The aim of a thin layer cap with active geocomposites is to reduce the thickness of the cap with the help of geotextiles and sorbents. The latter has the ability to remove contaminants from water whereas the geotextiles function as separation and filtration elements. As uncertainties are drastically reduced the cap thickness is approx. 20–30 cm for a new clean habitat layer and the active geocomposite (∼1 cm). The geotextiles avoid mixing of cap material and the seabed. Also, placement uncertainties and erosion from vessel maneuvering and currents will not occur as the isolation material, i.e. the amendment material, is sandwiched between two layers of geotextiles. These layers are joined by mechanical bonding techniques, such as needle-punching or sewing. Depending on the selection of geotextiles and binder techniques, different properties result for the final product, e.g., tensile strength, elongation, water permeability, etc. In this way, ideal optimal contaminant barriers can be customized. In contrast to sealing systems, such as geomembranes or geosynthetic clay liners, active geocomposites have a comparatively high permeability of k $\geq$ 1,0E-5 m/s. The permeability ensures that the groundwater discharge through the seabed remains unaffected, while the exposure path of the contaminant is interrupted with the help of the sorbents.

To remove contaminants from the pore water, different sorbents can be selected. The choice depends on the affinity of a sorbent towards the target pollutants. Activated carbon for example has a high affinity towards organic pollutants. Those organic contaminants frequently encountered in conjunction with sediments are for example polycyclic aromatic hydrocarbons (PAH), tributyl tin (TBT), or petroleum derived hydrocarbons (TPH). Inorganic pollutants are metals and metalloids, such as chromium, copper, and lead. Most inorganic contaminants are only slightly adsorbed by activated carbon. For the removal of metals, cationic sorbents are more effective.

For the design of a thin active cap a good understanding of the kinetics and the capacity of the amendments is of utmost importance (Niewerth & Wilke 2021). Depending on the annual groundwater discharge and the diffusion rate as well as the pore water concentration the life expectancy can be clearly calculated. Also, the use of professional software tool allows simulations of the cap performance for different designs based on scientifically proven findings. Reible and Eek (2017) published a simulation where different cap designs for isolation of a seabed with a PCB contamination were compared. The result is given in Figure 2. It shows that

Figure 2.   Simulation of cap performance for different cap designs (Reible & Eek 2017).

the PCB flux in the interface of the cap and the surface water is almost zero with the use of a thin active cap made of an active geocomposite with activated carbon ("1 cm AC mat") underneath a 30 cm sand layer mixed with a certain (unknown) amount of bulk activated carbon. The simulation was done with the help of the CapSim program developed by the Reible Group at Texas Tech University. It shows that the contaminant flux can be drastically reduced with the help of a well designed cap with active geocomposites on the long term.

3   CASE STUDY

From the 1880s until the 1980s a manufactured gas plant operated on the south bank of the Parramatta River approximately 10 km away from the cultural center of Sydney (Australia). Nowadays, the former industrial area has been developed into a modern housing estate as shown in Figure 3. During the time as an industrial area, the Parramatta River was used to ship coal and other production goods to the plant. The century long operation left high levels of polyaromatic hydrocarbons and recoverable hydrocarbons in the sediments. In May 2004, the Environmental Protection Agency of the State of New South Wales therefore declared the bay as a contaminated site in need of remediation. For this, the entire bay was divided into different areas depending on the level of contaminant concentration. The part of the bay which shows the highest concentration ($\leq$ 120 mg/kg PAH) was remediated with a combined method of in-situ stabilization under a thin layer active cap. First, the top layer of the contaminated sediments was stabilized with cement and other additives. Above of the stabilized seabed an active geocomposite with a filling of 3.4 kg/m^2 of activated carbon was installed. Thereupon 30 cm of clean sediments today build the new riverbed of the bay.

Figure 3.   Site remediation in front of modern housing estate (Courtesy of HUESKER Australia).

The work started in 2019 and ends up with the installation of the active cap in 2020. The 45,00 m long and 5,10 m wide active geocomposite was first anchored to the shoreline with the help of sand and armoring stones. Perpendicular to the shoreline they were rolled out from a floating pontoon with an unrolling device. A lowering frame was used to ensure controlled placement and ballasting. In this installation, a crane was used to move the bottomless frame to a precise position on the geocomposite. The weight of the frame pushes the mat down into the shallow riverbed, as shown in Figure 4. A long-arm excavator was then used to fill the frame with approx. 30 cm of sand. It was important that all mats maintained some overlap so that a continuous sorption layer was constructed. Accordingly, care had to be taken to ensure that the sand was applied only after the installation of two mats in the overlap area. Due to the width of 5.10 m, the sand was first be applied in the middle of the mat and finally the overlap area was covered. The installation of the approximately 5.000 m^2

Figure 4. Installation of active geocomposite with bottomless frame (Courtesy of HUESKER Australia).

area was carried out in five weeks, equivalent to 1.000 m^2 of active thin layer capping per week.

The active sediment cap – here in combination with an in-situ stabilization – filters out the contaminants from the uprising pore water and thus prevents accumulation in benthic and aquatic organisms. Moreover, the new residents can enjoy a beautiful view of the entire bay. Strange odors, black sediments, and an oil sheen on the surface of the water are a story of the past.

4 CONCLUSION

Contaminated subaqueous sites result in poor water quality and pose a risk to receptors, such as fish and benthic organisms. Remediation of the seabed is unavoidable at appropriate contaminant concentrations. In addition to removing sediments with a dredger, other remediation techniques are available. With sediment capping the polluted seabed gets isolated from the surface water. Thus, the pollutants transported with the pore water do not reach the surface. A sediment cap has the ability to protect the aquatic environment for many decades. Below the cap, the substances are partially degraded to a certain extent by natural biological and biochemical processes. Caps designed with active geocomposites consists of large-area, thin pollutant filters that adsorb the pollutants and thus represent permanently safe barriers for the pollutants despite a low thickness. A project in Australia demonstrated the successful installation of the products in a polluted bay. A large area was covered and thus secured in a very short time. This shows that the modern remediation technique is gaining relevance in more and more countries.

ABSTRACT: A composite bottom liner system consisting of a geomembrane over a geosynthetic clay liner (GCL) was constructed for a municipal solid waste landfill in California, USA, in 2004. The liner system then was left exposed without placement of overlying waste for over a decade. In 2016, samples of the GCL were exhumed from the sideslopes for laboratory testing. To investigate the impact of field exposure on the diffusion and membrane behavior properties of the bentonite, multi-stage through-diffusion tests were performed on the exhumed GCLs and a virgin specimen of the same GCL product. Membrane efficiency coefficients (ω) and effective diffusion coefficients (D^*) were measured for potassium chloride (KCl) source solutions. Preliminary results are presented to assess the impact of the long-term field exposure on diffusion and membrane properties of the GCL. Comparisons are drawn with the existing literature for diffusion and membrane behavior, which to date has been limited to testing of virgin GCLs.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) are widely used as barriers in hydraulic and chemical containment applications (e.g., landfills, impoundments). GCLs have been shown to exhibit low hydraulic conductivity, k, to water (i.e., $< 10^{-10}$ m/s), limiting advective flux of contaminants through the liner (Rowe *et al.* 2004). Laboratory studies have shown that GCLs also exhibit semipermeable membrane behavior and have low effective diffusion coefficients, D^*, further enhancing the long-term performance of the barrier system to restrict migration of contaminants into the environment (e.g., Malusis & Shackelford 2002a; Manassero & Dominijanni 2003).

The existence of membrane behavior in a GCL results in restriction of charged inorganic solutes from entering the pores of the bentonite, thereby reducing the total contaminant flux through the GCL and enhancing the barrier performance (Shackelford 2012). This phenomenon occurs due to electrostatic repulsion of anions from electrical fields surrounding adjacent bentonite particles (Fritz 1986). The membrane behavior of GCLs is quantified by the membrane efficiency coefficient, ω, which ranges from a value of 0 (no solute restriction) to 1.0 or 100% (complete or perfect chemical restriction) (Mitchell 1991). Experimental studies indicated significant membrane behavior in GCLs comprising sodium bentonite (NaB) (e.g., $\omega = 0.7$ in Malusis & Shackelford 2002b). Polymer-enhanced bentonites for GCLs also exhibited membrane behavior (Bohnhoff *et al.* 2014; Di Emidio *et al.* 2015; Tong

& Sample-Lord 2022). In addition, multiple studies on NaB and GCLs measured ω and diffusion simultaneously, and reported an inverse correlation between ω and D^* for chloride (e.g., Dominijanni *et al.* 2013; Shackelford *et al.* 2016).

Experimental diffusion and membrane behavior research to date has focused solely on virgin GCLs (i.e., GCLs that have never been exposed to field conditions). Processes that have been identified to adversely affect GCL performance in the field, such as cation exchange and downslope bentonite migration, may also degrade membrane behavior and diffusion performance. However, aside from the preliminary work of the authors, no known studies have attempted to measure membrane behavior and diffusion properties of GCLs that have been exhumed from field sites. Thus, performance-based modeling capabilities and understanding of coupled flows in clay barriers are limited by current datasets of potentially unrepresentative values of ω and D^* obtained from laboratory testing of virgin GCLs.

The experimental study described in this paper included measurement of ω and D^* for GCL samples exhumed from a liner system in San Luis Obispo, California, USA after 12-years of field exposure. Testing was performed on GCL samples exhumed from the top and bottom of a landfill sideslope, as well as on a virgin GCL that was manufactured during the same time period as the installed liner. Results were compared between the exhumed and virgin specimens under the same testing conditions, as well as values reported in the literature for virgin GCLs that utilized similar testing methodologies.

2 MATERIALS AND METHODS

2.1 *Exhumed and virgin GCL samples*

The virgin and exhumed GCL samples were both Bentomat DN (CETCO, USA). Bentomat DN is a needle-punched nonwoven-nonwoven product made with sodium bentonite. Properties of the GCL determined through conformance testing included a bentonite mass per unit area of 4.9 kg/m^2 and k of 2.8×10^{-11} m/s. The average swell index (SI) reported by the manufacturer was 26.0 mL/2g.

The exhumed samples were obtained from a geomembrane-GCL composite bottom liner system that was installed at a municipal solid waste landfill in San Luis Obispo, California (USA) in 2004. The geomembrane was 1.5 mm-thick black HDPE. The composite liner system was left uncovered for 12 years (Figure 1a), after which point the GCL samples were exhumed in 2016. A utility knife was used to cut a strip sample from the corner of the east and south slopes. For the membrane behavior and diffusion testing program, sub-samples (300 mm x 300 mm) were cut from the strip sample from near the top and bottom of the slope (Figure 1b). Details of the liner exhumation are provided in Hanson and Yesiller (2019).

The SI, bentonite mass per unit area, and k also were measured for GCL samples exhumed from the top and bottom of the slope. The SI of the sample exhumed from the top

Figure 1. Photographs of: (a) site in San Luis Obispo, California, USA; (b) example "top" and "bottom" of slope exhumed sample locations.

of the slope was 25.5 mL/2g, which was similar to the original *SI* reported by the manufacturer. However, the *SI* of the sample exhumed from the bottom of the slope had decreased to 9.5 mL/2g, suggesting significant cation exchange occurred between the NaB and subsoil for the GCL located near the bottom of the slope over the exposure period. The GCL exhumed from the top of the slope had a bentonite mass per unit area of 3.9 kg/m^2 and average thickness of 6.0 mm. In contrast, the GCL exhumed from the bottom of the slope had a bentonite mass per area of 4.9 kg/m^2 and average thickness of 11.7 mm. These mass/area results supported field observations that significant downslope bentonite erosion had occurred. The *k* of the GCL samples exhumed from both the top ($k = 7.7 \times 10^{-7}$ m/s) and bottom ($k = 1.2 \times 10^{-8}$ m/s) of the slope had increased by 3-4 orders of magnitude above the original values reported from the manufacturer and conformance testing. The increase in *k* for the top sample likely was due to bentonite loss, whereas the increase in *k* for the bottom sample was attributed to reduced swell.

The virgin sample was obtained from a Bentomat DN GCL roll that was manufactured around the same time period as the field installation. This GCL remained stored in a laboratory setting at California Polytechnic State University-San Luis Obispo.

2.2 Diffusion and membrane behavior testing

Membrane efficiency (ω) and chloride effective diffusion coefficients (D^*) were measured simultaneously using a closed-system, through-diffusion apparatus as described in detail in Malusis *et al.* (2001) and depicted in Figure 2. The apparatus includes a hydraulic control system with a double-syringe flow pump to circulate solutions, an acrylic cell to contain the specimen and porous disks, pressure transducers to monitor pressures at the specimen boundaries, and stainless steel connections throughout the apparatus (to prevent corrosion or volume change). The apparatus is used to simultaneously circulate a higher concentration solution across the top boundary of the specimen and a lower concentration solution across the bottom boundary, thus creating a concentration difference (ΔC) across the specimen. If a GCL exhibits membrane behavior, a hydraulic pressure difference (ΔP) will develop across the specimen due to the applied ΔC. The ΔP is measured via pressure transducers at the boundaries of the specimen and used to quantify the membrane efficiency as (Malusis *et al.* 2001):

$$\omega = \frac{\Delta P}{\Delta \pi} \qquad (1)$$

where, $\Delta \pi$ is the theoretical maximum value of ΔP that would result across an ideal membrane subjected to the same ΔC. Values of $\Delta \pi$ for single-salt solutions can be determined in accordance with the van't Hoff expression (Katchalsky & Curran 1965).

In preparation for testing, all specimens were trimmed to a diameter of 71 mm. The test specimen thicknesses for the virgin GCL, GCL exhumed from the top of the slope, and GCL exhumed from the bottom of slope were 7.1 mm, 6.8 mm, and 11.8 mm, respectively. Prior to

Figure 2. (a) Photograph of one of the closed-system apparatuses to simultaneously measure membrane behavior and diffusion; (b) schematic of conditions within the cell.

introducing salt solution to start the diffusion and membrane behavior testing, deionized water (DIW) was circulated across both boundaries of the specimen. The purpose of this DIW stage is to establish steady baseline conditions before introducing the concentration difference, and measure any initial ΔP that exists across the specimen with $\Delta C = 0$ condition (referred to as the baseline pressure difference, ΔP_o). After completion of the DIW stage, the top solution was switched to 5 mM KCl to commence diffusion and membrane behavior measurements. After steady-state diffusion and pressure conditions were achieved for the 5 mM KCl stage, the top boundary solution was then increased to 10 mM KCl. Each KCl stage typically took three to five weeks to complete.

Recorded ΔP values that developed due to membrane behavior were corrected for ΔP_o (i.e., effective pressure difference, $\Delta P_e = \Delta P - \Delta P_o$) and then used to calculate membrane efficiency in accordance with Equation 1. Samples of the top and bottom boundary outflows were collected every 2 days and subsequently analyzed for EC, pH, temperature, and ion concentrations (Cl^-, K^+, Na^+, Ca^{2+}, Mg^{2+}). The Cl^- concentrations in the bottom boundary outflows were used to determine D^* values based on the commonly used "steady-state method" analysis procedure (e.g., Dutt & Low 1962; Olsen $et\ al$. 1965; Shackelford 1991):

$$D^* = -\left(\frac{L}{n\Delta C}\right)\left(\frac{\Delta m}{A\Delta t}\right) \tag{2}$$

where L is the specimen thickness, A is cross-sectional area, n is porosity, Δt is the time increment over which the liquid outflow sample was collected from the bottom boundary (2 days for this testing), and Δm is the mass of Cl^- that diffused through the specimen over the time interval (calculated as the Cl^- concentration of the outflow sample x volume of the outflow sample).

This paper presents the preliminary results from the first two salt concentration stages (5 mM and 10 mM KCl) for the virgin and exhumed GCLs. The results of the subsequent higher concentration stages (up to 50 mM) are beyond the scope of this paper. The purpose of using KCl (vs. another salt) and solutions within that concentration range was to allow for comparison of the results with most of the literature data for similar tests on virgin GCLs.

3   PRELIMINARY RESULTS

The measured steady-state effective differential pressures (ΔP_e) and calculated membrane efficiency coefficients (ω) for each test stage are presented in Table 1. For all of the specimens, ω decreased as the source salt concentration increased, which has been widely observed in the membrane behavior literature and attributed to diffuse double layer

Table 1.   Summary of membrane behavior test results.

GCL Specimen	Source KCl Concentration, C_o mM	Effective Pressure Difference, ΔP_e kPa	Membrane Efficiency Coefficient, ω %
Virgin	5	10.3	51.2
	10	8.6	23.6
Exhumed from Top of	5	1.0	3.7
Slope	10	2.8	5.3
Exhumed from Bottom	5	2.0	8.9
of Slope	10	0.56	0.95

compression as salt diffuses into the bentonite pores (Di Emidio *et al.* 2015; Dominijanni *et al.* 2018; Fritz 1986; Shackelford *et al.* 2003).

The values of ω for the virgin GCL in Table 1 are consistent with ω ranges reported in the literature for other virgin GCLs. For example, Malusis and Shackelford (2002b) reported ω values of 52 % and 42 % for a similar Bentomat GCL (porosity, $n = 0.86$) from a multi-stage test with 3.9 mM and 8.7 mM KCl concentrations, respectively.

In contrast, values of ω for the exhumed GCLs were substantially lower than those for the virgin GCL in this study. Comparison of ω for the virgin and exhumed GCL specimens is presented graphically in Figure 3. The ω values of the GCL exhumed from the top of the slope were lower than the virgin GCL ω values by factors of 13.8 and 4 for the 5 mM and 10 mM stages, respectively. The reduced ω for the GCL exhumed from the top of the slope was likely due to the lower bentonite mass per area (3.9 kg/m^2), which had been attributed to downslope erosion based on field observations.

Figure 3.   Membrane efficiency coefficients for the virgin and exhumed GCL specimens.

The ω values of the GCL exhumed from the bottom of the slope were lower than the virgin GCL ω values by factors of 5.7 and 25 for the 5 mM and 10 mM stages, respectively. Unlike the GCL at the top of the slope, the GCL from the bottom of the slope had experienced an increase in bentonite mass per area (4.9 kg/m^2). The increase in bentonite mass per area would have been expected to maintain (or potentially increase) the original membrane behavior. The destruction of membrane behavior for the GCL at the bottom of the slope likely was due to cation exchange. Evidence of cation exchange occurring at the bottom of the slope was supported by the lower *SI*.

Figure 4 presents the ion concentrations measured in the liquid outflow samples collected during the diffusion and membrane behavior tests. As shown in Figure 4a for the virgin GCL and Figure 4b for the exhumed GCL from the top of the slope, the outflow samples had higher concentrations of Na^+ than Ca^{2+} or Mg^{2+}. This observation is consistent with the high *SI* values of the virgin and top GCL (*SI* = 25-26 mL/2g), representative of a bentonite with significant Na^+ occupying the exchange complex. In contrast, Figure 4c for the exhumed GCL from the bottom of the slope shows Na^+ concentrations that are an order of magnitude lower than the Ca^{2+} and Mg^{2+} concentrations. This observation further supports the hypothesis that cation exchange was the primary cause of the reduction in ω for the GCL at the bottom of the slope. Future testing will include measurement of cation exchange capacity and bound cation composition for detailed explanation of the observed behavior.

The concentrations in Figure 4 were used to determine the cumulative mass of Cl^- that had diffused through the specimens with time (normalized to specimen area), as shown in Figure 5. Values of D^* were calculated in accordance with Equation 2. For the 5 mM KCl stage, D^* values for the virgin, top exhumed, and bottom exhumed GCL specimens were 6.29×10^{-11} m^2/s, 2.43×10^{-11} m^2/s, and 1.02×10^{-10} m^2/s. For the 10 mM KCl stage, D^* values for the virgin, top exhumed, and bottom exhumed specimens were 7.97×10^{-11} m^2/s, 3.24×10^{-11} m^2/s, and 1.03×10^{-10} m^2/s.

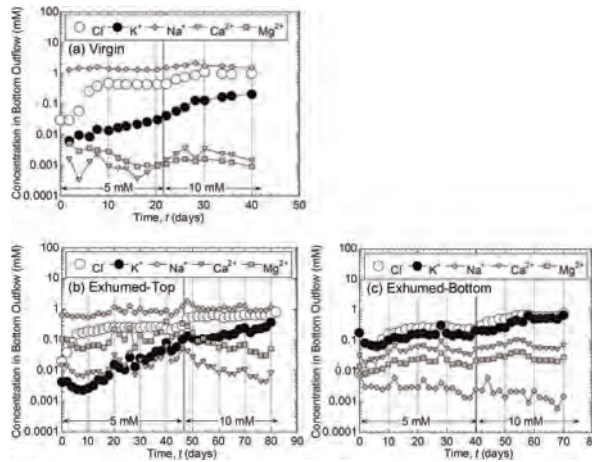
For all of the specimens, D^* increased as C_o increased, consistent with the literature for diffusion in bentonite and expectations based on diffuse double layer effects. However,


Figure 4. Measured ion concentrations in the bottom outflow samples with time for the (a) virgin GCL specimen, and GCL specimens exhumed from the (b) top and (c) bottom of the slope.
Figure 5. Cumulative mass of chloride (per unit area, per time) that diffused through each of the GCL specimens for the (a) 5 mM and (b) 10 mM test stages.

unlike the membrane behavior results, differences between the D^* values for the virgin GCL versus the exhumed GCLs appeared to be minimal to insignificant. Comparison of D^* values may have been complicated by the presence of other ionic species that were not included in the chemical analysis presented in Figure 4. For example, diffusion of chloride may have been impacted by simultaneous diffusion of other anionic species (e.g., sulfate). Additional testing is required to refine conclusions being drawn regarding the impact of the field exposure on the GCL diffusion properties.

4 CONCLUSIONS

The study represents the first experimental evaluation of coupled membrane behavior and diffusion properties of GCLs exhumed from the field. The membrane behavior was determined to be highly impacted by the field exposure, exhibiting significant decreases in ω, which were attributed to downslope bentonite migration and cation exchange with the subsurface. Impacts of the field exposure on diffusion properties were less apparent, with no consistent trend in D^* observed for the virgin versus exhumed GCL specimens. Further study is underway to confirm the extent of cation exchange that occurred in the bottom GCL and to perform more comprehensive diffusion analysis.

Available data in the literature for ω and D^* values of GCLs are primarily based on laboratory studies of virgin GCLs. The results of this study suggest that predictions of long-term performance using coupled transport models, which consider membrane behavior likely underestimate the total contaminant mass flux transporting through the barrier if virgin GCL properties are used.

ABSTRACT: Geosynthetic clay liners (GCLs) are thin, hydraulic and chemical containment barriers with low hydraulic conductivity ($\leq 3 \times 10^{-11}$ m/s) to water or dilute chemical solutions. However, when used to contain liquids with more aggressive chemistries, the hydraulic conductivity of GCLs can be several orders-of-magnitude higher. Polymer enhanced bentonites are developed for use in GCLs to maintain low hydraulic conductivity upon exposure to liquids with aggressive chemistries. Polymer loading is an important factor affecting the hydraulic conductivity of enhanced-bentonite GCLs (EB-GCLs). Measurements of polymer loading are conducted as part of manufacturing and construction quality assurance/quality control (QA/QC) of EB-GCLs, and to assist in interpreting outcomes of hydraulic conductivity testing of EB-GCLs. Methods used to quantify polymer loading of EB-GCLs are reviewed in this paper, with focus on loss on ignition (LOI) and total carbon (TC) analyses. Both methods may be component methods in that measurement of the parameter of interest (i.e., LOI, TC) is required for the sodium bentonite and polymer components as well as the bentonite-polymer mixture. In addition, composite LOI and TC methods are described whereby the polymer content is determined directly via calibration of measured LOI or TC for an enhanced-bentonite series with different, known polymer contents. Each method can be used without direct measurement of the base materials or calibration for use in QA/QC. Examples are provided from tests conducted with poly(acrylic acid), sodium carboxymethyl cellulose, covalently crosslinked poly(acrylic acid), and a bentonite polymer composite to illustrate the application, accuracy, and limitations of the methods.

1 INTRODUCTION

Enhanced bentonites refer to sodium bentonite that has been amended with polymers such as sodium carboxymethylcellulose or poly(acrylic acid) for use in containment applications involving liquids with aggressive chemistry. These applications include containment solutions with high ionic strengths or extreme pH for which unenhanced sodium bentonite will have an unacceptably high hydraulic conductivity due to limited bentonite swelling. The applicability of enhanced bentonites in geosynthetic clay liners (EB-GCLs) has been documented extensively in the literature (e.g., Chen *et al*. 2019; Scalia *et al*. 2014, 2018; Tian *et al*. 2016a,b).

Polymer quantification of the enhanced bentonites component of EB-GCLs is essential for quality assurance and quality control (QA/QC) in terms of ensuring the correct polymer content and the uniform distribution of the polymer across a manufactured roll. Currently, polymer quantification commonly is performed using a loss-on-ignition (LOI) method, such as described in ASTM D7348-13 (ASTM 2013). Scalia *et al.* (2014) used LOI to determine a polymer content of 28.5 % in an enhanced bentonite referred to as bentonite polymer composite (BPC) by first measuring separately the masses lost on ignition by the system components, viz., the polymer used for enhancement (polyacrylate) and the bentonite (LOI = 74.7 % and 1.6 %, respectively). However, as discussed subsequently, issues exist with LOI methods (Gustitus *et al.* 2021; Norris *et al.* 2022). A second established method used for measuring the organic content in soil samples known as the total carbon (TC) analysis (ASTM D6316, ASTM 2017) also has been evaluated for polymer quantification of the enhanced bentonite component of EB-GCLs (Gustitus *et al.* 2021; Norris *et al.* 2022).

Both LOI and TC analyses can be conducted using component or composite procedures to determine the polymer content of enhanced bentonites. Component procedures rely on measurements conducted on the constituent bentonite and polymer materials individually to determine the polymer content of an enhanced bentonite comprising the same bentonite and polymer (but mixed at an unknown ratio). Composite procedures involve measurements conducted on mixtures of bentonite and polymer (i.e., enhanced bentonites) with known polymer contents to generate a linear calibration that is used to determine the polymer contents of an enhanced bentonite with an unknown ratio of the same bentonite and polymer. Both LOI and TC methods are based on development of calibration curves that are used to determine the polymer content of specimens.

Gustitus *et al.* (2021) identified three potential procedures for quantifying polymer contents in enhanced bentonites that were used for non-hydrated EB-GCLs comprising BPC. These methods were termed component LOI, composite LOI, and composite TC. Norris *et al.* (2022) also reviewed the methods of component LOI and composite TC that were evaluated by Gustitus *et al.* (2021) and developed a component TC method. These methods were evaluated using a range of enhanced bentonites containing different anionic polymer types.

This review combines work by Gustitus *et al.* (2021) and Norris *et al.* (2022) to propose a current best practice for quantification of polymer content of enhanced bentonites comprising EB-GCLs. The results of the component LOI, composite TC, and component TC procedures as described by Gustitus *et al.* (2021) and Norris *et al.* (2022) are compared for use in evaluating the polymer content of EBs

2 LOSS ON IGNITION

2.1 *Loss on ignition method*

Polymer quantification using the component LOI procedure uses known quantities of the polymer enhancements and the base bentonite to develop a known LOI for each individual component of an enhanced bentonite (e.g., Gustitus *et al.* 2021; Norris *et al.* 2022; Scalia *et al.* 2014). A known mass of either a specimen of sodium bentonite or enhanced bentonite with an initial gravimetric water content or a specimen of polymer is oven-dried in a ceramic crucible at 110 °C until no further loss in mass is measured. Specimens are ignited using a muffle furnace, cooled in a desiccator, and the final masses of the specimen and crucible after ignition (m_f) are measured. Then, the specimen LOI is calculated as follows:

$$\text{LOI} = \left(m_i - m_f\right)/\left(m_i - m_c\right) \tag{1}$$

where m_i = initial specimen and crucible mass after drying, and m_c = initial crucible mass. With the measured LOI, the mass fraction of the polymer of an enhanced-bentonite

specimen representing the ratio of polymer mass relative to total mass (i.e., polymer plus bentonite), r_p, is determined from the following relationships:

$$\mathrm{LOI}_p r_p + \mathrm{LOI}_b r_b = \mathrm{LOI}_{eb} \tag{2}$$

and

$$r_p + r_b = 1 \tag{3}$$

where LOI_p = fraction mass loss after ignition of a representative specimen of the polymer component, LOI_b = fraction mass loss after ignition of a representative specimen of the bentonite component, LOI_{eb} = fraction mass loss after ignition of the enhanced bentonite, and r_b = ratio or fraction of bentonite mass to total mass. Based on Equations 2 and 3, the expression for r_p is as follows:

$$r_p = (\mathrm{LOI}_{eb} - \mathrm{LOI}_b)/(\mathrm{LOI}_p - \mathrm{LOI}_{eb}) \tag{4}$$

Polymer quantification using composite LOI analysis is completed by measuring the LOI of mixtures of sodium bentonite and polymer at known polymer loadings to develop a calibration curve, which is specific to a given enhanced bentonite.

2.2 Review of loss on ignition method results

Measured polymer contents using both component and composite LOI from Gustitus *et al.* (2021) and component LOI from Norris *et al.* (2022) are shown versus the actual polymer contents in Figure 1. The results from Norris *et al.* (2022) for the component LOI procedure were consistent with those of Gustitus *et al.* (2021). Residual polymer contents, calculated as the difference between actual polymer content and calculated polymer content and reported in terms of percent dry mass of enhanced bentonite, are shown versus actual polymer content in Figure 2 and summarized in Table 1. The component LOI method results in both underestimation of actual polymer content by up to 2.4 % and overestimation of actual
Figure 1.   Measured polymer contents using loss-on-ignition analysis versus actual polymer contents of enhanced bentonites.
Figure 2. Residual polymer contents (actual minus measured) versus actual polymer contents of enhanced bentonites.

Table 1. Summary of residual polymer contents (= actual – measured) from Gustitus *et al.* (2021) and Norris *et al.* (2022).

Method	Loss-on-Ignition (LOI)		Total Carbon (TC)	
	Component	Composite	Component	Composite
Number of measurements	44	36	30	48
Mean residual polymer content (%)	–0.19	–0.12	0.13	0.26
Standard deviation of residual polymer contents (%)	1.1	0.33	0.14	0.37
95 % confidence interval of residual polymer contents (%)	0.3	0.11	0.05	0.11

polymer content by up 2.6 %, regardless of specimen mass or polymer type, with a residual standard deviation of 1.1 %. The results from the composite LOI method performed were better than those for the component method, but both methods underestimated polymer content by up to 1.0 % and overestimated polymer content by up to 0.8 %, with a residual standard deviation of 0.3 %. The underprediction or overprediction of actual polymer loading versus measured polymer loading of component LOI testing varied depending on the sample tested and the polymer loading.

Gustitus *et al.* (2021) found that polymer quantification via the component LOI method was inaccurate due to changes in the thermal degradation of the polymers tested in a bentonite-polymer mixture. The degree of accuracy of the application of the individually measured polymer loss to the mass loss of the polymer in a bentonite-polymer mixture was shown to depend on the types of thermal degradation reactions the polymer underwent during ignition (endothermic and/or exothermic), which were analyzed via thermogravimetric analysis (TGA) and differential scanning calorimetry (see Gustitus *et al.* 2021). Although TGA is not analogous to LOI (TGA involves ignition under argon, a nonoxidizing environment, whereas LOI involves ignition in a muffle furnace, an oxidizing environment), Gustitus *et al.* (2021) provided

evidence that the difference in masses remaining between polymers heated individually versus polymers heated in bentonite mixtures produced a source of bias that could over- or under-estimate the final polymer content in non-hydrated BPC.

3 TOTAL CARBON ANALYSIS

3.1 *Total carbon analyses methods*

Polymer quantification using the component TC procedure uses known quantities of polymer enhancements and the base bentonite to develop a known TC for each individual component of the enhanced bentonite (Gustitus *et al.* 2021; Norris at al. 2022). A known mass of a specimen of sodium bentonite, enhanced bentonite, or polymer is oven-dried in a ceramic crucible at 110 °C until no further loss in mass is measured. Specimens then are combusted in a calibrated TC analyzer (induction furnace). For component TC analysis, r_p is determined as follows:

$$r_p = (TC_{eb} - TC_b)/(TC_p - TC_b) \qquad (5)$$

where TC_{eb} = measured fraction of total carbon for enhanced bentonite, TC_b = baseline measured fraction of total carbon for sodium bentonite, and TC_p = baseline, measured percent total carbon for polymer. The calculation for r_p is based on the summation of r_b and r_p equal to unity (Equation 3).

As with the composite LOI, the composite TC analysis is conducted by measuring the total carbon of mixtures of sodium bentonite and polymer at known polymer loadings to develop a calibration curve. The developed calibration curve is specific to a given enhanced bentonite.

3.2 *Review of total carbon analyses results*

The resulting measured polymer contents using the composite TC method from Gustitus *et al.* (2021) and both component and composite TC methods from Norris *et al.* (2022) are shown versus the actual polymer contents in Figure 3. Residual polymer contents, calculated

Figure 3.   Measured polymer contents using total carbon versus actual polymer contents of enhanced bentonites.

as the difference between actual and calculated polymer contents in terms of percent dry mass of enhanced bentonite, are shown versus actual polymer content in Figure 2 and summarized in Table 1. Comparison of the results in Figures 1 and 3 indicates that polymer quantification by TC provided more accurate prediction of polymer content than by LOI. The composite TC method both underestimated the actual polymer content by up to 1.3 % and overestimated the actual polymer content by up to 0.5 %, with a residual standard deviation of 0.4 %. Unlike the results for polymer quantification by LOI, the component TC method resulted in lower residual polymer contents. The component TC method resulted in underestimation of actual polymer content by up to 0.6 % and overestimation of actual polymer content by less than 0.1 %. Component TC yielded the lowest residual standard deviation of 0.1 %. These results illustrate that, for the materials evaluated in this study, the TC method provided a more accurate method of measuring polymer content of the enhanced bentonites than did the LOI method.

