A crucial property of this system is its immediate activation during an earthquake, something that prevents the occurrence of strong bending moments at the base of the columns. The elements may be easily replaced after a seismic event. Moreover, the global static scheme of the structure remains unchanged. In the current study, given the relevant width (i.e. 20 m) of the portal frames along the transverse direction, the braces are installed only along the longitudinal direction, and in particular within the central bay of the perimeter portal frames (see Figure 1b). The braces are connected to the bottom and the top portions of the columns, thus occupying the entire clearance below the girders: consequently, the central field of masonry infill must be removed and the glazing of the correspondent ribbon window dismounted; then, after the retrofitting intervention, lightweight infills made of green or sustainable materials are put in place only for closure purposes, and the glazing is just remounted.

3 NUMERICAL MODELLING

Two 3D numerical models of the case study building, with and without the retrofit, were created in OpenSees. In both building models, a concentrated plasticity approach with a plastic hinge at the base of the columns was used to describe the global structural nonlinear behaviour; in the adopted model, the stiffness of the entire element is obtained by connecting in series the stiffness of the rotational spring and the one of the column element. The plastic hinge model was defined using the *ModIMKPeakOriented* material, as implemented in OpenSees, whose mechanical parameters were assigned according to Bosio et al. (2023). A rigid link was introduced on top of each column so as to properly account for the eccentricity between the column and the main beam axis. Beam-to-column frictional connections were modelled by means of the *flatSlider-Bearing* element of OpenSees, which allows for the translation in both the main horizontal directions at the attainment of the friction force computed following the Coulomb model. The friction coefficient was evaluated according to the model proposed by Magliulo et al. (2011) for neoprene-concrete friction, as a function of the normal stress acting on the sliding surface. On the other hand, pinned connections (i.e. pure hinges) were introduced to model the beam-to-column dowel connections for the girders. The properties of the roof system, as described in Section 2, justify the adopted assumption of rigid diaphragm for the roof: in particular, the roof elements were explicitly introduced as elastic elements, rigidly connected to the beams. The masonry infills were modelled following the work by Liberatore et al. (2018), based on the equivalent strut approach. With reference to the Italian “double-UNI” infill masonry, with a thickness of 24 cm, the stress and strain values provided by Bosio et al. (2023) were adopted herein. Such values were introduced in OpenSees using the *Concrete01* material. For each field of masonry infill, two *twoNodeLink* elements with the latter material and embedding the infill’s mass were employed to model two diagonal compression-only connecting struts. Given the presence of a ribbon window on all sides of the case study building, an additional lumped plastic hinge was introduced, through a *zeroLength* element, at the intersection between the upper end of the equivalent strut and the column, so as to model the behaviour of the upper part of the column (i.e. the squat or short column), failing in flexure.

The friction rotation dampers were introduced in the retrofitted structural model adopting the following strategy. First, in order to simulate the presence of steel profiles that allow for relative rotations but prevent joint sliding along both the main directions, the beam-to-column frictional connections, modelled by means of *flatSliderBearing* elements in the unretrofitted model, were replaced with pinned connections; it is important to note that rotations are allowed only in the in-plane (transverse) direction and prevented in the out-of-plane direction, as well as about the axis

of the main beams. Then, within the three-hinge scheme described above, the two lateral hinges that are left free to rotate were modelled as pinned connections by means of *zeroLength* elements with sufficiently low rotational stiffness. On the other hand, the central hinge where sliding surfaces are applied was introduced in OpenSees as a *zeroLength* element characterised by a rigid-plastic behaviour only in the rotational degree of freedom of interest; in particular, an elastic-perfectly plastic behaviour was assigned (using the *MultiLinear* material of OpenSees), with “large” initial stiffness and moment capacity equal to 40 kNm: the latter value was selected for this application among the three values of moment of activation considered by Santagati et al. (2012), namely 40, 80 and 120 kNm, related to the properties of the cup springs (see Figure 2b). The three *zeroLength* elements are connected to each other, as well as to the column and the main beam, by rigid links. It is noteworthy that the horizontal rigid link connecting one of the lateral hinges to the column is attached to the upper node of the *zeroLength* element (i.e. the plastic hinge) introduced at the base of the short column adjacent to the ribbon window: with this configuration, the formation of the plastic hinge and the consequent occurrence of the “squat column” effect is somehow hampered, though not prevented.

Coming to the second retrofitting solution, firstly the *twoNodeLink* elements that model masonry infills in the central bay of the perimeter portal frames along the longitudinal direction were removed. Then, the junction was modelled with one central node plus four additional lateral nodes along the directions of the upper and lower portions of the braces; four *zeroLength* elements with very low rotational stiffness (i.e. pure hinges) were then introduced between the deriving four couples of nodes. The lower portions of the braces were modelled as elastic elements having the properties of HEA200 profiles with S275 steel, with one end node attached to the correspondent node of the junction, and the second end node attached to the base node of the column (i.e. beneath the base plastic hinge). On the other hand, the entire upper portions of the braces were modelled with two *twoNodeLink* elements, representing the dissipative sacrificial elements, with one end node attached to the correspondent node of the junction, and the second end node attached to a *zeroLength* element (a pure hinge), itself connected to the lower node of the rigid link introduced on top of each column. A *BoucWen* hysteretic material in OpenSees was calibrated against experimental results related to a single sacrificial element of class 60, constituted of 60×4 mm S355 steel lamellas. To model the presence of four sacrificial elements arranged according to the scheme in Figure 2c, four identical calibrated *BoucWen* materials were created, each couple was combined in parallel (using the *Parallel* material of OpenSees) and then the two derived parallel materials were combined in series (through the *Series* material of OpenSees), obtaining a material with an axial force capacity of nearly 30 kN; subsequently, the *MinMax* command of OpenSees was employed in order to simulate the failure of the system when the demand displacement falls below or above certain minimum and maximum threshold values, fixed at -0.06 m and 0.06 m herein, based on the experimental behaviour. The resulting material was finally assigned to each *twoNodeLink* element, only along its axial direction, whilst a rigid elastic behaviour was applied in the other directions. The numerical model featuring both the adopted retrofitting solutions is characterised by an increased global stiffness, reflected in a reduction of the fundamental period from 1.45 s to 0.45 s; this is mainly caused by the presence of the friction rotation dampers and the pinned connections, which lead the model to exhibit a different static scheme with respect to the unretrofitted case.

4 ANALYSES AND RESULTS

This Section presents the results of the pushover analyses carried out along both the main directions, on both the unretrofitted and retrofitted models (see Figure 3). Given the regularity in plan of the building, the latter may be considered to behave independently along the two directions: therefore, the two adopted retrofitting solutions play a role only along the direction in which they are applied, namely the transverse direction for the rotation dampers and the longitudinal direction for the diagonal braces. However, the pinned connections representing steel profiles introduced along the transverse direction do provide a stiffening effect also along the longitudinal direction.

Since the employed dissipation devices can dissipate the ingoing seismic energy only in dynamic conditions, with static analyses it is possible to only capture the increase in lateral stiffness, strength and ductility due to the installation of the devices, not their dissipation capabilities.

From Figure 3a, it is readily gathered that the unretrofitted structure (curve in blue) has a quite low capacity along the transverse direction, owing to the occurrence of the “squat column” effect: a plastic hinge, indicated by a change of slope in the pushover curve, is formed in the short columns adjacent to ribbon windows, only at the four corner columns that enclose infills. In the retrofitted structure, the “squat column” effect does still occur, although for a much higher base shear value (curve in red). However, thanks to the presence of a total of 20 rotation dampers that can withstand a moment capacity of 40 kNm, as well as steel profiles preventing joint sliding, the building exhibits a significant (nearly fourfold) increase in lateral stiffness and strength.

Coming to the longitudinal direction, Figure 3b shows that the unretrofitted model (curve in blue) has a base shear limited to a value of around 400 kN, due to the attainment of the friction force in the frictional beam-to-column connections: in the latter condition, the pushover curve becomes flat, indicating that the beam freely slides until loss of support. On the other hand, the retrofitted building exhibits an increased lateral stiffness and a much larger resistance (curve in red), as expected. It was observed that the latter increase in lateral resistance is mainly due to the presence, in the ten portal frames along the transverse direction, of pinned connections preventing rotations about the axis of the main beams (see Section 3): the relevant role of the diagonal steel braces embedding the Resilio devices will be much better highlighted by undertaking dynamic analyses on the investigated case study building, which will be the object of future work. It is finally interesting to note that in the retrofitted model, given that the masonry infills do not collapse and the lower (main) parts of the columns do not yield, the “squat column” effect occurs again, with the formation of a plastic hinge (indicated by a change of slope in the pushover curve) in the short columns adjacent to ribbon windows.

Figure 3. Results of the nonlinear static analyses for both models, along a) the transverse (x) direction, and b) the longitudinal (y) direction, with close-up on the blue curve for the unretrofitted model.

5 ENVIRONMENTAL IMPACT ASSESSMENT OF THE ADOPTED DEVICES

LCT is a holistic approach for the evaluation of environmental, social, and economic impacts of products through each of their life cycle stages, where there is the potential to reduce resources consumption and improve operational performance (Passoni et al. 2022). In this Section, preliminary LCT-based evaluations are carried out to qualitatively assess the sustainability of the considered devices, accounting for the life cycle impacts of the retrofit components themselves.

The main stages that are typically considered throughout a given product’s life cycle are: (i) the production phase, including raw materials extraction, transportation, and manufacturing; (ii) the construction phase, including transportation and installation; (iii) the use phase, including use, maintenance, repair, refurbishment, replacement, energy and water use; and (iv) the end-of-life phase, including demolition, transportation, processing and disposal of waste

materials. An additional stage is represented by the so-called beyond-life stage, which considers possible reuse, recycle and recovery of salvaged materials.

Specific LCT performance targets can thus be assigned to each of the above life cycle phases, with a view to minimise all the potential related impacts. The LCT qualitative targets evaluated herein, based on those discussed in much more detail in Passoni et al. (2022), are the following:

- in the production phase, the choice of eco-efficient materials (e.g. recycled/reused materials or renewable biomaterials) for retrofitting could be useful to avoid/minimise the impacts of extraction and manufacturing, and preferring local materials could limit transportation distances and fossil fuel consumption to reach production plants;
- in the construction phase, easy assemblage and/or prefabrication of the retrofit components could reduce duration of works, costs, emissions of air pollutants, and disturbance to buildings' occupants, whereas the use of components of reduced size could limit the impacts of transportation to the construction site (while also optimising the use of materials);
- in the use phase, the adopted materials and techniques should allow for easy reparability, durability, maintenance, adaptability and flexibility to future needs (e.g. dry techniques), while also ensuring the suitable level of indoor comfort and safety against seismic hazard;
- in the end-of-life phase, retrofitting solutions conceived for easy deconstruction/demountability, recyclability and/or reusability of materials and/or retrofit components should be preferred.

Figure 4 summarises, through a LCT indicator (LCTI), the potentials of environmental impact reduction at each life cycle phase of the considered dissipation devices, the latter being compared to traditional retrofitting techniques for precast structures, e.g. concrete or steel jacketing of structural members. The green leaf and warning symbol indicate an expected better and worse performance, respectively, given the provided description, whilst a white box indicates no significant improvement (or similar performance) with respect to traditional interventions. The A3 module only was assigned a warning symbol in this qualitative assessment (given the relevant impact of structural steel manufacturing, as discussed in Gervasio & Dimova 2018), whilst three of the four white boxes are related to not applicable phases. It can be thus concluded that the retrofitting solutions discussed herein for precast industrial buildings are expected to be environment-friendly at most of the applicable life cycle phases, while also guaranteeing a high level of seismic protection to the building itself, thus reducing operational building's impacts due to potential seismic damage repair activities, as shown in Section 4.

	LIFE CYCLE PHASE	LCTI	DESCRIPTION
PRODUCTION	A1 Raw material supply	🌿	Recycled/reused materials, material optimization
	A2 Transport	🌿	Local materials, material optimization
	A3 Manufacturing	⚠️	Impactful production of steel components
CONSTRUCTION	A4 Transport	🌿	Reduced size of components
	A5 Construction/Installation	🌿	Prefabrication, reduced emissions of air pollutants, dry technique
USE	B1 Use	☐	Non-toxic materials, as in traditional interventions
	B2 Maintenance	🌿	Durable materials, dry technique
	B3 Repair	🌿	Durable materials, dry technique, low seismic damage
	B4 Refurbishment	☐	Not applicable
	B5 Replacement	🌿	Durable materials, dry technique, low seismic damage
	B6 Operational energy use	☐	Not applicable
	B7 Operational water use	☐	Not applicable
END OF LIFE	C1 Deconstruction/demolition	🌿	Easy disassembly, reduced size of components, dry technique

6 CONCLUSIONS

It is known that the seismic response of reinforced concrete precast industrial buildings can be generally improved by imposing the dissipation of an appropriate amount of energy. Given that the benefit of dissipation devices to the life cycle seismic performance of precast structures has not been fully explored, this paper investigated the effectiveness of energy dissipation devices in improving the seismic response of precast buildings, while also qualitatively assessing their potentials of life cycle environmental impact reduction. Seismic retrofitting with two dissipation devices was considered herein, namely a friction rotation damper and a bracing system with dissipative sacrificial elements. Two three-dimensional numerical models of a case study building representative of the Italian building stock in the '70s, with and without the retrofit, were created in OpenSees and subjected to pushover analyses in both the main directions. Although with static analyses it is possible to only capture the increase in lateral stiffness and strength due to the installation of the devices, not their dissipation capabilities, the obtained pushover results provided reassurance on the efficiency of the proposed retrofitting solutions in improving the seismic performance of existing and new precast industrial buildings. Lastly, it was concluded that such retrofitting solutions are expected to be environment-friendly at most of their life cycle phases, owing to the use of recycled/recyclable, local and durable materials, the reduced size of components, the dry installation and disassembly processes, as well as the high level of seismic protection.

ABSTRACT: The use of lightweight and/or recycled aggregates for concrete elements in industrial applications for Civil and Industrial Engineering is strongly increased in recent years. Starting from classical use of pumice and other lightweight aggregates, the industry production of expanded clay and perlite offers interesting mix design that can optimize structural and energy performances of cladded panels. The authors illustrate recent experiences of research projects on the recycling of stone aggregates from demolition of r.c. structures in which mechanical properties are compared with natural aggregates. Several mix designs based on expanded perlite are also investigated in terms of mechanical and thermal performances optimizing both aspects: they are especially dedicated to full unit masonry walls and to create insulating-reinforcing panels to be coupled with masonry walls. Finally, is referred an experimental investigation with a concrete mix design of recycled aggregates, coming from collapsed buildings in central Italian area hit by earthquake 2016.

1 INTRODUCTION

This work presents the first result of an experimental campaign on the use of recycled aggregates in cladding panels. Cladding panels appears, in the context of precast concrete constructions, one of the most challenging elements for the application of recycled concrete. This because of the significant volume of material involved (on average 1/3 of the concrete of the whole concrete structure) and of the function of this elements (structural and thermal performances). Generally, from 70% to 80% of the volume of concrete is made up of natural aggregates.

It is estimated that 40% of the total energy and 50% of the total natural resources are used in construction activities. Nowadays, the construction sector is producing a significant amount of demolition waste and such waste constitutes the largest volume of all waste (Cheng et al., 2015). Construction and demolished wastes account for 25% to 30% of the whole waste that is being produced in Europe. The central part of Italy is prone to earthquake and has severely affected by earthquakes in the past 20 years (Rovida et al., 2016, Hofer et al., 2016). Post-disaster waste is an area of main concern and the debris can be recycled and used in the construction of new structures (Andreini et al, 2014) (Faleschini et al., 2017). Here the recycled waste obtained from the 2016 Earthquake in Italy will be employed for recycled concrete in the precast construction industry.

From this, the strategic relevance to use recycled aggregates in precast panels. In this work a mix design of concrete with fully recycled aggregates is proposed and studied aiming to compare the structural and thermal performances with respect to standard plain concrete currently used in production chain of Manini Prefabbricati.

2 STATE OF THE ART

At the State of the Art the innovative use of concrete, using special aggregates or additive to obtain best structural and thermal performance and to have more sustainable production chain is a very significant challenge. The walls constitute the total weight of the structure, hence reducing the weight of the walls results in the reduced size of the foundation. The lightweight concrete panels also make it easy to move and mount these components in an easier way (Cavaleri et al., 2003). Precast concrete structures, with heavy self-weight, should be optimized for construction because they inevitably require heavier equipment, which makes transportation more challenging and necessitates the use of stronger bearing and support elements, especially considering the seismic action, and this could increase the overall cost of the project (Yardim et al., 2013).

Adopting lightweight concrete (LWC) reduces dead weight (Sajedi and Shafigh, 2012). Moreover, concrete with light-weight particles can have less thermal conductivity improving the energetic performance of the building. Typically, several Lightweight Aggregates (LWA) materials, including expanded glass (EG) aggregates, expanded clay (EC), pumice aggregate and plastic bottles, can be used to produce LWC. However, with these materials, the strength of the concrete generally decreases, so the application of these materials has its own limitations in terms of the mechanical response of the concrete (Adhikary et al., 2020). Several attempts are made to make LWC using some natural and artificial lightweight materials including shale, pumice, expanded clay, glass, etc., (Divya Bhavana et al., 2017, Kurpinska and Kuřak, 2019, Singh, 2016).

The use of the steel fibres and the LWC based on the fly ash aggregates were investigated and it was found that these fly ash lightweight aggregates can produce some concrete with a compressive strength of 40 MPa (Longarini et al., 2014). The addition of the steel fibers in the lightweight aggregate concrete will increase the compressive strength and the tensile strength of the LWC (Güneyisi et al., 2015). (Mboya et al., 2019) investigated the effects of the scoria and pumice on the performance response of the concrete. They found that natural scoria and pumice binders can be substituted up to 10% without compromising the mechanical properties including permeability, modulus of rupture and the compressive strength of the concrete .

It is found that by using volcanic pumice, a concrete that is 30 to 40% lighter than typical concrete and has good insulation and structural strength properties can be produced (Campione et al., 2001, Hossain, 1999). Khankhaje, et al. used oil palm kernel shell (OPKS) as a partial replacement of the coarse aggregate in concrete mixes and concluded that OPKS amount had adverse effects on the mechanical properties of the concrete. The shape of the OPKS particles was round that disturbing the micro arrangements of the concrete resulting in inferior mechanical properties including the strength of the concrete (Khankhaje et al., 2016). This is just an example of construction materials based on bio natural aggregates. (Sassu et al., 2016) used the bio natural aggregate i.e., hemp shives and cork granules in concrete and recommended such material for non-load bearing structural components or combined with other structural elements. The experimental study evaluated the effects of these materials on the flexural and compressive response of concrete and found that the cork granules showed better mechanical performance. Such materials are recommended to use in insulating wall panels.

University of Cagliari has been starting work about production, performance and durability of recycled aggregates and recycled aggregate concretes since 2009. The most recent research project, “Materials for Sustainable Building and Infrastructure - Recycled Aggregates” (MEISAR), funded by Regione Sardegna, has aimed at developing an eco-sustainable chain of concrete constructions by enhancing recycled aggregates (Pani, L. et al., 2019, Pani, L. et al., 2021). The study featured several applications, including the substitution of recycled aggregates (instead of natural aggregates) in reinforced concrete. Seven different concrete mixtures were casted: one mix control made with only natural aggregates, and six mix made with recycled coarse aggregates from the demolition and crushing of the concrete structures (beams and foundation blocks) of the Sant’Elia Stadium in Cagliari. The samples are differentiated by the origin of the recycled aggregates and by the different percentages of replacement of the recycled coarse aggregate (introduced in place of natural aggregate). A production of compounds made with 30%, 50% and 80% recycled coarse aggregates instead of natural ones, was provided. In this case, no substantial differences in compressive and in splitting tensile strengths between the different

mixtures have been observed. In fact, in some cases the recycled concrete samples showed slightly higher strengths with respect to the natural mix control samples (Pani, L. et al., 2020).

Additional tests were also carried out on blocks with recycled aggregates obtaining quite similar results and slightly lower compressive strength at 70% replacement rate and an almost unchanged strength for lower replacement rates. Further tests performed on structural elements such as plinths and columns at life (or at a smaller scale) showed similarly encouraging results. (Pani, L. et al., 2022).

The history of structural concrete highlights a non-negligible problem: the significance of mixing process (segregation of aggregates) and effectiveness of the casting that can produce a variable mechanical behaviour of concrete and so in the structural response. (Puppio et al., 2017, Puppio et al., 2019) investigated the impact of the material variability on global and local seismic response of the structure. (Crespi et al., 2022, Puppio et al., 2017) also proposed a simplified method to consider the material irregularity while performing the seismic assessment. The mechanical properties of the concrete i.e., effective compressive strength greatly affects the response of the structural elements in case of seismic activity. Three material strengths were considered during the study to check the global response and seismic performance (De Stefano et al., 2020).

The use of recycled aggregate has become an alternative material to the natural aggregate in construction industry worldwide. It will directly control the accumulation of the waste along with saving the natural resources (Noguchi et al., 2015, Quattrone et al., 2014, Fauzi et al., 2021). (Attri et al., 2021) used the recycled aggregates to prepare concrete paver blocks and found that the 45 % of the coarse aggregate and 40% fine aggregate can be replaced without compromising the strength of the structural elements (Ruslan et al., 2021) replaced the natural aggregates with recycled aggregates in the precast wall panels mix. The researcher found that by replacing the 50 % natural aggregate can enhance the effectiveness of the wall panels by 179.5% compared with the wall panels prepared with the natural aggregates only. Moreover, using the wall panels with 50 % recycled aggregate can have 203.26 kN higher ultimate load capacity compared with the wall panels with 0 % and 100 % natural aggregate samples.

As discussed, lightweight or recycled aggregates represent an interesting application in the building of cladding panels. Recycled aggregates from Assisi'2016 earthquake is a 0km-resource for the Manini's production in Bastia Umbra, but it also has a high symbolic value for what the Assisi Earthquake represented for Umbria and for Italy. For all the explained reason the strategic role of this experimental campaign.

3 METHOD

The standard production of precast prototypes is based on a proprietary concrete mix that optimizes the available natural resources and the mixture processing. The mix design *B* (mdB) is used by Manini for the construction of ordinary structural member, and it represents the base mix for the integration of the recycled aggregates (mix design *A* - mdA). The only difference between mdB and mdA is in the coarse aggregates: natural in the first case and recycled in the second case.

The mix designs are both based on the same concrete quantity and water to concrete ratio and an experimental structural and thermal characterization has been achieved according to the following European Standards:

- Shape, dimensions and other requirements for specimens and moulds: UNI EN 12390-1 (Table 1).

Table 1. Specimens.

Tests	Dimensions [mm]			n.
Compression - mdA	150	150	150	5
Tension - mdA	150	150	150	5
Elastic modulus - mdA	cylinders $\phi=150$			3
Thermal conductivity - mdA	100	100	50	10
Thermal conductivity - mdB	100	100	50	10

- Making and curing specimens for strength tests: UNI EN 12390-2.
- Uniaxial compression tests: UNI EN 12390-3 (5 specimens).
- Indirect tension tests: UNI EN 12390-6 (5 specimens).
- Secant modulus of elasticity in compression: UNI EN 12390-13 (3 specimens).
- Thermal conductivity: UNI EN 12664 (10 specimens for each mix design) (Table 1).

4 EXPERIMENTAL CAMPAIGN

4.1 Test set up

Uniaxial compression tests and tensile splitting tests are carried out by applying an increasing force until the specimen's failure. The uniaxial compression tests are carried out, according with UNI EN 12390-3, applying a quasi-static force throughout rigid steel plates. Tensile strength is determined according to the recommendations of UNI EN 12390-6, through the application on the cubic specimen of a linearly distributed load on a narrow region along its length. In this case failure is obtained due to orthogonal tensile stress generated in the diametral plane. The modulus of elasticity is measured under compression on cylindrical specimens, according to UNI EN 12390-13 (Method B). The test is based on three stress cycles. Load application starting from a non-zero-base stress to the upper stress; every loading condition is maintained for a period not exceeding 20 seconds, following which the strain is recorded by means of a couple of electrical strain gauges 50mm length glued on each of two diametral opposite measurement lines. The stabilized secant modulus of elasticity $E_{C,S}$ is defined as:

$$E_{C,S} = \frac{\Delta\sigma}{\Delta\varepsilon_S} = \frac{\sigma_a^m - \sigma_b^m}{\varepsilon_{a,3} - \varepsilon_{b,2}} \quad (1)$$

where:

$\Delta\sigma$ Difference between measured upper and lower compression stress.

$\Delta\varepsilon_S$ Difference between average strain at upper stress on loading cycle 3 and at lower stress on loading cycle 2.

The test machines used for the experimental campaign above are illustrated in Figures 1 and 2.

Figure 1. Testing machine for compression tests on cubical specimens (a); testing machine for splitting tensile tests on cubical specimens and for modulus of elasticity in compression on cylinder specimens (b).

Thermal conductivity tests are performed by means a heat flow meter measuring device, model Taurus TCA300, at three different mean specimen temperature: 10 °C; 20 °C; 30 °C. The thermal flow is generated by a temperature gradient (ΔT) of 20 K between the heating and the cooling plates. The thermal flow Q propagating in the unit time on the surface of section A in the thickness direction, is connected to the conductive properties of the material and to the other measured quantities by the:

$$\dot{Q} = \frac{\lambda \cdot A \cdot \Delta T}{s} \quad (2)$$

Thermal conductivity λ is calculated from Equation 2, known the thermal flow Q . The device Taurus TCA300 is in Figure 2 while the scheme for the thermal conductivity test is showed in Figure 3.

Figure 2. Thermal conductivity measuring device, model Taurus TCA 300.

Figure 3. Inside view of the heat flux measuring device and scheme for the thermal conductivity test at the temperature of 10°C.

4.2 Tests

Tests are performed at the Material Testing Laboratory and at the Technical Physics Laboratory of the Department of Civil, Environmental Engineering and Architecture (DICAAR) of the University of Cagliari.

Both mechanical and thermal stress are carried out after a 28-day curing period. The specimens are classified by means of progressive numbers, NP:xx as Figure 4 shows. Dimensions, weight, and density are resumed in Table 2. In the case of specimens for thermal tests, the specimens with recycled aggregates are labelled by the letter *A* while the plain concrete by Manini is identified by the letter *B*. The labels of the specimens are showed in Figure 3.

Figure 4. Labels of the specimens: cubic specimens for uniaxial compression and indirect tension tests (a); cylindrical specimens for the elastic modulus (b); two samples of specimens for thermal tests (c).

Mechanical tests carried out by Manini Prefabbricati on the original mix design (after 28 days of aging) highlight the following average values:

- Density 2387 kg/m³;
- Cubic compressive strength 48.4 N/mm²;

Figure 4 shows some pictures of the tests already performed.

Figure 5. Mechanical tests: uniaxial compression test (a); splitting tensile test (b); determination of secant modulus of elasticity in compression and uniaxial compression test (c).

The specimens tested for thermal conductivity were previously milled to regularize their faces from any surface roughness. The thermal conductivity test has been carried out according to the following procedure: the specimen is equipped by a sheep wool side heat guard to generate a one-dimensional heat flow through the transverse direction of s width and then placed within the heat flow meter measuring device between the heating and the cooling plate. Each individual established temperature range value is maintained for 180 minutes, while the average parameters are acquired and updated every 3 minutes; each test takes approximately 9 hours.

4.3 Results

Main geometry of the specimens for mechanical testing is summarized in Table 2. Data obtained from tests are:

- Density 2239 kg/m^3 ;
- Cubic compressive strength 47.0 N/mm^2 ;
- Splitting tensile strength 3.0 N/mm^2 ;
- secant modulus of elasticity gives the values of 32.7 GPa .

Main results of the thermal conductivity tests are summarized in Figure 6. The average thermal conductivity is:

- $0,493 \pm 0,04 \text{ W/mK}$ for the concrete with recycled aggregates (mdA).
- $0,502 \pm 0,05 \text{ W/mK}$ for plain concrete (mdB).

Table 2. Main data of the specimens with recycled aggregates.

P.N.	Dimensions			Density
	[mm]			D [kg/m^3]
938	149	150	149	2270.2
939	152	150	151	2175.6
943	148	149	149	2233.9
950	148		300	2276.7
940	150	150	150	2269.6
941	151	149	149	2240.2
942	151	150	149	2254.9

5 CONCLUSIONS

The thermal conductivity of the specimens obtained by recycled concrete does not change significantly. The compression strength of recycled concrete specimens seems to be satisfactory for structural uses (mean value of 47 MPa) showing the (97% of the strength of the original mix design). The density of the specimens is 2239 kg/m^3 (94% of the density of the original

Figure 6. Determination of thermal conductivity for specimens with recycled aggregates (mdA), and with plain concrete by Manini (mdB).

mix design). The experimental campaign should be enforced to ensure statistical significance of the results, anyway the first data are encouraging. In this perspective, the use of recycled aggregates on concrete structures can ensure the following advantages:

1. Recycled aggregates obtained by demolition of damaged buildings from seismic prone areas reduces the environmental and economic impact of the reconstruction phases.
2. Satisfactory compression strength permits the structural use for panels or other precast elements.
3. The use of recycled aggregates on precast elements reduced the critical issue of ensuring quality control, respect to onsite casting elements: the uncertainty of recycled elements can be better managed in precast element layout respect to onsite works.

Further tests at the scale of material should be arranged to best investigate the above performances as well as the material compatibility with tradition reinforcing bars. Moreover, tests at the element scale (panels, beams, columns) can better assess the feasibility of the described idea.

ACKNOWLEDGEMENT

The Authors would like to sincerely thank the Material Testing Laboratories of Manini Prefabbricati in Bastia Umbria (which also manufactured the samples) and the and the Laboratories of DICAAR of University of Cagliari for their availability to perform the test campaign in a short time with effective cooperation.

ABSTRACT: The growing demand of sustainable precast structures for multi-storey constructions is often driven by the optimisation of cross-sections and reinforcement volumes of the structural elements. The present paper describes a real building recently designed and assembled with the installation of crescent-moon hysteretic dampers in the beam-column joints, recently proposed and patented. The joint continuity allows for an optimisation of the lateral load resisting system, reducing the size of the columns with respect to the classical precast frame structural arrangement with hinged joints, whilst protecting columns and beams from the large actions deriving from the classical moment-resisting cast-in-situ or partially precast technological solutions. After the complete detailed design of the case study building employing the 3 solutions described above, the precast dissipative one being designed with dynamic non-linear analysis, the results of an environmental impact analysis are compared and discussed, confirming a reduced environmental impact for the dissipative solution, with respect to both precast with hinged beam-column joints and moment-resisting cast-in-situ alternatives.

1 INTRODUCTION

The demand of precast structures for the construction of multi-storey buildings is growing, mainly due to the advantages offered by pre-stressing technology, speed of assemblage, robust performance, quality checks, etc. The most economical and typical beam-to-column joints in such buildings are hinged, which however makes the structure not always compatible with the requirements of drift limitation and reasonable column cross-sections. This issue becomes critical in zones of medium/high seismicity. Moreover, the adoption of wall panel or coupled wall/frame structures often results not compatible with architectural requirements. In typical cast-in-situ concrete frames, the stiffness and resistance of the spatial frame structure relies on moment-resisting beam-to-column joints. Such a solution is accompanied by large bending moments insisting on the joints, both in static and seismic load combinations. Indeed, combining this with the capacity design principle of strong column/weak beam for ductile seismic design, the dimensions of the elements also typically become large.

Emulative precast structures with wet-completed full moment-resisting joints typically become too complex if spans larger than the usual for cast-in-situ structures are employed. Recently, dry-assembled precast frame structures with hinged joints adaptable to clamped after dead loads are transferred was proposed by Dal Lago et al. (2018) thanks to the late activation of mechanical couplers, thus optimising the bending moment insisting on the joints.

This paper presents an alternative solution consisting in equipping the beam-to-column joints with crescent-moon steel hysteretic dissipative devices with elastic-plastic behaviour, allowing to control the degree of rotational stiffness of the joints, whilst thresholding the moments after yielding of the devices is attained. Such devices are conceived as structural seismic fuses, to be replaced after possible heavy use after strong earthquakes. This detail was recently proposed and patented by Manini Prefabbricati S.p.A. with deposit No. 102019000025459.

The efficacy of this joint is shown through a real case study building located in an Italian university campus, designed following dynamic non-linear analysis. An axonometric view and a picture of the case-study building made by 3 floors for a total height of 15 m and a total built surface near 3.000 m², are shown in Figure 1. The optimisation of the cross-sections of structural elements attained thanks to the proposed joint is also accompanied by enhanced environmental sustainability, typically mined for reinforced concrete structures by the components of reinforcing/insert steel and cement.

The main strategies currently tackled to reduce the environmental impact of structures can be essentially framed in two. The first strategy, object of wide research activities in the last decades, consists in partially or totally replacing the most impacting components with green alternative ones, such as sulfoaluminate cement instead of Portland (Coppola et al. 2018), or composite material rebars instead of steel (Dal Lago et al. 2017). Such replacements, on the basis of the current knowledge, are generally accompanied with a reduction of the structural performance and/or cost competitiveness of the structure. The second strategy, less extensively tackled in literature, consists in reducing the consumption of material volume, following the adoption of sophisticated technologies (e.g. pre-stressing and highly-technological moulds for precast structures) associated with a process of structural optimisation.