4 CONCLUSIONS AND RECOMMENDATIONS

Measurement of accurate polymer contents is essential for QA/QC of manufactured EB-GCLs. Based on the results of tests conducted by Gustitus *et al.* (2021) and Norris *et al.* (2022), the following recommendations are made. For polymer quantification of non-hydrated enhanced bentonites or EB-GCLs (i.e., initial polymer content), the component TC procedure provided more accurate results. This method requires known TC masses of both polymer and bentonite components. The TC method also can be used solely for QA/QC based on a product-specified TC threshold value representing a minimum polymer content or matching an as-tested product.

User guide of design standards for geosynthetics in landfills applications

A. Hérault*
Freudenberg Performance Materials, France

Ph. Delmas*
Chairman of French Standardisation Committee on Geosynthetics, France

ABSTRACT: Geotextiles and geotextile-related products are used in several applications in landfills, particularly for drainage, filtration and reinforcement functions. This paper describes the bottom and side slope applications of waste storage cells as well as capping applications including veneer soil gripping over the slopes. Needed design parameters, to be defined with the project owner, are listed to help designers. Specifications are given to help in establishing relevant requirements in the tender phase. The described specification and product approval processes are based as much as possible on design values to promote competition, product-specific reduction coefficients making the link with characteristic values of the performances. The manuscript provides as well details on test conditions which have to be taken care of by the tender officer.

1 INTRODUCTION

Geosynthetics are construction products covering a large scope of applications in many types of structures. Therefore, they are used by a very large number of end-users and designers who can't be experts in geosynthetics and need help particularly in the case of highly technical applications, sometimes in the context of sensitive projects, especially for human or environmental safety. On top of that, a wide range of materials structures are available on the geosynthetics market to ensure the same function. That's why, when they are faced to new/innovative type of construction materials like geosynthetics, a lack of knowledge leads engineers to be very fearful in the use of alternative solutions and products which don't fulfill initial specifications at 100%. Moreover, in many cases, specifications are a copy paste of a technical data sheet in which all properties are not relevant for the given application, therefore, this prevents free competition without any technical reason. This is neither a win-win situation for the end user nor for the contractor. The information of geosynthetics market players is necessary to open as much as possible the door to all solutions that work well. More familiar users of geosynthetics with a little bit deeper knowledge are indeed more flexible and open to alternative solutions because they are able to understand appropriate designs when available and to skip variations in non-essential product properties.

To help the users of geosynthetics confronted to the complexity linked to the number of existing standards, recommendations and/or guideline, in the design procedure of their structure, the French IGS chapter (Comité Français des Géosynthétiques) has decided to

write a series of dedicated fascicles. The goal of these "user guides" is to define the required justifications, including the relevant assumptions and properties to be considered in the design of structures using geosynthetics, in accordance with French and European existing documents and precise the relevant design procedure.

This paper presents a synthesis of the first thematic fascicle for applications of geotextiles and geotextile related products in landfills, which was published in 2021 together with a preliminary fascicle common to all structures using geosynthetics.

2 APPLICATIONS AND REQUIREMENTS

Geotextiles and geotextile-related products are involved with different functions in different construction stages of landfills (Figure 1):

— At the base and on side slopes of the cell for protection, leakage detection and/or leachate drainage, and reinforcement in the case of piggybacking,
— On capping for protection, drainage/filtration of seepage water, biogas and as veneer reinforcement.
Figure 1.   Applications covered by French design standards.

2.1 *Base and side slopes of the cell*

At the base and on side slopes of the cell, protection of the foundation soil, groundwater and surface water is ensured by a geological barrier known as a "passive safety barrier" consisting of soil layers fulfilling the following criteria:

— At the base of the cell (slope $< 14\%$), from top to bottom, a clay layer with permeability less than or equal to 10^{-9} m/s over at least 1 m thick and a soil layer with permeability less than or equal to 10^{-6} m/s over at least 5 m thick,
— On the side slopes (slope $> 14\%$), a clay layer with permeability less than or equal to 10^{-9} m/s over at least 1 m thick.

At the base of the cell, the geomembrane is in contact with the clay and covered with a granular drainage layer minimum 0.50 m thick with a permeability greater than or equal to 10^{-4} m/s. This drainage layer may, with the agreement of the authorities, be replaced by a hydraulically equivalent leachate collection and drainage system that combines a drainage geocomposite, a puncture resistant geotextile and a layer of granular material of reduced thickness ensuring the required protection function. In some cases, the puncture resistant geotextile can be combined with the drainage geocomposite, always taking care that the protection of the geomembrane is ensured. This drainage layer has to be resistant to mechanical, thermal and chemical stresses throughout the entire time of filling operation, post-operational period and aftercare period. Hydraulic justification of the alternative system by equivalency is described in the French design standard NF G38-061 (AFNOR 2017).

On the side slopes, the geomembrane is covered with protection geotextile and possibly drainage composite or any equivalent system over the entire height.

2.2 *Capping*

The French ministerial decree of 15 February 2016 regarding the landfill of non-hazardous waste specifies that no later than two years after the end of filling operations, any cell shall be covered with a final cover that may include geosynthetics. According to this ministerial decree, this final cover shall consist of the following layers, from the bottom to the top:

— geomembrane;
— seepage drainage layer consisting of either granular material with protective and filtration geotextiles or a geocomposite;
— veneer soil layer.

For waste subject to biodegradation, it is necessary to provide a drainage and gas collection system, its design is not described in this fascicule since it is not yet covered by a design standard.

In the case of sealing by geosynthetics, the design has to consider several failure mechanisms on the slopes. They are all described in this user guide.

2.2.1 *Sliding of the veneer soil layer*

In order to prevent internal or external shearing of the cover soil layer, the project slope angle shall be consistent with the shear characteristics of the cover material, whatever the reinforcement product considered, with or without a three-dimensional structure. Three-dimensional structures ensure the external sliding stability only, at the base of the layer, sometimes confine the layer, but in all cases, the cover soil will come back to its natural slope angle when this one is lower than the project slope angle. The French IGS chapter's guidelines for the use of geosynthetics in erosion control (Comité Français des Géosynthétiques 2003) specify on page 48 (§II.3) the stability level (internal shear) that can be expected for topsoil.

A buildup of water pressure on the base of the cover soil layer due to a lack of drainage, or a design considering a water level in the cover soil, can lead to the cover soil sliding. When needed, it must be taken into account in the design by considering an effective stress that reduces the shear resistance, and by taking into account the destabilizing forces of the flow.

2.2.2 *Tensile break of a geosynthetic*

The tensile stress of the geosynthetic with the highest modulus in the covering structure depends on the slope geometry, dead loads, live loads, and the smoothest interface friction angle. In order to prevent stresses in the geomembrane, the interface with the lowest friction angle, which will be considered in the design, should be located above the geomembrane.

2.2.3 *Anchorage failure*

The geometry of the cover slopes of landfills has to take into account the limitations related to the installation and the stabilization of the cover layer. Particular attention must be paid to the required anchorage at the top of the slope: designer has particularly to check that the available space allows the construction of a suitable anchorage trench, designed in accordance with the French design standard NF G38-067 (AFNOR 2017), while limiting the depth of the trench to comply with the regulations on the maximum depth of the trench admissible without shoring (art. R. 4534-24 of the French Labour Code). This is particularly needed to define the intermediate berm geometry, which should be wide enough to allow the traffic of construction machinery and to anchor the reinforcing geosynthetic of the downstream slope, and therefore prevent lifting of the reinforcing layer.

After warning on some wrong application of design standards, the user guide makes some suggestions to solve anchorage issues on berms.

3   PHASES OF DESIGN AND TENDER

National and European regulations are described in a preliminary fascicle of the user guide that is common to all applications of geotextiles and geotextile-related products. The document reminds in particular the criteria and principles of the Eurocodes such as consequences classes, design working life, geotechnical categories, limit states and combinations of actions, partial factors on actions and reduction coefficients over materials performances. The user guide sets as the target of the design and specification process the definition of the calculation assumptions and the required long-term performance(s) ensuring the proper functionality of the structure until the end of its design working life.

Then, in the tender submission phase, the submitted product performances have to be justified by the manufacturer: long-term performance specification allows each supplier to select the right product in its product portfolio, taking into account its specific reduction coefficients. These reduction coefficients are applied to the short term product performance, while respecting, when relevant, the specific test conditions as defined in some test standards and reminded in this user guide of design standards. These reduction coefficients are a way to take into account durability requirements by checking long term performances of the geosynthetic due to chemical environment, installation damage and tensile creep behavior for the reinforcement products, compressive creep behavior for drainage geocomposites, including filter fleece intrusion in the drainage core.

4   SPECIFICATIONS RESULTING FROM A DESIGN AND RELATED JUSTIFICATIONS

4.1   *Drainage on the base (slope <14%) and side slopes (slope ≥ 14%)*

At the base of the cell, drainage is usually provided by a drainage layer of granular material with a thickness of 0.50 m and a permeability of 10^{-4} m/s. Alternative solution consists in a layer at least 0.30 m thick of the same granular material to ensure the filtration and protection of the underlying geomembrane from the waste, with a drainage geocomposite on the underside that is hydraulically equivalent to the 0.20 m of replaced granular material. Multi-layer geosynthetic system provides as well the needed protection efficiency. On the other hand, the drainage function is often secondary on the sides of cells where the protection function is predominant.

Below are listed for the drainage function the design performances to be specified in the tender texts and to be justified by the contractor and his suppliers.

4.1.1 *Leachate drainage on the base and side slopes*

For the base, the user guide recommends to specify a design water flow capacity higher or equal to the discharge flow capacity of 0.20 m of granular material with a permeability of 10^{-4} m/s. A safety factor of 1.10 has to be applied on the discharge capacity of the geocomposite for leachate drainage. The compressive stress to be considered is calculated with the height of the waste plus the 0.30 m layer of protective drainage material. The hydraulic gradient is given by the slope of the substrate. On the side slopes, the proposed design flow rate is higher than or equal to the discharge flow capacity of 0.50 m of granular material with a permeability of 10^{-4} m/s. These flow rates shall be specified by stating the type of boundary conditions to be applied to measure the performance of the drainage composite, i.e. for this application, rigid plate to simulate a rigid geomembrane on one side and a standardized foam layer according to EN ISO 12958 to simulate a soil layer on the other side.

4.1.2 *Tensile strength and elongation*

They have to be consistent with the installation conditions.

4.1.3 *Durability*

Refer to EN 13252 Annex B for the maximum allowable time of UV exposure and predicted minimal durability. When applicable, indicate the time of extended exposure to weathering and UV or the expected exposure (kLy), together with the required residual tensile strength at the end of the exposure period. A specific study will then be needed to justify the allowable exposure time of the product. The polymers used have to be suitable for usual basic environment (pH > 9) of leachate.

4.2 *Drainage on flat slopes of capping (slope <14%)*

On the flat slopes of capping, four hydraulic design options are suggested:

- usual 0.50 m thick granular drainage layer with a permeability of 10^{-4} m/s can be replaced by a drainage geocomposite which is hydraulically equivalent,
- or consider input flow rate in the drainage composite based on permeability of the topsoil layer,
- or based on volume of rainfall actually reaching the drainage system as a function of the duration of the rainfall event, by considering e.g. a decennial rainfall occurrence, and the slope-dependent infiltration rate,
- last option, the most conservative one which leads to add intermediate collector drains, considers design flow rate based on a decennial rainfall occurrence and a rain duration of one hour with a 50% infiltration rate. The rainfall intensity is determined using the Montana formula, the local coefficients of which can be obtained from the national meteorological authorities. In order to take into account a rainfall event of an exceptional nature, it is proposed to consider a coefficient of 1.5 on the rainfall calculated from Montana's coefficients a and b.

Below are listed for the drainage function the design performances to be specified in the tender texts and to be justified by the contractor and his suppliers.

4.2.1 *Drainage of seepage water on flat slopes*

The design flow rate will be specified with the actual compressive stress of the project and the hydraulic gradient based on the slope angle, preferably without water level in the cover layer. This flow rate shall be specified by stating the type of boundary conditions to be applied to measure the performance of the drainage composite, i.e. for this application, usually rigid plate to simulate a rigid geomembrane on one side and a standardized foam layer according

to EN ISO 12958 to simulate a topsoil layer on the other side. Inappropriate test conditions can lead to major deviations between actual product performances and test results (Touze *et al.* 2014). Due to the new performance test standard EN ISO 12958-2:2020, new boundary conditions provided by project-specific soil layer or standardized sand layer are now available for design performances assessment. The consequences of sand layer boundary conditions over drainage geocomposites performances can vary from one product to another (Stoltz *et al.* 2016).

4.2.2 *Tensile strength and elongation*
They have to be consistent with the installation conditions.

4.2.3 *Durability*
Refer to EN 13252 Annex B for the maximum allowable time of UV exposure and predicted minimal durability, special care has to be taken to determine the time of ultraviolet exposure prior to re-covering.

4.3 *Veneer reinforcement and seepage water drainage on slopes (slope $\geq$ 14%)*

Below are listed for each function the design performances to be specified in the tender texts and to be justified by the contractor and his suppliers.

4.3.1 *Veneer reinforcement*
Design value of the maximum tensile stress in the geosynthetic in accordance with the French design standard NF G38-067 (AFNOR 2017) and post-construction elongation limited to 3% max. between the 10h and design working life isochronous curves. The tensile stress has to be specified together with an assumption on the considered friction angle for the smoothest multi-layer watertight system interface.

4.3.2 *Seepage water drainage*
Similar to §4.2 with the appropriate runoff ratio according to NF G38-061 annex B (AFNOR 2017).

4.4 *Base reinforcement (Piggybacking)*

In order to simulate potential excessive subsidence of the old waste due to the cell extension, a nominal cylindrical subsidence diameter of 1 to 2 m is suggested by the user guide with a maximum elongation of the reinforcement geosynthetic of 3% in the long term to prevent damage of the HDPE geomembrane functionality.

Below are listed the design performances to be specified in the tender texts and to be justified by the contractor and his suppliers.

4.4.1 *Reinforcement*
Design value of the tensile stress at 3% long-term elongation. At the justification stage, it is calculated from the isochronous curve corresponding to the design working life, and the characteristic short-term tensile strength affected by reduction coefficients related to installation damage and durability. The design temperature depends on the cell filling operation conditions and the stored materials.

4.4.2 *Durability*
Refer to EN 13252 Annex B for the maximum allowable time of UV exposure and predicted minimal durability. When applicable, indicate the time of extended exposure to weathering and UV or the expected exposure (kLy), together with the required residual tensile strength

at the end of the exposure period. A specific study will then be needed to justify the allowable exposure time of the product.

5 CONCLUSION

This paper has presented the first thematic fascicle of a series of fascicles under preparation and under publication by the French IGS chapter, devoted to help the users of geosynthetics confronted to the complexity linked to the number of existing standards, recommendations and/or guideline, for the design of their structure. Dealing with the applications of geotextiles and geotextile related products in landfills, this paper shows how to define the required justifications, including the relevant assumptions and properties to be considered in the design of structures using geosynthetics, thus in accordance with French and European existing documents and precising the relevant design procedure.

Advanced application of bituminous geomembrane (BGM) for waste capping in Australia

P. Kendall*
National Business Engineer, Axter Australia Pty, Australia

R. McIlwraith*
Director, Axter Australia Pty, Australia

ABSTRACT: A cap is an engineered impermeable barrier designed to cover the top of contaminated waste and prevent precipitation leaching from the waste and into the environment. In landfills, the cap also serves to control gas emissions from the waste. Materials used in a cap must not only survive aggressive installation conditions, but they must also be resilient to the deteriorating effects of long service life and environmental exposure. Bituminous geomembranes (BGMs) have been proposed by various authors as a material well suited to perform the barrier function of a cap in both exposed and unexposed conditions. In Australia, the application of BGMs for capping contaminated waste is growing rapidly. This paper describes three recent successful capping projects designed using a BGM barrier including one mining application and two landfill applications. For each project, the technical background of the site is explained and the important factors of the capping design and installation are described. The examples presented will give designers greater confidence in the use of a BGM as a cap in new and technically challenging applications.

1   INTRODUCTION

1.1   *Waste capping systems*

A waste capping system can have various design features but its primary function is to serve as a barrier to isolate waste from environmental exposure. By restricting the migration of liquid, solid, or gaseous mass into or out of the waste body, the liner plays the critical role of encapsulation. While the focus of this paper is on the liner, the capping system must safely manage the drainage of precipitation onto the barrier and expulsion of gas that may be generated within the waste. Compacted clay, geosynthetic clay liners, polymeric geomembranes, and engineered soil phytocaps are all examples of materials which have been used as hydraulic barriers in waste capping systems.

A wholistic evaluation of liner alternatives, which can include the use of Multi-Criteria Assessments (MCAs), works to optimize the technical, environmental, and economic outcomes of a capping system designs (Paulson 2018). Bituminous geomembranes have gained favor in this wholistic design approach due to their combination of physical properties as well as innovations in safe and measurably controlled electrical hot-air welding installation methods.

1.2 Bituminous geomembrane for waste capping systems

1.2.1 Composition of BGM

BGMs have multiple components. The crucial components are the bitumen for is hydraulic properties and the geotextile for mechanical properties. The features of the bitumen and geotextile can be controlled for desirable properties. A common configuration of a BGM is shown in Figure 1 which features a needle punched continuous filament non-woven polyester geotextile and Styrene-Butadiene-Styrene (SBS) modified bitumen. The geotextile is fully impregnated with bitumen in the manufacturing process and additional bitumen coats the geotextile. The mass and mechanical properties of the geotextile can vary depending on the grade. Additional elements can be incorporated into the structure of the BGM. These elements include an anti-perforation root barrier film, a glass fiber fleece, and a sand or other mineral surface coating. A removable film can be manufactured as an alternative to the anti-perforation film. The removeable film is removed during installation to reveal a tacky bitumen layer which provides higher frictional properties for installation on steep slopes.

Figure 1. Diagram of a typical BGM composition.

1.2.2 Material properties

Different grades of BGM can be manufactured by varying the reinforcement geotextile and the amount of bitumen incorporated into the liner. In this manner, thickness and mechanical properties can be controlled. Intrinsic properties of the BGM can be identified and measured. The properties outlined in Table 1 describe some of the unique generally applicable properties of BGMs which result in various aspects of their design functionality.

The properties described in Table 1 translate to useful functional features of BGMs. The following is an overview of some of those features:

1.2.2.1 Virtually no thermal wrinkling

BGMs experience virtually no thermal wrinkling due to an extremely low coefficient of thermal expansion (Peggs 2008). Wrinkling of geomembranes can be problematic for installers as well as designers. Many other geomembrane materials such as polyethylene are

Table 1. Typical intrinsic properties of bituminous geomembranes.

Property	Standard	Units	Value
Coefficient of Thermal Expansion	ASTM D 1204-02	$°C^{-1}$	1E-05
Density	ASTM D 792-20	g/cm^3	1.27
Elongation at Break	ASTM D 7275	%	>60
Friction Angle (sand side)	NF EN 495-2	°	39.5
Cold Bending - Lowest Temperature	ASTM D 746	°C	−20
Water permeability	ASTM E 96	m/s	$< 6.10^{-14}$
Gas permeability methane transmission rate	ASTM D 1434-82	$m^3/(m^2.d.atm)$	$< 2.10^{-4}$

known to contract and expand dramatically with temperature. This can lead to extensive wrinkling during day and tensile strain at night if the liner is not covered immediately. Wrinkles prevent intimate contact between the liner and the subgrade which reduce its effectiveness as a barrier (Rowe 1998).

1.2.2.2 Extreme heat or cold exposure
BGMs have been installed in the extreme cold of Northern Canada and Siberia as well as the dry heat of the Australian Pilbara region and Chile's Atacama Desert.

1.2.2.3 Steep slope angles
Steep slope capability allows for more versatile design options and potentially more waste storage volume per unit area of cap. The BGM can be made with a peel off siliconized release paper which reveals a very tacky, high friction angle underside. Higher friction prevents sliding and allows cover soils to be placed at steeper angles. Angles as steep as 1:1.3 have been installed in Australia.

1.2.2.4 High wind resistance
Wind is an important consideration for both designers and installers. The weight of the liner is critical to resist wind uplift (Giroud 1995). BGMs are very dense and heavy with a specific gravity of 1.2 and a thickness of up to 5.6mm. The high weight allows for a safer installation in higher wind conditions and less need for temporary ballasting. For designers, the weight of the BGM is a positive factor to counter wind uplift suction forces.

1.2.2.5 High puncture resistance
BGMs are reinforced geomembranes with a strong polyester continuous filament geotextile imbedded within the liner. The geotextile, combined with the protective bitumen, is very resistant to puncture and abrasion. This makes the material well suited to accommodate the installation process as well as aggressive interfacing materials such an angular drainage aggregate (Blond 2014).

1.2.2.6 Single-layer construction
Unlike other polymeric geomembranes, BGMs do not suffer from the phenomena known as stress cracking. This is due to the geotextile and bitumen composition of the geomembrane. This allows a BGM to interface with aggressive soils and aggregates without the need of additional protection geotextiles. Lab tests have shown that a BGM can withstand extreme pressure over large stones without puncturing (Blond 2014).

1.2.2.7 Storage and installation in a wide range of weather conditions
A BGM can be installed in light rain and damp conditions. Prior to welding, the seams should be dry. A 200mm self-release protection strip, which keeps the seam dry and clean, should be removed prior to welding. The rolls can also be securely stored on site without risk of moisture or UV damage.

1.2.2.8 Strong seams
The BGM is installed with 200mm overlaps and heat welded seams. The weld fuses the bitumen together to form a strong hydraulically sealed barrier. Weld strength can be tested on site or sent to an independent third-party lab.

1.2.2.9 Bond with PE, concrete, and many other materials
Capping applications often interface with a wide variety of infrastructure elements such as concrete spillways, concrete pipe connections, older membrane installations, steel pipe connections and various other structures. Porous materials such as concrete are first coated with a bituminous primer to optimize direct welding to the concrete. For connections to polymer pipes, a bituminous mastic can be applied cold to seal around the pipe and a clamp can secure the BGM to the pipe. To bond to other types of geomembranes, self-adhesive bituminous strips of 0.5m or 1.0m width can be cold bonded to the geomembrane. The BGM can then be welded to the bituminous strip.

2 BGM CAPPING SYSTEMS FOR MINE WASTE IN AUSTRALIA

2.1 Mineral sands mine, Western Australia

2.1.1 Site background

A mining site in Western Australia processed mineral rich sand for over 40 years. Among the valuable minerals extracted from the sand are ilmenite, titanium dioxide, leucoxene, synthetic rutile, zircon, and various rare earth minerals. Mining of mineral sands produces a waste byproduct of a sandy composition. The sand is generally free draining and free of any large aggregate particles. After the processing and mineral extraction, this waste containing acid effluent, neutralized acid effluent, non-magnetic fines, char and iron concentrate can leach contaminants if precipitation is allowed to infiltrate the waste. An impermeable cap shown in Figure 2 was designed to function as the primary mechanism to prevent generation and mobilization of leachate and therefore no basal liner system was incorporated.

Figure 2.   Schematic of mineral sand waste capping solution.

The aggregate-free, processed sand is a forgiving material to serve as a subgrade for the cap liner. The sand waste stockpile was designed with mild slopes of 9° to 14°. The lengths of the slopes were as up to approximately 50m. The site location mean daytime temperatures range from 31°C in February to 17°C in July with an annual average rainfall of 640mm, most of which occurs in the summer months of December to March.

2.1.2 Capping solution

A 500mm cover layer was approved as the favorable system for developing a grassy-herbaceous plant cover for surface erosion control. The 500mm sand cover layer is designed to suffice for 10 years. This 10 year period is the estimated time to complete the full mine waste remediation works and final closure of the facility. The soft sandy interfacing materials combined with the rapid covering of the BGM allowed for a lighter grade of BGM to be used. The liner used was called SC1 with an average thickness of 2.2mm and a reinforcing geotextile of 250gsm. The selection of a thin liner with heavier reinforcement allowed for relatively larger roll dimensions of 5.1m × 140m. Longer rolls are beneficial to installation, particularly on the slopes where transverse welds are not permitted.

The 500mm site won sand layer was designed with 90% maximum dry density compaction. The sand was installed using a GPS assisted D6 Dozer. The dozer traveled along a platform of sand and pushed new stockpiles of sand over the liner. The GPS controlled dozer blade ensured the specified 500mm sand thickness and the dozer weight provided the compaction effort. A construction photo can be seen in Figure 3.

Figure 3.   Aerial image of site during construction.

3 BGM CAPPING SYSTEMS FOR LANDFILL AND MUNICIPLE WASTE

3.1 *Hervey range landfill, Queensland*

3.1.1 *Site background*

A municipal landfill presents a wide variety of dynamic phenomena to account for including stormwater runoff and gas collection to name a few. The material properties if a BGM can be taken advantage of for use on a municipal landfill cap, if the design can overcome the unique restrictions of that type of environment including:

- The BGM must bond to an existing capping system and integrate with various concrete and polymeric components of the landfill.
- The installation of the BGM must be done safely in the potential presence of flammable methane gas.

The site location mean daytime temperatures range from 30°C in February to 10°C in July with a mean annual rainfall of 1019mm.

This landfill was constructed with a regular progression of intermediate waste compartments known as cells. As more waste is deposited into a landfill cell, the cell will eventually reach capacity. At this point, a cap is installed, and a new cell is built to accumulate new waste adjacent to the previous cell. An outline of this cap design is shown in Figure 4. Critical to this sequence is the ability to hydraulicly seal the capping of the new cell to the previous cell. In this case the previous cell was capped with a textured coated Geosynthetic Clay Liner.

Figure 4.   Schematic of Hervey Range Landfill BGM Cap.

3.1.2 *Capping solution*

One of the motivations for using a BGM on this landfill cap was the ability to bond the liner with an existing capping liner from a previous cap installation in what is known as a piggyback installation. A BGM can be bonded to other membrane materials using a tacky adhesive bitumen strip. The strips used on this site measured 1.0m × 10m. The adhesive strip has a siliconized film which is removed to reveal the tacky bitumen side. The tacky side was bonded to the clean textured polyethylene coated side of a Geosynthetic Clay Liner. A weighted steel roller was used to apply pressure to bond the strip in ambient temperatures. Once the bituminous strip is bonded, the BGM can then be welded to the strip using BGM welding techniques.

The concept of using BGMs in landfill caps, which can have flammable methane gas present, required new developments in welding methods. The conventional gas torch welding methods can pose a risk of fire or explosion if methane gas is detected. Electrically powered hot air welders represent an existing technology which has been in use in the roofing industry for many years. Welding trials at the BGM factory and on replicated local site conditions revealed that these machines could achieve the same or improved performance of conventional torch welding. The use of these welders presents a risk profile similar to wedge welders which have been used on landfill caps successfully for many years.

The schematic in Figure 4 illustrates the various components used in this landfill cap. The BGM served the barrier function. Underneath the BGM was a network of strip drains to collect and expel any gas derived from the waste. Above the BGM was a drainage geo-composite which covered the entire surface of the BGM.

The landfill had various structural protrusions which interfaced with the capping system including concrete and polymeric pipes. For each of these protrusions, there is a process for securing the liner mechanically and sealing it hydraulically. Concrete can be primed with a thin bituminous primer which penetrates the pores of the concrete. The BGM can then be welded directly to the primed surface using a handheld hot air welder if there is a risk of methane gas. A large stainless steel pipe clamp is then tensioned around the concrete pipe. Polymer pipes such as HDPE can be hydraulically sealed without heat by applying a bitumen mastic to a BGM sleeve. The sleeve can be welded to the primary liner and clamped to the pipe using a stainless steel clamp. This process is captured in Figures 5a and 5b.

Figure 5. a) BGM to concrete connection, b) BGM to polymer pipe connection, c) photo during construction d) photo of completed cap with vegetation.

4 BGM CAPPING FORSYSTEMS FOR INDUSTRIAL WASTE

4.1 *Industrial waste at undisclosed site location*

4.1.1 *Site background*

For over 50 years paper was manufactured at this undisclosed industrial site in Australia. The site consisted of 7 hectares of industrial buildings, 30 hectares of wastewater treatment ponds, and 28 hectares of on-site landfill. The site is intended to be remediated to a state suitable for development and public use. Adjacent to the site is a sensitive woodland with a protected koala population. As a result of the long and varied use of the site, many known contaminants have been detected and incorporated into the remediation process. These contaminants include per and polyfluroalkyl substances (PFAS), asbestos, metals, dioxins, polychlorinated biphenyls (PCBs), ash and coal wastes, paper wastes and fuel storage residues. A capping system is critical to prevent the mobilization of any residual contaminants remaining in the solid waste and to make the surface safe and suitable for future use. Due to decomposition of certain waste constituents, the liner was to be installed in the potential presence of methane gas and a gas collection system was incorporated into the capping system. A depiction of the capping system can be seen in Figure 6.
Figure 6.   Schematic of industrial waste site cap profile.

4.1.2 *Capping solution*

A multi-component cap was designed to encapsulate the wide range of waste constituents and account for gas generation. A heavy BGM installed with electrically powered hot air welders was designed to function as the barrier of the capping system. The heavy BGM provides a strong geotextile which provides greater protection against installation damage and a robust barrier for varied future use cases of the cap.

As Figure 6 indicates, a drainage geocomposite was installed above the liner to accumulate and direct stormwater runoff away from the waste body. The drainage geocomposite was composed of a geonet with nonwoven geotextiles on both sides.

For the areas of the cap with higher slope, a geogrid was used to help retain the 500mm of soil covering the cap.

5   CONCLUSION

The three distinct capping projects described above were installed between the years 2020 and 2023 and were designed by three separate engineering design consultants. This snapshot in time highlights the increased adoption of BGM capping systems in Australia. While BGM technology has been in exitance and in use for many decades, innovative installation methods like the hot-air welder have created new application areas for BGMs in caps. A wholistic evaluation of a capping system presents a design engineer with wide variety of barriers including compacted clay and polymeric liners. Consideration of the unique material properties of BGMs in such an evaluation has driven increased usage in waste capping systems in Australia.

Suction behavior of geosynthetic clay liners with polymerized bentonite

M.K. Khan, G.D. Emidio & A. Bezuijen
Laboratory of Geotechnics, Ghent University, Zwijnaarde, Belgium

G.D. Emidio
Pollux Consulting, Evergem, Belgium

ABSTRACT: Geosynthetic clay liners (GCLs) are widely used as a hydraulic barrier due to their low hydraulic conductivity. However, wet and dry cycles by diurnal and seasonal temperature changes and contact with electrolytes induce cracks and compression of the diffuse double layer. This hampers the efficiency of bentonite contained in the GCL. Under this situation, the polymerized bentonite (HYPER clay) has demonstrated better performance against cracking compared to untreated clay. One of the possible reasons for the enhanced efficiency might be the improvement in suction/water retention capacity. Thus, the suction characteristics of the HYPER and untreated clay GCLs were investigated. The paper presents the filter paper total suction test's results of GCLs, along drying and wetting paths, in the form of soil water retention curves and its comparison with the results of the water activity method. Distilled water and seawater were used as wetting solutions. The results showed a higher water retention capacity of HYPER clay GCLs compared to untreated clay. In short, the improved performance of HYPER clay GCLs under wet and dry cycles is partly due to enhanced suction characteristics.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) are 5–10 mm thick and made of a layer of bentonite clay that is either adhered to a geomembrane or sandwiched between two sheets of geotextiles. According to the NF EN ISO 10318-1 standard (AFNOR 2015), a clay geosynthetic barrier is defined as a factory-assembled structure of geosynthetic materials in the form of a sheet in which the barrier function is essentially fulfilled by clay. GCLs experience a variety of environmental conditions throughout their lifespan, including heat gradients and wet-dry cycles. Take *et al.* (2015) demonstrated that the temperature of a GCL composite liner can climb up to 70°C due to daily thermal change when it was directly exposed to solar radiation, while the temperature in brine and solar ponds was even significantly higher, at 90°C (Rowe & Shoaib 2017; Yu & El-Zein 2019), which causes fissures to emerge and thus increases hydraulic conductivity. Furthermore, the influence of ionic solutions must be taken into consideration. The effects of the ionic solution on the GCLs' performance are observed to be more detrimental (Di Emidio *et al.* 2015). In essence, the type of solution and the initial prevention of cracks caused by heat gradients are crucial for the overall efficiency of GCLs.

Sodium carboxymethyl cellulose (Na-CMC) based HYPER clay (HC) GCL was used to study the effects of dry and wet cycles by De Camillis *et al.* (2017). After the fourth wet-dry cycle in seawater (SW), the authors discovered that the hydraulic conductivity of the HC GCLs was three orders of magnitude lower than that of normal GCLs. The changes in the

moisture content of GCLs signify an unsaturated condition. Under these circumstances, permeation is associated with the water retention curve, which is the relationship between suction and water content (WRCs). The increased water retention of HC is anticipated to be one of the factors contributing to its better performance against wet-dry cycles; thus, the study of water retention of GCLs is needed.

The composite structure and broad range of suction to be measured in the case of GCL make it challenging to quantify the water retention behavior. To measure this retention capacity, various approaches have been devised. The vast range of water retention behavior can be conveniently quantified using non-contact filter paper methods (Acikel *et al.* 2015, Risken *et al.* 2016). (Beddoe *et al.* 2010; Hanson *et al.* 2013) measured water retention curves by humidity or vapor evaporation technique, but the technique is time-consuming (Rouf *et al.* 2020). Additionally, approaches based on relative humidity are only considered reliable for the dry end of the water retention curve (Agus & Schanz 2007). Seiphoori *et al.* (2016) investigated GCL's water retention in free swell conditions using the dew point method. The technique was found to be quick and could measure suction at a range of 20 kPa to 110 MPa.