Recent research (Bonamente et al. 2014, Lamperti Tornaghi et al. 2018, Abey & Anand 2019, Wang et al. 2020, Baldoigrani et al. 2022, Dal Lago et al. 2022b, Nagireddi et al. 2022) demonstrated that precast structures, although employing more performing and impacting materials with respect to traditional cast-in-situ concrete structures, allow for a strong reduction of total volume of material employed for the construction, which results prevailing in the sustainability balance, and much more efficient than replacing cement or steel with green alternative materials (Baldoigrani et al. 2022, Dal Lago et al. 2022b). Such a balance tends to even more pend towards precast structures if analysing the sustainability in the framework of a Life-Cycle Analysis (LCA – Rodrigues et al. 2018), where additional factors contribute, including higher durability due to the adoption of high-quality concrete, absence of cracks in service due to pre-stressing, demountability, enhanced resilience, etc. Counter-balancing effect include the consumptions of precast production plants, and the transportation of the elements.

With the aim to quantify the advantages of the proposed dissipative solution in terms of environmental sustainability, the same structure was designed according to the following solutions:

1. precast frame with beam-to-column joints equipped with dampers;
2. precast frame with hinged beam-to-column joints;
3. cast-in-situ frame with moment-resisting beam-to-column joints.

Figure 1. Structure at study: (a) axonometric view with main structural elements and geometry; (b) picture of the building near completion.

The present paper tackles the sustainability analysis with reference to the prime material consumption only, leaving to further publications currently ongoing extensions of the research in terms of wider LCA.

2 DESIGN OF THE STRUCTURAL FRAMES

2.1 Precast frame with beam-to-column joints equipped with dampers

Due to the highly non-linear and dissipative behaviour of the hysteretic crescent-moon dampers, and to the difficult framing of such original system in the classical seismic force-based design with response spectrum analysis, non-linear dynamic analysis was employed to check the previously proportioned structural members. The Finite Element Method (FEM) numerical model employed to this aim, shown in Figure 2, is made with linear beam elements for all frame members, since all non-linearities are expected to be concentrated in the joints. In particular, the column base was equipped with non-linear spring elements to which moment-rotation bi-linear diagrams were attributed (Figure 3), and the beam-to-column joints were modelled with a saddle combination of rigid links and non-linear spring elements provided with Bouc-Wen hysteretic behaviour calibrated on the basis of experimental qualification tests (Figure 4). The floor decks, made with adjacent pre-stressed elements making a double-flat hollow cross-section (similarly to the one described in Dal Lago et al. 2022a) after steel sheets are placed in the open central core of the elements and in-situ concrete topping is cast, were modelled with semi-rigid diaphragm, simulating the effective in-plane floor stiffness. Cladding panels were introduced as masses without stiffness, thanks to the adoption of special sliding connectors decoupling their motion from that of the frame (Toniolo & Dal Lago 2017).

Design resistance was considered for concrete class C45/55, rebars mild steel grade B450C, and 7w-strand pre-stressing steel fp1860.

The design process followed these steps: (a) evaluation of the structural performance under first-phase static loads without dissipative devices; (b) activation of the dissipative devices; (c) application of second-phase static loads; (d) non-linear dynamic time history analysis for different hazard scenarios encompassing limit states of Operability (OLS), Damage (DLS), Life-Safety (LSLS), and Collapse (CLS).

Figure 2. Deformed shape and activated plastic hinges (green dots) at the end of one of the dynamic NL analyses at collapse limit state.

For each limit state, the response under 7 triplettes (X,Y,Z) of artificially-generated EC8-spectrum-compatible accelerograms was evaluated (EN 1998-3:2005). The stationary part of the accelerograms was assumed to be 10s long. The pseudo-stationary time window of the accelerograms followed a 2s time interval with accelerations of increasing amplitude starting from zero, and was set to be followed by a tail of 13 s with accelerations of decreasing amplitude. Thus, the whole duration of a single ground motion is 25 s. The mean of the maximum values evaluated through the 7 triplettes for each limit state was considered for the checks.

Figure 3. Column elements: (a) picture during assemblage; (b) bi-linear moment-rotation curves attributed to the base spring.

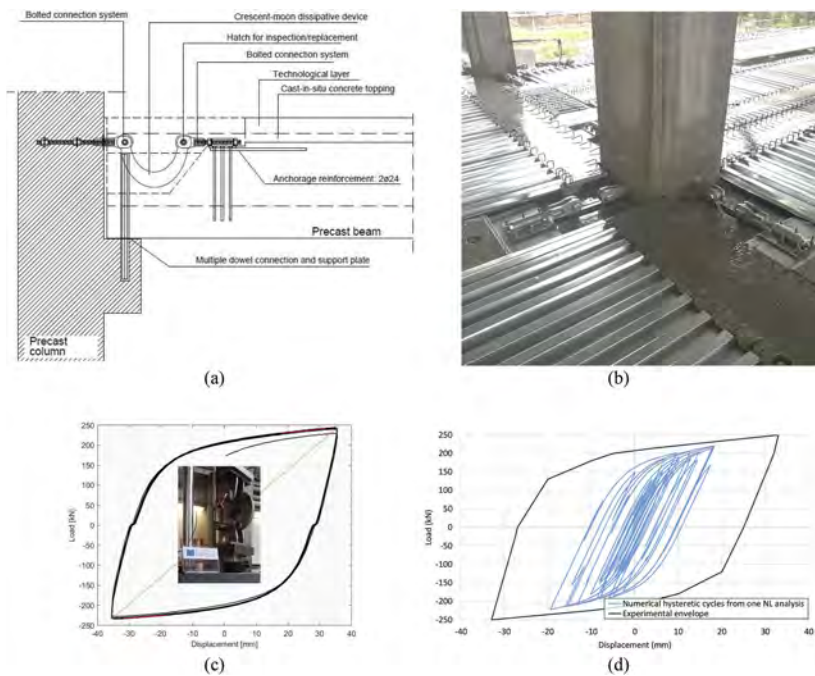

Figure 4. Dissipative beam-column joint with hidden crescent-moon hysteretic dampers: (a) schematic description; (b) picture from real building; (c) experimental hysteresis of crescent-moon damper; (d) non-linear force-displacement diagram attributed to spring elements in the model.

Figure 2b shows the deformed shape of the frame structure and the activation of the column base plastic hinges after an analysis related to CLS. The exemplificative hysteretic response of a crescent-moon device under the same analysis is shown in Figure 4d.

On the basis of the analysis results, it was observed that the column base attained a minimum capacity over demand ratio (C/D) of 2.39, evaluated based on the ultimate rotation capacity. Critical for the design resulted indeed the interstorey drift of the last storey in OLS, equal to 0.331% versus a maximum value which, according to the class of use III of the building, was equal to 0.333%.

In order to synthetically estimate the hysteretic contribution of the dissipaters, acting in parallel with the contribution of the column bases, further analyses were run assuming a perfect elastic response of the dissipative devices considering an equivalent secant stiffness associated to the mean local device displacement obtained in the first series of NLTHA for each LS.

The comparison with the first series of analyses allows to compute the reduction factor β associated with the displacement reduction due to the hysteresis of the dissipative crescent-moon devices. The spectral demand reduction due to the added dissipation effect may be expressed in terms of added equivalent viscous damping (e.g. within the capacity spectrum method – Dal Lago & Molina 2018) or by increasing the force reduction (behaviour) factor q (e.g. within the force-based design method – EN 1998-3:2005), within the assumption of equivalent anelastic displacement for flexible structures. Considering Eq. (1):

$$q_D = \beta \times q_{lim} \quad (1)$$

where

q_{lim} is the limit behaviour factor in the context of modal analysis with response spectrum, assumed equal to 2.0 for the considered case study;

q_D is the behaviour factor to be attributed to the presence of the dissipative devices.

The value of the behaviour factor of the dissipative structure q_D is calculated as 2.56 following a β coefficient of 1.28 for LSLS, and as 2.78 following a β coefficient of 1.39 for CLS, respectively. It is highlighted that the above values are directly referred to the case study analysis, based on a conservative limit behaviour factor assumed in the design phase, where even at CLS the full deformation capacity of frame structure and dissipative devices was far to be attained, and hence these values could potentially be extended.

With the aim to validate the estimation carried out with the above method, further linear dynamic analyses with response spectrum were carried out utilising a CLS spectrum and adopting the behaviour factor q_D determined as above. The total base shear obtained in the two main directions (3009 kN and 2934 kN in X and Y directions, respectively) resulted close to the peak values of the NLTHA (3121 kN and 3321 kN in X and Y directions, respectively).

The contribution of the proposed dissipative joint led to large benefits in the proportioning of the column cross-section, which was set to be square with 80 cm of side, assumed constant along the height. The bending moment transmitted by the joint, thresholded by yielding of the hysteretic dissipative devices, attained a maximum contained in 189 kNm at LSLS. Hence, the partial continuity of beams and columns did not lead to additional reinforcement for all frame members in seismic load combinations with respect to that calculated for gravity load combinations, and the typical details requested to ensure ductility around beam ends for typical cast-in-situ members resulted indeed not necessary.

The foundations were made with footing RC plates supported on 4 piles of diameter 0.60 m and length of 20 m.

2.2 Precast frame with hinged beam-to-column joints

Within this solution, representative of the typical precast solution for this typology of buildings, the design was carried out assuming columns cantilevering from their clamped base and perfectly hinged beam-column joints. Since this structural typology is framed in the current normative, a traditional design process was carried out following modal analysis with response spectrum on the basis of a force reduction (behaviour) factor q equal to 2.0.

Figure 5 shows the envelope of bending moments on the columns in direction X. A maximum base bending moment per single column of 2879 kNm was evaluated at LSLS. This led to the adoption of square cross-sections of side 1.10 m.

The foundations were evaluated to be similar to the previous case.

Figure 5. Precast frame with hinged beam-to-column joints: envelope of bending moments on columns.

2.3 Cast-in-situ frame with moment-resisting beam-to-column joints

The design of the cast-in-situ frame was carried out assuming a traditional “shear-type” frame structure, on the basis of modal analysis with response spectrum assuming a force reduction (behaviour) coefficient equal to 2.76. Figure 6 shows the resulting bending moment envelopes on both column and beam elements.

Maximum bending moments equal to 3317 kNm and 3634 kNm were evaluated at LSLS for individual column and beam members, respectively. This led the cross-sections to be designed as square with side of 1.20 m and T-shaped with height of 1.40 m and thickness of 0.60 m for column and beam members, respectively.

Foundations were designed to be very similar to the previous cases, except for a slight increase of pile length to 22.5 m.

Figure 6. Cast-in-situ frame with moment resisting beam-to-column joints: envelope of bending moments on (a) columns; (b) beams.

3 ENVIRONMENTAL IMPACT ANALYSIS

The environmental impact of the structural organism of the case study building designed according to the 3 different technological solutions described above is analysed with reference to the contribution of primary structural materials. In order to quantify environmental impact, reference was made to the ponderation indexes of Global Warming Potential (GWP) relative to the different materials employed, and to their single components. Such indexes have been taken from Environmental Product Declarations (EPD) spontaneously issued on a voluntary basis by Italian producers (where present) following the procedure described in EN:15804:2012+A2:2019 and UNI EN ISO 14025:2010. Global indexes (sum of items A+B+C) were considered, since mostly relevant to quantify the impact deriving from the use of primary structural materials.

The GWP values utilised in the computation are reported in Table 1 expressed in terms of equivalent carbon dioxide (eqCO₂) referred either to unity of mass or volume of material. The summation of the concrete components for different concrete grades were evaluated based on actual mix designs employed by Manini Prefabbricati S.p.A.

On the basis of the complete quantity list of materials employed for each designed solution, the balance of environmental sustainability was evaluated, as synthetically reported in Figure 7. It is noted that the impact of about 600 tons of eqCO₂ related to the foundations is practically equivalent for all solutions, with slight increase in the case of the cast-in-situ frame due to the longer piles employed.

Differently, it can be observed a relevant difference related to the superstructure, ranging in between 835 and 1100 tons of eqCO₂. Referred to the built surface of the building, these values range in between 278 and 367 kgeqCO₂/m². The results shown in Table 2 demonstrate that the more sustainable solution is the proposed one with dissipative beam-to-column joints, where the additional impact related to the physical steel devices and anchorage systems is more than balanced by the reduction of concrete and reinforcement in columns with respect to the traditional precast solution with hinged beam-to-column joints (+12% of eqCO₂), and in both columns and beams with respect to the cast-in-situ frame (+31% of eqCO₂).

Table 1. GWP weighted indexes for the different materials and composites employed.

MATERIAL	DENSITY (ton/m ³)	GWP (kg Co ₂ eq/ton)	GWP (kg Co ₂ eq/m ³)
CEMENT CEM I 52,5 R	3.15	910	2866.5

Emission of eqCO ₂ for the superstructure [10 ⁵ kg]		
sol.1 precast dissipative	8.35	-
sol.2 precast traditional	9.34	(+11.9%)
sol.3 cast-in-situ	10.96	(+31.3%)

4 CONCLUSIONS

The non-linear time history analysis of the real case study building provided with semi-rigid beam-column joints with dissipative crescent-moon hysteretic dissipaters installed showed a seismic behaviour characterised by a good balance between the requisites of (a) limitation of drift, and (b) member strength according to the different limit states analysed. This behaviour is associated with the hysteretic added damping provided to the structural assembly by the dissipaters through flexural stiffening, energy dissipation, and thresholding of the actions on the frame structures after attainment of yielding. The alternative design of the same building

with either ordinary precast with hinged beam-column joints or traditional cast-in-situ with clamped joints, led to larger cross-sections and reinforcement volume. The environmental impact analysis of the 3 alternative solutions classified the precast dissipative one as the more sustainable due to the following reasons: with respect to the ordinary precast, the contribution of the metallic dampers and their anchoring systems more than balanced the larger column cross-section of the ordinary precast solution, with 12% equivalent CO₂ emission less for the super-structure; with respect to the traditional cast-in-situ solution, the contribution of the use of more performing though impacting materials much more than balanced the larger volumes of concrete and reinforcement of the less optimised traditional cast-in-situ solution, with 31% equivalent CO₂ emission less for the superstructure. It is currently under development an extension of the environmental impact analysis herein presented which includes factors other than the consumption of prime materials, following a more general LCA approach.

ABSTRACT: Coal extraction generates coal mining wastes (CMW) that lead to additional environmental burdens. This study assesses the potential environmental benefits of using these CMW as secondary materials in the production of precast concrete cladding panels. Potential environmental impacts are measured using life cycle assessment (LCA). The system under assessment is a multi-functional system, including both the management of CMW and the production of concrete panels. Company data have been used to perform the assessment. Preliminary results show, for the business-as-usual (BAU) scenario, that the main impacts associated with wastes management are due to diesel consumption and direct emissions to groundwater. For the concrete panel production, the impacts are primarily induced by cement production. This BAU scenario will be compared to a recycling scenario where CMW are incorporated into concrete production. Based on this comparative LCA, recommendations as to the use of CMW into construction products will be provided.

1 INTRODUCTION

In order to meet the Paris agreement, governments and stakeholders of the civil society call for phasing down or transitioning away from coal as an energy source. Yet, according to the International Energy Agency in 2021, coal fired power generation reached 769 TWh, a level higher than before resulting in record levels in terms of CO₂ emissions as well (IEA, 2022a). Thermal coal accounted for 78% of the total coal consumption, which reached almost 8 billion tons in 2022 (IEA, 2022b).

This coal is extracted from various mine sites leading to important volumes of coal mining wastes (CMW). Some authors report that for each ton of coal produced, 0.4 to 0.5 ton of waste is generated (Pactwa et al., 2020). In Poland, for example, around 35 million tons of CMW is generated every year (Warcholik et al., 2014). Wastes associated with hard coal extraction and processing can lead to environmental and social issues when stored. Storage of

coal mining waste can lead to soil and/or water pollution depending on the sulfur or heavy metals content of the wastes. Fire hazard is also a risk associated with the storage of CMW that can lead to atmospheric pollution (Pactwa et al., 2020).

Apart from environmental and social concerns, handling and storing mining wastes also has an economic cost for mining companies and the society. Direct costs for mining companies include for example the workforce, equipment and fuel needed to handle the wastes from the production plant to the waste storage area. Given the social and environmental issues, monetized externalities can also be associated with CMW costs. As per Wang et al. (2020), the costs associated with the waste storage in terms of land function loss and use sum up to 3.57 USD/t.

To limit the amount of CMW stored and the associated economic, social and environmental costs, solutions to use them as secondary raw materials are being explored. One of their use as secondary raw materials could be as geomaterials in the construction sector (Vo et al. 2022). The research project MINRESCUE is exploring this pathway by assessing the inclusion of CMW as raw materials for the production of precast concrete panels to be used in industrial buildings. In order to assess the potential environmental benefits associated with this solution, a comparative life cycle assessment (LCA) has been performed considering, on the one hand, a *business-as-usual* (BAU) scenario representing how CMW are today handled and, on the other hand, a *recycling* scenario where these CMW are used as secondary materials for concrete panel productions. In this work, an emphasis is put firstly on the modelling of the BAU scenario and its resulting environmental impacts (Section 2) and secondly on the key parameters to focus on in the modelling of the *recycling* scenario (Section 3).

2 LIFE CYCLE ASSESSMENT OF THE BUSINESS-AS-USUAL SCENARIO

Over the last decades, LCA has gained interest as a decision-support tool to assess the environmental performance of products and services to support company or policy decision-making. LCA considers a so-called life cycle perspective, covering all life cycle stages in a cradle-to-grave perspective (i.e. from raw materials extraction to end-of-life disposal). It accounts for both direct and indirect impacts, in a multi-criteria framework that includes various impact categories (e.g. carbon footprint, toxicity-related issues, resource consumption). In particular, LCA enables i) the identification of environmental hotspots; ii) the comparison of different scenarios to identify the best performing scenario and potential burden-shifts from one impact category/life cycle stage to another. The implementation of LCA is framed by ISO standards (14040 and 14044) and follows four different steps, as hereafter detailed (see Sections 2.2, 2.3 and 2.4).

2.1 Definition of the BAU scenario

This study focuses on two different industrial activities in their current functioning:

- i) Coal mining, with focusing on waste management operations and considering currently operating mine sites in Poland in particular, the BAU scenario considers current on-site operations, where part of the mining waste is reused (e.g. in roadbed) while the remaining part is disposed of through on-site stockpiling.
- ii) Precast concrete elements production, focusing on pre-cast concrete panels currently produced by the NTS company in Italy. The BAU scenario in particular entails considering the current concrete mix (i.e. including cement, sand, gravel, filler, additive and water) as used by the NTS company.

2.2 Goal and scope

The product system here under study can be considered a multifunctional system providing two different functions: i) the management of solid wastes resulting from coal processing; ii) the production of pre-cast concrete panels.

It is decided to capture both functions in the functional unit of this study, rather than privileging one over the other. In this context, the functional unit is defined as:

The management of 1 ton of solid wastes resulting from coal processing, and the production of 1 pre-cast concrete panel.

The system boundaries include: i) the production and consumption of reagents, ancillary materials, energy and water; ii) the direct emissions to the environment generated by the operations under study; iii) the transport of raw materials; and iv) the production of the infrastructure and equipment.

Moreover, these boundaries cover all unit operations associated with:

- The processing of wastes prior to their final disposal or reuse;
- The final disposal or reuse of the wastes;
- The production of concrete;
- The casting of concrete into pre-cast panels.

The upstream coal mining and processing operations have been here excluded from the boundaries.

Figure 1. System boundaries for the BAU scenario.

The environmental impacts have been calculated using the Simapro LCA software, considering the European life cycle impact assessment method (EF method 3.0; Fazio et al. 2018). This method, established by the Joint Research Centre (JRC) of the European Commission (EC), encompasses 16 impact categories recommended by the JRC in the context of the European Product and Organization Environmental Footprint (PEF/OEF), which aims to establish a common method to measure and communicate the life cycle environmental performance of products and organizations in the EU.

2.3 Life Cycle Inventory (LCI)

The foreground system (i.e. all processes for which specific data have been collected and used in the modelling) has been modelled primarily using data provided by companies. These data were completed with generic data (e.g. from the ecoinvent LCI database) and assumptions in cases of data gaps.

The compiled inventory encompasses data about:

- Energy consumption, including the electricity necessary to concrete mixing and casting into pre-cast panel as well as the diesel necessary to fuel the machinery operating the coal waste storage area. Data about electricity consumption were obtained from calculations based on technical specifications related to the used equipment. As for data on fuel consumption, the latter were drawn from the ecoinvent LCI database, in the absence of data specific to the machinery implemented on-site.
- Raw materials and chemicals consumption, in particular for manufacturing concrete, which requires various constituents such as concrete, sand, gravel and other additives. This concrete mix is based on the actual mix as used by the NTS company for manufacturing of its precast concrete products.
- Water consumption, for concrete production.
- Transport, especially regarding the supply of concrete constituents to the NTS manufacturing plant.

- Infrastructure, considering the concrete mixing plant as a whole. In particular, it is assumed that the plant is solely made of “low-alloyed” steel, with deriving the total weight of the plant from technical specifications.
- Equipment, necessary to handling waste and operating the coal waste storage area (e.g. conveyor belt, stackers, bulldozers). In the absence of specific information regarding each piece of equipment implemented on-site, generic data drawn from the ecoinvent LCI database were used as a proxy for modelling some pieces of equipment.
- Land occupation, considering the superficial land occupation and transformation induced by the coal waste storage area.
- Emissions to the environment, in particular considering potential long-term emissions of substances to groundwater, resulting from the waste storage area. The quantification of these emissions is based on a geochemical model, as currently implemented in the widely used LCI database ecoinvent. The model is adapted by using specific on-site data obtained from one mine site. These data encompass the coal tailings composition, the characteristics of the waste storage area and specific data regarding the climatic conditions.

2.4 *Life cycle impact assessment and interpretation*

In a life cycle perspective, the management of 1 ton of solid wastes resulting from coal processing, and the production of 1 pre-cast concrete panel potentially induces a total of 607 kg CO₂-eq (climate change), 0.197 CTUh (human toxicity, non-cancer effects) and 0.192 kg P-eq (eutrophication, freshwater). The complete list of impacts, considering the 16 impact categories from the EF method 3.0, is detailed in Table 1.

Overall, the production of concrete panels stands for the main contributor to the environmental impacts, as it dominates the impacts for 15 impact categories out of 16 (with contributions ranging from 84.1% to 100%; Table 1). Coal wastes management only stands out in the case of freshwater eutrophication, as it accounts for 69.4% of the impacts.

With reference to the production of concrete panels, the use of cement stands out as the main environmental hotspot as it accounts for the largest share of impacts with respect to all impact categories (more than 60% of the impacts for all categories excepting water use, for which cement represents about 40% of the impacts – Figure 2). Aside from cement, the use of electricity (in particular for the casting process) appears to have a relatively modest contribution to the impacts, regarding the “ozone depletion”, “ionizing radiation”, “land use”, “water use” and “resource use, fossils” impact categories (more than 10% of the impacts).

The impacts induced by coal waste management are essentially driven by the machinery operating on-site as well as direct emissions to environment (Figure 3). In particular, the diesel consumed by the machinery is responsible for the most significant part of the impacts with respect to 11 impact categories out of 16, with bulldozers and ZGOT stackers respectively accounting for about 60% and 40% of these impacts. Four impact categories, namely toxicity-related categories and freshwater eutrophication, direct emissions of substances to groundwater account for the largest share of the impacts (more than 90% of the impacts). Finally, impacts relative to “land use” are due to the land occupation and transformation as induced by the coal waste storage area.

3 MODELLING THE RECYCLING SCENARIO

3.1 *Definition of the product system*

Regarding the recycling scenario, the boundaries of the system cover the same functional reality as the BAU scenario (cf. Section 2.2). In comparison with the BAU scenario, this recycling scenario includes unit operations associated with the preparation of waste and its transport to the concrete panel production site.

Table 1. Resulting impacts for the functional unit under assessment and contribution of each part of the functional unit considering 16 impact categories from the EF method 3.0.

Impact category	Unit	Concrete panel production	Waste management
Climate change	kg CO2 eq	6.04E+02 99.47%	3.21E+00 0.53%
Ozone depletion	kg CFC11 eq	2.40E-05 97.26%	6.75E-07 2.74%
Ionising radiation	kBq U-235 eq	1.97E+01 99.01%	1.98E-01 0.99%
Photochemical ozone formation	kg NMVOC eq	1.43E+00 98.94%	1.53E-02 1.06%
Particulate matter	disease inc.	1.36E-05 98.79%	1.67E-07 1.21%
Human toxicity, non-cancer	CTUh	1.97E-01 100.00%	1.81E-07 0.00%
Human toxicity, cancer	CTUh	2.07E-07 91.24%	1.99E-08 8.76%
Acidification	mol H+ eq	1.86E+00 99.26%	1.38E-02 0.74%
Eutrophication, freshwater	kg P eq	8.13E-02 30.61%	1.84E-01 69.39%
Eutrophication, marine	kg N eq	5.42E-01 99.10%	4.95E-03 0.90%
Eutrophication, terrestrial	mol N eq	5.89E+00 99.09%	5.41E-02 0.91%
Ecotoxicity, freshwater	CTUe	8.24E+03 84.10%	1.56E+03 15.90%
Land use	Pt	2.67E+03 88.54%	3.46E+02 11.46%
Water use	m3 depriv.	8.40E+01 99.91%	7.44E-02 0.09%
Resource use, fossils	MJ	3.38E+03 98.73%	4.35E+01 1.27%
Resource use, minerals and metals	kg Sb eq	3.02E-03 99.95%	1.49E-06 0.05%

Figure 2. Contributions to the environmental impacts of concrete panel production, considering 16 impact categories from the EF method 3.0.

As the project is still on-going, the actual mix-design to produce a concrete panel with the incorporation of CMW is not yet fully finalized. Once crushed at the right granulometry, the CMW would be mixed with natural aggregates in a proportion yet to be quantified (cf.

Figure 3. Contributions to the environmental impacts of coal wastes management, considering 16 impact categories from the EF method 3.0.

Section 3.2) to obtain the concrete to be used in the panel production. CMW would replace both a fraction of fine and coarse natural aggregates in the concrete production.

Figure 4. System boundaries for the recycling scenario.

3.2 Accounting for recycled products durability

In the framework of the MINRESCUE project a comprehensive investigation has been performed by the last author's group on the performance of concrete containing recycled CMWGs from different sources, with preliminary results reported in detail in (del Galdo et al., 2022). The investigation has considered compressive and flexural strength, fracture energy and shrinkage and has confirmed, as from some exemplary results on compressive strength shown in Figure 5, that, while the mechanical properties suffer some reduction because of the replacement of natural aggregates with CMWGs, when the latter are employed to replace fine aggregates or a combination of fine and coarse aggregates, an overall set of mechanical performance can be obtained which still complies with those required by several engineering applications.

This, on the one hand, paves the way for a valorization of CMWGs in the construction industry and on the other hand, strengthens the motivation for this study, corroborating first of all the possibility that the intended precast structural elements can be produced with concrete incorporating CMWGs as a recycled aggregate in partial replacement of natural ones and furthermore that the expected service life could be comparable, though quantitative assessment of durability performance for the aforesaid concretes is still on-going.

3.3 Differences expected against the business as usual scenario

Given the results presented in Section 2.4 and the product system presented in Section 3.1, some results of the comparison of the recycling scenario against the BAU scenario could be

Figure 5. Evolution of cube compressive strength for mixes incorporating different types and replacement percentages of CMWGs.

anticipated. Firstly, for the BAU system, the concrete panel production is the higher contributor for a large majority of the impact categories and in this concrete panel production, cement production is the highest contributor. In the envisioned recycling scenario, CMW will replace sand and gravel but not cement; those impacts won't so not be diminished by the inclusion of CMW in the concrete mix.

However, recycling of CMW will have a direct effect on different impact categories. It will firstly diminish all impacts associated with on-site CMW management and in particular, the impact for which the direct emissions are the greatest contributor (Figure 3). Among these impacts, the category "Eutrophication freshwater" will be the most affected by the consideration of the recycling scenario (cf. Table 1).

If the recycling scenario will directly lower some of the impact categories, its specific unit process will however have other impacts. It is the case of the waste processing unit process that consists of an energy consumption to obtain the desired wastes granulometry. It is also the case of the waste transport from the mining site to the plant producing the concrete panels. The type of energy used and the transportation distance could be parameters that have strong influence on the resulting comparison. Given this fact, sensitive and scenario assessments will be performed on those parameters in order to find the tipping point where the recycling scenario may no longer be more environmentally friendly than the BAU scenario.

4 CONCLUSIONS

In order to conclude this study, work still needs to be done. In particular, durability performance of the concrete panel containing CMW should be quantified, the mix between primary and secondary materials for the recycling scenario should be defined and finally, the LCA of the recycling scenario should be performed to compare the results against the ones obtained for the BAU scenario.

Results of the comparison between the BAU and the recycling scenario would lead to recommendations for both the mine operators and the concrete panel producers on the development of an optimized scenario regarding different parameters such as the distance between the mine site and the producer of the concrete panels. This optimized scenario should minimize the environmental impacts associated with the inclusion of CMW into concrete production moving from linear to circular economy.

ACKNOWLEDGEMENTS

This project has received funding from the Research Fund for Coal and Steel under Grant Agreement No. 899518 MINRESCUE “From Mining Waste to Valuable Resource: New Concepts for a Circular Economy”. GIG research activities were co-funded also by Polish Ministry of Education and Science.

The value of accelerating the infrastructure planning process

A.B. Elvarsson, B.T. Adey & O. Roman

Chair of Infrastructure Management, ETH Zürich, Switzerland

ABSTRACT: Infrastructure planners strive to ensure that infrastructure meets the needs of stakeholders in the short, medium and long-term. This is a challenging task because there is considerable uncertainty associated with future stakeholder needs, and the infrastructure built to meet these needs has a life-time spanning decades, if not centuries. Additionally, the planning of either new infrastructure or the modification of existing infrastructure usually requires years, or even decades, meaning that stakeholder needs often change during the planning process itself.

Planners' responsiveness, i.e., how quickly planners can adjust to changing stakeholder needs, depends on the planning processes in which the planners are embedded. The relationship between improving responsiveness (in this paper the time taken to increase rail capacity to acceptable levels) and its impact on stakeholder needs (in this paper the unmet demands for acceptable travel comfort) is investigated using three fictive but realistic infrastructure planning process alternatives. The planning decision enabling the capacity increase is the expansion of the tracks from single to double track between Uster and Aathal in the Canton of Zürich, Switzerland. The responsiveness and travel comfort are modelled given an uncertain population growth.

The results show that the responsiveness of infrastructure planners (1) plays a role in the ability to meet stakeholder needs, (2) can be measured and (3) provides argument that in developing planning processes, considering planner responsiveness could be worthwhile. The specific example shows that being more responsive outperforms acting early in approximately 90% of the scenarios modelled.

1 INTRODUCTION

Infrastructure systems are planned to meet stakeholder needs. In the planning of these systems, the ability to meet stakeholder needs is quantified through the service provided to stakeholders, i.e. the benefits of providing a service (e.g. travelling by rail for commute) or costs due to a lack in service (e.g. not having a seat during commute). The planning phase starts with the decision to engage in planning, often triggered by the identification of stakeholder needs. The time that it takes for planning decisions to take effect to meet stakeholder needs is to be explored so that it can be considered more explicitly in decision-making in practice. The planner's ability to provide stakeholder needs more quickly is named 'responsiveness'; a more responsive planner will be able to improve the service level to an adequate state more quickly than a less responsive planner.

In this paper, the authors propose to assess the impact of responsiveness of planners when making a decision and compare it to making a decision earlier. For an example of the rail service in the corridor Dübendorf-Hinwil at times of a growing population, an intervention of a double-track between Uster and Aathal is to be realized in the face of an uncertain population growth. Two fictitious approaches to reduce the negative impacts of stakeholder needs are compared: (1) a more responsive planner with a shorter time from decision to realisation is compared to (2) acting earlier, by lowering the threshold at which an intervention is made. We compare the net benefits experienced by users in overcrowded trains and the effect that a time reduction in the infrastructure planning process has on the net benefits.

In this paper we find that responsiveness (1) plays a role in the ability to meet stakeholder needs, (2) can be measured and (3) provides argument that in developing planning processes, considering planner responsiveness could be worthwhile.

2 BACKGROUND

In the field of long-term planning decision-support, there have been advances made with a focus on including uncertainty in an explicit manner in decision-support models. This field has been referred to as adaptive planning and has two major branches.

On the one side, there has been a focus of efforts on methods to ensure robust-decision making. Central to this paradigm is the idea of finding a dynamically robust plan (Kwakkel et al., 2015). Numerous approaches and tools have been developed to adapt dynamically to one or more uncertain factors to develop pathways to ensure that an end-goal objective (e.g., climate neutrality by 2050) can be reached (Haasnoot et al., 2012, 2013; Herman et al., 2015; Ranger et al., 2013).

On the other side, there has been a focus of efforts on the flexible design of engineering structures. The implementation of the flexibility in engineering structures was elaborated in the work of de Neufville and Scholtes (Neufville & Scholtes, 2011). To better evaluate engineering variants under uncertainty, these flexibilities are treated as an option to intervene so that the methods of real options can be applied to systems under uncertainty. The triggering of these options enables the adaptive planning of systems (Cardin et al., 2013; Elvarsson et al., 2021; Martani et al., 2022; Neufville & Scholtes, 2011; Neufville & Smet, 2019). The implementation of the flexibility is one way to reduce the downside of uncertainty, or maximise the impact of potential upsides, generally leading to lower total costs or higher net benefits (Neufville & Scholtes, 2011).

What unites both branches is that engineers ensure adaptiveness of planning processes, so that engineers remain flexible to adjust and ensure that they can meet the needs that do arise over time and are not stuck in a suboptimal system state.