This paper presents insight into WRC of the polymerized HC GCL's WRC and compares it to untreated GCL using non-contact filter paper and dew point method along both wetting and drying paths in deionized water (DW) and seawater (SW).

2   MATERIALS AND METHODS

Sodium bentonite was used, which was treated with sodium CMC to prepare the polymerized clay and subsequently sent to GCL manufacturer to manufacture the prototype needle-punched fiber GCLs (Khan *et al.* 2022).

GCL specimens with a square shape were cut from the prototype roll of UC and HC GCLs for respective wetting and drying paths. The perimeter of the samples was sealed with tape to avoid preferential drying at the edges and loss of the bentonite (Figure 1). For the hydration of the GCLs, DW and SW were used. DW was used as a reference solution, whereas SW represented severe ionic interactions. The properties of the materials are shown in Table 1.

Figure 1.   Filter paper setup for measuring total suction.

For the wetting path of the water retention curve, wetting liquids were added with the help of a sprayer. After the addition of the liquids, the samples were sealed in the plastic bag and left for the homogenization period of 3 weeks. Subsequently, the two filter papers were placed on the mesh, which was placed on the sample, and the samples were sealed in the plastic bag and left for the equilibrium period of 2 weeks (Figure 1). After the equilibrium period, the water content of the filter paper was measured as specified in ASTM-D5298

Table 1. Physical and chemical properties of the materials.

Bentonite	Specific gravity	Plastic limit %	Liquid limit %	CEC meq/100g	Plasticity index	Swell index in SW ml/2g	Swell index in SW ml/2g
UC	2.66	46.9	625.2	85.1	578.3	34	8
HC	2.25	142.5	765.6	56.5	623.1	45	9

GCL		Type		Mass g/m^2		Solution	EC mS/cm
Carrier geotextile		Non-woven		2.25		DW	0.01
Cover geotextile		Woven		1.25		SW	32.7

(2000). Afterward, the additional liquid was added to the sample and the same procedure was repeated.

For the drying path of the water retention curve, the samples were hydrated for 1 month. Lin and Benson (2000) suggested that swelling equilibrium is nearly achieved after 400 h (16.6 days). Therefore, a hydration period of 1 month was chosen for this study. For each subsequent measurement, the sample was dried in the oven at 40°C for 2 h and then left for evaporation through the cover and carrier geotextile at 20°C. Whatman grade 42 filter papers were used, and contamination of the filter papers was avoided by using metal tweezers during handling. The measurement of the filter water content of the filter papers follows the ASTM D 5298 calibration curve. The equations for the ASTM calibration curve are as follows.

$$w_f \leq 45.3\%, \quad Log_{10}(h) = 5.327 - 0.0779 w_f \tag{1}$$

$$w_f > 45.3\%, \quad Log_{10}(h) = 2.412 - 0.0135 w_f \tag{2}$$

where, h = Suction (kPa) and w_f = filter paper water content (%)

The lab calibration curve was also developed, and measurements were compared with that of the ASTM calibration curve. Different samples were used for both wet and dry paths.

For the calibration curve of the filter papers, the humidity sensors, and different solutions of known relative humidity were used. The filter papers were allowed to equilibrate for 7 days with the environment of known relative humidity. The suction was calculated from the water activity by using Eq. 3.

$$h = -\frac{RT\rho}{M} . \ln(R_h) \tag{3}$$

where, h is suction in kilo Pascals (kPa), R is the universal gas constant, which is equals to 8.31 Joule per mole kelvin ($J.mol^{-1}.K^{-1}$), T is the temperature in Kelvin (K), R_h is the relative humidity fraction, ρ is the density of water in kilogram per cubic meter (kg/m^3) at temperature T and M is the molecular weight of the water, which is equals to 0.018 kilogram per mole (kg/mol).

Subsequently, the water content of the filter papers was measured, and curve was plotted as shown in Figure 2. The slope of the second part of the calibration curve (Equation 5) is higher as compared to that of ASTM curve (Equation 2) due to non-contact filter paper measurement (Leong *et al.* 2002), which is desirable for the total suction estimation.
Figure 2. Filter paper lab calibration curve.

The equations for the lab calibration curve are as follows.

$$w_f \leq 25.06\%, \quad Log_{10}(h) = 5.4771 - 0.1358w_f \tag{4}$$

$$w_f > 25.06\%, \quad Log_{10}(h) = 31.8828 - 1.1897w_f \tag{5}$$

where, h = Suction (kPa) and w_f = filter paper water content (%)

For the comparison between the ASTM and lab calibration curve, tests in chilled mirror dew point water activity meter (WAM) were also conducted. The GCLs were cut in accordance with the dimensions of the sample cup (3.64 cm in diameter). For the wetting path of the water retention curve, the sample cups were placed in the 30°C oven and subsequently wetting liquids were added with the help of a sprayer. After the addition of the liquids, the samples were covered with a lid and left for the conditioning period. After every 24 hours, the water activity and temperature were measured with the help of the AQUALAB WAM until the last measurement approximated the preceding measurement. To reach the equilibrium value in the water activity meter for each measurement required 5 to 10 minutes. Afterwards, the additional liquid was added to the sample and the same procedure was repeated until water activity approached the value of 1.

In both filter paper and WAM tests, the samples were allowed to swell freely. Free swelling and shrinkage imply a change in the void ratio. Preferably, the void ratio should be kept constant while quantifying water retention curves since the decrease or increase in void ratio tends to shift the water retention curves upward or downward, respectively (Ghavam-Nasiri *et al.* 2019). However, due to considerable change in the voids of GCL's geotextile and swelling of the clay in GCLs, it is difficult to keep the void ratio constant, or otherwise, accurately measure the volume change of the water retention curve samples. Hence, the present study is limited to free swell conditions.

3 RESULTS AND DISCUSSIONS

3.1 *The effect of clay type on water retention curve*

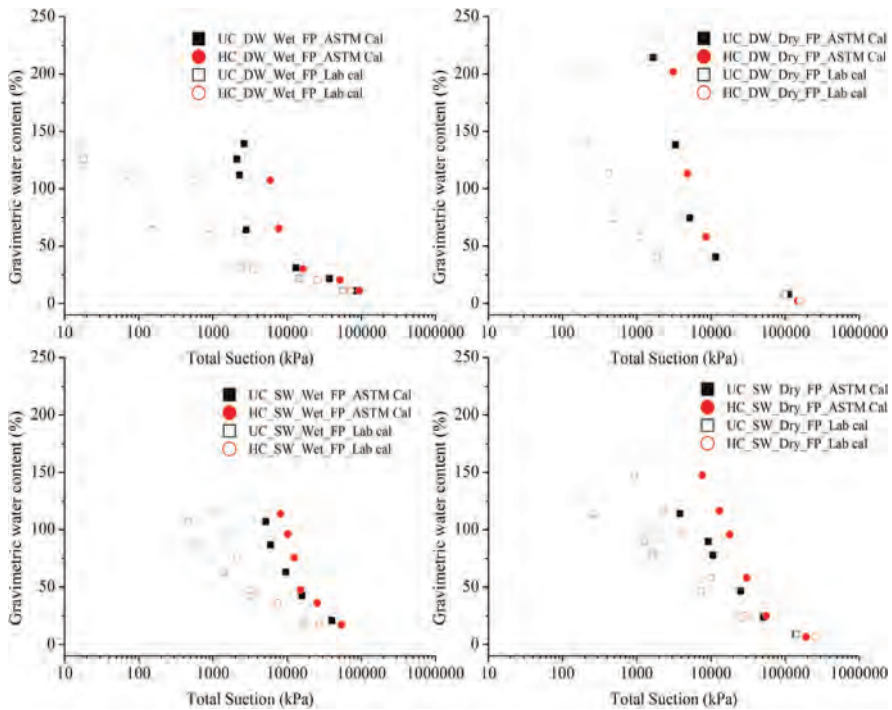
The total suction results of UC and HC GCLs in terms of gravimetric water content along both wetting and drying path are presented in Figure 3. The Figure shows the suction


Figure 3.   Gravimetric water retention curves of untreated and Hyper clay GCLs along a) wetting path and b) drying path in deionized water and along c) wetting path and d) drying path in seawater estimated with ASTM and lab calibration curves.

decreases as expected. Besides, the water uptake increases towards lower suction due to increase in swelling. This increase in water uptake is higher in the case of polymerized clay due to higher swelling as depicted by Table 1. At higher suction, greater than 10^5 kPa, the suction of untreated and polymerized GCLs appears approximately similar. In general, HC GCLs showed higher water retention along wetting and drying path for both DW and SW solution.

The suction characteristics are frequently linked to the material's pore size distribution, pore structure, and material composition (Likos & Wayllace 2010). Because of the composite nature of the GCL, which constitutes geotextile and bentonite, trimodal pore structure is evident. Geotextile has apparently large pore/opening size of around 0.1–0.2 mm (Bouazza et al. 2006). Bentonite has been characterized by inter-particle and intra-particle pore sizes of 2–50 nm (Villar & Lloret 2008). Along the wetting path, the bentonite in the GCL went through different suction regimes depending upon the pore sizes starting from dry state to tightly adsorbed state, adsorbed and ultimately to capillary regime (Lu 2016). At lowest suction, the geotextile capillary prevails, which is totally dependent upon its material texture and pore sizes.

In the dry state, the bentonite possesses highest suction, which decreases with the increase in water content and in the tightly adsorbed and adsorbed regime, the suction is found to be greater than 10^4 kPa (Lau et al. 2022). In this regime, surface hydration occurs through hydrogen bonding between the negatively charged bentonite surface and water. The higher hydration energies associated with exchangeable cations in the montmorillonite mineral controls the water retention (Akin & Likos 2016). The positively charged cations attract the dipolar water molecule and layers of dipole water molecules add on and consequently

increase the gravimetric water content. The water in the region of cations and surface of the bentonite is termed as adsorbed water. From the Figure 3, the water content in this regime (at 10^4 kPa) lie in the range of 20 to 50% and descends in the order SW dry path > SW wet path > DW dry path > DW wet path. The higher water content in the drying path can be attributed to hysteresis behavior.

With the further increase in water content, the water starts movement in the interlayer space and establishes capillary connection, which indicates the start of the capillary regime (Acikel *et al.* 2018). This is usually indicated by a sharp rise in water content. Besides, considerable swelling can be observed in this regime. The saturation level in presence of DW is higher compared to that in SW due to compression of the diffuse double layer in SW, which leads to lower swelling and hence lower saturation gravimetric water content. In addition to this, the presence of ions enhances the total suction due to osmotic component of the suction. The osmotic component is more apparent in the case of SW, that is why the transition point of adsorbed to capillary regime lies at the higher water content in SW. For the UC, the SW affected UC more as compared HC since the difference between UC GCL and HC GCL increases for the same suction. The higher water retention of the HC GCL can be attributed to the type of polymer i.e. the Na-CMC which is an anionic polymer that intercalates within the bentonite platelets and results in additional swelling and chemico-osmotic efficiency (Di Emidio 2010) and, ultimately, higher water retention (Khan *et al.* 2022).

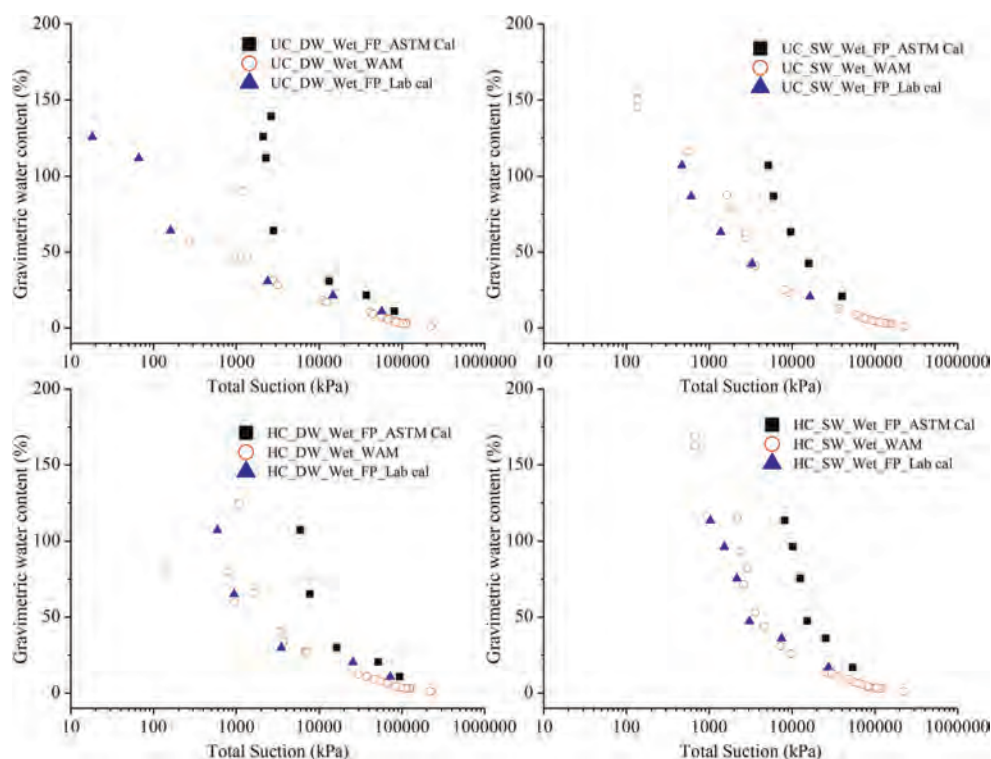

Figure 4. Comparison of water retention curves estimation determined by ASTM and lab calibration curves with the results of water activity method.

3.2 *Comparison of ASTM and lab calibration curve*

The results calculated from ASTM standard calibration curve and lab measured calibration curve of the GCLs along wetting path, and chilled mirror dew point WAM are shown in Figure 4. The Figure demonstrates that the findings of the lab calibration curve closely resemble those of WAM while those of the ASTM calibration curve overestimate the results when compared to lab calibration curve and WAM results. Towards higher suction closer to 10^5 kPa, the filter paper results showed higher value of suction for same water content.

When comparing the filter paper test to the WAM test, the highest difference in the filter paper lab calibration and WAM results was found to be 0.45 log suction (Figure 4b). Besides, an increase of 2.7% and 6% log suction was seen for UC_DW and UC_SW, respectively, at roughly 10^5 kPa. The ASTM calibration curve overestimates more than the lab calibration at lower suction, particularly at suction less than 117 kPa due to the sharp slope of the lab calibration curve (Figure 2). Comparing the results of the ASTM calibration curve to the lab calibration curve, the values for UC DW, UC SW, HC DW, and HC SW are overestimated by around 3 to 163%, 9 to 39%, 2 to 36%, and 6 to 30% log suction, respectively. It is therefore preferable to create a calibration curve for the lab setting while performing the filter paper test.

4 CONCLUSIONS

This study compares the water retention curves of UC and HC GCLs. In comparison to the UC GCL, the HC GCL demonstrated a higher gravimetric water content at a given suction. Besides, the higher ionic strength in seawater increased the osmotic suction of GCLs in both UC and HC and thus enhanced the overall suction. It has also been found that the choice of calibration curve has a substantial impact on the findings. The ASTM calibration curve overestimated the result as compared to lab calibration. Therefore, while conducting the filter paper test method, the lab calibration curve must be generated for accurate results.

In conclusion, the higher water retention of HC GCL would increase its resistance to heat gradients and enable it to act as a long-lasting barrier that would help safeguard subsurface water resources.

Permeable contaminant filter for storage and passive decontamination of PFAS-polluted soil

HUESKER Australia Pty. Ltd.

ABSTRACT: For many decades, per- and polyfluoroalkyl substances (PFAS) were used in firefighting foams at airports and military sites. Today, large amounts of soil and consequently groundwater are contaminated with PFAS. Upon reuse of sites, there must be a definite plan on how the contaminated excavated soil will be addressed. Typically, present waste disposal regulations require the soil to be landfilled. However, transport and disposal of enormous amounts of soil make projects expensive and unecological. For storage or reuse of contaminated soil in the vicinity of the excavation innovative contaminant filters are developed. The target is to treat the soil passively, i.e., without labor, energy, or fresh water. Natural precipitation is used to dissolve PFAS from the soil body and transport downwards through the structure. A permeable contaminant filter is placed at the bottom of the stockpile area. This geocomposite consists of a highly effective amendment sandwiched between two layers of geotextiles. The selective agent extracts PFAS from leachate. To develop a long-life contaminant filter, four performance factors must be considered: affinity, kinetics, capacity, and irreversibility. Affinity describes the tendency of the sorbent to uptake particular pollutants. Regarding PFAS, it is essential that long- and short-chain PFAS are included. The kinetics of the amendment determines whether it is possible to reduce contaminant concentrations below the specified permissible threshold while the seepage percolates through the filter at a natural flow rate. The capacity must be greater than the product of the leachate concentration, the total amount of seepage over a defined period, and an appropriate safety factor. Irreversibility precludes subsequent desorption and thus enables long-term safety of the impoundment. Additionally, there are interdependencies between these factors. The determination of the performance factors and their influence on the design concept are presented and discussed in this paper.

1   TECHNICAL STRUCTURES MADE OF POLLUTED SOIL

Technical structures, such as noise barriers, infrastructure embankments, or commercial and industrial areas, are increasingly being constructed from substitute building materials due to soil scarcity and to avoid long transport routes. Among other materials, these are soils with environmentally relevant compounds. When using substitute building material for structures, they must be designed and evaluated such that they do not contribute to soil and groundwater contamination. In Germany, the possibility of reusing contaminated soils for technical structures is linked to the eluate concentration. In case of comparable high

Perfluorooctane sulfonic acid, **PFOS**	≤ 0.1	≤ 0.2	≤ 1.0

concentrations certain containment measures are required. In the Guideline for PFAS Assessment of the German Federal Ministry for the Environment (BMUV 2022) provisional maximum permissible concentrations for PFAS are defined in the 2:1 l/s-eluate. These values result in a recovery classes (RC), which in turn decides on the containment measure to be taken.

The division into the three classes results from the consideration that the concentration in the technical structure is also transported into the subsoil over time. In case of low concentrations, an open replacement is possible since the subsoil is thus only exposed to low concentrations. To avoid the transport of high concentrations of contaminants, the measure used nowadays is the encapsulation of the contaminated soil by means of an impermeable cap. With new technologies, such as permeable contaminant filters, unrestricted open emplacement is possible, even if the eluate concentrations are at RC 3 or higher. The leachate which contains the contaminants is filtered before it continues to percolate into the uncontaminated subsurface at the permissible pollutant concentration of RC 1, as shown in Figure 1.

Figure 1. Schematic of technical structure with contaminant filter at the base of the structure and leachate concentration.

In addition to groundwater protection, the advantage of this approach is the successive decontamination of the soil. The infiltration of rainwater into the structure is used specifically to dissolve PFAS compounds. The leachate loads itself with the environmentally relevant components and transports them to the permeable filter. To eliminate the concern of pollutants entering the subsurface, the effective removal of the contaminants and a long-term binding of PFAS to the filter must be proven and ensured. Extensive testing with the newly developed permeable contaminant filters was performed to meet these requirements.

2 GEOCOMPOSITE PERMEABLE CONTAMINANT FILTER

Permeable contaminant filters, or also called active geocomposites, consist of a carrier layer and a cover layer of woven and/or nonwoven geotextiles. The geotextiles serve as a package to permanently stabilize the amendment and thus to install it in the field with a uniform layer thickness. All layers are frictionally joined by needle punching or stich bonding which prevents internal erosion of the fine granular or powder active material. In addition, the fabrics also separates the soil layers. The selection of the most sufficient geotextiles allows the setting of an optimal contact time, which is very crucial for leachate treatment. The core of the geocomposite is composed of an amendment layer, which removes PFAS from infiltrating water. It consists of a highly effective amendment or blend of amendments for PFAS. Since leachate properties can vary widely, project-specific selection of the most effective amendments is again recommended. For designing technical structures four performance factors must be considered:

a) Affinity: Strong tendency to remove long and short chain PFAS.
b) Kinetics: Ability to remove all PFAS below thresholds at usual leachate velocities.
c) Capacity: Quantifiable large amount for pollutant uptake over certain period of time.
d) Irreversibility: Binding between amendment and PFAS that cannot be reversed by natural processes.

A contaminant filter can be characterized as technically effective if a strong affinity and a short contact time result in a high percentage removal of contaminants. If at the same time a high capacity and a strong binding led to a long service life the filter turns out to be economically efficient. The four parameters and their interdependencies were analyzed in laboratory and outdoor tests to understand effectiveness and efficiency.

3 RESULTS FROM LABORATORY AND OUTDOOR TESTS

3.1 *Laboratory tests*

To determine the performance factors, an independent laboratory was commissioned to carry out an extensive test program. Initially, jar tests were conducted in which the amendments are stirred in the leachate for the defined time. At different time points, the sorbents are removed and the water is analyzed for contaminant concentrations. The leachate contained PFBA, PFPeA, PFBS, PFHxA, PFPeS, PFHpA, PFOA, PFHxS, PFOS, and others whereby the individual concentrations of the six congeners shown in Figure 2 were artificially increased. Thus, the concentrations ranged from about 2 μg/l to 15 μg/l per individual compound. A strong uptake of all substances of up to 99.9 % was observed, as shown in Figure 2. In addition to the affinity, a first picture of the kinetics was obtained. It was found that not only the capacity but also the kinetics varies at different concentrations. A very strong removal of all PFAS from the leachate was detected during the first five minutes (a lower duration was not possible in the experiments). It is estimated that about 90% of the treatment success takes place within the first two minutes.
Figure 2. Removal of PFAS from leachate in jar tests.

Figure 3. Setup of the column experiments and results at very high concentrations.

Since jar tests confirmed the expectation of high effectiveness, column tests were performed in the next step. These tests more accurately represent the application of geosynthetic contaminant filters in the field than jar tests and are therefore essential. A round sample of the geocomposite was percolated at a defined leachate flow rate in the column shown in Figure 3. Accordingly, a velocity of k = 4.9E-05 m/s was obtained. The eluate was collected in plastic containers and the PFAS concentration was analyzed. The column tests again show a high effectiveness. The test leachate was again spiked with the same six congeners as previously used in the jar tests, but for the column test a concentration of about 1,000 μg/l per congener were added. The reason for this concentration was to determine the capacity limit in a manageable time. Without detecting any breakthrough (maximum capacity not reached), the test was terminated after 7,000 μg/g of PFAS were removed by the amendment. Based on this experiment and confirmed by results from tests of third parties, a capacity of 20,000 μg/g or more can be assumed for very high concentrations. At low concentrations, the expected capacity is correspondingly lower.

Not only the study of the total capacity provides important information for the design of technical structures with contaminant filters, but also the development of the effectiveness as a function of PFAS loading. In Figure 4, the green line represents a theoretical 100% removal of all dissolved PFAS. The orange line shows the actual removal through the filter recorded in the experiments. The result shows that the effectiveness is higher than 99% until the first 110,000 μg of PFAS is sorbed. This corresponds to a capacity of approx. 2,800 μg/g. In the further course, while the concentration remains constant a certain saturation sets in, and consequently the effectiveness decreases. After approx. 250,000 μg of removed PFAS the effectiveness is approximately 75%. This corresponds to a capacity of 7,100 μg/g. After that, however, the capacity limit has not been reached, so that the estimated capacity of 20,000 μg/g to breakthrough seems possible, but only at the expense of efficacy.
Figure 4. Effectiveness of active geocomposite depending on PFAS loading.

Finally, irreversibility, i.e., the desorption behavior of the amendment, was investigated. For this purpose, the loaded granular agent was placed in a glass with deionized water for a total period of two months and shaken continuously. In this way, it was investigated whether PFAS detach after uptake. The desorption rate was less than 0.1%. Consequently, the binding strength can be described as extremely high.

3.2 Outdoor tests

The success from the laboratory tests was repeated in outdoor tests with PFAS-contaminated soil from a former US airbase in Germany. These series of tests were carried out in close cooperation between HUESKER Synthetic and CDM Smith. Large-scale lysi-meter tests, shown in Figure 5, were build up. Three different rain events were simulated in different 1 m³ HDPE-containers, their effect on PFAS mobilization was investigated and the effectiveness of the active geocomposites was tested. As a control, all rain scenarios were also carried out in a container without the contaminant filter. In the test setup, the active geo-composite was laid out in the bottom of a container that was open at the top. A con-taminated silty sand with a thickness of 0.70 m was placed on top. The leachate produced during the respective rainfall simulations was collected and analyzed at different times. The

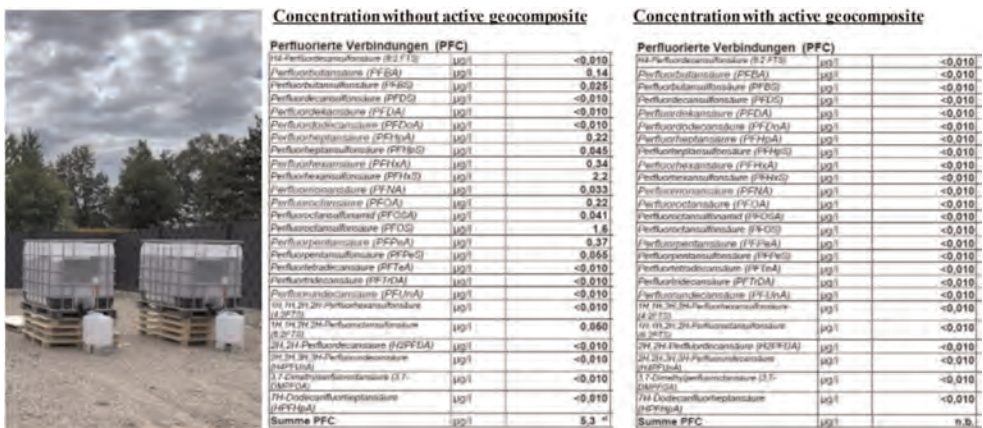

Figure 5. Outdoor trails in HDPE-container and results of rain event 3.

water quantities follow the definitions for moderate, heavy, and extremely heavy rain events according to the German Weather Service (Deutscher Wetterdienst, DWD):

- rain event 1: moderate rain with 10 L/m^2 in 60 minutes
- rain event 2: heavy rain with 30 L/m^2 in 60 minutes
- rain event 3: extremely heavy rain with 50 L/m^2 in 60 minutes

The rainfall simulations led to a mobilization of PFAS from the soil in all test approaches. PFAS levels in the soil leachate averaged about 3–5 μg/l, as shown by the control approach from the container without contaminant filter. These concentrations are also at the level of the analytical laboratory tests of the soil material (10:1 shaking method according to DIN 38414 – S4).

Regardless of the simulated rainfall event, no PFAS were detected in the leachate after filtration by the active geocomposites. The values given in Figure 5 show the result of an extremely heavy rain (rain event 3).

4 DESIGN OF TECHNICAL STRUCTURE

Based on the data obtained from the tests, technical structures can be designed. These structures made of contaminated soils can be noise barriers, infrastructure embankments, utility trenches, etc. If it is ensured that the soil does not have a negative impact on the subsoil and groundwater, it can be used as a building material for these structures.

To design a technical structure with a contaminant filter, information about the leachate velocity is required. It must be verified that the residence time of the leachate in the amendment layer of the contaminant filter is longer than the minimum contact time determined from the column tests. For a road embankment, Finken et al. (2019) used a numerical flow model to calculate the leachate rate based on individual soil layers and infiltration rates, as shown in Figure 6. Comparing the velocities in this technical structure (1.6E-02 m/d) with the flow rates from the outdoor tests, the velocity in the structure is about 68 times lower. Accordingly, the contact time is sufficient to allow significant removal of PFAS by the active geocomposite underneath the embankment.

To evaluate the durability, it must not only be calculated whether the filter works in general, but likewise how long it can be used in the field. For this, a concentration of 10 μg/l total PFAS and an average annual amount of leachate at the interface between the contaminated soil layer and the subsurface of 260 L*m^2/a are used for calculation. The amount of leachate was also taken from Finken et al. (2019) for the structure shown in Figure 6. It is

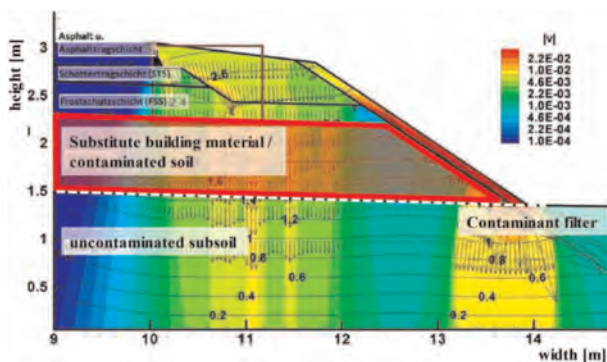

Figure 6.   Leachate rates through a road embankment given in m/d (Finken et al. 2019).

based on an annual precipitation of 859 mm/a and takes into account evaporation and surface runoff.

As described in chapter 3.1 for high PFAS-concentrations a strong effectiveness (almost 100%) is given until a capacity of approx. 2,800 μg/g. However, as the concentration of 10 μg/l is much lower than the concentration in the column tests, the capacity is correspondingly lower. Based on empirical data, the capacity for low concentrations is conservatively estimated to be six to seven times lower. This leads to a capacity of 400 μg/g with almost 100% effectiveness. As described, however, this does not necessarily imply that the capacity limit has been reached. Since it is very likely that other dissolved organic contaminants are also taken up by the amendment, the total capacity is not available for PFAS only. To take this into account, a safety factor of 4 is applied. Accordingly, only 25% of the total capacity is mathematically available for the uptake of PFAS. To reach a sufficient life expectance, an active geocomposite with 3,000 g/m^2 of amendment is chosen. As a result, the service life of the contaminant filter can be estimated at 132 years. This value does not imply that the PFAS concentration is likely to decrease over the years, since the pollutants are discharged from the technical structure with the leachate. For example, if it occurs that the concentration decreases to 9 μg/l after 30 years, the life expectancy increases to 143 years.

5   CONCLUSION

The wide dispersion of PFAS in soil due to their easy solubility and current waste regulations mean that very large excavation quantities must be landfilled or treated ex situ in construction projects on contaminated sites. The reuse of contaminated soil in technical structures represents a solution to avoid long transport distances and disposal. However, sealing these structures results in micro landfills in which the pollutants remain (at best) permanently. Active geocomposites are a new containment and treatment measure. As a permeable filter, the geocomposites are installed underneath the technical structure. It provides a barrier to the contaminants but not to the leachate. In this way, the natural flow path of water is maintained while protecting the clean underground. Since technical structures built in this way are not sealed, precipitation will leach the PFAS over time and direct them into the filter. It must be ensured that the filter effectively removes the substances – i.e., down to the de minimis thresholds – and permanently binds them. The amendment presented in this paper shows very good properties in extensive tests. From a legal point of view, there is the question to be answered if the use of soil with RC 3 leachate is allowed to be used in an open unrestricted emplacement if it is ensured that the concentration underneath the structure is lower than RC 1 values. Since, for example, the German Water Resources Act names the groundwater level as the place of assessment, this question should basically be answered in the affirmative. To control the effectiveness, punctual control shafts can be built. Moreover, first sensor-based eluate measurements already exist and possibly can facilitate the monitoring of the filter under the technical structure soon.

The compatibility of natural and geosynthetic materials for the design of landfill barriers

H. Bannour

Assistant Professor, ISSAT Sousse, University of Sousse, Tunisia

ABSTRACT: Waste disposal facilities (landfills) need to be designed with two distinct and complementary barriers; polymeric and mineral low permeable materials i.e composite liners. In order to prevent contamination of subsoil and groundwater by the leachate provided by wastes, composite liners need to be installed with very strict regulations. Nonetheless, with the luck of natural sites meeting regulations and considering economic and technical concerns, designers used to search for an equivalent design solution on a landfill geographical site by considering alternative materials providing similar protection of the potential environmental impact of wastes on water resources and aquifers. This is where a thin low permeable material such as geosynthetic clay liners (GCLs) or treated soils as polymer-enhanced bentonite–sand mixture (PEBSM) could be added as reinforcement. In this study, analytical and numerical equivalency analyses have been performed on relative concentration evolution of inert contaminant through the geosynthetic reinforced barrier and soil liner in comparison with conventional low permeable soil in the same contamination configuration. Numerical modeling has been used to reproduce contaminant transfers into the entire barrier to the aquifer by SEEP/W and Ctran from Geostudio (2012). In this study, we found that the reinforcement of a non-regulatory passive barrier with a GCL or a PEBSM could provide similar protection level and in some cases enhance it by limiting the evolution of the contaminant migration into the groundwater and subsoil. In conclusion, equivalency is possible for passive barriers through different design solutions; however it is important to pay attention to provide minimum thicknesses of materials to avoid preferential flow paths. This study was inspired from the French guide line for equivalency of landfills passive barrier BRGM/RP-69449-FR (2019). As a result of this study, the proposed methodology for calculating contaminant transport through passive barriers was validated and could provide a reliable tool for other hydraulic applications.

1 INTRODUCTION

Landfills are planned nowadays using a multi-liner approach. Each individual liner allows the environment to be adequately long term protected against aggressive effect of leachate provided by wastes.

Under the EU Landfill directive for Non-hazardous wastes, soil, groundwater, and surface water must be protected by the geological barrier and a composite liner. This latter includes a geomembrane (GMB) and existing low permeable clayey soil or reconstituted one. Essentially, it limits leachate flows and contaminant concentrations in the landfill's environment through its base and sides. It must consist of a mineral layer that satisfies certain hydraulic-conductivity and thickness requirements for the bottom and sides.

The EU Landfill directive defines the following requirements on the geological barrier for non-hazardous waste or compacted clay liner (CCL):

– there must be, from top to bottom, a soil layer with a hydraulic conductivity less or equal than 10^{-9} m/s for at least one meter thick then a soil layer with a permeability less than 10^{-6} m/s for at least 5 meters thick;

– for sides, 1 m thick of the low permeable soil layer presenting a hydraulic conductivity less or equal to 10^{-9} m/s is required.

However, this is a theoretical approach to regulatory design. In a practical point of view, to keep this low hydraulic conductivity at landfill sides, the storage facility must be excavated into the entire deposit with a hydraulic conductivity less than 10^{-9} m/s. This situation is quiet infrequent, and the regulation allows passive barrier reconstruction; when geological barriers don't present local enough specific conditions. Their construction can be completed and reinforced by other materials that provide similar protection. The design of a reinforced passive barrier is justified by an equivalency study that is presented in this paper.

2 EQUIVALENCY JUSTIFICATION ELEMENTS FOR PASSIVE BARRIER

2.1 Qualitative justification for equivalency

If the geological barrier does not naturally provide sufficient regulatory protection, the equivalency study must be conducted by designers after a reliable geological and hydrogeological site modeling.

Ground water is the main target of passive barriers at the bottom of landfills. Indeed, its surface must be kept away from low permeable materials (k < 10^{-9} m/s). For more protection, the distance should be at least 2 m thick.

In terms of potential impact of landfills on ground water resources, two distinguished barriers can be considered equivalent if they offer an equivalent level of ground water protection from a given contaminant migration and concentration. For more security, a minimum thickness of the whole barrier and more specifically of the low permeable material is required. For the whole barrier thickness serves as a security guarantee by reducing risk associated with heterogeneous materials and preferential flow paths.

Currently, equivalency is assured by reinforcing the passive barrier with a thin material exhibiting a low permeability (k < 5×10^{-11} m/s) as a geosynthetic clay liner (GCL) or a treated soil such as a polymer-enhanced bentonite–sand mixture (PEBSM). The permeability is the important parameter that accesses the performance of any lining system. Indeed, the successful association of a low permeable material with a GCL or a PEBSM can reduce significantly the leakage and contaminant migration into the subsoil and the ground water (Rowe & Abdelatty 2012; 2013; Sukumara & Arnepalli 2020). A GCL are defined according to EN ISO 10318 (AFNOR) as a manufactured geosynthetic hydraulic barrier consisting of clay supported by geotextiles or geomembranes, or both, that are held together by needling, stitching, or chemical adhesives. PEBSM is a mixture of a granular material (sand) mixed with a small amount of sodium type bentonite and a minute amount of polymer with certain proportions adopted in many lining and covering applications (Hosny & Rowe 2019)

An alternative solution to conformity requirements is to also increase the thickness and/or reduce the permeability of the attenuation layer (the higher permeable soil) based on the technical and economic conditions of the site.

2.2 Quantitative justification for equivalency and backgrounds

When a quantitative equivalence justification is required, the geological and the hydrogeological data obtained from the site must be used for comparative justification. In addition, the estimation of the contamination level occurring through the barrier and reaching the aquifer is the key providing a quantitative justification of the equivalency for passive barrier.

Indeed, the combination of advective and diffusive transport quantification makes it possible to correctly predict the transport of leachate contaminants in the presence of a hole in the GMB through the composite liner (Rowe & Abdelatty 2012). Advection is provided by the hydraulic gradient across the liner whereas diffusion is provided by concentration gradient.

Furthermore, there is a requirement to calculate the evolution of the relative contaminant concentration C/C_0 into the aquifer and accessing the complete transfer of the contaminant to the environment where:

C is the contaminant concentration through the aquifer as a function of time $[M.L^{-3}]$

C_0 the source concentration through the landfill waste considered as unitary and constant over time represented on the top of the passive barrier $[M.L^{-3}]$.

As a consequence, an easy way to perform equivalency between various distinguished barriers is to compare their relative concentration evolution through the liner.

Then, the purpose of this study is to estimate using a quantitative approach equivalency of various mineral barrier configurations. Numerical modeling using SEEP/W and Ctran from Geostudio make it possible to combine advective flow to diffusive one for the estimation of the level of the contaminant migration (C/C_0) into the aquifer and its corresponding time of occurrence as described in the following case of study for equivalency of mineral barriers.

3 CASES OF STUDY: REINFORMNT JUSTIFICATION BY AN EQUIVALENCY STUDY

3.1 *General features of the composite liners cases and boundary conditions*

9 scenarios cases have been considered for equivalency justification and divided into 3 cases (Table 1 & Figure 1). The two-dimensional multilayers are considered covering a surface of 50 m over a free seepage face representing the aquifer. In the first case (–1–), we considered a soil liner barrier in –a– with a CCL at the top with a hydraulic conductivity k = 1×10^{-09} m/s and a silty soil as an attenuation layer (k = 7×10^{-07} m/s). This barrier could be considered as a regulatory barrier as it satisfies conditions presented in the introduction. It has been considered in –b– a higher permeable soil in the place of the silt represented by silty sand with a hydraulic conductivity equal to 1.2×10^{-5} m/s. As this case is not satisfying the regulation, it has been suggested in that case to reinforce it by the mean of a 0.01 m thick GCL (which hydraulic conductivity is equal to 5×10^{-11} m/s) and in –c– by the mean of a 0.07 m thick PEBSM with the same hydraulic conductivity. In the second case (–2–), we have kept the thickness of the whole regulatory barrier i.e. 6 m and just reducing the thickness of the low permeable soil i.e. the CCL from 1 m to 0.5 m in –b–and –c–. For the third case (–3–), the thickness of the low permeable soil i.e. the CCL has been also reducing to 0.5 m with keeping the same initial thickness of 5 m for the high permeable soil (hydraulic conductivity k < 10^{-6} m/s). The third case has been considered to access the effect of the reduction of the low permeable soil (the CCL) thickness on the contaminant transfer into the whole barrier. Simulations have been performed under 0.3 m hydraulic head and a specific unitary concentration on the top of the multilayered barrier for respectively advection and diffusion.

Table 1. Scenarios of the different cases studied.

| Cases Scenarios	Case –1–			Case –2–			Case –3–		
	–a–	–b–	–c–	–a–	–b–	–c–	–a–	–b–	–c–
GCL	–	1 cm	–	–	1 cm	–	–	1 cm	–
PEBSM	–	–	7cm	–	–	7 cm	–	–	7 cm
CCL	1 m	1 m	1 m	1 m	0.5 m	0.5 m	1 m	0.5 m	0.5 m
Silt	5 m	–	–	5 m	5.49 m	5.43 m	5 m	5 m	5 m
Silty sand	–	5 m	5 m	–	–	–	–	–	–

Figure 1. General features of the passive barrier cases: (a): Case–1–; (b): Case –2–; (c): Case –3–.

3.2 Material properties

The multilayers presented in this study are considered homogeneous and continuous. Interfaces are also considered horizontal. Material properties under saturated and unsaturated condition have been provided from the study of Carsel & Parrish (1988) which characteristics are presented in Table 2.

The chloride solute used in simulation will migrate through the soil and GCL due to two processes: diffusion and advection. The one-dimensional advection-dispersion equation used in Ctran analyses for a homogeneous, isotropic material are defined as:

$$D_i \frac{\partial^2 C}{\partial z^2} - v_z \frac{\partial C}{\partial z} = \frac{\partial C}{\partial t} \qquad (1)$$

C is the concentration $[M.L^{-3}]$; Hydrodynamic dispersion coefficient Di expressed in $[L^2/T]$ for each material layer has been provided according to flow results as follows:

$$D_i = \alpha_i \frac{\inf}{\theta_i} + D_0 \tau_i \qquad (2)$$

Where: α_i is the dispersivity of the layer $[L]$; inf: the infiltration or the ground water velocity $[L/T]$, θ_i the volumetric water content $[L^3/L^3]$; D_0 the contaminant diffusion coefficient in water for a non reactive chloride equal to 2×10^{-09} m^2.s^{-1}.

Table 2. Material properties (Carsel & Parrish 1988).

Material	θ_{sat} (%)	θ_{res} (%)	K_{sat} (m/s)	n	τ
GCL	50	10	5×10^{-11}	-	0.3
PEBSM	50	10	5×10^{-11}	-	0.3
CCL	38	6.8	1×10^{-09}	1.09	0.3
Silt	46	3.4	7×10^{-07}	1.39	0.5
Silty sand	41	6.5	1×10^{-05}	1.89	0.6

The dispersivity α_i is about approximately the tenth of the layer thickness; the volumetric water content θ_i was numerically calculated from the corresponding unsaturated hydraulic conductivity of the layer provided from seepage calculations as follows (van Genuchten 1980):

$$K(\theta) = K_s \theta_D^{0.5} \left(1 - \left(1 - \theta_D^{\left(\frac{n}{n-1}\right)} \right)^{\frac{n-1}{n}} \right)^2 \ with\ \theta_D = \frac{\theta - \theta_r}{\theta_s - \theta_r} \tag{3}$$

Where: $K(\theta)$ [m/s] is the unsaturated hydraulic conductivity under the volumetric water content θ_i [m^3/m^3]; K_s is the saturated hydraulic conductivity; θ_{s_i} is the saturated water content [m/s]; θ_{r_i} is the residual water content [m/s] and n is an experimental parameter.

A constant concentration boundary condition of 1.000 g/m^3 is used to represent the contaminant in the bottom liner. A free exit condition allows mass to leave the domain via advection and dispersion id the concentration C exceeds 0 g/m^3. Sorption was not included in this example.

4 RESULTS AND DISCUSSION

Figure 2 shows the evolution of the relative concentration in an aquifer of a landfill over time. Figure 2(a) represents the results of case –1–, while Figures 2(b) & 2(c) represent the outcomes of cases –2– and –3–.

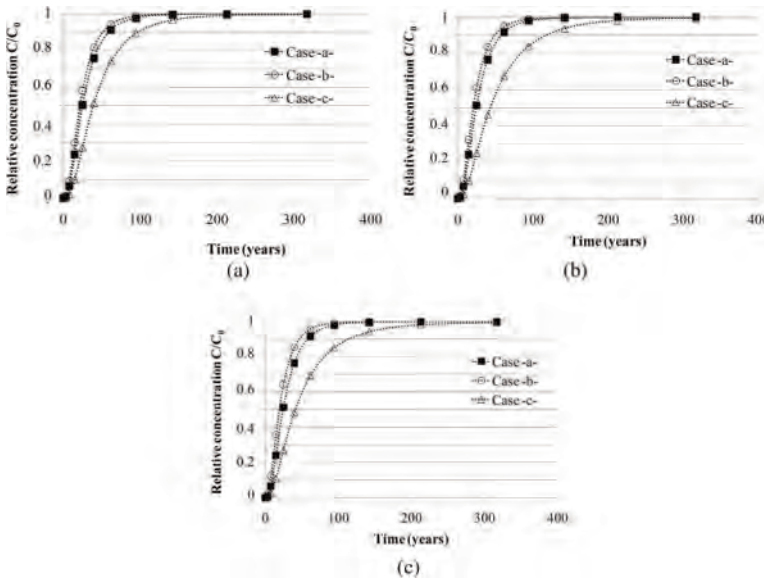

Figure 2. Results of simulation of the evolution of the relative concentration C/C_0 with time through the passive barrier: (a): Case 1; (b); Case 2; (c): Case 3.

In all case studies, numerical simulations showed very similar results in terms of complete contaminant transfer and time to reach it for scenarios –a– and –b–. There is a slightly lower relative concentration evolution with time in scenario –c–. This could be explained by the PEBSM being thicker than the GCL and slowing the contaminant transfer process.

Accordingly, when the regulations could not be met in terms of thickness or hydraulic conductivity of the layer, it appears that reinforcement of the soil barrier with GCL or a thicker material (PEBSM) may be beneficial for the whole barrier and can be used to reduce the contamination of the aquifer over time. In the French guideline, various types of reinforcement configurations for barriers are presented based on numerical and theoretical calculations.

5   CONCLUSION

It is possible to reinforce nonhazardous landfills with low permeable materials when the geological site configuration cannot meet regulatory barrier specifications, for example using geosynthetic clay liners (GCL) or treating soil with polymer enhanced bentonite sand mixtures (PEBSM). Here, a simple and practical methodology is proposed to quantitatively justify equivalency using contaminant migration through a soil barrier. This study was inspired by the French guideline BRGM/RP-69449-FR (2019). Simulations have been conducted for a significant amount of time. The study concluded that in all reinforcement cases, GCLs represent a sufficient equivalent solution for regulations that could not be met (in terms of sufficient thickness or hydraulic conductivity). Additionally, a thicker PEBSM material enhances the barrier's performance. Based on the results of the simulations, this can be regarded as a very significant result, since it reduces risks related to heterogeneous materials and preferential paths. Other hydraulic applications and barrier configurations could be addressed using this methodology.

A systems engineering and risk assessment-based approach for the design of landfills

A. Dominijanni, N. Guarena & M. Manassero
Politecnico di Torino, Torino, Italy

ABSTRACT: The long-term performance of modern landfills is governed by a set of systems, including the landfill cover and the bottom barrier. In order to minimise the environmental impacts of a landfill, a systems engineering approach may be adopted for the landfill design. Such an approach requires analysing the interactions between the different components of each system involved and then evaluating the response of the entire system assembled to quantify its overall engineering performance. The effectiveness of the lining systems is demonstrated through the verification that the risk for human health and the environment due to pollutant migration is limited to an acceptable level. This risk is quantified through the calculation of the pollutant concentration in the groundwater, which is expected to remain less than some prescribed level at a compliance point. The paper describes a simplified approach to the analysis of pollutant transport, which allows the pollutant concentration in the groundwater to be calculated under different boundary conditions and taking into account the role played by several geosynthetics, such as geonets, geomembranes and geosynthetic clay liners, which are used in landfill lining systems.

1 INTRODUCTION

Modern landfills are required to guarantee the safe disposal of waste for the foreseeable future in order to protect human health and the environment from the harm caused by the release of contaminants. The long-term performance of landfills relies upon the effectiveness of the cover and bottom barrier systems. All the barrier or lining systems include a high-permeability component, which is aimed at collecting and removing the percolating liquids, and a low-permeability component (or liner), which limits liquid infiltration and/or contaminant migration.

Rowe (2011, 2018) pointed out that in order to minimize the environmental impacts of a landfill, a system engineering approach to the design should be adopted. This approach involves decomposing the entire system into subsystems that consist of simpler identifiable components. The performance of the individual components, as well as the interactions between different components of the system, have to be assessed before the response of the entire system can be quantified to obtain its overall engineering performance.

A simplified approach is proposed to model the interaction between the waste, the lining system and the aquifer that is located underneath the landfill. The aquifer represents the natural resource to be protected by limiting the impact due to the migration of contaminants from the waste. As a result, the performance criterion adopted for the design is that the lining system must ensure that the concentrations of pollutants in the groundwater remain less than some prescribed threshold level at a specified compliance point, which is typically a monitoring well that is located downgradient from the landfill. The threshold concentration value of a given pollutant is related to a corresponding risk for human health and the environment

through a toxicological model that takes into account the pollutant features and the exposure paths (Dominijanni & Manassero 2021; Dominijanni *et al.* 2021a).

The lining system typically includes a leachate collection system, which involves a series of perforated pipes in a granular drainage layer that are aimed at minimizing the leachate ponded head. The drainage layer may be replaced by biplanar or triplanar geonets, which are characterized by a high in-plane transmissivity. Geonets are covered with a geotextile on their upper and lower surfaces to preserve their drainage function by preventing direct contact with soil particles. The leachate collection system overlies the low-permeability barrier component, which may consist of compacted clay layers (CCLs) and/or geosynthetic components, such as geomembrane layers (GMLs) and geosynthetic clay layers (GCLs). GMLs can be coupled with CCLs and GCLs to form composite liners that provide optimal groundwater protection performance. Moreover, the aquifer located beneath a landfill is typically separated from the waste not only by these artificial layers but also by a natural foundation or attenuation layer (AL), which plays an important role in limiting contaminant migration (Dominijanni & Manassero 2021).

The interaction analysis between the waste, the lining system and the aquifer can be carried out on the basis of a conceptual model that identifies the leachate produced by the waste with the source of contamination and a monitoring piezometer (which may be real or virtual), placed downstream of the landfill, with the point of compliance, as shown in Figure 1.

Figure 1.   Reference scheme for the interaction analysis between the waste, the lining system and the aquifer. The pollutant released by the waste migrates vertically through the engineered lining system and the natural attenuation layer up to the underlying aquifer, where pollutant transport becomes horizontal.

2   ASSESSING THE LANDFILL SYSTEMS INTERACTION

The waste, the lining system and the aquifer are considered as control volumes characterized by an internal homogeneous concentration.

The contaminant mass in the waste disposal facility decreases over time due to degradation processes and migration through the barrier system. The mass balance may be expressed as follow:

$$H_w B_l \cdot \frac{dc_l}{dt} = -J_{s,ad} - J_{s,d} - \lambda H_w c_l \tag{1}$$

where H_w is the waste thickness, B_l is the bulk leachate partition coefficient, c_l is the contaminant concentration in the leachate, $J_{s,ad}$ is the contaminant advective flux through the barrier system, $J_{s,d}$ is the contaminant diffusive flux through the barrier system and λ is the decay constant of a linear or first-order decay reaction.

The contaminant migration has been decomposed into a pure advective flux, $J_{s,ad}$, and a pure diffusive flux, $J_{s,d}$, for the sake of simplicity, although the two transport mechanisms are actually coupled in a single advective-diffusive flux. Accepting this modelling simplification allows the advective flux to be expressed as follows:

$$J_{s,ad} = a_w \cdot q \cdot c_l \tag{2}$$

where a_w is the portion of barrier area that is wetted by the leachate and q is the vertical volumetric liquid flux that takes place through the mineral barrier underlying the geomembrane.

The parameter a_w depends on the number, size and shape of the holes in the geomembrane. An empirical equation for the calculation of the leakage rate through a circular hole with a diameter ranging from 100 mm to 600 mm in a geomembrane with imperfect contact with the underlying mineral layer was provided by Giroud (1997):

$$Q = C_q \cdot A_h^{0.1} \cdot h_p^{0.9} \cdot k_{eq}^{0.74} \cdot \left[1 + 0.1 \left(\frac{h_p}{L} \right)^{0.95} \right] \tag{3}$$

where Q is the flow rate, C_q is a dimensionless quality coefficient of the contact between the geomembrane and the underlying mineral layer, which can be assumed equal to 0.21 for good contact conditions and 1.15 for poor contact conditions, A_h is the circular hole area, h_p is the hydraulic head on top of the geomembrane, k_{eq} is the equivalent hydraulic conductivity of the underlying mineral barrier and L is the thickness of the mineral barrier.

The equivalent hydraulic conductivity, k_{eq}, is calculated as the harmonic mean of the hydraulic conductivities of individual layers:

$$k_{eq} = \frac{L}{\sum\limits_{i=1}^{N} \frac{L_i}{k_i}} \tag{4}$$

where k_i and L_i are the hydraulic conductivity and the thickness of the i-th layer, respectively, and N is the number of layers and $L = \sum\limits_{i=1}^{N} L_i$.

The vertical flux through the mineral barrier underlying the geomembrane is given by Darcy's equation:

$$q = k_{eq} \frac{h_p + L}{L} \tag{5}$$

If the holes are assumed to be all equal to each other and their number per unit area is n_h, the wetted portion of the barrier area may be estimated as follows (Dominijanni *et al.* 2021a, b; Giroud 1997; Katsumi *et al.* 2001):

$$a_w = \frac{n_h Q}{q} \tag{6}$$

where Q is the flow rate through a single hole.

In the absence of the geomembrane, the parameter a_w is equal to 1 as the whole barrier area is wetted by the leachate. Instead, the condition $a_w = 0$ corresponds to a geomembrane without holes.

An approximate estimation of the diffusive flux, $J_{s,d}$, in Equation 1 can be obtained by introducing mass transfer coefficients or diffusivities to account for the transport through the barrier system. Under such assumptions, $J_{s,d}$ may be expressed as follows:

$$J_{s,d} = a_w \Lambda_{d,w}(c_l - c_{b,w}) + (1 - a_w)\Lambda_{d,nw}(c_l - c_{b,nw}) \tag{7}$$

where $c_{b,w}$ and $c_{b,nw}$ are the average contaminant concentrations in the barrier system in correspondence to the wetted and non-wetted portions of the landfill barrier, respectively, and $\Lambda_{d,w}$ and $\Lambda_{d,nw}$ are the related diffusivities. $\Lambda_{d,w}$ and $\Lambda_{d,nw}$ are related to the diffusion coefficients of the components of the barrier system as follows:

$$\Lambda_{d,w} = \frac{1}{\sum_{i=1}^{N} \frac{L_i}{n_i D_i^*}} \tag{8}$$

$$\Lambda_{d,nw} = \frac{1}{\frac{L_g}{K_g D_g} + \sum_{i=1}^{N} \frac{L_i}{n_i D_i^*}} \tag{9}$$

where n_i and D_i^* are the porosity and the effective diffusion coefficient of the i-th layer, respectively, L_g is the thickness of the geomembrane, K_g is the partition coefficient between the geomembrane and the contaminant, and D_g is the diffusion coefficient of the geomembrane.

The average concentrations $c_{b,w}$ and $c_{b,nw}$ in the barrier system are found from the contaminant mass balances in the corresponding control volumes:

$$n_b R_{d,b} L \cdot \frac{dc_{b,w}}{dt} = qc_l + \Lambda_{d,w}(c_l - c_{b,w}) - qc_b - \Lambda_{d,w}(c_{b,w} - c_{aq}) - \lambda \cdot n_b R_{d,b} L \cdot c_{b,w} \tag{10}$$

$$n_b R_{d,b} L \cdot \frac{dc_{b,nw}}{dt} = \Lambda_{d,nw}(c_l - c_{b,nw}) - \Lambda_{d,nw}(c_{b,nw} - c_{aq}) - \lambda \cdot n_b R_{d,b} L \cdot c_{b,nw} \tag{11}$$

where n_b is the average porosity of the mineral layers of the barrier system, $R_{d,b}$ is the average retardation factor of the contaminant through the barrier system and c_{aq} is the contaminant concentration in the aquifer that is located underneath the barrier system.

The mass balance of the contaminant in the underlying aquifer allows c_{aq} to be determined:

$$n_{aq} R_{d,aq} L_{aq} \cdot \frac{dc_{aq}}{dt} = a_w qc_{b,w} + a_w \Lambda_{d,w}(c_{b,w} - c_{aq}) + (1 - a_w)\Lambda_{d,nw}(c_{b,nw} - c_{aq}) +$$
$$q_{aq,0} c_{aq,0} - \left(q_{aq,0} + a_w q \frac{\ell}{L_{aq}}\right) c_{aq} - \lambda \cdot n_{aq} R_{d,aq} L_{aq} \cdot c_{aq} \tag{12}$$

where n_{aq}, $R_{d,aq}$ and L_{aq} are the porosity, the retardation factor and the thickness of the aquifer, respectively. $q_{aq,0}$ and $c_{aq,0}$ are the aquifer horizontal specific discharge and the contaminant concentration in the aquifer upstream from the landfill, respectively.

Equations 1, 10, 11 and 12 describe the interaction between the waste, the barrier system and the aquifer. The aquifer represents the natural resource to be protected from the potential harm caused by the contaminant migration from the waste leachate. As a result, the determination of c_{aq} allows the impact of landfill contamination on the potential use of the groundwater to be assessed. For instance, c_{aq} may be compared with a threshold value related to the production of drinkable or irrigation water from a well located in correspondence with the compliance point just downstream from the landfill.

3 APPLICATION EXAMPLE

The following example is provided to illustrate how the previously defined set of equations can be employed in order to assess the effectiveness of a landfill barrier system. The solution of Equations 1, 10, 11 and 12 may be obtained numerically by using the forward Euler method to integrate with respect to the time t, or analytically by using similarity transformations.

The barrier system consists of a composite liner constituted by a 2.5 mm thick geomembrane liner (GML) and a 1 m thick compacted clay liner (CCL), which overlies a 3 m thick attenuation layer (AL), as shown in Figure 2.

The height of the ponded leachate in the leachate removal and collection layer, h_p, is assumed equal to 0.3 m, and the hydraulic head difference between the top of the mineral layers and the bottom of the attenuation layer, is supposed equal to 3 m (Figure 2).

The physical, hydraulic and transport parameters that have been assigned to the geomembrane and the mineral layers are reported in Figure 2 and in Table 1.

The analysis is developed for benzene, which is a common component of municipal solid waste landfill leachates. The release of benzene is assumed to occur from a 30 m-thick waste deposit, which is characterized by a bulk leachate partition coefficient $B_l = 4$. The decay constant λ is calculated from the upper value for the half-life of benzene given by Howard *et al.* (1991), which is 730 days, and results in being equal to $1.1 \cdot 10^{-8}$ s^{-1}.

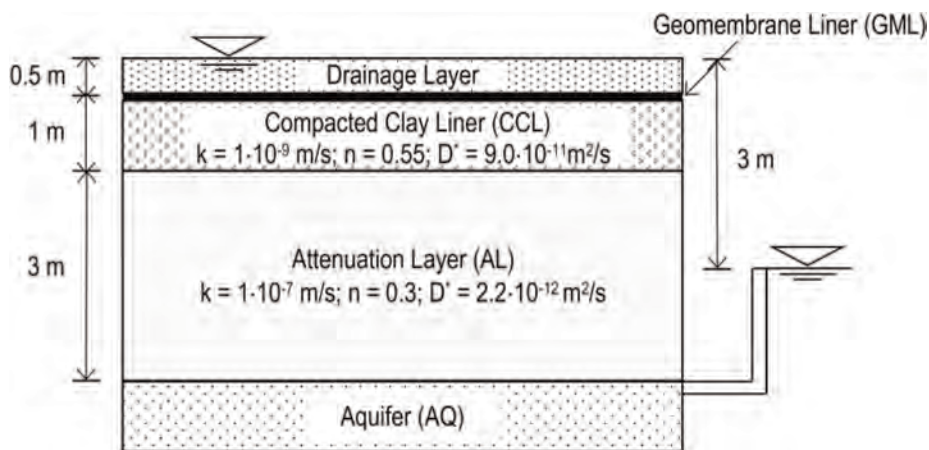

Figure 2. Scheme of the barrier system considered in the example analysis.

Table 1. Physical, hydraulic and transport parameters of the geomembrane and the mineral layers of the barrier system.

Parameter	Mineral layers	
	CCL	AL
Thickness, L (m)	1	3
Hydraulic conductivity, k (m/s)	$1 \cdot 10^{-9}$	$1 \cdot 10^{-7}$
Porosity, n (-)	0.55	0.3
Effective diffusion coefficient, D* (m²/s)	$9.0 \cdot 10^{-11}$	$2.2 \cdot 10^{-10}$
	Geomembrane	
Thickness, L_g (m)	0.0025	
Partition coefficient for benzene, K_g (-)*	30	
Diffusion coefficient for benzene, D_g (m²/s)*	$0.35 \cdot 10^{-12}$	

*data from Sangam and Rowe (2001).

The average porosity n_b of the barrier system is equal to 0.36. The retardation factor $R_{d,b}$, which is estimated from a distribution coefficient $K_d = 1.33$ ml/g (Hrapovic 2001) and an average dry density $\rho_d = 1.6$ g/cm³, results equal to 6.9.

The aquifer located beneath the landfill is assumed to be characterized by a porosity n_{aq} equal to 0.3, a retardation factor $R_{d,aq}$ of 8.1 and a thickness L_{aq} of 10 m. The horizontal groundwater volumetric flux just upstream from the landfill, $q_{aq,0}$, is equal to $1 \cdot 10^{-6}$ m/s (= 31.6 m/ year). The concentration of benzene upstream from the landfill, $c_{aq,0}$, is assumed to be null.

The analysis has been conducted to simulate the decrease in benzene concentration in the leachate released by the waste over time and the simultaneous increase in benzene concentration in the aquifer located beneath the landfill. The obtained results are shown in Figure 3. The benzene concentration in the waste leachate starts from a value of 1,000 mg/l and reduces to a value of about 1 mg/l after 20 years and 10^{-3} mg/l after 40 years. The reduction in benzene concentration is governed by the degradation process, which is modelled as a first-order decay reaction.

Figure 3. Results of the performed analysis, which show the change in time of the benzene concentration in the landfill leachate, c_l (on the left), and in the aquifer, c_{aq} (on the right).

The analysis takes into account the transport properties of the barrier system, which limits the advective transport through a negligible contribution. Assuming 2 holes/hectare in the geomembrane and poor contact conditions between the geomembrane and the underlying compacted clay liner ($C_q = 1.15$), the portion of the barrier area that results in being wetted is equal to only 0.7%.

The benzene concentration in the aquifer increases up to a peak value that is reached after about 3.5 years. The peak value of about $1.2 \cdot 10^{-4}$ mg/l is lower than the screening value that is indicated by the Italian regulation (10^{-3} mg/l). As a result, the benzene does not appear to cause any harm to the groundwater quality due to the effectiveness of the landfill barrier system.

4 CONCLUSIONS

The proposed approach for modelling the interaction between the waste, the lining system and the aquifer located beneath the landfill allows the impact of contaminant release on the groundwater quality to be assessed. The role played by the geosynthetics and the natural attenuation mechanisms, such as degradation and sorption, in limiting the contaminant migration can therefore be fully appreciated.

Geosynthetic sorption sheet—Another function of geosynthetics?

T. Kato, A. Takai, Y. Zhang, L.W. Gathuka & T. Katsumi
Graduate School of Global Environmental Studies, Kyoto University, Kyoto, Japan

Y. Kinoshita
Graduate School of Engineering, Former Student of Kyoto University, Kyoto, Japan

ABSTRACT: This paper discusses a novel geosynthetics sorption sheet that provides both sorption and traditional geosynthetic functions. In particular, the geosynthetic sorption sheet facilitates both water drainage and chemical barrier function. In this paper, batch sorption tests are used to evaluate the sheet's attenuation performance. The results of soil tank tests involving a 110 x 80 x 12 cm tank are also discussed. A key finding was the higher sorbed extent of arsenate compared with arsenite. The sheet absorbed more than 80% of the arsenic when it was contacted for 15 minutes with 0.1 mg/L of arsenate. Based on the soil tank test, ground particles surrounding the sheet are more important to seepage water distribution than the sheet itself.

1   INTRODUCTION

Excavated soils with geogenic contamination such as arsenic (As) or boron (B) are generated from various construction projects since these elements are widely distributed in several geologic strata such as marine clay layers, sedimentary rocks, hydrothermally altered rocks, etc. In Japan, these soils and/or rocks are expected to be used in embankments or other geotechnical applications to reduce the volume of soil disposal as well as to reduce the use of new soil materials. For such application, proper management against geogenic contamination is a primary engineering concern since groundwater contamination due to possible leaching of toxic elements is required to be prevented. Given the importance of developing economical and effective utilization methods for geogenic contaminated soils, effective countermeasures should be established.

Geosynthetic sorption sheets have been developed to contain the toxic elements from geogenic contaminated soils. By being installed below the excavated soils with natural contamination, the geosynthetic sorption sheet is expected to trap the contaminants. It might release the infiltrated water free from contaminants into the base soil layer to prevent groundwater contamination. The geosynthetic sorption sheet consists of sorptive material attached or adhered to the fabric. Several types of sorptive materials, such as hydrotalcite, are applied, and several types of fabric can also be used. Although knowledge has been accumulated on the sorption performance of various kinds of sorptive materials, sorption performances considering the effect of practical conditions, such as preferential flows and overburden pressures, need to be evaluated (Kinoshita *et al.* 2021). Therefore, in this study, the effect of preferential flow in the soil layer overlying the geosynthetic sorption sheet is experimentally evaluated.

2 GEOSYNTHETIC SORPTION SHEET

Utilization of surplus soil is quite important for material recycling. The amount of soil generated from construction work was more than 130 million m^3 in 2018 in Japan (MLIT 2020). Since such a large amount of soil is generated, the soil should be utilized as a geo-material for embankments, fill, etc., while geogenic contaminants are often contained in the excavated soil higher than the environmental standard values (e.g., Kato *et al.* 2023; Tabelin *et al.* 2018). Therefore, proper countermeasures must be taken to prevent contamination of the surrounding environment. However, if such contaminants are of natural origin, the exceeding degree is often within several times the standard value (e.g., Ito & Katsumi 2020; Naka *et al.* 2016). Toward sustainable development, although the standard is exceeded, if the concentration is relatively low, geogenic contaminated soils should be utilized as embankment material with proper countermeasures.

Containment methods using a geomembrane may be an effective way when geogenic contaminated soils are used for embankments. However, the interface between the geomembrane and soils may become a sliding surface. Further, the containment may be an excessive countermeasure, considering the low-concentration toxic chemicals such as the geogenic contaminants.

Geosynthetic sorption sheets have been developed as a promising countermeasure for geogenic contamination (e.g., Kinoshita *et al.* 2021; Miyawaki *et al.* 2022). Herein, the geosynthetic sorption sheet is placed under the excavated soils, as shown in Figure 1. This geosynthetics sorption sheet offers a new function of sorption, in addition to the traditional geosynthetics functions (reinforcement, barrier, drainage, separation, filtration, stabilization). Since the infiltration can be permitted, pore water does not accumulate in the embankment. Furthermore, the upper soil layer can be compacted. Therefore, the stability of the embankment can be maintained. While the sheet is cost-effective and has workability, some challenges remain to be solved. The reliability of the material may decrease in the case of clogging or preferential flow. For instance, when there is preferential flow, a limited area of geosynthetic sorption sheets may be involved in the sorption of toxic chemicals. Furthermore, the sorption kinetics should be investigated since a short contact time is expected for the sheet considering the in-situ condition.

Figure 1. Application of the geosynthetic sorption sheet for geogenic contaminated soils.