However, as the value framework concerning planning decisions not only consists of construction costs, but increasingly considers environmental, social and economical costs beyond the decision-maker, we find that our processes become increasingly time-sensitive. This is particularly true for transportation infrastructure, which are socially important with demand increasing as population grows and long duration planning processes persist (Saxe et al., 2021). In Switzerland, the expansion step until 2035 in rail infrastructure was legally decided on approximately 17 years in advance (Schweizerische Bundesrat, 2018a), whereas the expansion step for road was decided on approximately 5 years in advance until 2023 (Schweizerische Bundesrat, 2018b). While the time since decision to plan until realization can have many benefits through increased stakeholder interaction & coordination and the possibility of improved solutions through detailed studies, the added value of being more responsive and its impact on decision-making is less explored.

3 METHODS

First, a scenario is generated providing the expected growth in population and therefore in demand. The sample of population growth scenarios is generated via the Latin hypercube sampling method (McKay et al., 1979). The population grows annually.

Given a current state of the network, the scenario's demand is compared to the supply every year of a simulation. The service provided to users is then quantified and summed over the entire planning period. The service provided depends on the compared three alternatives of the planning process. The alternatives differ in the time taken to operationalize the planned change after an intervention is carried out.

If the supply is sufficient, no action is taken. If the supply is insufficient, based on the trigger condition defined by each planning process, a capacity expansion is proposed once the trigger condition is met. If the decision to intervene is made, the improved capacity is only realized a specified amount of time after the decision is made.

The comparison of the different alternatives is performed with the methods of Engineering options analysis, a decision-support tool for decision-making under uncertainty (Neufville et al., 2019; Neufville & Scholtes, 2011). Since the population growth is uncertain, 500 Monte Carlo simulations are run to explore the impact of differing futures on the outcome of the net benefits.

4 CASE STUDY

The rail service in the corridor between Dübendorf and Hinwil connects people of the Glattal region to Zürich, the main regional hub. The corridor is connected to Zurich through the north via Wallisellen to Zürich-Oerlikon and through the East via tunnel through Stettbach to Zürich-Stadelhofen. The railway corridor is illustrated in Figure 1.

Figure 1. An illustration of the railway network between Dübendorf and Hinwil. Not to scale.

The provision of rail service to meet the demand is currently hampered by rail network bottlenecks, i.e., the limited supply of infrastructure, specifically due to a single-track segment between Uster and Aathal. To enable a capacity development, an infrastructure planner will respond by having a second track built on the 4 km segment. The impact of differing planning alternatives focusing on the time taken to operationalize planned changes was modelled, and the three alternatives consisted of either triggering the intervention (1) when peak hour demand levels reach 3.5 times the seat capacity or, (2) acting earlier, at 3.1 times the seat capacity. Alternatively, the planner could be (3) more responsive by reducing the planning time from 20 years to 8 years. The first planning process alternative we name “Reference”, the second “Early action” and the third “More responsive”.

The built infrastructure defines the capacity of the service, quantified in the number of seats provided per peak hour. The railway service on the infrastructure is provided by the Federal Railway Company (SBB) and the Zurich Transportation Agency (ZVV). The capacity is defined by the service planned before and after the track expansion (Schweizerische Bundesrat, 2018a; Stadtrat Uster, 2019).

While it is already decided that in the network development step until 2035, the Federal government funds the construction of a second track on the 4 km long stretch between Uster and Aathal for 180 million CHF (Schweizerische Bundesrat, 2018a, 2018c). It is assumed that this decision has not yet been made. Instead, a fictitious triggering condition is determined, which, when met, triggers the decision to develop the single track between Uster and Aathal to a double track. Subsequently after the track can be operationalized, capacity gains are made.

For the modelling of the system, the corridor is split into three parts (from now on sub-regions), based on the locations of the single track bottlenecks, from Dübendorf to and including Uster (DÜB-UST) from Uster to Wetzikon (UST-WTZ) and then to Hinwil (WTZ-HIN). The population of the different sub-regions and the portion of the population assumed to travel via rail in a peak hour to Zürich are reported in the following Table 1. The share of population travelling in the peak hour reduces as distance from Zürich increases. Consequently, the rail demand is assumed to be the highest between Dübendorf and Uster as the train will carry the passengers from the other sub-regions travelling into Zürich.

The population growth is uncertain. It is expected to grow annually between 0.5% and 2.5%. For each of the 500 scenarios generated, a single value in this range is generated for the average population growth over 40 years from 2021 to 2060. The growth rate is assumed consistent across all sub-regions.

Table 1. Assumptions to evaluate the demand for each sub-region.

Demand	Sub-regions		
	DÜB-UST	UST-WTZ	WTZ-HIN
Population in 2020	86'931	26'113	11'117
Assumed share of population travelling to Zürich in peak hour	14%	12%	8%

In the following Table 2, the supply of rail services is summarized. The number of seats provided from each of the sub-regions to Zürich in an hour, assuming 350 seats per wagon with two wagons per line service. The lines S3, S9, S14 and S15 travel in the corridor every half hour each, where S9 has an end station in Uster and S14 is the only line to travel from Wetzikon to Hinwil (SBB, 2020).

After the double-track between Uster and Aathal will be realized, it will not only increase the capacity of rail timetable slots between Uster and the east of the valley, but also free up space in the Uster train station as the S9 normally blocks one of the tracks and respective platform before heading in the opposite direction since it can be relocated to elsewhere or the service expanded to go further into the corridor (Stadtrat Uster, 2019). Therefore, it is assumed there will be an overall increase in capacity throughout the corridor. Hinwil will still be constrained by the single track segment between Wetzikon and Hinwil (Bundesamt für Verkehr (BAV), 2017; Schweizerische Bundesrat, 2018a).

Table 2. Assumptions to evaluate the supply for each sub-region.

Supply	Sub-regions		
	DÜB-UST	UST-WTZ	WTZ-HIN
Frequency of the service to Zürich in peak hour	8	6	2
Seat capacity in peak hour			
-> before the development	5600	4200	1400
-> after the development	8400	5600	1400

The demand is simulated over time. It grows with the population and the assumed share of the population travelling to Zürich in the peak hour is assumed unchanged. In peak hours, people will not only sit, but also stand. It is assumed that the infrastructure planner will see it necessary to intervene once the peak demand between Dübendorf and Uster is higher or equal to 3.5 times the seat capacity on the rail service. Once the trigger condition has been met, the duration of planning the pre-defined intervention and realizing it is assumed to be 20 years. This is considered the reference alternative.

To improve the service provided to stakeholders over the planning period, the planners generate solutions to better meet stakeholder needs. On the one hand planners can act early and change their triggering condition to 3.1 times the seat capacity to more preventively offset the lead time. Generating simulations with the different trigger conditions leads to the empirical cumulative probability distribution curves for reaching the triggering condition over time as shown in the following Figure 2.

By reducing the triggering condition to 3.1 instead of 3.5, the condition is met between 5-24 years earlier, depending on the scenario. In all scenarios, the triggering condition was met by 2060. In reality, the need to intervene is not determined in such a discrete manner by being triggered at such a particular value, as resources and budget also constrain the creation of intervention programs. However, it is assumed in this paper for modelling purposes.

On the other hand, planning processes could be enable planners to be more responsive. In this example, the time that it takes to modify the system so that it provides an adequate level

Figure 2. The probabilities of meeting triggering condition for two different values, 3.1 and 3.5.

of service is reduced, albeit with an unchanged triggering condition. The ‘reference’ time from decision until realization is set at 20 years. This is similar to the time horizon defined by the Expansion Step Rail 2035 (Schweizerische Bundesrat, 2018a). It is assumed that this can be reduced from 20 years to 8 years to model the impact of being able to meet stakeholder needs more quickly, i.e., planners being more responsive.

The different planning process alternatives that planners would follow to improve the service provision as discussed above are summarized in the following Table 3. The early-action alternative triggers an intervention at a lower threshold, whereas the responsive alternative will take less time to implement the planned change.

Table 3. Assumptions to evaluate the infrastructure supply for each sub-region.

Supply	Alternative		
	Reference	Early-action	Responsive
Time since triggering until realization	20	20	8
Triggering condition	3.5	3.1	3.5

For all passengers who do not have a seat once the train is travelling between Uster and Dübendorf towards Zürich in the morning peak hour a discomfort cost is calculated. We assume that all standing passengers have a value of discomfort of 7 CHF per trip. The value was chosen as it is approximately the opportunity cost of choosing the train as a mode. It corresponds approximately to the fuel cost if the stretch were travelled by the private car at single occupancy. We furthermore assume 3 equal peak hours per day and 250 workdays per year as well as a 2% discount rate. The total discomfort costs are simulated for each of the process alternatives for all scenarios. Dependent on the population growth, the costs will differ.

Figure 3 shows the resulting empirical cumulative distribution functions of the discounted discomfort costs over the forty years. Both the responsive (dashed orange line) and early-action (dotted green line) alternative have consistently lower costs than the reference case.

Figure 3. Discomfort costs over the forty year planning period in million CHF.

Figure 4. Savings per planning variant relative to the reference variant, in million CHF.

The modelled discomfort costs differ per process alternative and by scenario and range from approximately 1700 million CHF to 3000 million CHF over the 40 year planning period.

In Figure 4, the savings per scenario are put in relation to the reference case. The figure shows the results of the difference in costs of the more responsive alternative and the reference case (the blue dashed line) and the difference between the early-action alternative and the reference case (the orange dotted line). By comparing the two lines, one can see the distribution of the scenarios for which it would be beneficial to choose to be more responsive or act earlier. The benefit of the responsive alternative becomes apparent: A planner acting more responsively will yield higher savings (i.e., reduction in discomfort costs) in about 95% of scenarios. Simply put, this is because the more responsive planner acts quickly to a need that is arising as opposed to the planner acting early in case the need will arise. Due to the uncertain population growth, the need will not always arise as quickly as expected. However, in 100% of the scenarios, the early-action planner provides savings over about 43 Million CHF in comparison to the reference case. This is because of the comfort savings by acting earlier. The highest savings yielded by an early-action or a responsive planner in a specific scenario are about 120 Million CHF over the forty year planning period from 2021 to 2060. In about 90% of the scenarios, the responsive alternative will yield more than 60 Million CHF savings compared to the reference case. These results of the distribution of the savings relative to the reference are also summarized in Table 4.

Table 4. Savings per alternative compared to the reference alternative.

Savings in Mio CHF	Savings per alternative compared to reference	
	Early-action	Responsive
Expected value	75.9	98.0
Percentiles		
5th	45.7	34.6
20th	53.2	91.1
80th	97.7	113.7
95th	115.1	117.8

The question remains under what circumstances the early action planner reaps higher benefits than the responsive planner. The early action planner will reap the most benefits when the population growth is slow enough, so that during the 20 years time until the planned changes come into effect, the costs do not outweigh the comparative alternative of acting later, but faster. The responsive planner provides more benefits with increased growth.

Figure 5 compares the savings observed plotted over the differing growth percentages, which is considered the uncertain variable. If over 1% annual population growth is expected, it makes sense to prefer this particular responsive planning process over the modelled early action process.

Figure 5. Savings per planning alternative compared to the population growth rate.

5 DISCUSSION

In this paper the perceived discomfort costs due to an uncertain increasing demand in rail services is modelled. The model is set up in a simplistic manner to illustrate the quantification of the costs linked to the responsiveness of planners. The more responsive alternative outperforms the early-action alternative in most scenarios. Simply put, this happens because a planner acts responsively to a need that is arising as opposed to acting early in case the need will arise. In high growth scenarios, being responsive yields higher comfort cost savings than having acted earlier. This is due to the costs inflicted on the users during the time which the early action planned change is being realized (taking 20 years), which the responsive planner manages to overcome more responsively (in 8 years).

In reality, the planning process cannot be easily shortened. The planning process generally includes stakeholder engagements, budgeting negotiations, land acquisition processes and other constraints requiring more time. Furthermore, given that the shortening of the processes is possible, it is very possible that this expediation will bear some costs that should be considered in the evaluation process.

Having established the potential to focus on responsiveness of planners, the outlook on future research based on this work not only addresses the need for better models for the planning of complex infrastructure systems incorporating the value framework of the relevant stakeholders. The conversion of these attributes into costs and benefits is vital to be able to make an objective appraisal between planning alternatives or competing planning visions.

Based on the above, the next steps include the mapping of planning processes and to what extent they could be adapted to better meet uncertain stakeholder needs. Further research is also required on appraisal tools, how they may consider costs during the planning time and explicitly consider future uncertainty.

6 CONCLUSIONS

A responsive planning process alternative is analyzed for a fictitious, but realistic case study. The results show that more responsive planners are better able to reduce the travel discomfort experienced by users and provide additional savings in comparison to an early-action planner, who triggers interventions at a lower triggering condition. The results illustrate that being more responsive can be of value and that infrastructure planners should be mindful of the time duration of planning processes from the time of decision to plan until the implementation of the planned change.

Furthermore, it is shown that the responsiveness of infrastructure planners (1) plays a role in the ability to meet stakeholder needs, (2) can be measured and (3) provides argument that in developing planning processes, considering planner responsiveness could be worthwhile.

Stakeholder inclusive port development planning for an uncertain future

M. Eskafi

EFLA Consulting Engineers, Reykjavik, Iceland

Faculty of Civil and Environmental Engineering, University of Iceland, Reykjavik, Iceland

ABSTRACT: Ports have always been evolving to satisfy stakeholders' new or changing demands. The long design lifetime of a port system calls for uncertainty considerations in the planning process. A structured framework is presented to deal with opportunities and vulnerabilities derived from uncertain developments. A three-dimensional decision surface is presented to quantify the salience of stakeholders. A problem structuring method and a fuzzy multi-attribute group decision-making method are integrated to define the success of the plan. Salient stakeholders are engaged to identify uncertainties. SWOT analysis is conducted to recognize opportunities and vulnerabilities. Effective actions are planned to seize opportunities and manage vulnerabilities in a projected lifetime. Port authorities and decision makers can strategically implement the actions in the face of uncertainty that emerges in the planning horizons. The results indicate that the uncertainties mainly present opportunities in the short-term horizon, while during the middle-term horizon the port is confronted with vulnerabilities.

1 INTRODUCTION

A port is a complex set of functions, as it has emergent and nonlinear behavior in which multiple interactions between different components are possible. Port sectors are in a state of radical change, and the main challenge in port planning is to deal with uncertainties. Dealing with uncertainties in the planning process increases the success of projects (Taneja 2013). Analytical and quantitative tools, even those that model dynamic decision making, cannot deal with the qualitative nature of uncertainty. Forecast models have uncertainties associated with input data and models (Eskafi et al. 2021a). Scenario planning, as an alternative approach, may not seize opportunities offered by transitions in port planning projects. Scenarios cannot capture trend-break /breakthrough developments. In this vein, Walker, Haasnoot, and Kwakkel (2013) emphasized that a static optimal plan using a single most likely future may fail if another future materializes. Instead of investing efforts to reduce uncertainties, different methods at different time horizons should be applied to coexist with and benefit from uncertainties (Herder et al. 2011), just as the framework in the present study offers. In the context of uncertainty and complexity, policymaking (setting a course of action) to deal with uncertainty in projects works better than relying only on predictions (Lempert and Popper 2005). Furthermore, Adey et al. (2022) stated that management flexibility facilitates dealing with uncertainty in investment decision making.

In this study, a framework is developed based on four components to identify the uncertainties that are manifested during the projected lifetime of the plan and deal with them in the planning process. The components are: 1- stakeholder analysis to a) identify port stakeholders, b) define the success of port planning, c) identify uncertainties around stakeholders' activities and objectives, and d) determine different planning horizons; 2- different methods to systematically address uncertainties; and 3- SWOT analysis to identify opportunities and vulnerabilities derived from uncertainties; 4) effective actions to seize opportunities and manage vulnerabilities and thus deal with uncertainties. Decision makers can strategically implement the actions in the face of uncertainty that emerges in the projected lifetime of the port.

2 BACKGROUND AND METHODS USED

A single-issue focus of dealing with uncertainties, including opportunities and vulnerabilities, is no longer sufficient. To deal with uncertainties against projected, probable, plausible, possible futures, a framework is developed and adapted to port planning as shown in Figure 1.

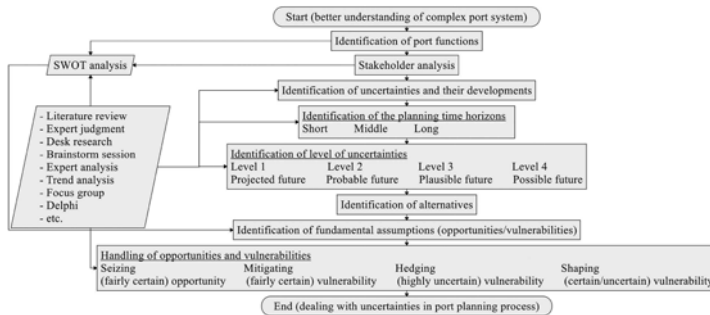

Figure 1. A framework of dealing with uncertainty in the port planning process, (Eskafi et al. 2021b).

2.1 Identification of port functions

The main functions of a port represent the main purposes for which the port is used. Prior to the planning and design of ports, it is necessary to determine their functions (Ligteringen 2017). The functions of a port play important roles in decision making for greenfield and brownfield port development plans. To determine the port functions and port activities, information was obtained through the literature, port visits, and interviews with the Port Authority.