3 MATERIALS AND METHODS

3.1 *Materials*

Figure 2 shows the geosynthetics sorption sheet manufactured by TOYOBO CO., LTD used in this study. One side of the sheet is a hydrophilic long-fiber nonwoven fabric coated with an artificial hydrotalcite compound. The hydrotalcite is adjusted to a nano-size of about 10 nm, and 5.0×10^{-2} kg/m^2 of hydrotalcite is coated. The thickness of the sheet is 2.8 mm. The
Figure 2.   Geosynthetics sorption sheet used in this study.

hydraulic conductivity is 1.7×10^{-3} m/s (JIS A 1218 2009). The pore size range of the sheet was approximately 10–120 μm, and the average pore size d_{50} was 47 μm.

3.2   Batch sorption tests

Batch sorption tests were conducted to evaluate the sorption performance against arsenic (As) contamination under different contact time to evaluate the sorption kinetics. Figure 3 shows the test setup. Since arsenic mainly exists in the solution as either arsenite [As(III)] or arsenate [As(V)] (Mohan & Pittman 2007), As(III) and As(V) solutions were prepared with the sodium arsenite (NaAsO$_2$) and sodium dihydrogen arsenate (Na$_2$HAsO$_4$ 7H$_2$O) salts, respectively. The salts were dissolved in distilled water to prepare concentrations between 0.1–20 mg/L. A 200 mL of As solution and the geosynthetic sorption sheet cut to 80 mm $\times$ 50 mm were put in a plastic bottle. Afterward, the bottles were horizontally shaken between 5 minutes and 24 hours at 150 rpm using a mechanical shaker (TAITEC TS-10) under room temperature ($\sim$20°C). Three replicate tests were performed for each solution.

Figure 3.   Set up of the batch sorption tests.

After the sample preparation mentioned above, centrifugation at 3000 rpm for 10 min and filtration with a 0.45 μm membrane filter was carried out to separate the liquid from the solid. The pH of the filtrate was measured using a pH/EC meter (Horiba F-54). The As concentrations were measured using an atomic absorption spectrophotometer (Shimadzu AA-6800). The As removal ratio was calculated using equation (1), shown below:

$$R = \frac{C_0 - C}{C_0} \times 100 \tag{1}$$

where R refers to the removal ratio of As (%), C_0 refers to the As concentrations before the batch sorption tests (mg/L), and C refers to the As concentrations after the batch sorption tests (mg/L).

3.3 Water flow conditions using soil tank tests

Soil tank tests were conducted to evaluate the effect of the preferential flow on the performance of the geosynthetic sorption sheet. The tests were conducted using three different silica sands. Table 1 shows the properties of the silica sands. The soil tank employed was 110-cm wide, 80-cm high, and 12-cm deep, as shown in Figure 4(a). The bottom part of the soil tank consisted of six valleys and water sampling holes (drilled in the bottom of the valley), as shown in Figure 4(b). The seepage water was drained from each water sampling port.

Filter paper was installed at the sampling port at the bottom to prevent the soil particle from flowing out of the tank. Then, the soil layer below the sheet was filled. The air-dried silica sand was filled to achieve a compaction degree of 90%, based on the maximum dry density and optimum water content shown in Table 1. The layer was filled to a height of 1.5 cm from the valley's top, as shown in Figure 4(b). Once the soil layer was filled, the horizontality of the surface layer was confirmed using a level. Next, the geosynthetic sorption sheet cut to 108 cm in width was laid on the soil layer. After that, the same silica sand of the bottom layer was compacted on the geosynthetic sorption sheet with a height of 1 cm. After confirming the horizontality of the top surface of the soil sample using a level, a 3 cm × 3 cm non-woven fabric was laid above the water sampling port (C) to prevent disturbing the silica sand.

After filling the tank with sample, the pump was adjusted to spray water with an intensity of 200 mL/h. Water was sprayed directly above the water sampling port (C), assuming the preferential flow. First, the amount of infiltrated water from each sampling port was measured. Once the difference in the discharged water per hour from the port per hour was less

than 5%, it was considered that steady state condition was attained. Then, tests were terminated after measuring the amount of water released per hour. The water contents of silica sand near each port were also measured. Each soil tank test was repeated twice.

4 RESULTS AND DISCUSSION

4.1 Arsenic sorption performance

Figure 5 shows the results of the batch sorption tests. The removal ratio of As(V) was higher than that of As(III), as shown in Figure 5(a). This is because more than half of As(III) exists in the neutral region as H_3AsO_3 with no ionic form or $H_2AsO_3^-$ as an anion with a single form (Smedley & Kinniburgh 2002). On the other hand, more than half of As(V) exists in the state of having the divalent anion $HAsO_4^{2-}$ or the monovalent anion $H_2AsO_4^-$. Since the hydrotalcite compound capture arsenic due to anion exchange (Bhaumik et al. 2005), relatively high sorption performance can exhibit for As(V), which shows stronger electric attraction, while the anion exchange was relatively challenging to occur for As(III).

Figure 5(b) shows that the sorption reaction of As reaches nearly equilibrium at 12 hours because almost the same removal ratio is obtained between 12–24 hours. Even though the short contact time is applied, more than 60% of arsenic can be sorbed by the sheet. This result supports the sorption sheet can be one of the promising countermeasures against geogenic contamination. In addition, the higher the initial concentration of arsenic, the lower the removal ratio obtained. Sorption performance of the geosynthetic sorption sheet is affected by the arsenic concentration of leachate, thus the leaching concentration of a given excavated soil should be carefully investigated.

In the case of As(V) with C_0 = 0.1 mg/L, the removal ratio was higher than 80% at the contact time of 15 minutes. Therefore, if the arsenic contained in the leachate is about 0.1 mg/L of As(V), which corresponds to 10 times the environmental standard value in Japan, enough sorption capacity could be performed even with a short contact time of 15 minutes. This result suggests that sufficient sorption performance can be expected even with a thin geosynthetic sorption sheet that cannot ensure a long contact time with the geogenically contaminated seepage.

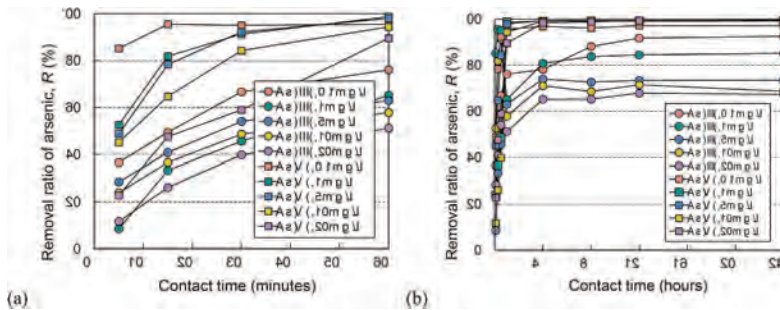

Figure 5. Results of the batch sorption tests of (a) 0–60 minutes, and (b) 0–24 hours.

4.2 Drained seepage from the soil tank tests

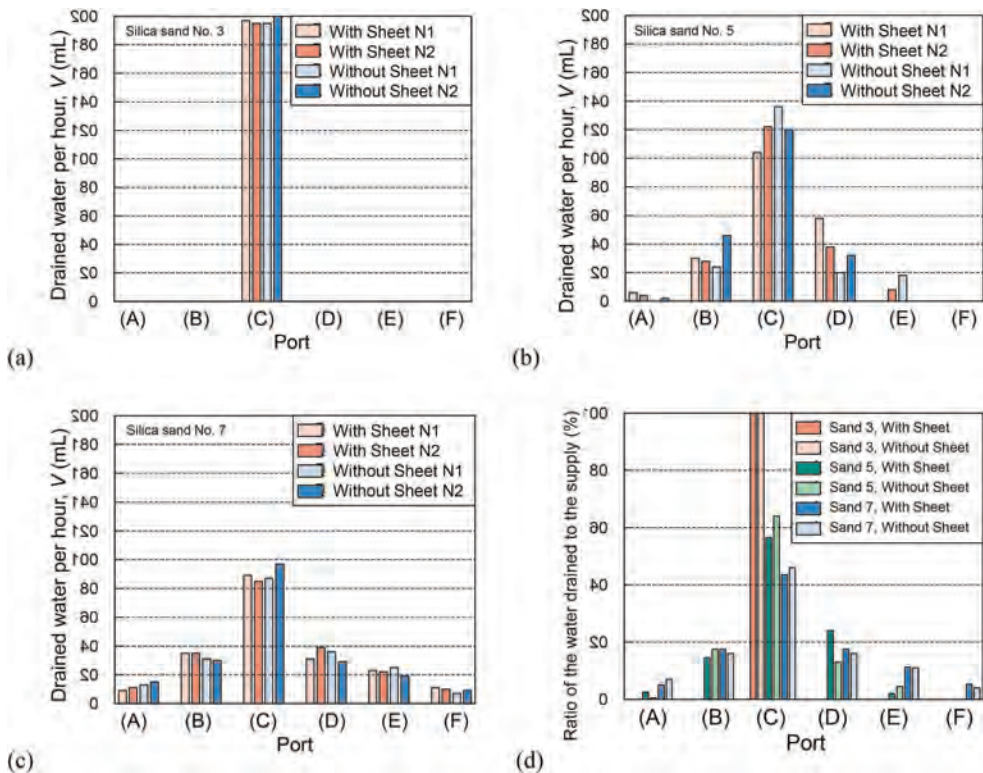
Figure 6 shows the amount of drainage per hour from each water sampling port in a steady state when watering is performed. As shown in Figure 6(a), when silica sand No. 3 with a large particle size was used, almost all 200 mL of water sprinkled was drained from the port (C). Judging from Figure 6, the soil tank test was conducted with relatively good


Figure 6. Results of the soil tank tests for (a) Silica sand No.3, (b) Silica sand No.5, (c)) Silica sand No.7, (d) comparison of the effect of installing geosynthetic sorption sheets.

repeatability for duplication. When silica sand No. 5, with a smaller particle size than silica sand No. 3, is used, infiltration water was obtained not only under the watering position (C) but also from (A) to (E), as shown in Figure 6(b). The amount of drainage from (C) was the largest. These results confirmed that a certain amount of infiltrated water could be distributed even with silica sand No. 5, which has a relatively larger grain size than No. 7 and is single-grained soil. As shown in Figure 6(c), when silica sand No. 7, which has a smaller particle size than silica sand No. 5, is used, the amount of drainage from directly below the watering position (C) decreases, and (A) and (E) further increased the amount of water discharged. This result suggested that the infiltration water could be more distributed in the ground with smaller grain sizes.

Figure 6(d) shows the ratio of the amount of drained water from each port. The average value of the test results of two repetitions is shown. For example, focusing on port (C) in Figure 6(d), with silica sand Nos. 5 and 7, the amount of water from (C) was slightly affected by the presence of the sorption sheet, but the difference was not significant. The particle size of the ground surrounding the sheet may affect the seepage water distribution more than the presence the sorption sheet.

5 CONCLUSIONS

When applying geosynthetic sorption sheets, materials that can attenuate contaminants in a short time should be selected. This study revealed that the geosynthetic sorption sheet

exhibits high sorption performance for arsenic even under short contact times. Especially in the case of low concentration, such as geogenic contamination, high sorption performance is expected.

The embankment using geogenically contaminated soils should be constructed to permeate seepage water evenly to the sheets. The seepage water was more distributed in the ground with smaller grain sizes. One reason is that the smaller the soil particles, the greater the suction. Therefore, the surrounding soil layer should be sufficiently compacted when installing a geosynthetic sorption sheet. Further, applying fine-grained soil is recommended so that the soil layer retains pore water for longer periods.

Filtration and drainage

Effect of installation under Nordic conditions on drainage geosynthetics: ROUGH project

H. Ehrenberg
Naue GmbH & Co. KG, Germany

C. Recker
Sintef Community, Münster, Germany

Ph. Delmas
Sintef Advisor, France

ABSTRACT: On request of Finnish Transport Infrastructure Agency (Finland), Norwegian Public Roads Administration (Norway) and Swedish Transport Administration (Sweden), Sintef (Norway) has prepared guidelines on the use of geosynthetics in Nordic conditions. The ROUGH project (RecOmmendations for the Use of GeosyntHetics in Nordic conditions) has been realised together with several manufacturers of geosynthetics. The paper focuses on the behaviour of drainage geosynthetics during installation in Nordic conditions. The test conditions included prior storage at Nordic temperatures under which the products were also installed, Nordic conditions such as crushed rock and compaction, followed by laboratory tests of the exposed and unexposed geosynthetic samples.

1 INTRODUCTION

In order to be able to propose recommendations for the use of different kinds of geosynthetics in Nordic conditions, an investigation was carried out to collect information and provide data on their behaviour during installation in Nordic conditions (sub-zero temperatures, soil types and working conditions) (ROUGH project 2022). The investigation included a full-scale trial at a site in Northern Finland, 15 km southeast of Kemi along the E8/E75. Drainage geosynthetics were installed at sub-zero temperatures ($-10°C$) under Nordic conditions, followed by tensile and compressive creep testing of the exhumed materials alongside non-exposed materials at temperatures of $+20°C$, $0°C$, $-10°C$ and $-20°C$. Installation and removal of the geosynthetics took place on 5th and 6th February 2020.

The drainage geosynthetics were installed on the locally available frozen soil. A layer of crushed rock was then dropped over the drainage geosynthetics and compacted using typical construction machinery. The test setup was dismantled, materials were excavated, and samples taken for laboratory tests.

Two different drainage geosynthetics have been tested with different product structures and produced with polyolefin.

2 CLIMATIC CONDITIONS FOR THE INSTALLATION TRIAL

The temperature was recorded on site and compared with the data provided online by the Finnish Meteorological Institute (www.ilmatieteenlaitos.fi) from the nearest weather station at Kemi Airport (distance 20 km). Temperatures measured on site matched the weather data. For

this reason, the data recorded hourly by the Finnish Meteorological Institute were used to indicate the temperatures during the storage on site and installation of the geosynthetic products. During installation of the products and compaction of the layers of crushed rock material, the air temperature ranged between – 7°C and – 15°C. No snow needed to be removed from the test section and no snowfall occurred during the installation and filling work. During the deconstruction/recovery of the samples on Thursday, 6th February 2020, temperatures between – 4°C and – 7°C were recorded.

3 CRUSHED ROCK MATERIAL

The material used for the subgrade was a typical locally available soil which was frozen.

The material used for the base layer was typical for Finnish road construction and unbound granular subbases. Figure 1 displays the particle-size distribution of the material used together with the limit values presented in Finnish guidelines InfraRYL for the base course. The material is named as "KaM 0/56" which means it is crushed rock GO 0/56 mm based on SFS-EN 13242.

Figure 1.   Particle-size distribution of crushed rock used and the Finnish limit values for base material.

4 TRIAL SETUP AND CONSTRUCTION

Construction of the trial sections followed Finnish specifications for road construction. Figure 2 shows the cross-section of the setup. The material used for the subgrade was a typical locally available, frozen soil. The material temperatures were checked with a penetration thermometer approx. 5 – 10 cm below each layer surface.

Figure 2.   Cross-section of field trial setup.

In order to minimise positional influences, each product was cut in half and installed at two different locations along the test field. Before installation, the locations of specimens for further laboratory testing were marked. A drawing of the arrangement of the products, and specimens of the products, are given in Figure 3.

TEST SETUP B: DRAINAGE

TOP VIEW AND LOCATION OF SPECIMEN SCALE 1:100

RAMP AREA

RAMP AREA

| Test point	E [MPa]
TP1	117
TP2	82
TP3	98
TP4	97

Figure 3.   Arrangement of drainage geosynthetic samples.

The drainage geosynthetics were then placed, and finally the base layer of 0/56 crushed rock was dropped with an excavator bucket on the geosynthetics with a measured height of 1.0 m and compacted to a finished layer thickness of 30 cm.

Compaction was done with a 12.6-ton dynamic roller. Five dynamic roller passes were used for compaction of each layer. Compaction control was carried out with a dynamic load plate testing device (a.k.a. portable falling weight deflectometer). The location and results of the compaction control of each layer relative to the sample location were registered. During the compaction process the subsoil had a temperature of about – 6°C. Freshly delivered crushed rock material had a temperature of approx. – 6°C. Before installing the geosynthetics, subbase temperatures of about – 12°C were recorded.

5   RECOVERY OF SAMPLES

Samples needed to be cut from the drainage specimens for testing and evaluation of installation damage. To avoid additional damage to the samples during recovery a suction technique was used. The upper 20 cm of the base layer were removed carefully by excavator as shown in Figure 4 and the remaining 10 cm using a vacuum suction lorry.

Figure 4.   Removing soil with the vacuum / sucking lorry.

Figure 5.   Marked samples for sampling.

After all, the base layer had been removed, samples were cut from the previously marked locations as shown in Figure 5 and labelled. The marking included the product identifier and location in the installed test setup. For transport to the laboratory, the samples cut out were stacked in a robust wooden box with fabric between to avoid mechanical damage or other degradation during the transport.

6 LABORATORY TESTING

Tests were performed on conditioned samples returned from the field trial ('damaged') and on samples taken from the same product specimens not delivered to site ('undamaged'). Temperature conditioning of the undamaged samples provided information on the effect of the temperature on the product behaviour.

6.1 *Testing in temperature-controlled environment*

The damaged samples from Kemi were tested at $+ 20°C$ to determine the corresponding evolution of several characteristics. The tests were focused on the compression behaviour (EN ISO 25619-2) and the hydraulic capacity (EN ISO 12958-1), but also on tensile behaviour (tensile strength and strain acc. EN ISO 10319).

Parallel testing on undamaged samples was carried out in a temperature-controlled chamber as shown in Figure 6. The test specimens were temperature-conditioned for one hour before testing began. After placing the samples in the test rig, the chamber temperature was allowed to stabilise at the required test temperature before testing commenced. The tests were carried out following EN ISI 26619-2 to determine compression strength/strain characteristics.

Non-damaged samples were tested at $– 20°C$, $– 10°C$, $0°C$ and $+ 20°C$.

Figure 6.   Compression test specimen before realisation of test in temperature-controlled chamber. The temperature-controlled chamber can be seen at the back of the photo.

6.2 *Results – Influence of the installation under crushed rock at a temperature of – 10°C on mechanical and hydraulic behaviour of the drainage composites*

Comparison of the tensile strength and strain (20 cm) of the products exposed at Kemi to the installation at $– 10°C$ in crushed rock and tested at $+ 20°C$ in the laboratory versus the "virgin" products shows that the 2 drainage geosynthetics show a similar behaviour when

exposed to the Kemi installation conditions with a reasonable reduction in tensile strength (between ∼ 25 % to ∼ 30 %) and a slightly higher (but still reasonable) reduction in tensile strain (between ∼ 30 % to ∼ 40 %).

Considering the compression behaviour, the 2 products show quite a similar increase of the compression strain when exposed to the Kemi installation conditions (between ∼ 20 % and ∼ 30 %). Whereas the compression strength shows a greater difference between the 2 products, almost no change for 1 product where the other shows a decrease of compression strength of ∼ – 30 %.

The evolution of the drainage waterflow capacity of the products (when exposed, or not, to the Kemi installation conditions) shows a similar decrease on waterflow capacity as on the increase of compression strain (between ∼ 20 % and ∼ 30 %).

6.3 Results – Influence of the temperature (between + 20°C and – 20 °C) on mechanical behaviour of the un-damaged drainage composites.

The tensile tests realised at different temperatures on the undamaged drainage geosynthetics show a quite similar behaviour for the 2 products: a regular increase in the compression strength when the temperature decreases until – 20°C, an increase in the compression strain when the temperature decreases until – 10°C and then remaining constant until – 20°C.

The measurement of the compression strain under 1 MPa is also very interesting to evaluate the evolution of the drainage capacity of the geosynthetic under load. The tests (acc. EN ISO 25619-1) realised at different temperatures (+ 20°C, 0°C, – 10°C, – 20°C) show (Figure 7) almost no influence of the different temperatures on the results (the increase of strains is always ≤ 10 %).

Figure 7. Evolution of the drainage capacity when the products are exposed to the Kemi installation conditions: reduction of waterflow capacity versus increase of compression strain.

7 CONCLUSIONS

When the drainage geosynthetics tested are installed under crushed rock and compacted under normal conditions at – 10°C, the reduction in both tensile strength and tensile strain remains in a reasonable range, which is acceptable for normal use of drainage composites. This means that, if a product is correctly designed for a positive temperature (e.g., + 20°C) for the defined geotechnical conditions of installation (type of soils, drop height, compaction, etc.), no extra installation damage due to negative temperature (−10°C) was observed on the tensile strength and strain.
Figure 8. Evolution of the strain at 1 MPa of the products when exposed to different temperatures (+ 20°C, 0°C, – 10°C, – 20°C).

The compression strain at 1 MPa enables a comparison of the behaviour at different temperatures under the same geotechnical conditions. The laboratory tests show that there is almost no influence of strain at 1 MPa at the different temperatures down to – 10°C. As shown on the samples from Kemi ($-10°C$, crushed rock, compaction), a compression strain increase seems related to a similar reduction in water flow capacity.

Thus, it can be expected that the decrease of the water flow capacity linked to low temperature (e.g. – 10°C) should be reduced by only $\sim$ – 4 % to – 5%. The effect of the minus temperature ($-10°C$) on the further hydraulic capacity of the geosynthetic drainage composites appears to be negligeable.

For the defined Nordic conditions in the Kemi study (soil type – gravel, drop height 1 m, compaction, etc.), it is shown for 2 drainage geosynthetics that if these are properly designed to cause minimal installation damage at the usual plus temperatures at the site (i. e. above zero °C), there is no need for extra reduction factors when these products are properly installed at the temperatures below the freezing point of – 10°C.

Factors affecting the long-term performance of biplanar geonet-geocomposites

E. Blond
Eric Blond Consultant Inc., Montreal, Canada

A. Maskal
Solmax, Houston, TX, USA

ABSTRACT: Geonet-geocomposites are a common replacement for granular drainage layers, providing drainage, venting, and capillary separation for controlling water content in soils, and controlling hydraulic head around buried structures. This paper describes the mechanisms influencing the long-term compressive properties and flow rate of biplanar geocomposites. For the same structure of product, a relation between the mass per unit area and the capacity of the product to resist sustained stress is quantified using laboratory tests covering aspects such as creep and geotextile intrusion. Results are explained in the context of recent normative developments, i.e., in ISO 18228-4, and ASTM D7931.

1 INTRODUCTION

Drainage geocomposite are widely used to replace granular drainage materials and consequently reduce overall project carbon footprint. HDPE biplanar geonet-geocomposites are the most commonly used geosynthetic drainage products, with the largest number of documented case histories.

However, HDPE can creep, as do most polymers. Therefore, long-term flow capacity of drainage geocomposites must be established, especially for moderate- to high-compressive load applications. These considerations are well-covered in design and specification standards such as ISO 18228-4 and ASTM D7931.

2 IMPACT OF THE STRUCTURE OF BIPLANAR GEONETS ON THEIR PROPERTIES

A drainage geocomposite is comprised of filter geotextiles laminated onto one or both sides of a geonet core. The focus of this paper is biplanar geocomposites in which the geonet core is comprised of two stacked layers of ribs. The ribs within a given layer are parallel to one another and oriented at an angle to the ribs in the other layer. The two layers of ribs are extruded simultaneously to form a monolithic, seamless product as described on Figure 1.

The geonet and the geotextiles both contribute to the performance of a geocomposite. The geonet core is designed to provide compression resistance and to maintain an open structure for carrying water and gases, and the geotextile acts as a filter and supports adjacent materials between the ribs to resist intrusion into that void space.

Wider spacing between ribs allows higher flow capacity within the body of a geonet when used between rigid boundaries. Narrower spacing reducing geotextile span that would allow

Figure 1.   A drainage geocomposite.

the geotextile to sag into the core (i.e., geotextile intrusion, which directly affects its drainage capacity).

Tall/narrow rib shapes provide more open space to accommodate fluid flow, while wider/round ribs have a uniform moment of inertia that resists rollover when placed under compressive load. A slenderness factor can be defined as the ratio between the height and the width of the rib. For a similar mass per unit area, a higher slenderness factor will create a product with higher flow capacity under low normal loads, while a lower slenderness factor will create products with better compressive and creep resistance.

Properties of the geotextile and their lamination onto the geonet core can also affect the geotextile intrusion and consequently the drainage capacity. Higher tensile modulus and lower mass geotextiles generally reduce the amount of intrusion that occurs. The lamination process increases the tensile modulus and confines loose geotextile fibers by calandaring the interior geotextile surface, thereby reducing flow friction from the geotextiles. The lamination process may also slightly increase the crystallinity of the core by way of exposure to a second heating step followed by a (slow) air cooling as opposed to the much faster water quench water cooling used when manufacturing geonets. The thermal history during the lamination process thereby improves the compressive properties of the geonet-geocomposite.

The lamination process involves 2 cylinders between which the geocomposite passes. The distance between these cylinders will affect the shape of the core of the geocomposite, hence its mechanical properties. It will also affect the final thickness of the product, hence its flow rate. Light-weight products with ribs exhibiting a large shape factor may initiate strand rollover during lamination, which can reduce either, or both short- and long-term compressive properties of the geocomposite.

Overall, the long-term hydraulic properties of geonet-geocomposites is the result of a variety of choices which are to be made during the manufacturing process. The most critical ones include the properties of the raw materials (HDPE resin, additives, polypropylene fibers), mechanical properties of the geotextile(s) before lamination, shape of the ribs of the geonet (slenderness factor), distance and angle between the ribs, mass per unit area of the geonet, lamination process and distance between the lamination rolls. However, a range of products is produced from a given extrusion die, varying the mass per unit area of the core. Therefore, when the manufacturing parameters are consistently set from one grade to the other, it is possible to establish trends connecting basic manufacturing parameters such as mass per unit area with the engineering properties of the product.

3   DESIGNING USING ISO 18228-3 OR ASTM D7931

3.1   *Standard and theoretical background*

Long-term flow 'q_{allow}' is assessed using a method first developed by BAM in Germany (reference), adapted by GSI (GRI GC8), and eventually by ASTM D7931 and ISO 18228-4. It is based on a short-term flow test (q_{100}, measured after 100 hours) and reduction factors.

$$q_{allow} = \frac{q_{100}}{RF_{CR} \times RF_{CC} \times RF_{BC} \times RF_{GI} \times RF_{L}} \qquad (1)$$

With:

- q_{100}: Flow rate obtained on the geocomposite after 100 hours seating time using representative normal stress, hydraulic gradient, and boundary conditions.
- RF_{CR}: Reduction Factor for Creep.
- RF_{CC} and RF_{BC}: Reduction Factor for Chemical Clogging and Biological Clogging.
- RF_{GI}: Reduction Factor for (long-term) Geotextile Intrusion, beyond the initial intrusion.
- RF_{L}: Reduction Factor for Laboratory uncertainties.

q_{allow} and q_{100} can be replaced by transmissivity θ_{allow} and θ_{100}. Figure 2 illustrates the effect of creep, geotextile intrusion on the volume of the cavity available for water to circulate, as well as on the differences between the short-term geotextile intrusion, which is already captured in q_{100}, and the long-term geotextile intrusion caused by additional creep of the geotextile.

Figure 2.   Distinction between creep, long-term, and short-term geotextile intrusion.

Creep and geotextile intrusion RF are defined using the strategy illustrated on Figure 3:

(1) A creep test accelerated using the Stepped Isothermal Method (SIM) per ASTM D7361, to assess the residual thickness of the core after a given service life. The test must be performed under a test load greater, or equal to the anticipated service load. The change of thickness between 100 hours (i.e., the seating time used in Equation 1) and the service life (typically 100 years) is assessed using the SIM test.
(2) Using a representative short-term compression test, it is possible to define surrogate loads σ_{100h} and σ_{SL} that will compress the core to the thickness reached after 100 hours or the service life.
(3) Using flow capacity tests performed under the surrogate loads σ_{100h} and σ_{SL}, it is possible to assess the effect on the flow capacity of the product of a deformation of the core to a magnitude equivalent to the creep deformation anticipated over a duration of 100 hours, or the Service Life 'SL', using a short-term flow test. To distinguish the effects of the creep of the core to the effects of the long-term geotextile intrusion, 2 tests are considered:
   (a)   A flow test using rigid boundaries, where the flow reduction is only caused by the change of thickness of the core, hence, to the creep of the core. Such a test is

performed to measure $q_{100h(R/R)}$ and $q_{SL(R/R)}$, the short-term flow capacities measured under the surrogate loads σ_{100h} and σ_{SL}.

(b) When boundaries of the geocomposite are not rigid, a flow test using boundaries representative of the anticipated service conditions (i.e., soil / rigid, or soil / soil), where the flow reduction is associated to the change of thickness of the core as well as additional geotextile intrusion into the core caused by creep of the geotextile. Such a test is performed to measure $q_{100h(R/S)}$ and $q_{SL(R/S)}$ (e.g., in the case of Rigid/Soil boundary), which are short-term flow capacities measured under the surrogate loads σ_{100h} and σ_{SL}.

(4) The value of RF_{CR} and RF_{GI} are calculated as follow:

(a) RF_{CR} is obtained by dividing $q_{100h(R/R)}$ and $q_{SL(R/R)}$.

(b) $q_{100(R/S)}$ is reduced by both creep and geotextile intrusion. When dividing $q_{100h(R/S)}$ and $q_{SL(R/S)}$, the value obtained is thus the product of both RF_{CR} and RF_{GI}. Hence, RF_{GI} is obtained by dividing $q_{100h(R/S)}$ and $q_{SL(R/S)}$, and then by dividing the obtained ratio by RF_{CR}.

$$\frac{Q_{100h(R/S)}}{Q_{SL(R/S)}} = RF_{CR(R/S)} \times RF_{GI(R/S)} \tag{2}$$

3.2 Practical approach – assessment of the RF_{CR} and RF_{GI} for a complete line of products

Assessing the value of Reduction Factors applicable to each normal stress, boundary conditions and grade of product likely to be encountered for all possible applications of drainage geocomposites would be extremely costly and time-consuming, should it have to be performed one product at a time. However, it was observed (Blond 2023) that for properties of biplanar geocomposites are correlated to the weight of the specimen when manufactured on the same production line, using the same resin and production parameters, and when the distance between lamination rolls is adjusted to create a thickness proportional to the weight of polyethylene.

Figure 3. BAM / ISO 18228-4 strategy for determination of the RF.

Based on this observation, it was possible to build a series of abacus, which can be used to establish RF_{CR} and RF_{GI} for any grade of product (i.e., mass per unit area of the core) from a given type of biplanar geocomposite manufactured on a given production line, using 240 g/m^2 geotextiles on each sides, and exhibiting a total mass per unit areas between 1400 and 2400 g/m^2 (including the geotextiles). These abacuses are reflecting experimental data obtained for this specific family of products, using specimens with mass per unit areas covering the range of products:

– Creep deformation versus applied stress, as a function of the total mass per unit area of the geocomposite, for a creep time of 100 hours (i.e., reference flow) and 100 years (i.e., a typical service life) (Figure 4). These abacuses were built by extending the result of a creep test performed to a given load to lower normal loads, considering a linear relation between applied load and creep deformation for a given service life.

– Surrogate load to be considered to reflect a creep deformation of 5, 10 or 15% (i.e., covering a range of typically acceptable creep deformation for a geonet geocomposite, to avoid excessive plastic deformation), as a function of the mass per unit area of the geocomposite. These abacuses were established based on a series of compressive tests where the mass per unit area of the geocomposite was controlled. For each service load considered, the compressive curve was translated to define a zero-deformation corresponding to the thickness of the product under that service load.

– Flow versus mass per unit area, for a variety of normal stresses.

Figure 4.   Creep deformation as a function of the mass per unit area.

Example of use of the abacus for the assessment of a geocomposite with a mass of 1700 g/m^2 (including 2x 240g/m^2 geotextiles) exposed to a load of 500 kPa for 100 years between soil and a geomembrane:

(1) Figure 4 indicates a retained thickness of 95.8% (100 hours) and 90% (100 years), hence creep deformations of 4.2 and 10%.
(2) The surrogate load can be read in Figure 5 as ∼900 kPa (by extrapolation) for 100 hours and 1500 kPa for 100 years.
(3) From Figure 6, it is possible to project the residual flow:
   – Rigid/Rigid boundaries, 1700 g/m^2: ∼$1.1 \cdot 10^{-1}$ l/s/m under 900 kPa (i.e., surrogate load for 100 hours under 500 kPa), and ∼$6 \cdot 10^{-2}$ l/s/m under 1500 kPa (i.e., surrogate load for 100 years under 500 kPa), hence $RF_{CR} = 1.1 \cdot 10^{-1}/6.10^{-2} = 1.8$.
   – Rigid/Sand boundaries, 1700 g/m^2: ∼6.10^{-2} l/s/m under 900 kPa, and ∼$1.6.10^{-2}$ l/s/m under 1500 kPa, hence $RF_{CR}.RF_{GI} = 6.10^{-2}/1.6.10^{-2} = 3.8$.