2.2 Stakeholder analysis

A port system involves a variety of stakeholders with a broad spectrum of involvement. Stakeholder analysis is often ad-hoc and relinquishes the spatial and temporal changing attributes of stakeholders. Therefore, a framework is presented to map stakeholders' salience using a fuzzy logic 3-dimensional (3D) decision surface for their effective and timely engagement in the planning process. The framework is depicted in Figure 2.

2.2.1 Identification of stakeholders

Stakeholder identification and their engagement in a project is an important task. Although focus groups, expert interviews, etc., can be used for stakeholder identification, these methods only develop an initial list of stakeholders. A project manager or a group may not have the skill to identify all stakeholders. A snowball technique is a suitable method for stakeholder identification as it benefits from the knowledge of networks. It assures a variety of suggestions from different perspectives to identify stakeholders (Colvin, Witt, and Lacey 2016).

2.2.2 Engagement of stakeholders

Decision making can be enriched by engaging stakeholders. In this study, stakeholders are engaged first by email and phone calls to provide general information about the project. Then face-to-face interviews are conducted to gather information about their objectives. Furthermore, a written survey is developed to aggregate input data for stakeholder salience measurement. A survey has several advantages in comparison to other methods of data gathering from stakeholders. A survey engages stakeholders in a task-oriented manner, encourages stakeholders to express their thought, and gives privacy to stakeholders for independent information sharing.

2.2.3 Differentiation and grouping of stakeholders

In this study, stakeholders are categorized into groups based on similarities in their contributions, interests, and influence. Stakeholders in a group can be viewed with a common area of

interest and power to the port planning. The groups can be unbundled in several sub-groups based on the overarching nature of engagement undertaken and their interrelations together and or to the port planning. To group stakeholders, a literature review on stakeholders' categorization is carried out.

2.2.4 Identification of stakeholders' objectives

Interviews can provide valuable information about stakeholders' objectives. To ensure the validity of data gathering, it is important to consider the education and experience of interviewees. In this study, to identify stakeholders' objectives, interviews are conducted with the widest possible range of stakeholders who are well informed about the interests, and influence of their activities into the planning. To identify objectives of port planning, the Value Focused Thinking (VFT) method is used. The VFT method provides a systematic approach for identification of values (e.g., idea), categorizing these values, converting them to the means objectives (i.e., what stakeholders wish to achieve), recognizing the relationships among objectives, prioritizing the means objectives to achieve the fundamental objective (i.e., the definition of success) (Keeney 1996).

2.2.5 Stakeholder mapping

To ensure in-depth consideration of the power, interest, and salience of stakeholders in decision making, stakeholders are mapped based on fuzzy logic. The Fuzzy Inference System (FIS) is applied to implement fuzzy logic. The FIS relates input (power, interest) and output (salience) variables, to develop the decision surface. Using the fuzzy logic approach, the stakeholders receive a degree of membership instead of a discrete class. A 3D decision surface for stakeholder salience measurement is developed by using the Fuzzy Logic Toolbox in MATLAB.

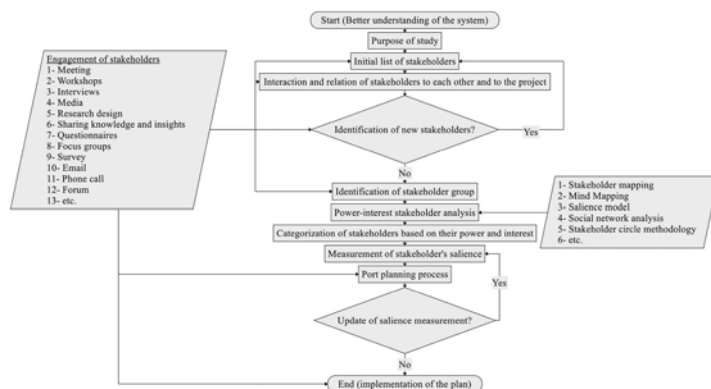

Figure 2. Steps in stakeholder salience analysis and prioritization, (Eskafi et al. 2019).

2.3 Definition of success

To discover the importance of identified means objectives (see subsection 2.2.4) and to properly prioritize them in the plan, separate meetings were held with the representatives of key stakeholders. The selection of the representatives is based on their short-, middle-, and long-term roles in port planning and development. In the meetings, they are asked to prioritize the means objectives.

2.3.1 Fuzzy multi-attribute group decision-making method

To define the maximum level of agreement among the stakeholders' preferences regarding the fundamental objective, the fuzzy multi-attribute group decision-making method is used. The method reveals the highest level of agreement on the means objective among the key stakeholders with a multiplicity of objectives. Therefore, the method facilitates reaching consensus among stakeholders on the success of the plan and may reduce holding meetings with all stakeholders that might be time consuming and conflicting.

2.4 *Identification of uncertainties and their developments*

One of the best ways to deal with uncertainties is to understand the sources, amount, and quality of information available (Uusitalo et al. 2015). Aven (2008) stated that uncertainty identification is a qualitative procedure using expert opinion, literature review, brainstorming sessions, group discussions, and interviews with stakeholders. In this study, to identify uncertainties, separate in-depth face-to-face interviews were conducted with representatives of key stakeholders. Separate interviews allowed each key stakeholder a more comfortable and honest information sharing, a high possibility of participation, and providing valuable input (Vu, Grant, and Menachof 2019).

2.5 *Identification of the planning time horizons*

Describing uncertainty propagation over time provides more complete information about the planning processes (Brier 2005). Nordlund (2012) stated that there is not a generally accepted standard to demarcate short-, middle-, and long-term horizons from the present time to the future. Masini (1993) asserted that time horizons vary and closely depend on the subject under consideration. In this study, a planning time horizon is defined as the farthest time that uncertain developments are addressed. The main drivers of uncertain developments related to the stakeholders' activities and objectives are examined to distinguish a time horizon.

2.6 *Identification of level of uncertainties*

Handling uncertainties based on their level is an appropriate approach. These levels express the severity of uncertainties and range from complete certainty to total ignorance. They are addressed based on the four levels of uncertainties (Walker, Haasnoot, and Kwakkel 2013). Van Dorsser et al. (2018) linked the four levels of uncertainties to different disciplines of the future field. Level 1 uncertainty is addressed by deterministic forecasting. Level 2 uncertainty is handled by probabilistic forecasting. Level 3 uncertainty is considered by (strategic) foresight. Level 4 uncertainty accounts for visualization of any possible future. The levels are recognized by gaining insight from the key stakeholders and a group of multidisciplinary experts.

2.7 *Identification of alternatives and fundamental assumptions*

In the presence of uncertainty, generating alternatives is a successful approach in planning (Walker, Haasnoot, and Kwakkel 2013). In response to the uncertain developments, several alternatives are developed over different time horizons, and consequently, their fundamental assumptions were explored. If a fundamental assumption moves the plan toward its success, it is an opportunity, and if it causes the plan to fail achieving its success it is a vulnerability (Haasnoot et al. 2013). To identify the opportunities and vulnerabilities, a port SWOT analysis was carried out.

2.8 *Handling of opportunities and vulnerabilities*

To handle fundamental assumptions, effective actions are planned to either seize opportunities or manage vulnerabilities. Taneja (2013) distinguished actions to deal with opportunities and vulnerabilities. The actions are mitigating, hedging, shaping, and seizing actions. Mitigating actions are in response to fairly certain vulnerabilities and reduce their potential adverse effects. Hedging actions spread and reduce highly uncertain adverse effects of vulnerabilities. Shaping actions affect certain and uncertain vulnerabilities to change their nature, prevent their development, and direct them toward a preferred plan. Seizing actions take advantage of fairly certain opportunities.

3 RESULTS AND DISCUSSION

3.1 *Study area and the port functions*

This study was carried out for the Ports of Isafjordur Network, which includes the Ports of Isafjordur, Sudureyri, Flateyri, and Thingeyri, in Iceland (Figure 3).

Figure 3. The Ports of Isafjordur Network. The study area is shown on the map of Iceland.

The Port of Isafjordur is the biggest container port in the Westfjords region and the distribution center for the network. The port network is the third busiest port of call for cruise ships in Iceland. By coastal shipping and road transportation, the network is connected to its hinterland.

The main functions of the port network are: 1- Transfer and storage of containerized and non-containerized cargo; 2- Industrial value-added activities, including marine productions; 3- Recreational activities, including servicing expedition and cruise ships, and sailing boats.

3.2 Stakeholder analysis

Using snowball sampling stakeholders were identified (Eskafi et al. 2019). Five port stakeholder groups were defined including: internal stakeholder, external stakeholder, legislation and public policy stakeholder, community stakeholder, and academic stakeholder. Fifty-one face-to-face interviews were conducted resulting in 314 values being elucidated from the interviews. From these values, a set of 8 means objectives were determined, namely: increasing competitiveness, increasing effective and efficient use of land, increasing safety and security, increasing hinterland connectivity, increasing financial performance, better environmental implications, creating flexibility and increasing positive economic and social impacts (Eskafi et al. 2020). To map stakeholders on the 3D surface, a survey was conducted between stakeholders. Figure 4 shows the results of the dynamic stakeholder mapping. The decision surface indicates the internal stakeholder group possesses a high degree of salience and is placed on the flat area of the decision surface. This indicates a stable role by this group in port planning. The acute slope of the decision surface (i.e., fuzzy area) indicates a rapid changing of the degree of membership in the attributes. Placement of a stakeholder group in this area means that small changes in their attributes (i.e., interest, power) lead to a rapid change in their salience. Figure 4 shows that the legislation and public policy, the external, and community stakeholder groups are placed on the steep slope.

3.3 Definition of success

Using the fuzzy multi-attribute group decision-making method, the highest level of agreement among the representatives of key stakeholder groups on the means objectives was ordered as: increasing competitiveness, increasing effective and efficient use of land, increasing safety and security, increasing hinterland connectivity, increasing financial performance, creating flexibility, better environmental implications, increasing positive economic and social impacts. This order is defined as the definition of success (i.e., fundamental objective) (Eskafi et al. 2020).

3.4 Identification of uncertainties and their developments

The outcome of interviews with the key stakeholders and literature review indicates that fishing and aquaculture activities are growing quickly to win markets. Export of farmed and wild,

frozen and fresh, and processed and unprocessed fish are expected to be the most sustainable cargo. Containers will continue to be attractive to transport cargo. Vessel size is increased to utilize economies of scale. Furthermore, expedition and cruise vessel calls are expected to increase. The increase in expedition and cruise vessel calls will grow coastal excursions and tourism activities.

Figure 4. A 3D decision surface for the relationship between power and interests of the stakeholder groups.

3.5 Identification of the planning time horizons

Five years (2020-2025) and 25 years (2025-2050) were considered as the short- and middle-term horizons, respectively. Five years was chosen as the short-term horizon because the Port Authority wants to develop the Port of Isafjordur within the next five years to meet the expected rapid and changing demands of fishing, aquaculture, and cruise activities. Also, this time horizon covers the Icelandic Road and Coastal Administration’s policy from 2020 to 2025 (Icelandic Road and Coastal Administration 2019). Furthermore, this five-year time horizon is in line with the short-term horizon indicated in the literature (e.g., Masini 1993). The ports’ users, including fishing, aquaculture, and transportation companies, are developing their commerce in the port network. A 25-year middle-term horizon would capture their development projects. A 25-year time horizon fulfills the middle-term horizon cited in the literature (e.g., Masini 1993).

3.6 Identification of level of uncertainties

In the short-term horizon, the uncertain developments around marine production can adequately be described and thus have level 1 uncertainty. The materialization of these developments can reasonably be explained by expert judgment. However, in the middle-term horizon, the size and probability of these developments cannot be estimated as they are faced with multiple influencing (political, societal, environmental, and financial) factors. Therefore, they have level 3 uncertainty in the middle-term horizon. At this level of uncertainty, foresight should be used to cover a range of plausible futures. The uncertain developments around the cargo flow and relevant activities can be projected in the short-term horizon. These uncertain developments have level 1 uncertainty. Thus, a reliable forecast provides the future state of the cargo flow. However, in the middle-term horizon, the level of uncertain developments increases as there is less information about the flow. These uncertain developments, therefore, have level 2 uncertainty and a probabilistic forecast can be used. The uncertain developments around expedition and cruise markets have level 2 uncertainty in the short-term horizon due to the COVID pandemic. At this level of uncertainty, the probabilistic forecast can be used. However, this market is expected to grow in the middle-term horizon and have level 1 uncertainty. To provide insight into these uncertain developments, expert judgment and reliable forecasts can be conducted.

3.7 *Identification of alternatives and fundamental assumptions*

To respond to the uncertain developments, different alternatives were generated to meet planning objectives in the short- and middle-term horizons. In the short-term horizon, uncertain developments lead to many opportunities. This is because the port network has a competitive position in the Westfjords region. However, in the middle-term horizon, the port network is confronted with a multiplicity of vulnerabilities. These vulnerabilities are mainly due to a lack of infrastructure and land in the port network for satisfying the increasing number of port users' demands.

3.8 *Handling of opportunities and vulnerabilities*

In the short-term horizon, as the port network has a competitive position, the Port Authority can seize opportunities by attracting cruise expeditions and cruise markets and increasing the storage and flow of cargo and containers, and the number of vessel calls. In the middle-term horizon, in response to the vulnerabilities derived from the volume of container/cargo flow, and the size and number of vessels, shaping and hedging actions can be used. These actions include the improvement of infrastructure in the port network including the small ports. The full list of actions for the port functions is presented by Eskafi (2021).

4 CONCLUSIONS

A structured framework was presented to facilitate the identification of uncertainties that manifest during the projected lifetime of the plan and deal with them in the planning process. The framework was applied to the Ports of Isafjordur Network in Iceland, to demonstrate its potential use in practice. A fuzzy logic 3D decision surface was used to identify the salient stakeholders and effectively and timely engage them in the planning. To reach a consensus among the key stakeholders on a definition of success for the plan, a fuzzy multi-attribute group decision-making method was applied. The highest level of agreement on the objectives among the key stakeholders was identified as prioritizing increasing competitiveness of the port. Uncertain development and their level were determined from the interviews with the key stakeholders. Opportunities such as increase in container and cargo flows, increase in marine traffic (e.g., container and cruise ships), and increase in aquaculture activities, and vulnerabilities such as climate change impacts, and lack of infrastructure for digitalization, automation, utilization of renewable energy were identified. The main results indicated that uncertainties mainly present opportunities in the short-term horizon, while in the middle-term horizon the port network is confronted with multiple vulnerabilities due to lack of infrastructure. To seize opportunities and manage vulnerabilities derived from uncertainties, effective actions were planned. The value of this framework lies in the nonlinearity of dealing with uncertainties in different time horizons. The theoretical contribution of this study is to meaningfully identify uncertainties that manifest during the projected lifetime of the plan and deal with them in the port planning process. Thus, inevitable changes become part of a recognized process and the plan is not forced to be remade repeatedly on an ad hoc basis. The managerial contribution enables decision makers to choose a preferred course of action and strategically implement the plan in the face of uncertainty.

ABSTRACT: Circular economy (CE) is increasingly used to accelerate the transition of infrastructure towards circularity and sustainability. However, a practical and accurate assessment procedure considering the stochasticity of influencing factors for CE implementation in infrastructures has not yet been fully developed. This paper first develops a CE index and models for predicting the CE performance of infrastructure over time based on functional circularity, embodied carbon and embodied energy. Time-dependent reliability theory is then employed to account for the randomness of factors, such as structural degradation rates, embodied impact coefficients, recycling rates and recycling efficiency. The proposed methods are demonstrated through a case study of three concrete structures with design for disassembly (DfD) and different recycled aggregate substitution rates. Results of the case study suggest that the structure with DfD and natural aggregate has a lower probability of unsatisfactory CE performance. The results will guide the future implementation of CE in infrastructures.

1 INTRODUCTION

Infrastructure currently emits 39.5 billion tons of greenhouse gas (GHG) emissions annually, which is about 79% of global emissions (UNOPS 2021). While infrastructure has played a crucial role in meeting the increasing service demands due to population growth and urbanization process worldwide, sustainable and circular development of infrastructures is in great need to overcome the significant environmental burdens. Thus, circular economy (CE) is adopted as a potential solution to reduce GHG emissions and increase the circularity throughout the value chains of infrastructures. CE is a systematic approach that focuses on narrowing, slowing and closing resource loops by implementing various regenerative and restorative strategies to benefit the environment, economy and society (Geissdoerfer et al. 2017). Design for disassembly (DfD) is an important CE strategy to be implemented in infrastructures and it focuses on reversible designs and reusing structural components (Sanchez et al. 2020). However, the successful implementation of CE strategies, e.g. DfD, relies on effective assessment procedures that comprehensively evaluate CE performance from different aspects.

CE performance can be assessed from two aspects, namely circularity and sustainability (Corona et al. 2019). Circularity assessment involves the quantification of the alignment degree of a system with the CE principles, i.e. narrowing, slowing and closing loops (Morsetto 2020). Sustainability assessment relies on life cycle assessment (LCA), in which the environmental impact of a system needs to be determined from various aspects, such as climate change, human health and fossil resource depletion (Potrč et al. 2021). There are many studies conducted on categorizing existing CE indicators according to their applicability to different assessment objectives and criteria, such as Kravchenko et al. (2019) and Saidani et al. (2019). In comparison, probabilistic CE assessments are relatively rare. Most existing CE indicators only focus on a single aspect, i.e. either circularity or

sustainability, which results in an incomplete evaluation of CE performance (Moraga et al. 2019). Furthermore, these indicators exclude time dimension and ignore the impact of durability on circularity performance (Figge et al. 2018). The uncertainty embedded in the life cycle of infrastructures, e.g. the structural degradation and uncertain environmental impacts of structural components with DfD in complex product, reuse and end-of-life treatment processes, are often ignored and the CE performance may not meet the CE assessment criterion (Lei et al. 2022). A thorough review of literature shows that a comprehensive and probabilistic CE assessment considering time-variant influencing factors for infrastructures has not been fully developed.

Some attempts have been observed to apply reliability theory to LCA, however, the circularity aspect of CE performance was not considered, such as Wei et al. (2016) and Shahtaheri et al. (2019). Lei et al. (2022) developed probabilistic CE assessment methods and an overall CE index to evaluate material circularity and environmental sustainability of building materials. Multiple uncertain variables in different end-of-life scenarios were considered, but the stochasticity of time-variant influencing factors, e.g. the structural degradation affects the long-term CE performance of reusable components, was ignored. It is well acknowledged that the degradation of concrete structures significantly influences the durability and environmental impacts of infrastructure. Considering the long life span of concrete components with DfD, structural degradation will reduce their ability to be reused directly after deconstruction. Therefore, integrating time-dependent reliability theory into CE assessment will further increase the accuracy of probabilistic CE assessment method in predicting long-term CE performance under the impact of time-variant influencing factors.

This work aims to develop CE assessment methods for infrastructures based on time-dependent reliability theory. Different time-variant influencing factors are considered, such as structural degradation rates, embodied impact coefficients, recycling rates and recycling efficiency. The objectives of this work include: 1. Develop a CE index for infrastructure based on time-dependent reliability theory; 2. Develop models for computing circularity and sustainability indexes considering time-variant influencing factors and their stochasticity; 3. Demonstrate the feasibility of developed methods by predicting the long-term CE performance of concrete structures. This work will help practitioners to understand the long-term CE performance of infrastructure, in particular, the time-dependent CE performance of reusable concrete structural components with different recycled aggregate substitution rates. The results of probabilistic CE assessment will guide the future adoption of CE strategies in infrastructure.

2 METHODOLOGY

2.1 Basics of time-dependent reliability methods

In the time-dependent reliability analysis, two critical elements need to be identified: the stochastic process $X(t)$ and the limit state function $G(X,t)$ which changes with time (Li and Yang 2022). In this study, circularity and sustainability are modelled as stochastic process $X(t)$. The limit state function $G(X,t) = G(X_p, X_b, t)$ is used as the assessment criteria that describes the relation between the performance of circularity and sustainability at time t , denoted by $X_p(X,t)$ and the corresponding threshold, denoted by $X_b(t)$ of the target system. The safe domain, i.e. satisfactory performance zone, can be determined as $G(X,t) \leq 0 = [X_p(X,t) - X_b(t) \leq 0]$. For example, the embodied carbon performance is influenced by different time-variant factors, such as the structural degradation rates, embodied carbon coefficients and recycling rates after the deconstruction of components. The satisfactory embodied carbon performance thus represents the circumstance that embodied carbon is less than the threshold at time t . The unsatisfactory performance therefore depends on the time that the stochastic process $X_p(X,t)$ crosses out the safe domain for the first time, i.e. embodied carbon is larger than emission threshold at time t . The probability of the first occurrence of such outcrossing, is known as ‘first passage’ probability (Breitung and Rackwitz 1982) and is considered as the probability of unsatisfactory performance, or failure, as denoted by $p_f(t)$. Then, the rice formula can be adopted to determine the solution of the first passage probability as follows (Li and Yang 2022)

$$p_f(t) = P[X_p(\mathbf{X}, t) \geq X_b(t)] \leq p_f(0) + \int_0^t u dt \quad (1)$$

where $p_f(0)$ is the probability of unsatisfactory performance at $t = 0$ and u is the upcrossing rate. The detailed calculation process of upcrossing rate u is omitted here due to page limitation and can refer to Melchers and Beck (2017) and Li and Yang (2022).

2.2 Formulation of circular economy index

Based on the formulation of time-dependent reliability index, i.e. Equation (1), circularity assessment criteria can be developed as follows,

$$p_{f_{CR}}(t) = P[\mathbf{G}_{CR}(\mathbf{X}, t) \geq 0] = P[CR_p(\mathbf{X}, t) \geq CR_b(t)] \quad (2)$$

where $p_{f_{CR}}(t)$ is the probability of unsatisfactory circularity performance; $\mathbf{G}_{CR}(\mathbf{X}, t)$ is circularity assessment criteria, i.e. the limit state function for circularity; $CR_p(t)$ is circularity performances; $CR_b(t)$ is the corresponding circularity thresholds at time t . The sustainability assessment criteria can be determined analogously.

A new CE index therefore is developed based on these circularity and sustainability assessments criterion. Three components of CE were selected to be assessed in this study: functional circularity, embodied carbon and embodied energy, to represent the assessment criterion from circularity and sustainability aspects. The probability of failure for CE performance can be assessed in series, parallel or hybrid systems. A series system is modelled to consider three CE components equally, i.e. if one of these criteria is not met the overall CE performance requirement is not met. The probability of system failure $p_{f_{CE}}(t)$, i.e. unsatisfactory CE performance at time t , can be determined as follows (Melchers and Beck 2017)

$$p_{f_{CE}}(t) = P[F_{CR}(t) \cup F_{EC}(t) \cup F_{EE}(t)] \quad (3)$$

where $\mathbf{P}(\cdot)$ is the probability operator and $F_{CR}(t)$, $F_{EC}(t)$ and $F_{EE}(t)$ represent the event of unsatisfactory functional circularity, embodied carbon and embodied energy performances at time t , respectively. Thus, the time-dependent reliability index, i.e. CE index, is obtained as follows

$$\beta_{CE}(t) = -\Phi^{-1}[p_{f_{CE}}(t)] \quad (4)$$

where $\beta_{CE}(t)$ is the CE index at time t , $\Phi^{-1}(\cdot)$ is the inverse function of cumulative distribution function of standard normal variable. Therefore, a probabilistic CE assessment is formulated.

3 MODELLING OF FUNCTIONAL CIRCULARITY

The modelling of circularity assessment criteria, i.e. $\mathbf{G}_{CR}(\mathbf{X}, t)$, involves the determination of performance, i.e. $GR_p(\mathbf{X}, t)$, and related threshold, i.e. $GR_b(t)$, Hatzfeld et al. (2022) developed a functional circularity indicator (FCI) based on modelling functionality of products over use-time. Through measuring the integral surface of functionality over the use-time, FCI can be used to demonstrate multicyclic longevity, upcycling and downcycling effects and disruptive changes in circularity performance of product. A cross-functional circularity indicator (CFCI) was also developed to measure the time when the functionality of a product is reduced by half. In this study, FCI and CFCI are selected to model the circularity performance and threshold, respectively. Furthermore, CFCI is modified to represent half of the integral surface of functionality over the predicted service life of infrastructure. Therefore, $GR_p(\mathbf{X}, t)$ and $GR_b(t)$ can be determined as follows (Hatzfeld et al. 2022)

$$CR_p(\mathbf{X}, t) = FCI(t) = \int_{t_0}^t f(t) dt \quad (5)$$

$$CR_b(t) = CFCI(t) = \frac{1}{2} \int_0^{T_b} f(t) dt \quad (6)$$

where t_0 is the used time of components in previous use cycles; t is the use time in the current cycle; $f(t)$ is the functionality at time t ; T_b is the baseline service life of structures.

The structural degradation of concrete components is considered as a key factor leading to the loss of functionality in infrastructure. Thus, the changes in structural degradation rate, denoted by $D(t)$, can be used to model functionality over use-time. Concrete carbonation is a critical factor leading to the degradation of concrete structures. Thus, it is assumed that the structural degradation rate corresponds to concrete carbonation depth, which is approximately proportional to the square root of carbonation time (Xia et al. 2020). It is worth noting that the real degradation process of structural performance is affected by complex mechanisms and structural state factors, which is out of the scope of this study. The $FCCI(t)$ can be determined as follows

$$FCCI(t) = \int_0^t [I - D(t)] dt = \int_0^t \left(I - \frac{\sqrt{t_0 + t} - \sqrt{t_0}}{\sqrt{T_c}} \right) dt \quad (7)$$

where T_c is the predicted service life of structure; $t_0 + t \leq T_c$ to ensure structural safety. The inclusion of predicted service life of structures T_c in Equation (7) provides the opportunity to incorporate durability in circularity assessment criteria. Lognormal distribution is selected to model predicted service life. The mean value μ_{T_c} and standard deviation σ_{T_c} of predicted service life T_c to produce the lognormal distribution can be obtained from the literature. Through adopting different durability improvement technologies, predicted service life may change accordingly. The probability of unsatisfactory circularity performance $p_{fCR}(t)$ thus can be determined by Equation (2), in which the event of remaining functionality reduces to less than half of its original functionality is considered unsatisfactory.

4 MODELLING OF ENVIRONMENTAL SUSTAINABILITY

Environmental sustainability, such as embodied carbon and embodied energy, is modelled by following a similar procedure for functional circularity. LCA is commonly used in quantifying the environmental impact of infrastructures and thus is selected to formulate the sustainability assessment criterion. The modelling procedure follows related standards, e.g. ISO 14044/14040. This study only considers embodied carbon and embodied energy as two critical environmental impacts to be analyzed. Other environmental impacts, such as resource depletion and human health, can be easily included in the model by following the procedure outlined below.

Embodied carbon is the cumulative carbon emissions across all life cycle stages of infrastructures except for the energy and water use phases (Wolf et al. 2017). It can be further divided into initial embodied carbon, recurrent embodied carbon and demolition carbon. Initial embodied carbon represents the carbon emissions released in the product and construction stages. Recurrent embodied carbon consists of carbon emissions due to maintenance, replacement and reuse during the use stage of infrastructures. Demolition carbon is net carbon emissions that integrate all emissions, including potential avoided carbon emissions, of waste flow treatments in one single module.

For structures with DfD, the allocation of life cycle impacts between their multiple life cycles needs to be considered. Three common life cycle impact allocation methods, i.e. cut-off allocation (100:0), recyclability (0:100) and distributed (50:50) methods, either underestimate the benefits of CE practices or ignore the material quality degradation between life cycles (Lei et al. 2021). This study allocates life cycle impacts according to the structural degradation rate to address these gaps in using structural components with DfD.

The embodied carbon performance $EC_p(X_{(i)}, t)$ is determined as follows

$$EC_p(X_{(i)}, t) = EC(X_{(i)}) \times D(t) = EC(X_{(i)}) \times \frac{\sqrt{t_0 + t} - \sqrt{t_0}}{\sqrt{T_c}} \quad (8)$$

$$EC(\mathbf{X}_{(i)}) = f(IC_{(i)}, C_{(i)}, E_{(i)}) = \sum_{i=1}^n Q_{(i)} [IC_{initial(i)} + IC_{reuse(i)} + IC_{recycling(i)} \times CR_{(i)} \times ER_{(i)} + IC_{landfill(i)} \times (1 - C_{R(i)} \times E_{R(i)})] \quad (9)$$

where $EC(\mathbf{X}_{(i)})$ is the embodied carbon function based on variable $\mathbf{X}_{(i)}$; $\mathbf{X}_{(i)}$ are the vector carbon emission coefficients (kg CO₂-eq/kg) for product and construction, reuse, recycling and landfill processes ($IC_{(i)}$), the fractions of material mass being collected for recycling ($C_{R(i)}$) and the fractions of material loss during recycling process ($E_{R(i)}$); $Q_{(i)}$ is the mass (kg) of the material labelled i obtained from the bill of quantities.

According to the Paris Agreement, global carbon emissions need to be reduced by 30% to 60% by 2050 to achieve the 2-degree target. The Australian government has proposed a 43% emission reduction target by 2030. Based on these targets, the embodied carbon threshold $EC_b(t)$ can be determined as follows

$$EC_b(t) = EC_0 \times (1 - \alpha_{EC})^{t_0+t} \quad (10)$$

where EC_0 is the baseline embodied carbon (kg CO₂-eq) of analyzed infrastructure, e.g. total embodied carbon of concrete structure; α_{EC} is the annual emission reduction rate, which can be determined based on emission reduction targets obtained from related literature and government reports.

The embodied energy performance $EE_p(\mathbf{X}_{(i)}, t)$ and threshold $EE_b(t)$ can be determined by replacing $IC_{(i)}$ with embodied energy coefficients ($IE_{(i)}$) in Equations (8) to (10).

Then the probability distributions of identified basic variables, e.g. $IC_{(i)}$, $C_{(i)}$ and $E_{(i)}$, need to be determined. Due to the limited data and characteristics of previously identified rates and coefficients, normal distribution and lognormal distribution are selected to model different basic variables. Normal distribution is selected for embodied impact coefficients ($IC_{(i)}$ and $IE_{(i)}$) and lognormal distribution is selected for recycling rate and related efficiency coefficient ($C_{R(i)}$ and $E_{R(i)}$). The mean value and standard deviation of distributions for these variables can be obtained by conducting statistical analysis of data from, such as, ICE material inventory database (Hammond and Jones 2019) and national waste reports (DAWE 2020a, 2020b). After the probability distributions of basic variables are defined, Monte Carlo simulation can be carried out to obtain, for example, the mean μ_{EC} and standard deviation σ_{EC} of $EC(\mathbf{X}_{(i)})$. According to the central limit theorem, $EC(\mathbf{X}_{(i)})$ follows the Gaussian distribution if the number of variables is larger than say 5 (Johnson 2004). After the probability of unsatisfactory circularity and sustainability performances are determined, the result of the probability of unsatisfactory CE performance and CE index can be computed by Equations (5) and (6).

5 CASE STUDY

Three concrete structures with DfD are selected from the literature (Xia *et al.* 2020). Different recycled aggregate substitution rates are observed in three reusable concrete structures, i.e. natural aggregate concrete (NAC) with no recycled content, recycled aggregate concrete (RAC0.5) with a 50% substitution rate and recycled aggregate concrete (RAC1) with a 100% substitution rate. The concrete cover depth for three structures is identical, i.e. 25mm. This study defines 1 m³ concrete structure as the functional unit. Each functional unit consists of 1.03 m³ of concrete and 144.79 kg of steel bars. The material loss during the component pre-fabrication process and the increased material consumption due to adopting DfD are considered. For concrete structures with recycled aggregate, the service life will be shorter due to faster carbonation progress compared to the natural one. Thus, the predicted service life spans for three concrete structures are different, which are 91.56, 88.66 and 86.12 for NAC, RAC0.5 and RAC1, respectively (Xia *et al.* 2020).

In this study, three concrete structures are in their first use cycle, i.e. $t_0 = 0$. The reuse of structural components includes deconstruction, transport and construction processes. Deconstruction is considered as a reverse construction process. After one reuse cycle, three concrete structures are no longer suitable for direct reuse and therefore are deconstructed and sent to

recycling or landfill facilities. It is assumed that different recycled aggregate substitution rates will not affect the end-of-life process and all end-of-life materials travel the same distance from the demolition site to the recycling plant or landfill. The embodied carbon and embodied energy coefficients for each material are obtained from the EPD Australasia database and the ICE material inventory database (Hammond and Jones 2019). The fractions of different materials to be recycled and landfilled are obtained from Australian government reports. According to the national waste report, 81% of masonry and 90% of metal are recycled (DAWE 2020a). Recycling efficiency coefficients for concrete and steel are 80% and 90%, respectively, due to the material loss during collection, sorting and recycling (DAWE 2020b). An average coefficient of variance $CoV = \sigma/\mu$ and the autocovariance $C(t_i, t_j) = \sigma^2 \exp(\theta t_i t_j)$, where $CoV = 0.1$ and $\theta = -1 \times 10^5$, are assumed for all variables due to the absence of data.

The mean value and standard deviation of embodied carbon and embodied energy are computed using a simulation number of 1×10^6 based on the convergence study. Table 1 summarizes the characteristics of embodied carbon and embodied energy involved in probabilistic CE assessment. The mean values of embodied carbon for NAC, RAC0.5 and RAC1 are 645, 637 and 630 kg CO₂-eq/m³, respectively. In addition, the mean values of embodied energy for three concrete structures are 5567, 5482 and 5398 MJ/m³, respectively. A decrease in the embodied carbon and embodied energy of concrete structures are observed when the recycled aggregate substitution rate is increased. Then, the annual reduction rate for embodied carbon and energy is assumed as 0.00865 to achieve a 50% emission reduction by 2100. Therefore, the example results of the probability of unsatisfactory CE performance and CE index are computed and illustrated in Figure 1.