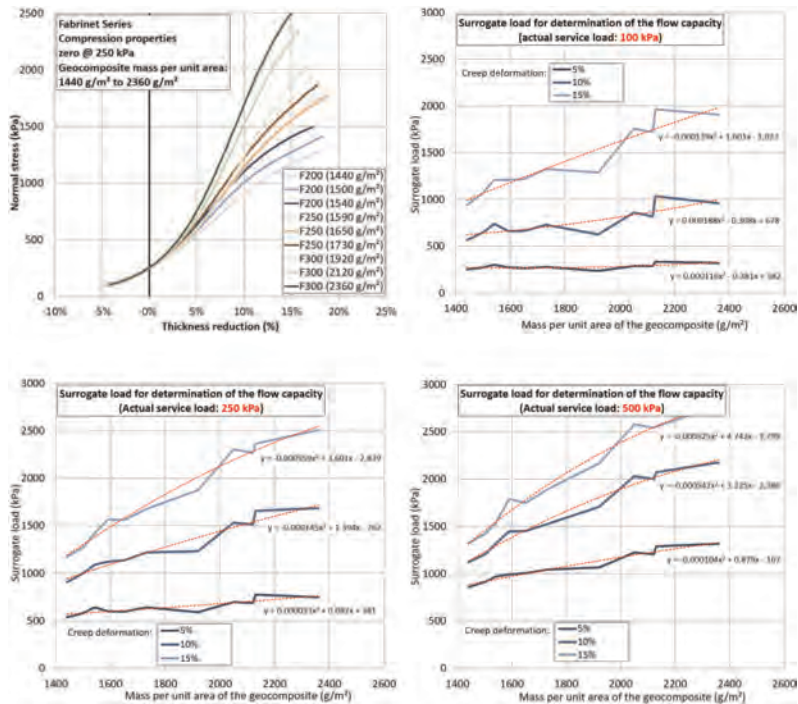
Therefore, it is possible to conclude that the reduction factors applicable to a 1700 g/m^2 geocomposite exposed to 500 kPa between sand and a geomembrane are: $RF_{CR} = 1.8$ and $RF_{GI} = 2.1$.


Figure 5.   Compressive behavior, Surrogate load as a function of mass per unit area and flow capacity.

4   DISCUSSION

Using equation 2, the abacus presented on Figures 4, 5 and 6 can be used to establish RF_{CR} (and RF_{GI} when applicable) of a product, based on the mass per unit area of the product, the applied load, and the service life.

These abacuses are only applicable to products manufactured with a specific resin using good manufacturing practices on a specific production line, and for which the thickness is to be proportional to the unit weight when laminating the geotextiles to the core. This can be verified by observing a monotonic and regular change of properties with the mass per unit area, as well as with the normal stress.

Based on data not presented here, it was found that changes made to the morphology of the product during the geotextile lamination process significantly affect the initial thickness of the core and its compression and creep behaviors. It is therefore not possible to extend the use of RF values obtained on a geocomposite to the geonet alone, i.e., not laminated to geotextiles.

5   CONCLUSIONS

Several factors affect the water flow capacity of a drainage geocomposite, and in particular the shape of the ribs, distance between ribs, type of geotextile used, and manufacturing parameters used during the lamination process.

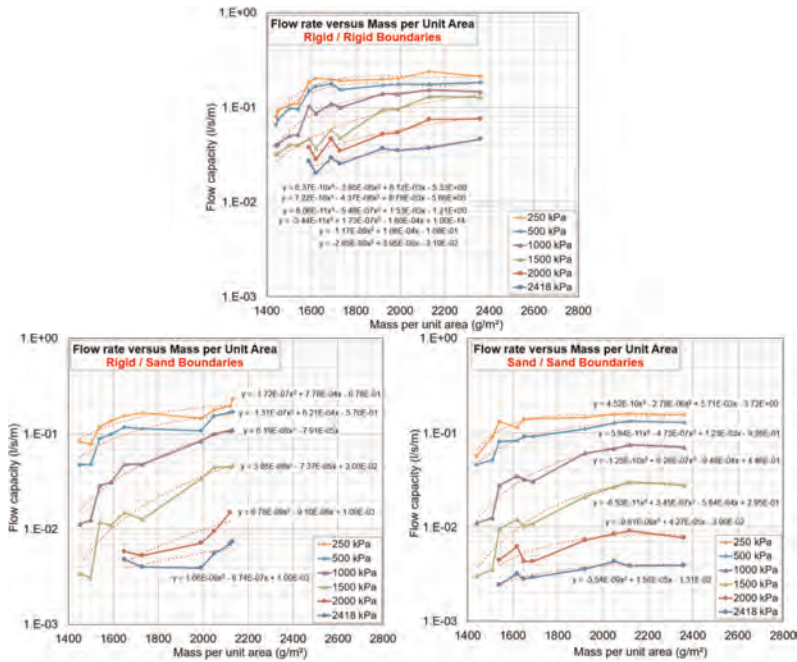
For a given line of products manufactured on the same equipment, using the same resin and extrusion parameters and good manufacturing practices, the mass per unit area of the geonet is considered to be directly correlated to both short- and long-term properties of the product. It is therefore possible to establish a series of abacuses to determine the reduction


Figure 6. Flow capacity as a function of mass per unit area and applied stress for 3 boundary conditions.

factors which should be used for creep RF_{CR} and geotextile intrusion RF_{GI}, based on the mass per unit area, the applied stress, the service life, and boundary conditions. This approach will facilitate determination of reduction factors adapted to any condition encountered on a project. It can also be used to optimize the mass per unit area of the core to accurately deliver the required long-term flow capacity.

Evaluation of biofilm adhesion and development in nonwoven geotextile in contact with wastewater

ABSTRACT: The contact between wastewater and geotextiles can lead to the development of biofilm due to microorganisms' activity resulting in the decrease of void ratio in the geotextile matrix (bioclogging). This phenomenon reduces the lifespan of geotextiles in works such as sanitary landfills, mining lagoons or wastewater stabilization ponds. However, geotextiles can also promote the removal of wastewater's compounds such as suspended solids, organic compounds, nitrogen (N) and phosphorus (P). The objective of this research is to evaluate the bioclogging evolution in two types of non-woven geotextiles of different weights after contacting with a wastewater. Laboratory experiments were carried out in permeameters colonized with wastewater biomass and fed with domestic synthetic wastewater (300 mg COD/L, 30 mg N-NH$_4$/L, 6 mg P-PO$_4$/L, C/N:4 and C/P:20). The results show rapid biofilm adhesion to both geotextiles and good stabilization conditions of the biofilm, but clogging was not significant for 80 days of contact. Removal of COD, N and P was slightly higher for the GT300 (around 82%, 55% and 36%, respectively), but considered good for both geotextiles.

1 INTRODUCTION

Geosynthetics have been used as drains and filters for some decades, where their high demand comes from a better-quality control in relation to natural materials as they are manufactured materials. Furthermore, the restriction of the use of natural materials is increasing. In addition, they have fast installation even under difficult subsoil conditions, competitive cost, among others (Lopes *et al* 2021; Palmeira 2003).

However, these materials are susceptible to clogging, either by bacterial growth, mineral precipitation and/or by soil migration between their fibers, mainly when applied as filtering materials in wastewater earth-based technologies (e.g. stabilization ponds and constructed wetlands), wastewater infiltration systems (e.g. drains and infiltration ponds for reclaimed water infiltration or soli aquifer treatment), wastewater drainage, mining ponds and sanitary landfills (Morais et al 2022). The contact between wastewater and geotextiles can lead to the development of biofilm due to microorganisms' activity, namely bacteria, with capability of biodegrading organic compounds, N and P (Albuquerque 2003). The biofilm adheres and develops on the fibers of the geotextile and its activity releases by-products that occupy the empty spaces of the geotextile leading to its clogging, called bioclogging (Guo et al 2020; Silva & Lodi 2020). Variations in temperature, organic substrates, inhibitory compounds, oxygen, and nutrients can alter the growth and maintenance of these biofilms. Typically, it can take up to 1000 hours for biological activity to start, grow and reach an equilibrium condition (steady state conditions) after contact with a wastewater (ASTM D1987 2018).

The mesh structure of non-woven geotextiles facilitates good adhesion and stabilization of biofilms, which can grow through the mesh between voids. Therefore, this research aims to evaluate the time that the biofilm and bioclogging take to be installed in the structure of two non-woven geotextiles, with different grammage, and influence the permeability in the media and the removal of organic matter, N and P after contact with wastewater.

2 MATERIAL AND METHODS

2.1 *Laboratory experiments*

Experiments were conducted in two permeameters with an internal diameter of 100 mm and a height of 200 mm, working in vertical flow. Each device has a 10 cm diameter of non-woven geotextile, with different characteristics (Table 1), composed by 100% poly-propylene fibers.

Table 1. Characteristics of the geotextiles.

GTX	Mass per unit area g/m^2	Permeability m/s	Thickness mm
GT120	120	6.3×10^{-2}	1.21
GT300	300	6.3×10^{-2}	2.30

Permeameters were fed with a synthetic domestic effluent (feeding solution). The two columns worked for 20 cycles (each cycle had 4 days), starting with the feeding phase (first day) and finishing with the draining phase (fourth day). Permeability tests were carried out, according to ASTM D1987, at a constant load of 25 cm.

At the beginning of each cycle, the water load in the permeameters was measured and water samples were taken to determine pH, dissolved oxygen (DO), chemical oxygen demand (COD), ammonia nitrogen (NH_4-N) and phosphorus phosphate (PO_4-P). At the end of each cycle, the manometric height in the permeameters was measured and samples of effluent water from the bottom of the permeameters (drained water) were taken for pH, DO, COD, NH_4-N and PO_4-P analysis. The measurements of DO, pH and temperature were carried out through probes CellOx 32 and, SenTix 41 connected to a Multimeter 340i (WTW, Germany). COD, NH_4–N, and PO_4–P were determined by colorimetric method using a RFID model DR3900 UV photometer (Hach, Loveland, USA) and the cuvette tests LCK 114, LCK 303, and LCK 350, respectively. Removal efficiencies were calculated through Eq. (1).

$$\Delta C = \left(\frac{Ci - Ce}{Ci} \right) \quad x \quad 100 \qquad (1)$$

Where ΔC = removal efficiency for parameter C (%); Ci = concentration of parameter C in the feeding solution (influent) (mg/L); Ce = concentration of parameter C in the drained samples (effluent) (mg/L).

2.2 *Synthetic effluent*

The synthetic wastewater was prepared based on the following composition (Albuquerque *et al.* 2012): buffer solution (8.50 g KH_2PO_4 + 21.75 g K_2HPO_4 + 33.40 g $Na_2HPO_4 \cdot 7H_2O$ + 1.70 g NH_4Cl/L), magnesium sulphate solution (22.50 g $MgSO_4 \cdot 7H_2O/L$), calcium chloride solution (36.43 g $CaCl_2 \cdot 2H_2O/L$), iron chloride solution (0.25 g $FeCl_3 \cdot 6H_2O/L$),

oligoelements solution (0.04 g $MnSO_4 \cdot 4H_2O$ + 0.06 g H_3BO3 + 0.04 g $ZnSO_2 \cdot 7H_2O$ + 0.032 g $(NH_4)_6 \cdot Mo_7O_{24} \cdot 4H_2O$ + 0.0555 g EDTA ($C_{10}H_{14}N_2Na_2O_8 \cdot 3H_2O$) + 0.0445 g $FeCl_3 \cdot 6H/L$), sodium acetate solution (20.20 g $C_2H_3O_2Na \cdot 3H_2O/L$, organic source as acetate), ammonia chloride solution (20.30 g $N-NH_4/L$, nitrogen source) and potassium nitrate solution (13.7 g KNO_3/L, as phosphorous solution).

Geotextiles were inoculated with 2 mL of a biomass previously acclimatized during two weeks in a semi-continuous reactor, which contained 6.68 mg/L SSV, 8.42 mg/L TSS, 311.20 mg/L COD, 11.20 mg/L $N-NH_4$, and pH of 7.40. Experiments were performed with the synthetic wastewater (feeding solution) with initial average loads of 450 mg COD/L, 25 mg NH_4-N/L and 19 mg PO_4-P/L. The average temperature during the tests was 20.8°C.

3 RESULTS AND DISCUSSION

Permeability did not change significantly for both geotextiles during the 20 cycles, which would mean bioclogging was not significant for that time of operation (approximately 80 days). Figures 1 to 3 show the evolution of the removal of COD (ΔCOD), NH_4-N (ΔNH_4-N) and PO_4-P (ΔPO_4-P) in the two permeameters. The removal of COD, N and P increased over time in both geotextiles, just after the first cycle, with the highest removals having been observed for the heavier grammage and thickness geotextile (GT300). To analyze the graphics, GT120 is the geotextile with a density of 120g/m^2 and GT300 the one with 300g/m^2.

During the first 5 cycles (20 days operation), there was an increase in COD removal of up to 73% for GT300 and around 28% for GT120 (Figure 1). The stabilization in COD removal (steady-state conditions) appear after the fourth cycle (16 days operation) for GT300 and after the thirteenth cycle (52 days operation) for GT120. From the fifth cycle (20 days operation) to the twentieth cycle (52 days operation), the average COD removal efficiency maintained the same value (around 80%) GT300. In the GT120 the average COD removal efficiency stabilized around the thirteenth cycle (52 days operation) between 65% and 75%.
Figure 1. Variation of COD removal in permeameters.

Regarding N removal (Figure 2), as ammonia-nitrogen, the removal efficiency in GT300 ranged from approximately 25% to 40% (30% on average) in the first two cycles (8 days operation) and stabilized after the third cycle (12 days operation). For the GT120, the equilibrium conditions stabilize around the fourteenth cycle (56 days operation), with a greater variation between the fourth and the thirteenth cycles (from 16 to 52 days operation). However, the final average efficiencies for both geotextiles were similar, around 50%.

Figure 2.   Variation of NH$_4$-N removal in permeameters.

The global average removal efficiencies for the 20 cycles (80 days operation) were 74%, 52% and 33% for COD, NH$_4$-N and PO$_4$-P, respectively, for GT120, and 82%, 55% and 36% for GT300. Therefore, the greater removal of organic matter, N and P in GT300 seems to be associated with its greater thickness and grammage, which would have allowed a greater development of biofilm, as observed in Albuquerque et al (2012) for a pozzolana-based partially aerated low-loaded biofilter.

Average phosphorus removal (Figure 3) ranged from 17% in the first 3 cycles (12 days) and stabilized around 31% from the fourth to the tenth cycle. While the behavior of microorganisms in the GT 120 is more linear, reaching stabilization around the fifteenth cycle.
Figure 3.   Variation of PO$_4$-P removal in permeameters.

COD, N and P removal results seem to indicate that the biofilm began to stabilize (i.e., under steady-state conditions) after approximately three cycles (i.e., after 12 days contact with the wastewater) for the geotextile GT300, when the processes of growth and detachment would already be in equilibrium. For the geotextile GT120, growth was slower and more constant, as it was a finer mesh, the detachment conditions last longer, the microorganisms apparently had a greater difficulty in getting into rapid equilibrium since the contact area mesh cross section was smaller.

4 CONCLUSIONS

This preliminary research shows biofilm adhesion and stabilization in a geotextile material placed inside permeameters, highlighting the main points:

- For the 300g/m^2 geotextile, *steady-state* conditions were observed after 5 cycles (20 days), with very good COD (82%) and NH$_4$-N (55%) removal and good PO$_4$-P (36%) removal.
- For the 120g/m^2 geotextile, *steady-state* conditions were observed for only after 10 cycles (40 days), reaching GT300 conditions only around 15 cycles. with very good COD (74%) and NH$_4$-N (52%) removal and good PO$_4$-P (33%) removal,
- The different behaviors between the two geotextiles seems to be because the mesh thickness provides a greater accommodation of microorganisms. More in the GT300 than in the GT120.
- Aerobic heterotrophic oxidation, nitrification and PAOs appear to be the predominant microorganisms in both permeameters.

ABSTRACT: The Nordic countries in Europe are faced with specific challenges when it comes to construction. Next to specific soil conditions, these regions are faced with significantly lower temperatures during wintertime than other regions in Europe. To confirm that the current best practices for geosynthetic installation are also applicable to these specific cold conditions or that new guidelines should be implemented for these specific conditions, full scale field testing has been conducted recently within the ROUGH project. A job site in the north of Finland was prepared to perform installation damage testing on nonwoven geotextiles used as filtration/separation geotextile in a drainage trench. Laboratory evaluation of the characteristics before and after installation provides a good view of the impact of installation in Nordic conditions: cold climate and typical Nordic soils.

1 INTRODUCTION

Finland, Norway and Sweden are three Nordic countries that extend beyond the arctic circle. These countries are all subject to some very specific conditions when performing construction works.

One of these conditions is a colder climate compared to other European countries. It is the aim of this study to thoroughly investigate whether the installation of geosynthetics is affected by these Nordic conditions (cold temperature, frozen soils, typical backfill like crushed rock), and, if so, additional guidelines are for example required when installing geosynthetics at sub-zero temperatures.

Geosynthetics are construction materials that are cost-effective and provide a long-term performance, making them very suitable and sustainable materials for use in different construction application, such as road construction, drainage trenches, railways, erosion control systems and others. Depending on the application the geosynthetic will fulfil one or more functions, typically being filtration, separation, drainage, reinforcement, stabilisation, erosion control, protection and sealing. There are different types of geosynthetics depending on

their structure. Typical types include nonwoven and woven geotextiles, geogrids, geomembranes and geocomposites.

The correct installation of any type of geosynthetic is important to make sure the material is functional in the construction project.

Within the framework of the ROUGH project (Recommendations for requirements on characteristics of geosynthetics and geosynthetic-related products relevant to Nordic country-specific conditions) (ROUGH project 2022) full scale installation tests were performed on nonwoven geotextile products to assess the function Filtration/Separation when the geotextile is used in a drainage trench application.

2 SITE SELECTION AND CONDITIONS

2.1 Site

Full scale site testing requires a test location where all the conditions are met, preparation of the testing ground, and installation of the geotextile can be done as close to actual site conditions as possible. In that case, the results found during the testing can actually be transferred to real applications.

For these site testing, a location was found in the north of Finland, very close to Kemi. The construction site was situated about 15 km southeast of Kemi, along the E8/E75, where a new road was being constructed (Figure 1).

2.2 Climatic conditions

For the installation damage testing, the goal was to realise the installation at temperatures between – 5°C and – 20°C.

Testing took place during wintertime, on 5 and 6 February 2020. During the testing, temperatures were recorded on site. These measurements were compared with more extensive hourly data from the Finnish Meteorological Institute. The data provided came from the nearest weather station, which was located at Kemi Airport, 20 km away from the test site. The temperatures that were measured on site matched those measured by the Finnish Meteorological Institute. Therefore, the extensive data from the weather station was used to evaluated and indicate the temperatures during the entire trial, from conditioning to deconstruction. These temperatures are given in Figure 2 and show that the air temperature was between – 7°C and – 15°C during time of installation and compaction.

No snow had to be removed from the test site and no additional snowfall occurred during installation.

Figure 1.   Location of the field.

Figure 2.   Temperatures during installation and recovery [°C] tests (Screenshot Google Maps).

3 MATERIALS USED

3.1 *Geotextile materials*

Four different nonwoven geotextile products were used from different manufacturers. The nonwoven materials were supplied to the site and also to the laboratory (reference samples). The material that was supplied to the site, was prepared before installation. All samples cut to the right length in pieces of 2 m wide. Marking for samples to be taken were made on the geotextiles beforehand and identification numbers were also put on the samples. Marking the samples places beforehand avoids biased sample selection afterwards in the lab, if some parts would be more or less damaged than other parts of the sample. For each type of geotextile product, 4 test specimens were prepared for installation.

3.2 *Granular material*

The material used is a crushed rock. The material was tested to determine its particle size distribution. The result of this distribution and the limit values of the InfraRYL guidelines show that the material can be classified as Crushed Rock GO 0/56mm (KaM 0/56) based on SFS-EN 13242. This is material that is typical for Finnish road construction and unbound granular sub-bases. The granular material had a temperature of approximately – 6°C when it arrived on-site.

4 TEST METHOD

To investigate what is the impact of the lower temperatures on the installation of the geo-synthetics in a filtration application, a drainage trench was made. The specifications of the Finnish guidelines for road construction were aligned to the test site conditioning with real jobsite parameters.

First of all, a trench was dug in the frozen in situ ground with a cross section of 1 m wide and a depth of 0.5 m. The trench was long enough to be able to place all geotextile samples next to each other in one trench. Figure 3 shows the cross section of the trench. The geo-textile samples were placed on the local soil in the trench and over the edges to keep them in place. The boundaries of the trench were marked on the geotextile samples. The local soil temperature, before installation of the geotextile, had a temperature of – 12°C. 4 samples of each geotextile were installed, 2 samples per type per drop height.

Figure 3. Cross section of the drainage trench.

After placement of the geotextile samples, the drainage trench was filled with the crushed rock material. 2 drop heights were used to add the granular material, 1.0 m and 2.0 m.

Once the trench was filled with granular material, compaction was done with a vibration plate (Type Wacker Neusion DPU6555 – 480 kg) in line with InfraRYL guidelines. Five passes were made for the compaction.

Figures 4 to 7 show the process of preparation, installation and compacting.

Figure 4.   Excavation of trench.

Figure 5.   Installed geotextile samples.

Figure 6.   Filling of the trench with granular material.

Figure 7.   Compaction of the granular material inside the trench.

The compaction was checked with a dynamic load plate testing device type "AL-Engineering Oy Loadman II". The results show a bearing capacity modulus of 109–128 MPa (drop height 1.0 m) and 124–138 MPa (drop height 2.0 m). Figure 8 provides an overview of the results relative to the sample location in the trench.

On the second day, the sample recovery took place. An excavator removed the top central part of the granular material in a careful way, making sure this excavation did not cause any damages to the geotextiles. A narrow trench bucket was used to manage this. The remaining part of the granular material was removed using a vacuum/suction lorry. The use of this vacuum lorry allowed for delicate removal of the last layers of rocks from the geotextiles alongside removal of rocks by hand. Figures 9 and 10 show the excavation process.
Figure 8.   Compaction controls values and arrangement of samples.

Figure 9.   Removal of top part of granular material by excavator.

Figure 10.   Removal of last part of granular material using a vacuum and by hand.

Once all granular material was removed, the geotextile samples were removed from the trench. The samples were wound onto a core and protected by a thick nonwoven layer on the outside. All samples were placed in a large wooden box for transport. As the samples were already marked before testing started, no sample selection was needed on site and the lab could perform the tests and use the identification on the samples.

5   LABORATORY TESTING

In order to evaluate the impact of installation damage, testing of the geotextile samples needs to take place under controlled environment and compared to the virgin material values.

Within this setup, all geotextile samples were evaluated for 1) Tensile strength (EN ISO 10319), 2) Energy index (EN ISO 10319), and 3) Characteristic opening size (EN ISO 12956). Testing was done on the exposed samples from Kemi and reference material.

For all geotextile samples, the samples were taken from predefined places, marked in advance. Samples were taken from the bottom of the trench, the edge, and the side of the trench.

These tests took place under laboratory conditions as defined in the referenced test standards at 20°C.

6 RESULTS AND DISCUSSIONS

The results of the samples from Kemi full scale experiment were compared to the results of the reference samples. For all 4 products some damage was observed, which is in line with the normal installation damage that also takes place under normal conditions. The results show that, if they are correctly designed for a positive temperature (e.g., + 20°C) for the defined geotechnical conditions of installation (type of soils, drop height, compaction, etc.), no significant influence was observed between the reference and exposed samples that indicate an additional damage due to the Nordic conditions in which the installation took place.

7 CONCLUSIONS

The extensive on site and laboratory testing conducted on these geotextile materials for use as a separation/filtration layer in a drainage trench was one of the major and biggest test setups conducted in recent years.

These tests allow for an evaluation of the possible impact of cold temperatures on the geotextile installation. The results show that their additional significant influence due to the cold temperature on the 4 samples tested.

If products are correctly designed for a positive temperature (e.g. + 20°C) for the defined geotechnical conditions of installation (type of soils, drop height, compaction, etc.), no additional installation damage is observed on the strength when the products are installed under the same conditions at – 10°C. Additionally, no clear influence of the location of the samples in the trench was observed on the strength.

No influence on the opening size is observed when the products tested are exposed in Kemi to installation at – 10°C in a trench with crushed rock under a drop height of 1.0 m & 2.0 m.

Additionally, no clear influence of the location of the samples in the trench was observed on the opening size.

Thermal prefabricated vertical drain for vacuum consolidation of Hong Kong marine deposits with temperature changes

Ze-Jian Chen & Jian-Hua Yin
Department of Civil and Environmental Engineering & Research Institute for Land and Space, The Hong Kong Polytechnic University, Hong Kong SAR, China

ABSTRACT: The consolidation of marine deposits for marine infrastructure, dredged mud disposal, as well as new reclamation, is a time-consuming process due to the low permeability of the soft marine clay. In vacuum preloading, the discharge efficiency of prefabricated vertical drains (PVD) significantly decreases with bending and clogging as soils consolidate. In this study, a physical model test was carried out for vacuum preloading on Hong Kong marine deposit (HKMD) slurry with a heating aided PVD for stepwise heating. The temperature distribution and evolution in the model, the water discharge volume of the slurry, and the response of water discharge rate to temperature change at different stages of consolidation are analyzed and discussed.

1 INTRODUCTION

Land shortage is one of the major challenges of urbanization and economic development, especially in coastal regions, which are usually the population and commercial centers, such as Hong Kong. Land reclamation and other marine infrastructures are of vital importance to urban development in these areas. In coastal regions, the land and seabed are usually covered with thick layers of soft marine deposits, with high water content, low strength, and high clay content. Marine reclamation and other construction activities, such as ground improvement and channel dredging, are closely associated with marine deposits to be effectively treated. In fact, due to lack of gravel and sand fills, it has been proposed and applied to use soft marine deposits as a fill material for reclamation (Yin *et al.* 2022). In these cases, the time-consuming consolidation process of dredged deposits as well as the natural in-situ deposits is a key challenge.

Vacuum preloading is effective in accelerating the consolidation of soft soils, with a sealing system, a vacuum source, and drains, mostly prefabricated vertical drains (PVDs) (Baral *et al.* 2021; Cai *et al.* 2017). Although PVD-vacuum preloading has been successfully applied in the past decades, there are still significant challenges, such as the deformation and clogging of PVDs, non-uniform consolidation, and formation of soils columns during vacuum preloading, which will reduce the rate of consolidation of the soils (Wang P. *et al.* 2020; Zhou & Chai 2017). Solutions have been proposed to such issues, one of which is to increase the temperature in the soft soils treated (Abuel-Naga *et al.* 2006; Artidteang *et al.* 2011; Du *et al.* 2021; Wang J. *et al.* 2020). Under elevated temperature, the viscosity of porewater is significantly reduced, and the permeability of the soil will be much higher (Cho *et al.* 1999; Chen *et al.* 2023). One convenient way of heating soft soils is to integrate the heating sources, such as electric heating wires with the PVDs to be inserted in to the soils. Previous studies showed that using such thermal PVDs, the speed of vacuum consolidation obviously increases with temperature, and the non-uniform consolidation effects is improved (Chen *et al.* 2022). Most studies are focused on isothermal tests. In practice, heating procedures might be complicated, and the temperature

effects might vary at different stage of consolidation. It is beneficial to understand the influences of temperature change at different consolidation state, towards a more efficient and less energy-consuming design of the heating scheme.

In this study, a reduced-scale axisymmetric model test was conducted on Hong Kong marine deposits. A PVD with heating wires was installed at the center of the soil, and a complicated heating-cooling-reheating schedule with vacuum pressure was implemented. The temperature distribution and evolution in the model, the water discharge volume of the slurry, and the response of water discharge rate to temperature change at different stage of consolidation are analyzed and discussed.

2 TEST SETUP

2.1 *Materials*

The soil material used was the Hong Kong marine deposits (HKMD), which is a typical type of marine clayey soil. The particle size distribution is shown in Figure 1. There is around 20% of clay particles (sized $<2\mu$m) and 62% of silt (sized $<50\mu$m) in the HKMD sample. The permeability of HKMD is back-calculated through oedometer tests using Terzaghi's theory. It is reported that the void ratio-dependent permeability follows $e = 1.487 \log k_v + 15.09$ under 20°C and $e = 1.435 \log k_v + 14.77$ under 40°C (Chen *et al.* 2022). It can be seen that permeability increases with temperature.
Figure 1.   Particle size distribution of HKMD in the model test.

2.2 *Design of the physical model*

The layout of the model is shown in Figure 2. Before consolidation, the HKMD was mixed with water and reconstituted into a slurry with a water content of 100%. A band-type PVD with thickness of 5mm, width of 100mm, and length of 500mm was installed at the center of a rigid steel cylinder with diameter of 294mm and height of 500mm. The heating wire was connected to aa temperature-control unit. A flexible heating wire was fixed on the surface of the PVD. Then the HKMD slurry was poured inside. Temperature sensors were installed inside the soil body to monitor the temperature distribution of the soils. Finally, the slurry was covered with a layer of plastic membrane for air sealing. The PVD was connected to a vacuum pump and a water collection chamber.

2.3 *Test schedule*

The slurry was firstly settled for a couple of days without vacuum preloading and heating. Then vacuum pressure of -50 kPa was applied in stages in one hour and maintained constant for the whole process. The temperature was controlled by tracking the sensor T0. The

Figure 2. Setup of the model test.

temperature of T0 was firstly set to 30°C for a while and cooled down to around 20°C for around 2 days. Afterwards T0 was increased again to 40°C for 11 days, then reduced to 30°C for 4 days, and to 20°C for 3 days. After that, T0 was again increased to 30°C for more than 20 days, and finally reduced to around 20°C by turning off the control system. The setting of temperature can be found in Figures 3 and 4.

3 TEST RESULTS AND DISCUSSIONS

3.1 *Temperature evolution and distribution*
Figure 3. Temperature–time curves at five locations.

Figure 3 shows the temperature evolutions at locations of T0, T1, T2, T3, and T4. T0 is connected to the temperature controller. First of all, it can be found that the temperature is not uniform within the soil. Possible reason is the heat loss by thermal diffusion and radiation the top and bottom boundaries. Another reason is the thermal convection with water flow from the surrounding soils to the PVD, compensating part of the thermal diffusion from PVD to the edge. In the lateral direction, temperature near the heating source at the middle (T3) is higher than temperature at the middle and boundary (T0 and T4), because the working temperature of the heating wire was higher that the setting. T0 and T4 are close, indicating good insulations at the lateral boundaries. Along the vertical direction, temperature at the middle depth (T2) is higher than T1 at the surface and T0 at the bottom, due to the heat loss at the surface and the boundary. The middle depth of soils received the most heat since it is farthest to the boundaries.

For the temporal distribution, firstly, it can be found that except T0 with stable control, temperature at all measuring points exhibits significant fluctuation. The reason for fluctuation is that the working temperature of the heating wire is as high as 70°C, and the

temperature control is a dynamic control process. Secondly, under the same T0 = 30°C, T2 gradually increases with time. This is due to the increasing thermal conductivity with gradual reduction of void ratio.

3.2 Water discharge volume

Figure 4 shows the volume of pumped water from the physical model with time. It can be found that the volume change of the slurry is significant, as the initial volume of the slurry was only around 30 L. During vacuum preloading, when there is a heating, a sharper slope of water discharge curve can be observed, even when the heating period is short. When there is a cooling process, the slope of water discharge curve immediately becomes much gentler. Therefore, heating process has fatal contribution to the consolidation settlement of clay slurry.
Figure 4.   Water discharge volume and temperature setting with time during vacuum preloading.

3.3 Effects of temperature change on water discharge rate

The consolidation of soils is dependent on both temperature and void ratio. It is important to investigate the rate of consolidation with temperature change at different stages of vacuum consolidation. The water discharge rate $\dot{V}_w$ is calculated by:

$$\dot{V}_w = \frac{dV_w}{dt} \approx \frac{V_{w,i+1} - V_{w,i-1}}{t_{i+1} - t_{i-1}} \tag{1}$$

where $\dot{V}_w$ is the water discharge rate, V_w is the volume of pumped water, "$i - 1$" and "$i + 1$" represent the measuring time moment before and after the current time moment, t is the elapsed time.

Figure 5 shows the water discharge rate and temperature with water discharge volume. Firstly, under a constant temperature, the rate of consolidation always decreases with time.

Figure 5.   Water discharge rate and temperature setting with time during vacuum preloading.

This is due to (a) the nonlinear compression and consolidation of the soil; (b) the reduced water discharge capacity due to deformation of PVD; (c) the clogging of the PVD as well as the formation of soil column, especially without heating (Chen *et al.* 2022). Secondly, with heating, the rate of consolidation always increases, due to the enhanced permeability by reduced water viscosity, especially in the clogged regions.

However, the test results indicate that the HKMS slurry might response to temperature differently at different consolidation stages. At the earlier stage, there is a trial heating to 30°C for only several hours. However, the increase of consolidation rate is very significant and sensitive. As the high-water content slurry has relatively low thermal conductivity, the heating mainly affects the middle region. Therefore, the consolidation of soils close to the PVD is especially accelerated, and soil column may form faster.

At the second heating stage from 20 to 40 for 11 days, the temperature is higher, but the increase of water discharge rate is rather slow. It seems that a certain period is needed for heating to make an obvious contribution. During the previous consolidation stage, the PVD is deformed, the soil column has formed around the PVD, and non-uniform consolidation is significant. Therefore, the effects of PVD heating on the consolidation rate slowly increases as the non-uniformity is slowly reduced after some water discharge under a higher temperature.

At the final stage, when the temperature of T0 was set from 40 to 30°C, the water discharge rate drops a bit and increases again to the original track. Meanwhile, a short cooling-heating cycle was conducted quickly at this stage, and the rate of water discharge quickly experienced a drop-rise cycle. The heating effects of consolidation rate is obvious at this stage. The reasons behind this phenomenon might be: (i) The soil is already dense, so the thermal conductivity is high and the temperature re-distribution is faster to cause quicker response in the soils. (ii) After a long-term of heating, the non-uniformity of consolidation has been reduced (Chen *et al.* 2022), which causes the further increase of consolidation.

3.4   *Final stage of soils*

After the test, the vacuum pressure was stopped and the membrane was removed. It was found that the soil was highly hardened. The soil surface is very dry, with some surface cracks. The water content of the surface was measured to be only 3%.

4   SUMMARY

In this study, a laboratory model test was conducted on HKMD slurry under vacuum preloading with heating and PVD. The slurry was subjected to non-isothermal conditions with different temperatures at different consolidation stages. Several remarks can be summarized as follows.