Table 1. Mean and standard deviation of embodied carbon and embodied energy for three concrete structures based on Monte Carlo simulation.

Probabilistic circular economy assessment variables		NAC	RAC0.5	RAC1	Distribution type
Embodied carbon (kg CO ₂ -eq/m ³)	Mean μ_{EC}	645	637	630	Normal
	Standard deviation σ_{EC}	79	78	78	
	Coefficient of variation ($\pm\%$)	12.2%	12.3%	12.4%	
Embodied energy (MJ/m ³)	Mean μ_{EE}	5567	5482	5398	Normal
	Standard deviation σ_{EE}	802	800	799	
	Coefficient of variation ($\pm\%$)	14.4%	14.6%	14.8%	

Figure 1. Probabilistic circular economy assessment results for three concrete structures.

6 DISCUSSION

A probabilistic CE assessment considering time-variant influencing factors is developed and tested on reusable concrete structures with different recycled aggregate substitution rates. According to the results, two reusable concrete structures with recycled aggregate, i.e. RAC0.5 and RAC1, have lower CE index results and higher probabilities of unsatisfactory CE performance than natural aggregate concrete, i.e. NAC, throughout the time. For example, in year 20, the probabilities of unsatisfactory CE performance of RAC0.5 and RAC1 are 22.9% and 30.2%, respectively, while that for NAC is only 16%. The CE index results of RAC0.5 and RAC1 are 0.74 and 0.52, respectively. At the same time, the CE index of NAC is 0.99. Therefore, the durability of reusable concrete structures has significant impacts on functional circularity and environmental sustainability. Without additional durability improvement actions, the input of recycled aggregates increases the probability of unsatisfactory CE performance of concrete structures with DfD.

It is worth noting that the mean values of embodied carbon and embodied energy of RACs are lower than that of NAC. This is because the use of recycled aggregate in RACs avoids the extraction and production of natural aggregates. However, the environmental benefit of recycled aggregate is limited due to cement being the largest source of embodied carbon and energy in concrete production. Furthermore, recycled aggregate accelerates the degradation process compared to natural aggregate in the same environment and carbonation time. Therefore, when combining different CE strategies, such as reuse and recycling, the trade-off between functional circularity and environmental sustainability needs to be carefully evaluated.

Different from most existing CE indicators, the developed CE index in this study has considered a wide range of time-variant influencing factors and their stochasticity to comprehensively evaluate the long-term CE performance. In circularity assessment, FCI is adopted to model the loss of functionality due to structural degradation of infrastructure during use. By defining different functionalities, FCI can be applied to various infrastructures that provide different services. In sustainability assessment, environmental impacts, i.e. embodied carbon and embodied energy, are allocated according to structural degradation rate. The structural degradation allocation method not only accounts for material degradation between multiple use cycles but also facilitates design for durability of reusable components. The implementation of probabilistic CE assessment can provide practitioners with decision-making confidence where the level of details in CE strategies is uncertain.

The limitations of present study need to be acknowledged. For example, only normal and lognormal distributions are considered in modelling the uncertain variables. Using different probabilistic distributions may result in different mean and standard deviation values for the circularity and sustainability performances of three concrete structures. Other distributions, e.g. gamma and triangular, need to be considered in future studies for comparing the effect of probabilistic distributions on the results. Also, in this study, a simplified structural degradation process is considered with focus on the carbonation only. It is acknowledged that the material degradation of concrete structures can be influenced by other factors, e.g. chloride ions, temperature and humidity. Future studies should also include these structural degradation factors to improve the accuracy of CE assessment.

7 CONCLUSIONS

A CE index has been developed for probabilistic CE assessment of infrastructures considering time-variant influencing factors in this paper. The time-variant models for FCI, embodied carbon and embodied energy have been established. The proposed CE index has been tested on three example concrete structures with DfD and different recycled aggregate substitution rates. Multiple uncertain and time-variant variables, such as structural degradation rates, environmental impact coefficients, recycling rates and recycling efficiency, are considered. It has been found that the combination of reuse and recycling strategy by sacrificing durability can lead to higher probabilities of unsatisfactory CE performance of infrastructures in the long term. It can be concluded that the CE index can integrate time-dependent reliability methods into CE assessment effectively. The developed methods and results provide a comprehensive understanding of CE performance and will guide the future adoption of CE in infrastructures.

ABSTRACT: There are currently many discussions around the need to design infrastructure systems that are more resilient and sustainable in the future, especially considering growing uncertainties from climate change, pandemics, geopolitical conflicts, and cyber/physical terrorism. It is widely recognized that infrastructure systems provide vital functions for society e.g., power generation, transportation, water management, and that they face much uncertainty and variability over their operating lifetime (+20 years). Yet, standard engineering methods provide limited guidance on how to best design such systems to make them more adaptable, evolvable, and reconfigurable to deal with future uncertainty and risks. The field of *Flexibility in Engineering Design* that emerged from the theory of real options provide systematic and innovative computational tools, algorithms, and digital processes to help designers and engineers better account for uncertainty and risks in early conceptual design activities. This paper provides an overview of the latest developments and future directions in this rapidly growing field. It discusses how flexibility provides the foundations for a unifying conceptual framework to create infrastructure systems that are both more sustainable and resilient. It introduces cutting edge techniques to support the design process based on principles from stochastic programming, robust optimization, deep reinforcement learning, and simulation games, including examples in energy and transportation systems.

1 INTRODUCTION

Infrastructures are complex engineered systems that play crucial roles for society and the world. They support power generation, resource production, healthcare, transportation, and allow us to explore our planet and beyond. Such systems typically operate for decades and face a wide range of uncertainty and risks during their operations, which are exacerbated by ongoing climate change, increasing likelihood of pandemics, geo-political tensions, as well as cyber and physical terrorism. Yet, such systems are often designed to accommodate projected capacity and are therefore often not adaptable to the impacts of changing conditions in markets, environments, regulations, and technology.

This paper presents recent research efforts to develop a data-driven framework leveraging concepts and techniques from machine learning, real options analysis, and flexibility in engineering design to improve the economic performance, sustainability, and resilience of future infrastructure systems operating under uncertainty. It is motivated in part by the fact that many countries

around the world, such as the UK, have set targets to decarbonize their economy by 2050, which will require massive investments in infrastructures, in the order of ~\$10 billion each year for the next 28 years (Krishnan et al., 2022). The research is motivated by climate change, which imposes further requirements for infrastructures to be more sustainable and resilient in the future.

The world is constantly witnessing the deployment of mega-infrastructure projects. For example in the UK, HS2, a railway system costed at £55 billion in 2015, is currently deployed to connect the Northwest and Southeast regions, stopping at major cities such as Manchester, Birmingham, and London (High Speed 2 Ltd., 2022). The development of electric vehicle take-off and landing (EVTOL) capabilities will soon require the deployment of new vertical airport (or vertiport) infrastructures and complex transportation networks. These are just two examples of complex engineered systems that will require careful design and capacity planning over time and space. HS2 provides an exciting research opportunity to revisit original designs and understand what could have been done differently, with an eye towards the remaining phases of the project. Vertiports present an opportunity to consider the design and operations of new infrastructures from scratch. Both systems will operate for decades and witness important changes in terms of demographics and needs, markets, regulations, and technology, especially as the world moves toward decarbonization and net zero. They will need to be sustainable by design and make best use of limited resources, but also be resilient, in view of the inevitable impacts of climate change. All such considerations call for the development of new thinking and methodological approaches to design complex engineered systems of the futures.

2 MOTIVATION

This paper is motivated by the realization that standard methods to assess the economic performance of complex infrastructure projects (e.g., net present value analysis or NPV) do not account well for uncertainty, and most likely mis-calculate the true future costs and benefits (Cardin and Cherian, 2022). This may significantly impact investments into achieving net zero by 2050. For instance, the HS2 project has been delayed severely with massive cost increases for several reasons that were largely foreseen (de Castilla and Westcott, 2013). Development of new vertiports is also subject to high uncertainty in terms of future demand, usage patterns, and technology development. Such development is cited by Uber as the main barrier to the future EVTOL transportation systems (Uber Technologies Inc., 2022). Another motivation is that standard design methods e.g., V-model in systems engineering (INCOSE, 2015) do not account systematically for intelligent management and adaptation strategies to deal with changing conditions and risks. Infrastructure mega-projects are often designed and optimized for a certain capacity, which often leads to rigid systems and plans that are costly to change if the future turns out different.

Ongoing research efforts builds upon the paradigm of *Flexibility in Engineering Design* (de Neufville and Scholtes, 2011). This paradigm has emerged from real options theory (Trigeorgis, 1996), and aims at designing systems that are adaptable, reconfigurable, and changeable in a cost-effective manner in the face of uncertainty and risks (Cardin et al., 2022b). Examples of flexibility include modular, multi-stage development projects, where deployment of subsequent phases is contingent on fulfilling certain socio-economic objectives, or the ability to reconfigure a system after an important disruption. One example of flexibility is the 25 de Abril bridge connecting Lisbon to the municipality of Almada in Portugal. Originally designed in the 1960s to carry four car lanes, the bridge was further designed to accommodate more car lanes if needed in the future and a railway on its lower platform. Decades later, this capacity expansion flexibility was exercised to accommodate growing traffic between the two shores. Growing demographic and changing economic patterns warrant full use of the six car lanes and two-railroad tracks infrastructure that exist today. Countless other studies have shown that flexibility improves expected economic value routinely by 10-30%, sometimes up to 80%, as compared to standard system design outcomes (Cardin, 2014, de Neufville and Scholtes, 2011). This is significant for investments in the order \geq £100 million. This value typically comes at an upfront cost early on, which is often much less than the future costs of adapting later, when operating conditions have changed.

The research efforts build upon the idea that flexibility is an important enabler of sustainability. Flexibility enables better value for systems that are already sustainable by providing contingencies to reduce exposure to downside risks (e.g., abandoning a project doomed to fail), and by helping systems to capitalize on upside opportunities (e.g., expanding capacity to capture higher demand). It promotes sustainability by enabling capacity deployment when needed, which reduces costs in NPV terms, and makes better use of limited resources by avoiding unnecessary deployments and reducing pollution. This contrasts with the approach to “build big” to maximize benefits from economies of scale, which irrevocably commits large resources at the start of a project, and where those may neither be needed, nor appropriately up-to-date when the time comes (Cardin and Hu, 2016). Flexibility also enables resilience, because it enables systems to reconfigure quickly after an unexpected shock, and to regain quickly pre-disruption performance levels. The NHS Nightingale hospital deployed in just nine days over the ExCel London Centre to increase critical care treatment capacity during COVID is an excellent example of how flexibility enabled resilience in a critical healthcare situation (Hospital Times, 2020).

Given that the complexity of designing and deploying future infrastructure systems is ever so increasing, this paper sets as vision to develop a much-needed computational paradigm for *Data-Driven Systems Design for Uncertainty, Sustainability, and Resilience*. The proposed vision is to exploit recent developments in machine learning and important principles from flexibility in design and real options theory to expand our ability to explore the computational design and decision spaces¹ than currently feasible with existing methods and practices. The goal is to find better design and operations solutions, quantify potential improvements in terms of economic, sustainability, and resilience metrics, and importantly to “close the loop” and understand how the solutions can be used by system designers and engineers in a realistic operational environment. This work will support engineers in their ability to provide better advise to policymakers and business leaders on important infrastructure design decisions, in line with the view shared by the Royal Academy of Engineering (2020).

3 RESEARCH DIRECTIONS

Sections 3-4 as well as Figures 1-2 below are reproduced with permission from the book chapter by Cardin et al. (2022a)².

The field of flexibility in engineering systems design is highly multi-disciplinary. It is still relatively new (by academic standards!) and therefore still has much to offer in terms of future research directions and opportunities. An interesting aspect is that, given its nature, it often benefits from new developments in different disciplines. For instance, recent developments in artificial intelligence, machine learning, and data science are widely applicable in this field, with considerably untapped potential. The same goes for developments in digital twin modelling and virtual reality as more tools to support the design and decision-making process emerge. Although not exhaustive, this section provides an overview of ongoing and future directions for research and applications.

3.1 Flexibility as enabler of sustainability and resilience

With much uncertainty about the future, and ongoing threats from climate change, cyber-physical terrorism, and pandemics, infrastructure systems are exposed to massive risks in the coming decades. Such risks may disrupt global financial, urban, economic and political landscapes, as seen recently through the COVID crisis.

Ongoing research shows that flexibility can play a crucial role as a core, enabling paradigm to sustain and improve value in infrastructure systems design and make systems more resilient.

1. The computational design space is defined as the abstract mathematical space containing all the feasible design and operational solutions for a particular engineering system considering uncertainty.

2. The book chapter is accessible at https://link.springer.com/referenceworkentry/10.1007/978-3-030-46054-9_35-1

Flexibility can help provide actionable strategies to mitigate risks and secure a better future. Flexibility enables sustainability – defined by the United Nations as “developments that meet the needs of the present without compromising the ability of future generations to meet their own needs” – by generating better value for systems that are already sustainable (e.g., renewable technologies), and by enabling system operators to deploy capacity and resources *if and when* needed. For example, a recent formulation exploiting decision rules captures intelligent management strategies based on uncertainty realizations in the form of *if-then-else* statements, which emulate the decision-making process in operations. Decision rules are connected to the design in the sense that the flexibility must be designed *a priori* for it to be used in operations. Those can be optimized stochastically using advanced mathematical techniques like stochastic programming and/or robust optimization (Caunhye and Cardin, 2017, Cardin et al., 2017). The solutions are dynamic in nature, intuitive from a managerial standpoint, and typically consist of an initial design plan augmented by a set of rules that will guide future expansions and system operations given uncertainty realizations. Flexibility in design enables better resilience in infrastructure systems, because it promotes “the ability of a system, community or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions” (United Nations). It provides important properties like adaptability and reconfigurability after an unexpected shock, to regain quickly pre-disruption performance.

An important opportunity in research is to develop a systematic, unified agile design framework that helps address ostensible confusion and indecisiveness in design practice that exist due to wide ranging and diverse views on sustainability and resilience. One benefit from systematic design activities focusing on flexibility is to provide a unifying framework to enable both system concepts simultaneously, while enabling engineers to focus on their design efforts. Indeed, despite the many facets to the problems of designing for sustainability and resilience (Chester and Allenby, 2019, Wied et al., 2020, Naderpajouh et al., 2018), flexibility is often discussed in both communities as an important enabling system property. This property can help further develop new frameworks to help generations of future engineers better quantify the added value from sustainability and resilience, whether using economic (e.g., profits, costs) or social metrics (e.g., environmental, social, and governance or ESG) (Schroders, 2020). The study by Caputo et al. (2023) provides an example where the value of flexibility in dynamic mobile micro-grid systems is quantified both in terms of expected costs and CO₂ emissions.

3.2 *Data-driven flexibility and real options*

Up until recently, there has been very little work aiming at leveraging the power of data science and machine learning in the context of flexibility and real options analysis. For example, flexibility strategies still rely in most parts on generic real option strategies (e.g., abandonment, capacity expansion, investment deferral) with exercise rules that are defined through human creativity (e.g., decision rules), and/or through Bellman’s expected reward maximization principles (e.g., maximize expected discounted cash flow). Large datasets that are produced or used by infrastructure systems may provide new combinations or rules, timing, and strategies that may not be intuitive to human designers, but that could very well complement existing approaches, by providing unexplored value-enhancing solutions and reconfiguration policies. For example, one could specify the moves that are allowed for a system to adapt and reconfigure (e.g., deploy new phase, expand or contract capacity, abandon the project) based on certain criteria (e.g., decision rules or policies, timings) and let the system combine these in different ways through a heuristic process to learn valuable strategies from the data. In this context, techniques such as deep reinforcement learning show tremendous potential as demonstrated in early research (Caputo and Cardin, 2022), and also generate other exciting new computational and mathematical problems (e.g., how to design optimal rules in a live, data-driven setting). The availability of large datasets also enables generation of better predictive models that can be used to improve scenario modelling in simulations. Overall, there is a new, largely unexplored field for the development of a new data-driven formulation for flexibility and real options in infrastructure systems design.

3.3 Simulation games and empirical studies

Another important direction for future research is to understand through empirical studies designers' and decision-makers' thinking and process during design activities and operations. Much research has been done where methods are demonstrated through applications in one or a few case studies. This may not be enough to fully validate a new design method.

Empirical studies enable collecting data on design and decision-making behaviors, describe, and make inferences based on statistical analysis. For example, one may devise "treatments", i.e., different methods to train designers on how to make best use of a decision rule or deep reinforcement learning policy to flexibility analysis. The effect of the different treatments can be assessed as compared to a baseline, or control treatment, along different performance indicators, i.e., dependent variables, such as the number of times the decision rules are used, quantitative performance assessment, etc. While such studies are usually conducted in a controlled environment that may not exactly correspond to the real world, this approach is nonetheless complementary to case study research since it relies on statistical main and interaction effects, as opposed to case study evidence that takes longer to generate, and in smaller sample sets.