(a) The temperature fluctuation at different locations is significant due to the dynamic control of the heating wire and the heat loss at the top and bottom of the soils, which should be paid attention in field application. With consolidation going on, the thermal conductivity is gradually increased.
(b) Under elevated temperature, the settlement of HKMD slurry is significantly increased. The rate of water discharge always increases with increasing temperature. A highly stiff layer can form after treatment with vacuum preloading and heating.
(c) At the earlier stage of consolidation, the response of water discharge rate to temperature is faster than at the middle stage of consolidation. With the formation of soil column and PVD deformation, the improvement of consolidation rate by heating will take a certain period. However, further explorations are necessary to clarify the specific mechanisms for such behaviours.

Consolidation of clay slurry fill using horizontal drainage enhanced geotextile sheet

H. Chen, J. Chu & S.F. Wu
School of Civil and Environmental Engineering, Nanyang Technological University, Singapore

W. Guo
School of Civil Engineering, Tianjin University, Tianjin, China

ABSTRACT: Due to a lack of granular fill materials, soft clay slurry dredged from seabed may have to be used for land reclamation. In this paper, a new product, the horizontal drain enhanced geotextile sheet (HDeGs), and a method to use HDeGs as horizontal drains for consolidation of soft marine clay using vacuum pressure is introduced. The construction procedure for the use of HDeGs and the vacuum preloading for consolidation of slurry clay for land reclamation is discussed. Model test has been conducted and the results have demonstrated the effectiveness of the proposed method. The advantages of using HDeGs over the other methods are elaborated. The potential of using this method for land reclamation projects is also discussed.

1 INTRODUCTION

Due to the lack of granular soil in Singapore, soft dredged marine clay or excavated soil has to be used for land reclamation as fill materials. Because of the low permeability and strength of soft clay, the reclaimed land using soft clay fills should be treated (Chu *et al.* 2009a; Lam *et al.* 2020). Although the vacuum preloading with prefabricated vertical drains (PVDs) is a common method for soil improvement, there are some disadvantages for the treatment of soft clay fills using PVDs (Bo *et al.* 2007; Chu *et al.* 2000, 2005, 2006, 2009a, b; Varaksin & Yee 2007, Yan & Chu 2005). One of the difficulties for the land reclamation using PVDs is that the soil improvement works only can be conducted after the fully infill of the soft clay. Another difficulty is that the ground is too soft for machines or workers to go on top to do soil improvement works (Broms 1987; Chu *et al.* 2012, 2021, 2021).

Some researchers have proposed a new soil improvement method for the treatment of soft clay fills (Chai *et al.* 2014, 2022; Chu & Guo 2016; De Lillis *et al.* 2017). In this method, the horizontal drains with vacuum pressure are applied in the treatment of soft clay fills. The horizontal drains are installed layer by layer using special barge and following by the infilling of soft clay fills. The vacuum pressure can be applied in the horizontal drains to accelerate the consolidation of soft clay fills as early as the first few meters soft clay is laid. Therefore, a working platform to support the improvement works of soft clay is not necessary since the soft clay has already been consolidated and solidified to a certain degree. Moreover, the containment bund does not have to be built as high as the maximum height of the reclaimed soft clay fills. By using this new soil improvement method, the overall reclamation duration will be cut down and the cost for land reclamation projects can be saved.

The horizontal drains, consisting of discrete prefabricated drains (PHDs), have been applied in some land reclamation projects in Japan, Korean and China (Chai *et al.* 2014;

Pu *et al.* 2022; Shin & Oh 2007; Shinsha *et al.* 2013; Shinsha & Kumagai 2014). To some extent, the treatment of soft clay fills using PHDs is effective. But the position of the pre-fabricated drains is deviated after the placement of soft clay fills. This causes deviation in the design, analysis, and quality control. A new product, horizontal drainage enhanced geo-textile (HDeGs), is proposed by Chu *et al.* (2015, 2016, 2021). The HDeGs, consisting of discrete prefabricated drains bonded with geotextile, make the convenient installation and predictable position. The reliability of the design and quality control of the construction can be improved. In this paper, the construction procedure for the use of HDeGs and vacuum preloading for the land reclamation using soft clay fills is illustrated. The advantages of vacuum preloading using HDeGs are elaborated. A model test of soft marine clay using HDeGs and vacuum pressure are conducted to demonstrate the effectiveness of the proposed method.

2 CONSTRUCTION PROCEDURE

Figure 1 shows the new product of horizontal drains, Horizontal Drainage enhanced Geotextile Sheet (HDeGs) (Chu & Guo 2015). For HDeGs, the discrete drains with a certain spacing are bounded with geotextile sheets. Both of the drains and geotextile sheets not only provide vacuum pressure, but also work as drainage paths due to the transmissivity of geotextile and large discharge capacity of drain. The prefabricated HDeGs can be rolled up and transported to the reclaimed pond for installation. With the use of geotextile, the installation of HDeGs is convenient and the position of HDeG sheets can remain in place.

Firstly, a layer of HDeGs is placed on the seabed within the containment bund using a barge as in Figure 2. Then, the first layer of soft clay fills is poured in to cover the HDeGs and the vacuum pressure can be applied in drains as in Figure 2a, b. While the first soft clay layer is under vacuum consolidation, the second layer of HDeGs can be laid on top of soft clay and then covered with another layer of soft clay. The process repeats until the desired elevation is reached. A layer of geomembrane will be placed on top of the HDeGs to seal the reclaimed area (see in Figure 2c) and the surcharge can be placed on the geomembrane after a certain time of vacuum consolidation. When the seabed is too soft, the PVDs can be installed first to improve the seabed soft soil and covered by a layer of sand blanket as in Figure 2d. Subsequently, the placement of HDeGs and soft clay fills can be carried out as mentions before.
Figure 1.   Configuration of horizontal drainage enhanced geotextile sheet.
Figure 2.   Construction procedure.

Because of the use of HDeGs, consolidation can take place as soon as the first layer of soft clay fills is placed and thus it will save considerable amount of consolidation time. For this reason, the spacing of the horizontal drains can be greater which in turn saves materials used for the horizontal drains. Furthermore, a working platform is not need. Therefore, the overall benefits of using HDeGs may exceeds that the benefits of using PVDs.

Many studies have shown that the electro-osmosis effect and the high temperature can help accelerate the consolidation process of soft clay (Abuel-Naga *et al.* 2006; Delage *et al.* 2000; Lee 2015; Lamont-Black *et al.* 2016). To incorporate the electro-osmosis effect into the HDeGs, carbon felt can be employed together with geotextile because of its flexible and lightweight. To improve the permeability of clay fills using high temperature, the heating wires can be bonded with geotextile to heat the clay fills around the HDeGs.

3 MODEL TEST USING HDEGS AND VACUUM PRESSURE

3.1 Soft marine clay

The soft marine clay with high-water content is chosen as testing material. The marine clay is collected from a sit along West Coast, Singapore and mixed with tape water. The basic engineering properties of soft marine clay are given in Table 1. The plastic limit and liquid limit of marine clay are 32% and 72%, respectively, and the fines content is 93%. The soil is classified as high plasticity clay. The compression and recompression index from oedometer tests are 0.50 and 0.10. The average coefficient of consolidation of soft marine clay is about 0.45 m^2/year.

Table 1. Basic engineering properties of soft marine clay.

Property	Soft marine clay
Specific Gravity	2.70
Liquid limit (%)	72
Plastic limit (%)	32
Plasticity Index (%)	40
Coefficient of consolidation (m^2/yr)	0.45
Compression index	0.50
Recompression index	0.10
Fine content (%)	93
Soil classification	CH

3.2 Testing setup

The Model test of soft marine clay using HDeGs are carried out in a consolidation tank with a dimension of 1.5 m (L) by 1 m (H) by 1 m (W) as in Figure 3. The HDeGs made of single drain (AliDrain) and single non-woven geotextile (Tencate TS10) is placed in the middle of soft marine clay. The drain used is 100 mm in width and 3 mm in thickness and the non-woven geotextile is 1 mm in thickness. The drain is connected to a jet pump via a reinforced plastic pipe and a L-shape connector. Pore-water pressure transducers (TML KPD-200KPA) are placed on the HDeGs and the bottom of tank to measure the pore pressure change in soft marine clay. The settlement on soil surface is measured by laser sensors (Keyence IL600).

The soft marine clay with 0.95 m of initial height and 140 % of initial water content are used. Due to the sedimentation and self-weight consolidation of soft marine clay, there are 10 cm of clean water above the soft marine clay surface before testing in Model test. The average water content and the height for vacuum consolidation are 117 % and 0.85 m. The average vacuum pressure from a jet pump is around −80 kPa. The duration of Model test are 18.7 hours. The laboratory vane shear tests with 50 mm by 33 mm of vane are conducted at different depths on a certain cross-section of treated soil. The water contents are measured at the corresponding positions.

3.3 Testing results

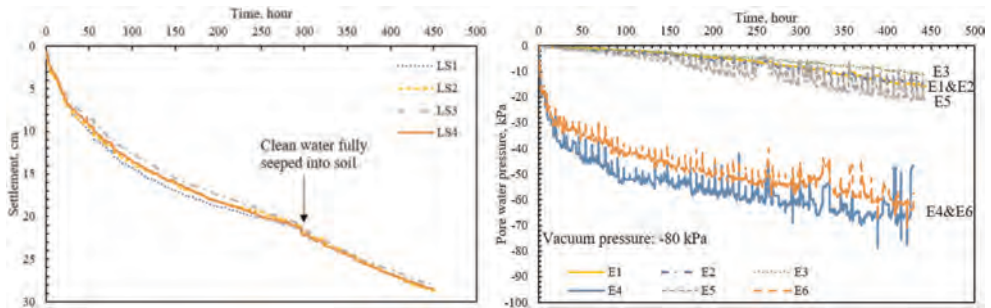
The surface settlement and pore water pressures measured in Model test are shown in Figure 4. Due to the 8 hours per day of laboratory testing duration, the testing results are fluctuating, and the effective consolidation time is 18.7 days. After testing, a 28.3 cm of final average settlement is achieved. The pore water pressure at different locations of pore pressure transducers decreases with the increase in the distance to the drain. However, the pore
Figure 3. Model test using HDeGs and soft marine clay.


Figure 4. Monitoring data for model test.

water pressures on HDeGs are considerable and close to the source vacuum pressure (around −85 kPa). According to Terzaghi's consolidation solution, the estimated pore water pressure at E1, E2, and E3 after 18.7 days is −11.9 kPa which is close to the measured average value −13.0 kPa. However, by using Chai's method for PHDs (Chai *et al.* 2014), the estimated pore water pressure at E1, E2, and E3 after 18.7 days is −0.01 kPa under plane strain condition. Therefore, the boundary condition of vacuum consolidation using HDeGs is more similar with that in Terzaghi's consolidation theory. This is the major difference between the proposed HDeGs method and the horizonal drain methods proposed by others before. The above observation suggests that the HDeGs play a nonnegligible role in pore pressure dissipation particularly when the geotextile sheet has a certain transmissivity.

The undrained shear strength and water content distributions with depth are shown in Figure 5. The soft marine clay near the HDeGs have a lower water content and larger undrained shear strength. The minimum water content is 43.6% and the maximum undrained shear strength is 15.25 kPa in the clay around the drain. Compared with the average initial water content of 117%, the average final water content of 60.9% is a substantial reduction. By using Asoka's method, the ultimate settlement is 41.0 cm. The degree

1571

of consolidation calculated using the average settlement is 69.1 % after 18.7 days. Therefore, the vacuum consolidation using HDeGs is feasible for the land reclamation using soft clay fills.
Figure 5.   Undrained shear strength (s_u) and water content (ω).

4   CONCLUSIONS

In this paper, a new product, horizontal drainage enhanced geotextile sheet (HDeGs), is proposed for the land reclamation using soft clay fills. The construction procedure of land reclamation of soft clay fills using HDeGs and vacuum pressure is illustrated. The advantages of the use of HDeGs are discussed. The potential benefits using HDeGs is introduced by incorporating the electro-osmosis and temperature effects.

A model test of soft marine clay is conducted to investigate the effectiveness using HDeGs and vacuum pressure. The testing results demonstrate the performance of vacuum consolidation using HDeGs is well. Both the prefabricated drain and the geotextile can transmit the vacuum pressure and provide good drainage. A 69.1 % of degree of consolidation can be achieved after 18.7 days of vacuum consolidation. A large reduction of water content and increasing of undrained shear strength are measured. Therefore, the vacuum consolidation using HDeGs is feasible for the land reclamation using soft clay fills.

Field tests on the impact of stones on geotextile compared with theory

A. Bezuijen

Bezuijen Consult, Berkel en Rodenrijs, The Netherlands

ABSTRACT: Impact of stones or blocks on a geotextile, for example during construction of a coastal engineering structure, can damage the geotextile. Using the results of laboratory tests, it was shown that, apart from the robustness of the geotextile and its maximum elongation, the friction between the falling stone and the geotextile and between the geotextile and the subsoil is of importance for the risk of damage to the geotextile. Furthermore, it was found, as could be expected, that the shape of the stone has a large influence. An analytical calculation model was developed and compared with the results of numerical calculations. Results show the influence of friction between the sand the geotextile and the stone. The influence of the shape of the blocks according to the model is less than expected based on laboratory tests. Overall elongation is the dominant failure mechanism for woven geotextiles, local elongation due to friction around the tip of the penetrating block, is dominant for non-wovens.

1 INTRODUCTION

When a geotextile is used in coastal protection it nearly always has (also) a filter function. Very general one can say that the opening size of the geotextile must be smaller than the average grain size. Various studies have refined this for different granular materials and different geotextiles (See Rakić *et al.* 2021 for a recent overview). All these filter rules assume that the geotextile that is placed in the coastal structure has more or less the same properties as the geotextile tested. However, regularly the geotextile is damaged during installation (Cheah 2017). This is a real risk when larger stones or blocks are placed on top of the geotextile. A damaged geotextile will not fulfil the filter rules, which may be the cause of damage to or even failure of the coastal structure.

Therefore, damage during installation has been tested in field and laboratory tests. For larger stones the drop test is used, see Figure 1 for a field and laboratory test example. A stone is lifted to a certain height above the geotextile to be tested and then dropped on the geotextile. Usually there is soil below the geotextile. This soil layer takes part of the load and in this way protects the geotextile. Tests performed without soil results in much more damage to the geotextile. The tests showed that the angle between the planes of the stone are very important. Stones with and angle of 60 degrees or less between the planes that impact on the geotextile were able to destroy geotextiles at a low falling height. Furthermore, it appears that wovens are more vulnerable than non-wovens. This is partly caused by the lower maximum elongation of wovens, but also by non-isotropic stress-strain relation in a woven, resulting in high stresses parallel to the warp and weft direction of the geotextile, but less in the other directions. Tests with two geotextiles on top of each other showed that mostly the lower geotextile was damaged and not only the woven or non-woven.

Figure 1. Examples of drop tests in the field and in a laboratory. The insert left shows an example of the damage to a geotextile. (photographs field tests courtesy of Van den Herik Contractors).

The paper will recapitulate some of the theoretical background. Using the theory developed by Bezuijen & Izadi, (2022), it will be shown what are the consequences and how does this fit with results from field tests. Since by Bezuijen & Izadi (2022) the influence of the geotextile is only partly taken into account, the theory is expanded for one type of block a bit further in this paper.

2 THEORY

2.1 *Elongation based on geometry*

Starting point for the recent research in the Netherlands and Belgium on the consequences of impact was a geometrical model (SBR-CUR 2017), see Figure 2.
Figure 2. Elongation geotextile due to impact from L_0 to L.

The loading on the geotextile is assumed to be at maximum when only the geotextile under the stone deforms during impact. On average, the part with the length L_0 will elongate until L. This allows to calculate the strain (ε_l) in the geotextile;

$$\epsilon_l = \frac{L - L_0}{L_0} = \frac{1}{\sin(0.5\beta)} - 1 \tag{1}$$

for a 2-dimensional situation of a wedge-shaped stone. In cases of a 3-dimensional situation with a cone shaped stone, the relation is:

$$\epsilon_l = \sqrt{\frac{1}{\sin(0.5\beta)}} - 1 \tag{2}$$

These geometrical relations show that the angle β, the angle between the two planes of the impacting stones or the angle of the cone is important. A small β will lead to a large elongation and more likely to damage. Since the elongation is determined by the angle β only, a geotextile with a large elongation at break will more likely survive the impact than a geotextile with a small elongation at break. This led to the conclusion in (SBR-CUR 2017), that for stones larger than 40 kg only non-wovens with enough elongation at break can be used.

Laboratory tests (Bezuijen & Izadi 2020) showed that reality can be more complicated than described in this model. It was found that rupture was possible even when the maximum possible geotextile strain at failure is more than calculated with equations (1) and (2). Furthermore, it was found that in case of two geotextiles the position of the geotextile (top or bottom) is of importance.

2.2 Dynamic model

Based on the laboratory tests mentioned above and discrete element calculations, Bezuijen & Izadi (2020) developed an analytical model. The essence of this model is, that when a stone penetrates into the soil, the soil has to move upwards to allow the stone to penetrate. Due to friction between the soil and the geotextile a force parallel to the geotextile is exerted on the geotextile. If the friction force between the soil and the geotextile is equal or lower than the friction force between the stone and the geotextile, there will be no extra loading on the geotextile because the geotextile will be pushed downward with the stone. However, if the friction force between the soil and the geotextile is higher than the friction force between the stone and the geotextile, the additional force exerted on the geotextile must be taken by the geotextile. In case the geotextile is not strong enough, it will break.

This model explains why in case of a layer of two geotextiles, the lowest one is damaged first. The friction between the lowest geotextile and the soil is higher than the friction between the two geotextiles. Furthermore, the upward sand movement is only influencing the lowest geotextile.

2.3 Dynamic model extended

The model described briefly in the previous section assumes that the resistance force is generated by the soil only but does not incorporate the contribution of the geotextile. When the geotextile is stretched, there will be a tension force in the geotextile. This tension force also reduces the penetration depth. For a wedge-shaped block, see Figure 3, the definition sketch also shown in that figure can be used.

Figure 3. Block type used in model and definition sketch. L is the length of the elongated geotextile. The arrows indicate the sand movement along the geotextile.

The relation between F_v and $F_\perp$ depends on the friction in the sand. Here it is assumed that there is friction between the sand and the geotextile, but that friction does not influence the ratio between F_v and $F_\perp$. With that assumption, the total vertical force on the block is composed of the force F_v, the resistance from the sand. This resistance is calculated using the classical bearing capacity formula for a shallow strip footing for non-cohesive soil without embedment depth:

$$F_v = \alpha 0.5 \gamma' B A N_\gamma \qquad (3)$$

where γ' is the 'effective' density, B the width of the footing, A the area and

$$N_y = 2(N_q + 1)\tan\phi \quad and \quad N_q = e^{\pi.\tan\phi}\tan^2(45 + \phi/2) \qquad (4)$$

The factor α depends on the geometry of the stone and is 1 for a strip footing and 0.6 for a square footing. The total vertical resistance force on the block can now be written as the sum of the resistance force in the sand, the friction between the geotextile and the block and the tension force T_b in the geotextile. With the definition sketch in Figure 3 it can be derived:

$$F_v = F_\perp \sin(0.5\beta) \qquad (5)$$

and for the total vertical resistance:

$$F_{tot} = 2[F_\perp \sin(0.5\beta) + F_\perp \tan\phi_b \cos(0.5\beta) + T_b \cos(0.5\beta)] \qquad (6)$$

The second term on the right-hand side of this formula is the friction between the block and the geotextile. The tension force in the geotextile, T_b, contributes to the vertical resistance force at the lowest point of the block at the intersection of the two planes. It should be noted that T_b is the tension force in kN on the block. This will require a tensile strength $T = T_b/A$ in kN/m of the geotextile.

This tension force in the geotextile has two origins. Normally the geotextile will be fixed at some distance from the impact. The geotextiles will stretch by the impact due to the deformation underneath the block. Not only under the block there will be deformation (as was suggested in SBR-CUR 2017) but also next to the block as can be seen in Figure 4. In this paper it is assumed that the deformation of the geotextile results in a stretching of the whole geotextile. This means that the average strain due to this stretching can be written as:

$$\varepsilon_{avg} = \frac{B/\sin(0.5\beta) + L_0 - B}{L_0} \qquad (7)$$

Next to this average strain, underneath the block there is an additional strain. The deforming sand will move upward resulting in an additional tensile stress in the geotextile, depending on the friction between the sand and the geotextile. The block, moving downward, will somewhat reduce the overall tensile stress in the geotextile but the tensile stress

Figure 4. Stretching of a geotextile during impact. The colors represent the pixel movement (adapted De Strijcker & Decraene 2017).

will be higher at the tip of the block. The net additional tensile stress in the geotextile is determined by the difference in friction angle between the sand and the geotextile and the geotextile and the block material respectively. It is assumed that the extra strain in the geotextile due to the difference in friction between the sand and the block is very localized and does not influence the average strain in the geotextile. Furthermore, it is assumed that full friction force is mobilized on both sides of the geotextile. With these assumptions the strains can be added, and the strain calculated with Eq. (7) can be seen as a pre-straining of the geotextile and the tensile force T_b can be written as:

$$T_b = F_\perp \tan \phi - F_\perp \tan \phi_b + \varepsilon_{avg} E_T A \qquad (8)$$

With ϕ the friction angle between the soil and the geotextile and ϕ_b between the geotextile and the block. E_T is the tensile stiffness of the geotextile. Since ε_{avg} can be determined from the block penetration, it is now possible to calculate the penetration of a block and the forces that can be expected. For a certain dump height, a block will impact with a certain velocity. Following the well-known equation $F = m.a$, F_{tot} in Eq. 5 is the total vertical force except the gravitational force (the weight of the stone). The mass of the block is known and with F_{tot} and the weight of the block, the acceleration can be calculated. Assuming a fixed small timestep, the acceleration times that step results in a change in the velocity and the velocity on a certain moment multiplied by that time step results in the displacement. This was programmed in a spreadsheet. In this spreadsheet a time step of 0.1 or 0.3 ms was used, depending on the penetration depth of the block.
Figure 5. Measured and calculated penetration compared for impact tests without a geotextile, friction angle 35.5^0.

Figure 6. Maximum penetration of block taken from high-speed video (250 fps), see also text.

3 COMPARISON WITH MEASUREMENTS

The model has been compared with impact measurements by De Strijcker & Decraene (2017). They measured the penetration for blocks with different angles β falling into sand but without a geotextile. For a block falling on a geotextile with sand underneath, it was not possible to measure the penetration depth since the block bounces back on the elastic geotextile. The comparison between calculated and measured penetration is shown in Figure 5. A friction angle of 30 degr between the stone and the sand was used. There appears to be a reasonable agreement.

4 PARAMETER STUDY

The calculation model is used to investigate the influence of various parameters. It appears that for the situation with a geotextile the maximum penetration in the experiments is less

than calculated with the friction angle mentioned above. As mentioned, the precise penetration depth could not be determined because the block bounces on the geotextile. However, an indication can be obtained from the high-speed camera images. Figure 6 shows the result for a geotextile with a tensile strength of 80 kN/m. From the dimensions of the block (the diagonal blue line on top of the block is 160 mm) a rough estimation of the penetration depth is possible, around 0.035 m. It is a rough estimation, because, as will be shown later, the time between touching the geotextile and reaching standstill is only around 6 ms for a block penetrating 0.035 m. This means that there are only around 2 frames in the video that records with 250 fps. Figure 6 shows the block a bit blurred because it still has a downward velocity. In the next frame the fall velocity is less. and the block is sharper shown than in Figure 6. However, the penetration depth is less in that frame, indicating that the block is already bouncing back.

Calculated values of the penetration are shown in Table 1 for various situations. First, in the calculation mentioned Calibration (Calibr.), the friction angle and the shape factor were increased to simulate the measured 0.035 m penetration. This appeared only possible with a rather extreme friction angle and shape factor. It is possible that the loading of the geotextile on the sand increases the stresses in the sand resulting in a strength increase of the sand. Furthermore, the calculation is purely 2D, neglecting the influence of the deforming geotextile at the front and back of the block as shown in Figure 6. A last possibility is, that the penetration depth derived from the figure is too small while the block has not reached complete standstill as explained above.

Table 1. Parameters used in various simulations. In bold are the changes with respect to the previous calculation.

Parameter	Calibr.	Calc. 1	Calc. 2	Calc. 3	Calc. 4
Drop height (m)	4	**2.5**	2.5	2.5	2.5
Block weight (kg)	40	40	40	40	40
Width of block (A) (m)	0.365	**0.26**	0.26	0.26	0.26
β (degr)	90	90	90	**60**	60
Friction angle (degr)					
sand – geotextile, ϕ	50	**45**	45	45	45
geotextile – block, ϕ_b	30	**20**	20	20	20
Shape factor α (-)	2.4	**1**	1	1	1
Density sand (kg/m^3)	15	15	15	15	15
Time step (ms)	0.1	**0.3**	0.3	0.3	0.3
Tensile strength (kN/m)	80	80	**40**	40	**80**
ε_{max} geotextile (-)	0.15	0.15	**1**	1	**0.2**
L_0 between fixations (m)	0.8	0.8	0.8	0.8	0.8
Impact velocity (m/s)	8.86	**7**	7	7	7
Penetration depth (m)	0.035	**0.06**	0.068	0.088	0.062
Max. calc. strain (-)	0.147	**0.11**	0.92	0.8	0.12

Apart from the Calibration, 4 calculations were run with more realistic values of the friction angle and the shape factor. These result in larger penetration depths, although the fall height was decreased to a more realistic maximum value that can be expected in field conditions, 2.5 m. Although the penetration depth is more in Calc. 1, the maximum strain is significantly less. This is caused by the huge deceleration in the Calibration calculation to stop the block within 0.035 m. The deceleration is nearly 340 times the acceleration of gravity.

In Calc. 2, the geotextile is changed to a theoretical non-woven with a lower tensile strength (40 kN/m) but a larger maximum allowable strain (100%). It appears that, according to the model, the calculated maximum strain under the block is considerably

higher than for the calculation (Calc. 1) with the woven geotextile with a strength of 80 kN/m at 15% strain. Using only the geometric criterion, as explained in Section 2.1, would lead to the same strain underneath the block, but the model considers that the non-woven geotextile can be stretched with a smaller force than the woven.

Calc. 3 and 4 show the influence of a block with a smaller β of 60 degr. According to this model this influence is only limited. There is a bit more penetration and also the calculated maximum strain is a bit higher than for a block with a β of 90 degrees.

Figure 7 presents the penetration and strains as a function of time for the Calibration calculation and Calc. 1. The contribution of friction to the total strain is high in the Calibration, but in Calc. 1, strain by elongation is dominant.

Figure 7. Penetration depth and strain caused by geometry changes (elongation) and friction in two calculations. Note the different scale of the strain. Parameters see Table 1.

5 CONCLUSIONS

The model described in this paper presents a rather accurate prediction of the penetration of a block into sand without a geotextile. The influence of the block angle β seems to be underpredicted by the model. It overpredicts the penetration when a geotextile is included and using the general accepted values for the friction angle in the sand and the shape factor. It should be realized, that, depending on the properties of the geotextile, this overprediction can lead to an underprediction of the possible installation damage on the geotextile. According to this model, a small penetration of a block during impact may lead to high tension forces in the geotextile and to damage, for both a woven and non-woven geotextiles.

Influence of lateral restriction on bags for dewatering sludge of water treatment plants

M. Moeller, D. Vidal & G.A. Oliveira
Aeronautic Institute of Technology, ITA, São José dos Campos, Brazil

ABSTRACT: Currently, a large amount of sludge is generated through water treatment plants. This sludge represents a problem, generally having its destination in water bodies without treatment and needing correct handling through a dewatering process. The paper aims to expose two variants of the dewatering technique with geotextile bags, analyzing its operations and dewatering processes. It describes field tests performed on two geotextile bag systems, a conventional bag and a bag with lateral restraint, both of which are submitted to two filling cycles. Field and laboratory tests were performed for both geotextile bags using sludge from a water treatment plant. Data about volume, height abatement, and solids content due to the dewatering were collected per time and compared between the two configurations. The results showed that the geotextile bag with lateral restrains could receive a greater volume of sludge, receiving more than 20% of the total volume received in the conventional bag. In the other hand, the conventional geotextile bag achieved a higher solid content, reaching 39% higher solids content than the bag with lateral restrains. The data obtained made it possible to conclude that both configurations were successful, resulting in dewatering efficiencies greater than 1000%.

1 INTRODUCTION

Consumerism governs the life of an increasingly growing world population and rampant economic growth, having as a consequence an immense waste generation, bringing environmental and health risks (Daly 2013). With population growth, more inputs are needed, and more waste is generated. This statement could not be more correct for the use of water, where it is directly and indirectly consumed and, through its use, it ends up generating waste in the form of effluents, which are wet and difficult to handle.

These effluents must be correctly treated and disposed of since water is a finite raw material, which, treated lightly, can cause irreversible damage, directly impacting human life. These impacts could be amplified through climatic and geographic changes resulting from the Anthropocene (Sol 2019).

There is, then, a need to treat these effluents. This treatment usually uses some dewatering technique in its initial stages, seeking to separate the solid phase from the liquid phase, allowing the destination of water for reprocessing and the solid phase for other processing steps. Therefore, dewatering techniques contribute to sustainable development. In addition, the environment is protected by contracting services that promote the correct handling of the generated sludge, preventing its undue disposal in water bodies.

In this context, geotextile closed systems have been successfully employed for the dewatering of sludges and sediments for many years (Fowler *et al.* 1997). In this research, two geotextile systems were compared: one corresponding to a conventional geotextile bag and one corresponding to a geotextile bag with lateral restraints. In order to compare these dewatering systems theirs filling volumes, geometric forms and solids content in time were addressed.

2 GENERAL CONCEPTS

2.1 Geosynthetic closed systems

Geotextile closed systems are permeable systems able to confine granular materials, sediments, and sludge with high water content. These systems are made with woven or non-woven geotextiles, with properties established as a function of the characteristics of the effluent to be discharged, having a custom length and perimeter (Fowler *et al.* 1997; Pilarczyk 2000).

The dewatering process in these systems is discontinuous and mixed, occurring mechanically by forced filtration through the filling pressure and, after this, by a natural process, dewatering by its own weight, drainage, and evaporation. The success of this technology was provided by the ability to retain the solid part while allowing the liquid component to exit, having a good filtering function (Moo-Young *et al.* 2002).

The term geotextile bag is usually used for a system with 5m^3 of maximum volume, usually in pillow form, while the term geotextile tube is associated with structures that assume a tubular shape after filling, whose transverse section presents between 3 and 30m in perimeter and its length reaching up to 200 m (Lawson 2006).

2.2 Conventional system conception

Conventional geotextile systems are based on the use of geotextile bags or tubes positioned over a flat drainage layer to collect and convey the effluent generated.

Various aspects of the problem, such as the volume of sludge or sediment to be discharged, the characteristics of the material, the filling speed or pressure, and the solids content to be achieved, must be considered when designing these systems. Discussing only the aspects directly related to the subject of this work, one can highlight the importance of evaluating the acting mechanical stresses and the response to hydraulic demands.

The maximum tensile load that the geotextile can support is crucial in determining the position of the seams and the maximum filling height. Lawson 2006 notes that the maximum tensile load occurs at the side of the system, as illustrated in Figure 1a.

The filling usually takes place in several cycles, as illustrated in Figure 1b. The number of filling cycles is associated with the maximum height the system can reach and the inherent characteristics of the design requirements.

(a) Distribution of the tensile load in the system perimeter (Lawson 2006)

(b) Cycles of filling (Yee & Lawson 2012)

Figure 1.   Relevant aspects of design.

Guo *et al.* (2014) point out that there is a difference between the fills of a system at the first fill cycle and a system already with consolidated material from previous fill cycles. In addition to the shape, width, and height being different for the two situations, so are the stresses acting on the geotextile membrane. High stresses accumulate at the top of the geotextile perimeter when filling a system with consolidating material. In reality, all fill cycles can achieve the maximum predicted height when the consolidation process does not imply a significant deposition of consolidated material, making it difficult to lift the lateral regions to recover the shape of the first fill.

2.3 *Geotextile system with lateral restraints*

Using containers for dewatering in geotextile bags or tubes avoids the need to prepare a drainage layer and facilitates the fluid collection and the final disposal of the particulate material.

The dewatering in geotextile systems laterally restrained is a mixed dewatering solution similar to the conventional geotextile system without lateral restrictions. The sludge or sediment is hydraulic pumping to the interior of a tube made from filtering geotextile positioned inside a special container. The container serves as a draining cradle and gives it lateral restraints.

The lateral restriction reduces the tensile stress on the system and allows for filling cycles that always reach the maximum height foreseen.

3 MATERIALS AND METHODS

3.1 *Materials*

The materials employed in this research were:

– two bags made of a woven geotextile in polypropylene yarns and;
– sludge from the water treatment plant that supplies the DCTA (Department of Aerospace Science and Technology).

The geotextile characteristics are shown in Table 1. The two bags are 2.5 m long and have a perimeter of 2.5 m, and are provided with filling nozzles of 0.3 m in height and 0.3 m in diameter centered on the top of their upper faces.

Table 1. Woven geotextile characteristics.

Property	Standard	Nominal Value	Unit
Ultimate tensile strength (both directions)	ISO 10319	105	kN,/m
Elongation at rupture (both direction	ISO 10319	10	%
Characteristic opening size	ISO 12956	149	µm
Permeability	ISO 11058	0.003	m/s

Avancini & Vidal (2018) presented the results of preliminary tests conducted with a sample of the sludge to characterize the sludge and evaluate the geotextile behavior from cone tests and pillow tests.

The sludge presented a mean value of solids content by mass (TSP) of 1.7 % and a dry density of the grains (Gs) of 2.58. The grain size distribution of the sludge particulate fraction, obtained in tests without deflocculant, showed that it is composed mainly of sand (90 %), with 3% silt and 7% clay. Energy Dispersive Spectroscopy (EDS) analysis indicates O, Al, Si, and Fe predominant presence.

Cone tests (not standardized) conducted with the woven geotextile and the sludge indicated a small filtration efficiency (16%) and a good dewatering (102%), related to the small amount of sludge used in the test did not allow for the formation of a pre-filter.

The pillow tests (D7880-D7880M 2013) were conducted according to the modified procedure proposed by Tominaga *et al.* (2012). The pillow received a total volume of 40 liters with a Filtration Efficiency of 90% in 24 hours, presenting between the first and the 7th minutes of dewatering, a Filtration Efficiency of 70%, with the filtration efficiency obtained considering Moo-Young *et al.* (2002) proposition.

3.2 Field tests

Two geotextile systems were considered for the field tests: a conventional geotextile system, CGS, and a geotextile lateral restrained system, LRGS. In function of the pillow test dewatering behavior, it was decided to conduct the field tests without sludge conditioning.

A draining crib was built to receive the geotextile systems. The crib was composed of a bottom coating of geomembrane, and a drainage layer led the percolate to its final destination.

One of the geotextile bags was stretched over the drainage crib, and the other was placed over the drainage crib but inside an artifact that ensured its lateral restriction, maintaining a maximum width of 0.8 m. Each side's excess bag lateral dimension (0.225 m) was managed upstream on the lateral side to facilitate complete filling.

Once the geotextile systems were correctly positioned over the draining crib, the filling cycles started. For this, a submersible pump was used, with a maximum working slope of 6.5 m and maximum and minimum flow rates of 1970 l/h and 550 l/h. For the filling cycles in the field tests, the flow rate was 1800 l/h ($\sim$ 30 l/min).

The filling cycles pumped wet material from one decanter of the water treatment plant, directly to the systems, without polymerization, until the height of approximately 0.45 m, where the pumping ceased. This process was repeated once more after five days from the initial fill-in. The total solids were measured (TS) for the percolated liquid.

The volume for each fill was measured, considering the pump flow and the filling time in each cycle. In addition, consolidation height data for the systems were collected shortly after completion and periodically during the draining process.

The dewatering in the bags was followed in time by measuring the bag height and the solids content (SC). In each system, five samples were collected equidistant for each measurement moment to determine the solids content at the time of dewatering.

Finally, the samples collected from the systems were analyzed, and their solids content was determined for each collection moment. It should be noted that the systems were kept in open outdoor spaces, subject to the weather and changes in the clime. Also, dewatering efficiency DE and filtration efficiency FE were calculetad through the following Equations 1 and 2 (Moo-Young *et al.* 2002).

$$DE = \frac{SC_{final} - SC_{initial}}{SC_{initial}} \; x \; 100 \; (\%) \tag{1}$$

$$FE = \frac{TS_{initial} - TS_{final}}{TS_{initial}} \; x \; 100 \; (\%) \tag{2}$$

4 RESULTS AND DISCUSSION

The field tests were conducted in the two geotextile systems described in 3.2. The systems were filled in such a way that each received two filling cycles. The conventional geotextile system, CGS, received a total of 2.31 m^3 and the lateral restrained geotextile system, LRGS,

received a total of 2.79 m^3. Figure 3 presents pictures of the tested systems obtained at different moments.

With the time-related data, it is possible to draw a chart expressing the filling cycles and dewatering process by decreasing height. Figure 2 presents the maximum filling and consolidation heights by time collected during the field tests.

Sludge samples were collected from both geotextile systems at the filling moment and at 12, 21, and 28 days to evaluate the solid content variation on time. Figure 4 presents images of the moments of sample collection for the two geotextile systems. Table 2 expresses the data found for the solids content and DE. Figure 5a illustrates the increase in solids content by mass in time for both geotextile systems. Figure 5b presents climatic conditions during the 28 days of dewatering.

It is possible to see from Figure 3 that the filling and dewatering curves by time occur similarly for the two cycles of each system, with the exception that the system with lateral

Time (days)	CGS		LRGS	
	Solid content (%)	DE (%)	Solid content (%)	DE(%)
0	1,7 ± 0,2	0	1,7 ± 0,2	0
12	16,3 ± 0,5	859	14,5 ± 0,3	753
21	24 ± 3	1312	17 ± 3	900
28	26,5 ± 0,8	1459	19,0 ± 0,7	1018

(a) Solids content by mass per time   (b) Climatic condition

Figure 5.   Solid contents and climatic condition during dewatering.

restraint managed to reach the maximum filling height even in the second cycle of filling. This is probably due to the lateral restrictions, which define the consolidation area and allow for an easier height gain in a new filling cycle. It would occur in a contrary way in the conventional system, where the densified material offers resistance to filling pressure in the filling cycles after the first, which is increasingly difficult.

Through Figure 4, it can be seen that densification occurs more quickly in the conventional system. The greater densification area and the smaller volume admitted reduce the thickness of the sludge layer and facilitate water exit could explain it. However, in the tests performed, only two filling cycles were made, and, in actual application cases, both systems would be filled to their maximum volume.

The analysis of climatic conditions (Figure 5b) indicates that the 21st day of dewatering was the period with the greatest range of temperature variation (up to 22°C). In addition, during this period, the wind velocity reached 30 km/h, the highest speed observed during the 28 days analyzed. However, there is still no way to directly associate these climatic conditions with the variability of the solids content observed for the samples collected after 21 days of dewatering.

The small width of the consolidation area relative to the lateral height of the restriction may have affected the dewatering efficiency in the retrained condition because the side walls at a much greater height than the top of the bag acted to reduce exposure to sun and wind, which assist the evaporation process.

5   CONCLUSIONS

The large volumes of sludge generated and the impacts of its direct release into the environment make it possible to realize that dewatering techniques are beneficial and increasingly

demanded. They reduce the volume of wet material, allowing it to be more easily transported, handled, and correctly disposed of.

Concerning the filling volumes, in agreement with the filling heights, it can be seen that the system with lateral restraints admitted greater volume than the conventional system, admitting about 20% more volume of sludge. Still, it can be seen that in an actual application case, the volume admitted tends to increase its proportion for the system with lateral restraints even more with the increasing of the geotextile bag size. Another advantage of lateral restriction is the reduction of tensile stresses in the lateral region of the bag.

The larger exposed area of the conventional system and a smaller thickness of dewatering sludge allowed this system to have 28 days after filling with a 39% higher solids content than the lateral restriction system. In actual field situations, this disadvantage would be reduced both by the fact that the filling cycles seek to achieve the maximum allowed volume and by the ratio of exposed width versus height of the lateral restriction is much higher than that employed in the tests.

The dewatering efficiency ED equation should be revised in further works, restraining its results from 0 to 100%. In that way facilitating comprehension.

Radial and axial analyze of the dewatering performance in geotextile tubes by bench-scale dewatering test

G.K. Kamakura, M.A. Aparicio-Ardila, C.A. Valentin & J. Lins da Silva
São Carlos School of Engineering (EESC), São Carlos-SP, Brazil

ABSTRACT: Researchers and professionals have used several test methods to evaluate the dewatering performance in geotextile tubes. The evaluation of geotextile tubes is done preliminarily by small-scale Falling Head Tests (FHTs), Geotextile-tube Demonstration Tests (GDTs), and full-scale pilot tests. Nevertheless, only a few studies have compared the outcomes of various dewatering tests, and even fewer have established accurate correlations between test methodologies. This work performed a pressurized two-dimensional dewatering test (P2DT) with a woven geotextile under different hydraulic pressure configurations (with and without internal pressure). In addition, GDT tests were performed for comparison. In this study, the P2DT and GDT tests evaluated the artificial slurry with chemical accelerators. The tests showed similar dewatering rates and final filter cake solids concentration. However, the GDT tests showed better turbidity results. The results indicated that geotextile tubes are an exciting alternative for slurry dewatering.

1 INTRODUCTION

As environmental awareness increases and more stringent regulations regarding slurry treatment emerge, technologies that seek to dewater it to facilitate the treatment and disposal of slurry gain relevance. Thus, due to the lower cost and good performance, using geotextile tubes has been a used alternative, which needs more studies to evaluate its applicability in each case.

The type of slurry treated influences the design of the geotextile tubes. The main factors considered are soil retention, permeability and clogging. In addition to the properties of the geotextile, other materials are essential to improve the system's efficiency, such as using.

The chemical conditioning of the slurry (with polymer) needs studies to select the best type of polymer and the adequate concentration (Satyamurthy & Bhatia 2009). There are recommendations and criteria for the filtration aperture for geotextiles employed for the filtration function. However, experience has shown that the criteria commonly used in filter design do not apply to dewatering in geotextile tubes, and those slurry properties are the dominant control factors (Moo-Young *et al.* 2002). For this reason, it is necessary to carry out tests on the benchtop and pilot scales to verify the dewatering performance in geotextile tubes. Researchers and professionals have used several test methods (laboratory or in-field) to evaluate the dewatering performance in geotextile tubes. These test methods include bench-scale tests, midscale or semi-performance tests (hanging bag test and the geotextile tube dewatering test) and full-performance tests.

According to Driscoll *et al.* (2016) and Ratnayesuraj & Bhatia (2018), the one-way filtration test does not represent the three-dimensional dehydration process in the field. Thus, the authors developed a pressurized two-dimensional dewatering test (P2DT) that evaluates radial and axial dewatering. The results of the P2DT test are more representative of in-situ conditions.

The research aims to analyze the dewatering process in radial and axial directions using P2DT with and without filling pressure and compare it with Geotextile-tube Demonstration Test (GDT). Each flow's percolated volume and turbidity were considered to compare axial and radial dewatering. In addition, the solids concentration and filter cake height were analyzed.

2 MATERIALS AND METHODOLOGY

2.1 Geotextile

The geotextile used was polypropylene woven geotextile. Dewatering applications often use this material. Table 1 shows some properties and characteristics of the material. The Geosynthetics Laboratory at the University of São Paulo (USP) in São Carlos, São Paulo, Brazil, conducted geotextile tests. The geotextile used is the same in Aparicio – Ardila *et al.* (2020) work.

Table 1. Geotextile properties.

Properties	Unit	Test Method	Value
Massa per unit area	kN/m	ABNT NBR ISO 9863-1	414
Thickness	mm	ABNT NBR ISO 9863-1	2.18
Apparent opening size	μm	ABNT NBR ISO 12956	200
Permittivity	s^{-1}	ASTM D4491	0.0024
Tensile strength per unit with MD x CD*	kN/m	ABNT NBR ISO 10319	108.9 x 105.6

*MD: machine direction; CD: cross direction.

2.2 Slurry

The slurry was artificially prepared in the laboratory, consisting of a mixture of distilled water and a soil sample. The granulometric curve of the soil shows that the grain size distribution comprises 57% sand, 8% silt, and 35% clay, according to the procedures of ABNT NBR 7181. This study used synthetic cationic polyacrylamide-derived polymer for the chemical conditioning of the slurry. The initial solids concentration was 15%, the polymer dosage was three mgPol/gST, and the turbidity of the slurry was 644 NTU.

2.3 Performance index

The most common indexes for evaluating dewatering performance are Filtration Efficiency (Equation 1) (Moo-Young & Tucker 2002) and Dewatering Efficiency (Equation 2). The FE index evaluated the improvement in effluent quality in the radial and axial directions separately. In addition to this index, to verify the improvement of the effluent, the turbidity of the effluent was measured, that is, the measure of relative clarity of a liquid that indicates the amount of Total Solids (TS) present in the effluent. The DE measures how effectively fluid the slurry fluid drains. Bhatia *et al.* (2013) recommend adopting the index Percent Dewatered (PD), shown in Equation 3, which can be easier to interpret than DE because the maximum value is 100%. The retention index and dewatering index adopted were turbidity and PD.

$$FE = \frac{TS_{initial} - TS_{final}}{TS_{initial}} \tag{1}$$

where FE = filtration efficiency; $TS_{initial}$ = initial total solids (mg/l); and TS_{final} = final total solids (mg/l).

$$DE = \frac{PS_{initial} - PS_{final}}{PS_{initial}} \tag{2}$$

where DE = dewatering efficiency; $PS_{initial}$ = initial percent solids of the sludge (%); and PS_{final} = final percent solids of the sludge (%).

$$PD = \frac{w_{initial} - w_{final}}{w_{initial}} \qquad (3)$$

where PD = percent dewatered (%); $w_{initial}$ = initial water content of the sludge (%); and w_{final} = final water content of the sludge (%).

2.4 P2DT

The procedures presented by Ratnasamy (2017) were adopted to perform the P2DT. Figure 1 shows a schematic model of the P2DT equipment used in this paper and built in the Geosynthetic Laboratory at the USP. Using two digital weighing scales, axial and radial flows are gathered and electronically recorded as a function of time.

Figure 1. Schematic diagram of P2DT setup.

The P2DT has a diameter of 15 cm and a height of 30 cm. A slurry mixing and supplying bucket was attached to the equipment at a one-meter height (10 kPa) to maintain comparable pumping pressures and pumping rates. To ensure the slurry uniformity in the supply bucket was constantly mixed by a rod during the filling process. In addition, the tests were conducted with and without the balloon to evaluate the application of a constant pressure of 10 kPa (applied by a balloon). Table 2 shows the soil, water and polymer amounts for each fill. The input volume of each cycle was selected based on Ratnayesuraj & Bhatia (2018).

Three fills were performed, with an interval of 30 minutes. A scale and a computer recorded the data for monitoring the volume of effluent during the filling cycles. After each filling cycle, the effluent turbidity of the collection bucket samples was measured for each cycle separately by collecting samples using the nephelometric turbidimeter model Ap2000 from Policontrol. The procedures presented by Ratnasamy (2017) were adopted to measure

Table 2. Amount of soil, water and polymer required for each test P2DT.

Filling	Initial Total Solids (%)	Volume (ml)	Soil (g)	Water (ml)	Polymer Dosage (mgPol/gST)	Polymer (g)
1	15	4000	600	3400	3	1.8
2	15	2500	375	2125	3	1.8
3	15	1750	265.5	1487.5	3	1.8

the thickness at the top of the radial filter cake (H), the thickness at the bottom of the filter cake (h), and the final filter cake solids concentrations after the three filling cycles.

2.5 Geotextile-tube Demonstration Test (GDT)

According to the procedure used by Ardila (2020) based on ASTM D7880, GDT was carried out. Figure 2 shows a schematic model of the GDT equipment used in this paper and built in the Geosynthetic Laboratory at the USP.

Figure 2. Schematic diagram of GDT setup.

The experiment used geotextile tubes with a 53 cm seam-to-seam width. The volume filling for the three cycles was 30,000 mL, based on Ardila (2020) and Ratnayesuraj & Bhatia (2018). A slurry mixing and supplying bucket was attached to the equipment at a one-meter height (10 kPa) to maintain comparable pumping pressures and pumping rates. To ensure the slurry uniformity in the supply bucket was constantly mixed by a rod during the filling process. Table 3 shows the soil, water and polymer amounts for each fill.

Table 3. Amount of soil, water and polymer required for each test P2DT.

Filling	Initial Total Solids (%)	Volume (ml)	Soil (g)	Water (ml)	Polymer Dosage (mgPol/gST)	Polymer (g)
1	15	30000	4500	25500	3	13.5
2	15	20000	1500	17000	3	9.0
3	15	10000	3000	8500	3	4.5

Three fills were performed, with an interval of 30 minutes. The effluent volume was measured for the initial five and after 25 minutes during the filling cycles. After each filling cycle, the effluent turbidity of the collection bucket samples was measured for each cycle separately by collecting samples using the nephelometric turbidimeter model Ap2000 from Policontrol. The outcomes shown are the mean of three tests.

3   RESULTS AND ANALYSES

3.1   *Effluent volume*

The P2DT assay evaluates axial and radial dewatering separately, while the GDT only evaluates total dewatering. Figure 3 shows the accumulated effluent volume of radial and axial effluent with and without the pressure of the three fills of P2DT.

Figure 3.   The effluent volume of P2DT with and without the pressure of the balloon.

Figure 3 showed a reduction in the ratio between radial and axial volume when the balloon applied a pressure of 10 kPa. Figure 4 shows the total accumulated effluent volume of GDT. Figure 4 shows that the dewatering volume initial rate is high in the first few instants and decreases with each filling cycle.

Table 4 shows the ratio of the radial, axial and total percolate by initial volumes from each fill. Based on the results in Table 4, applying pressure by the balloon increased the amount of axial effluent. The sum of the axial and radial ratio for the P2DT trials was lower than that obtained by the GDT trial for all fills.

Figure 4.   Effluent volume of GDT.

Table 4. Ratio of the final radial, axial and total percolate by the initial volume fill.

Test	Filling 1	Filling 2	Filling 3
P2DT without a balloon (axial)	0.18	0.09	0.12
P2DT without a balloon (radial)	0.49	0.49	0.40
P2DT with a balloon (axial)	0.25	0.18	0.18
P2DT with a balloon (radial)	0.39	0.30	0.30
GDT	0.77	0.68	0.60

3.2 Filter cake and percent dewatered

The heights h (internal measurement of the filter cake of P2DT), H (radial measurement of P2DT), TS_{final} and PD for each trial are present in Table 5. The tests presented similar results.

Table 5. Results of filter cake.

Test	H (cm)	h (cm)	TS_{final} (g/l)	PD (%)
P2DT without a balloon	4.6	4.3	51.78	82.95
P2DT with a balloon	5.8	5.6	48.77	81.08
GDT	–	–	51.23	83.05

3.3 Effluent turbidity

Table 6 shows the turbidity results of P2DT in each axial and radial filling, with and without pressure and for GDT. The turbidity of the effluent decreases with each fill for the P2DT trial indicating the improvement of the percolate. For the GDT trials, there was a significant reduction in turbidity from the first fill, possibly due to sedimentation in the tank.

Table 6. Mean and coefficient of variation (CV) turbidity values for the P2DT and GDT assay for each filling.

Test	Filling 1 (NTU)	Filling 2 (NTU)	Filling 3 (NTU)	CV 1 (%)	CV 2 (%)	CV 3 (%)
P2DT without a balloon (axial)	68	28	58.1	58.1	83.9	54.6
P2DT without a balloon (radial)	238	73	79.8	79.8	38.9	64.4
P2DT with a balloon (axial)	27	16	24.9	24.9	50.9	37.6
P2DT with a balloon (radial)	138	32	12.0	12.0	69.6	13.3
GDT	3.7	2	30.0	30.0	9.9	13.5

4 CONCLUSIONS

This paper evaluates radial and axial dewatering in P2DT testing using an artificial slurry conditioned with polymer and compares the results with the GDT. The results reported in the study indicated that the two-dimensional test (P2DT) could be an alternative to bench tests.

The turbidity results indicated that the effluent quality and the ratio between the total percolated and initial volume for the P2DT test were lower than the values obtained by the GDT, mainly in the radial direction due to the radial filter cake. On the other hand, the values of final solids content and dewatering percentage showed similar values. A significant improvement of the analyzed slurry was noticed in all cases, showing that geotextile tubes are an exciting alternative for sludge dewatering.

ABSTRACT: In this study, the compatibility of internally unstable soils with two non-woven geotextile filters was analysed by means of a method proposed by the Authors in a recent research. The method is based on a geometrical, experimental and micro-structural approach that considers the geotextile pore size distribution and its filtration opening size, the soil grain size distribution and its critical diameter of suffusion, the results of long-term filtration tests and the scanning electron microscope images of geotextile microstructure. The method application allowed the Authors to better evaluate the soil/geotextile filter compatibility under critical/severe conditions.

1 INTRODUCTION

Geotextile filters are successfully used in different civil and environmental geotechnical works. The filter function is to prevent the movement of fine particles from the base soil allowing the liquid to flow as freely as possible.

In some cases, when filter is in contact with an internally unstable soil, particles not belonging to soil skeleton and dragged by water flow may accumulate at base soil-geotextile filter interface (blinding) and/or may remain entrapped within filter pores (clogging). In this condition, the designer has to decide if to allow the passage of fine-grained soil particles free to move inside the soil skeleton, avoiding piping of the base soil, or if to retain an amount of these particles, avoiding filter clogging (Moraci *et al.* 2022; Palmeira 2020). Since filter interaction with internally unstable soils is considered an issue not yet properly understood, long term performance tests are recommended.

This study investigates the geotextile filter long term behaviour in contact with three internally unstable cohesionless soils. In order to assess the soil/geotextile filter compatibility a method recently proposed by the Authors (Moraci *et al.* 2023) was applied. The method is based on a geometrical, experimental and microstructural approach. The geometrical approach consists to compare the geotextile pore size distribution with the soil grain size distribution, considering the filtration opening size of the geotextile and the critical diameter of suffusion of the soil. The experimental approach is based on the performance of long term filtration tests that allow the evaluation of blinding, clogging and piping limit states. The micro-structural approach is based on the analyses of SEM (scanning electron microscope) images taken on the tested geotextiles in order to observe the clogging and blinding phenomena.

2 MATERIALS AND METHODS

The cohesionless soils investigated in this paper were reconstituted using gravel and marbles of various colours. Soil classification (ASTM D2487), the percentage of gravel, sand and fine, the coefficient of uniformity, CU (d_{60}/d_{10}), the coefficient of curvature C_c ($d_{30}^2/d_{10}d_{60}$) and the specific weight of the soils Gs are shown in Table 1.

Table 1. Soil index properties.

ID	Soil	Classification	Gravel [%]	Sand [%]	Fine [%]	CU [-]	C_c [-]	Gs [-]	Dc [mm]
9/WF	GW-GM	Well Graded Gravel with silt and sand	79	9	12	116.9	56.9	2.64	3.4
2R/WF	GM	Silty Gravel	47	30	23	876.9	3.1	2.67	4.0
4R/WF	GW	Well Graded Gravel	50	44.5	5.5	20.7	2.6	2.68	0.3

These soils resulted internally unstable according to Moraci *et al.* (2023). The critical diameter of suffusion, Dc (i.e. diameter of the largest particle passing across the constrictions of soil solid skeleton), showed in Table 1, was obtained according to SimulFiltr method (Moraci *et al.* 2012).

Two types of nonwoven geotextiles (GT) were used: a thick needle-punched (NP) geotextile and a thin heat-bonded (HB) needle-punched geotextile. The mass per unit area (μ_{GT}) is 600 g/m² for NP and 80 g/m² for HB, the nominal thickness (t_{GT}) is 2.8 mm for NP and 0.7 mm for HB geotextile. The filtration opening size (O_F), determined by means of capillary flow porometry (ASTM D6767-02), is 0.055 mm and 0.187 mm for NP and HB geotextiles, respectively.

The long term filtration tests were performed using the equipment illustrated in Figure 1.

Figure 1. Test apparatus (Moraci *et al.* 2023).

The test device is a permeameter cell with internal diameter of 150 mm. It allows us to perform tests on soil specimens of a height equal to 164 mm. The variation in local hydraulic gradients along the specimen is calculated by means of 6 piezometers located at a vertical spacing of average value equal to 35 mm. The distance between the piezometer number 5 and the soil/geotextile filter interface is equal to 25 mm. The tests were carried out under vertical downward flow with hydraulic constant load and without the application of a vertical load.

The blinding level was evaluated by the blinding factor, $BF = i_{cz}/i_s$, defined as the ratio between the gradient in the filter-soil contact zone (i_{cz}) and the gradient in the adjacent soil (i_s).

After filtration tests the geotextile impregnation level λ (Palmeira & Gardoni 2000) was determined as the ratio between M_s, the total mass of particles in the geotextile, and M_f, the total mass of geotextile fibres.

3 RESULTS AND DISCUSSION

The compatibility of the three internally unstable soils with the two nonwoven geotextiles was analysed by means of the geometrical, experimental and micro-structural approach proposed by the Authors (Moraci *et al.* 2023).

3.1 *Geometrical approach*

The geometrical approach consists to compare the pore size distribution (PSD) of the geo-textile filter with the grain size distribution (GSD) of the soil (Figure 2) considering the

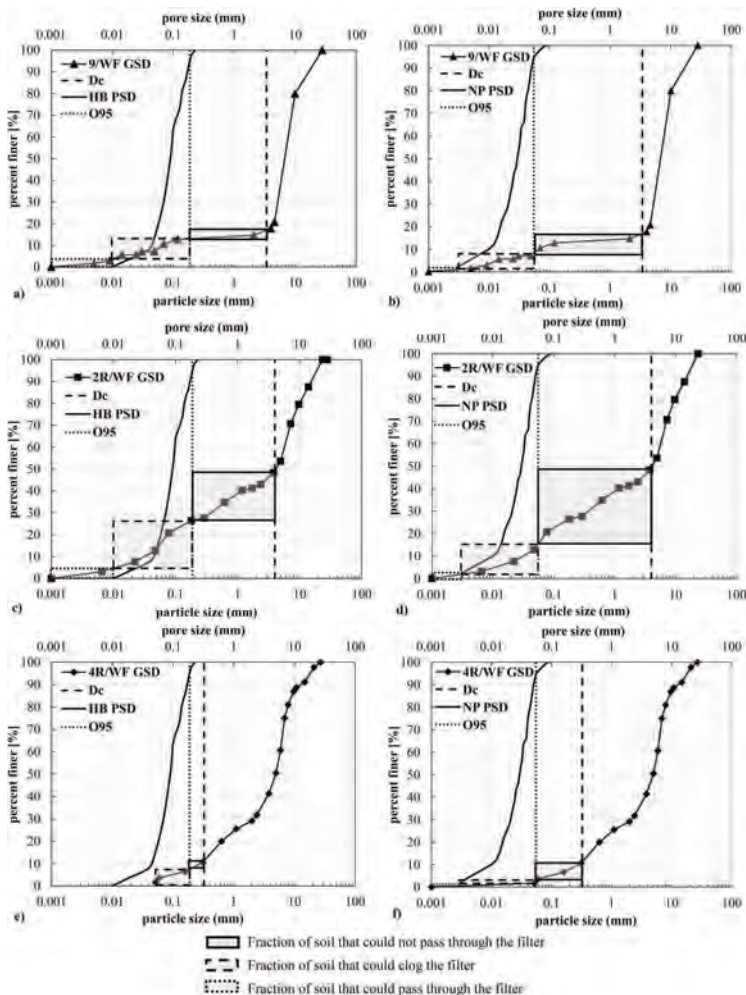

Figure 2. 9/WF GSD curve and PSD of a) HB and b) NP geotextile, 2R/WF GSD curve and PSD of c) HB and d) NP geotextile, 4R/WF GSD curve and PSD of e) HB and f) NP geotextile.

values of O_{95} and the values of Dc. This comparison allows to better understand if the mass of particles with a diameter lower than Dc could pass through the filter (perimeter area with dotted line), clog the filter (perimeter area with dashed line) or accumulate at soil-filter interface causing blinding (perimeter area with solid line).

The soil particles free to move inside the solid skeleton (with a diameter lower than Dc), able to clog or cross the geotextile filter are those with a diameter lower than O_F (perimeter areas with dashed and dotted lines in Figure 2). Not all the soil particles can cross (perimeter area with dotted line) or clog (perimeter areas with dashed line) the geotextile filter when there is a fraction of soil particles lower than Dc and greater than O_F (perimeter areas with solid line), because this fraction stops on the soil/geotextile interface generating a blinding phenomenon that produces a porosity decrease at the soil-filter interface. When blinding is significant, a geometric analysis providing information on the susceptibility to piping and clogging phenomena is very complex because the particles that accumulate in the soil/geotextile interface (blinding) produce a decrease in porosity and a new pore size distribution.

Comparing the GSD of 9/WF soil with PSD of HB geotextile (Figure 2a), it can be observed that the piping or clogging phenomena could occur. Piping phenomena is negligible when the same soil is in contact with NP GT (Figure 2b). Passing from HB to NP geotextile it can be noted that susceptibility to blinding increases according to reduction of O_F.

Considering 2R/WF soil, the susceptibility of geotextile to blinding phenomena increases passing from HB to NP geotextile (Figures 2c, d) whereas piping decreases. Finally, considering 4/WR soil in contact with HB geotextile (Figure 2e), a negligible piping and a moderate clogging could occur. Passing to NP geotextile the susceptibility of geotextile to blinding phenomena increases (Figure 2f).

3.2 Experimental approach

Long term filtration tests were carried out on the investigated soils (Table 1) in contact with two different geotextile filters. For each test, the level of blinding (BF), the soil mass passing through geotextile (M_p), the Piping level obtained dividing M_p by the specimen area, the impregnation level (λ), are shown in Table 2.

Table 2. Factors, characteristics and parameters derived from long term filtration test results.

	BF [-]	M_p [g]	Piping level [g/m^2]	λ [-]
HB – 9/WF	> 3	114.43	6475	2.90
NP – 9/WF	> 3	1.69	96	1.58
HB – 2R/WF	> 3	115.17	6517	2.11
NP – 2R/WF	> 3	2.14	121	1.49
HB – 4R/WF	≅ 3	25.8	1459	1.13
NP – 4R/WF	> 3	0	0	1.66

The calculated BF value is about equal to 3 for 4R/WF soil in contact with HB geotextile, whereas in the other investigated cases the values are greater than 3 due to the accumulation of particles on the geotextile surface. The amount of soil piped through the geotextiles varies from 0 to 115.17 g. The piping failure limit proposed by Lafleur *et al.* (1989) and equal to 2500 g/m^2 (Fatema & Bhatia 2018; Palmeira & Tatto 2015) was exceeded for 9/WF and 2R/WF soils in contact with HB geotextile. The clogging level was quantified by means of the impregnation level λ that ranges from 1.13 to 2.90.

Long term filtration tests are analysed using the geometrical approach shown in Figure 2.

For the 9/WF soil in contact with the two geotextiles, the movement of soil particles potentially able to move through the constrictions of the solid skeleton is equal to 18 % by weight (perimeter areas with solid, dashed and dotted line). The amount of soil particles that could blind

the filter is equal to 5 % and 10 % by weight (perimeter areas with solid line) for the HB and NP geotextile, respectively. The percentage by weight of soil particles potentially able to clog or to pass through the filter (perimeter area with dashed and dotted line) is equal to about 13 % and 8 % by weight for the HB and NP geotextile, respectively. Due to the greater amount of soil particles that accumulates on the surface of the NP geotextile, clogging and piping decrease as confirmed by the Piping level and by the λ value calculated at the end of the test.

For 2R/WF soil in contact with the two geotextiles, the amount of soil particles capable of blinding the filter increases from 20.65 % to 33 % by weight (perimeter area with solid line) passing from the HB to NP geotextile. The amount of soil particles that could clog or pass through the filter (perimeter areas with dashed and dotted line) reduces from 26.5 % (HB geotextile) to 14 % (NP geotextile) by weight. As expected from geometrical analysis, the piping is observed using HB geotextile because the soil particles able to pass through the filter are those in the perimeter area with dotted line and a fraction that belongs to the perimeter area with dashed line (piping level > 2500 g/m^2). Regarding NP geotextile, due to the greater amount of particles accumulated on its surface, the clogging decreases, as confirmed by the λ value, and piping is negligible.

Regarding 4R/WF soil in contact with the two geotextiles, the base soil fraction capable of blinding the filter (perimeter area with solid line) is equal to 4 % and 8 % for the HB and NP geotextile, respectively. Therefore, an increase of blinding is expected as confirmed by test results. For HB geotextile, the soil fraction able to clog or pass through the filter is low (7 % by weight, perimeter area with dashed line) and, therefore, also the piping and clogging levels expected are limited, as confirmed by test results.

The results derived from the geometrical approach and long-term filtration tests showed that the porometry of the filter could be acceptable if O_F is next to Dc value in order to limit the blinding level (as in the case of the HB geotextile in contact with 4R/WF soil). In order to limit the piping and clogging levels, it is necessary to take into account the amount of soil particles free to move inside soil skeleton (with a diameter lower than Dc) and potentially able to clog or cross the filter (with a diameter lower than O_F).

3.3 *Micro-structural approach*

SEM images revealed useful to provide qualitative and useful information about blinding or clogging phenomena for all investigated cases.

Figure 3 shows SEM images of the upstream face (i.e. the surface directly in contact with the base soil), cross-section and downstream face of HB geotextile in contact with 2R/WF soil.

Figure 3a shows the presence of the base soil particles accumulated on upstream face according to the levels of blinding ($BF > 3$) evaluated by long-term filtration tests. The geotextile cross-section image (Figure 3b) confirms the clogging level along the geotextile thickness ($\lambda = 2.11$). Figure 3c shows a small amount of fine particles and of precipitates accumulated on the downstream face (Figure 3c).

SEM images of the HB geotextile in contact with 4R/WF soil (Figure 4) confirm the stable behaviour of filter system with acceptable levels of blinding, clogging and piping observed in

Figure 3.   SEM images of HB geotextile in contact with 2R/WF soil: a) upstream face (magnification 220x); b) cross-section (magnification 131x) and c) downstream face (magnification 170x).
Figure 4.   SEM images of HB geotextile in contact with 4R/WF soil: a) upstream face (magnification 195x), b) cross-section (magnification 145x) and c) downstream face (magnification 175x).

the long term filtration test. Indeed, the upstream face of the geotextile after long term filtration test (Figure 4a) shows an acceptable level of blinding, the cross-section shows a limited level of clogging (Figure 4b) and the downstream face (Figure 4c) shows a negligible presence of soil particles.

4   CONCLUSIONS

This study allowed to confirm the utility of the geometrical, experimental and micro-structural approach, recently proposed by the Authors to analyse the geotextile/soil compatibility. For this purpose, the behaviour of two types of nonwoven geotextiles in contact with three internally unstable soils was analysed. Experimental results showed the reaching of blinding and piping limit states for the HB geotextile in contact with 9/WF and 2R/WF soils and a stable long-term behaviour for the same geotextile in contact with 4R/WF soil. Passing to the more closed NP geotextile, due to the accumulation of a greater amount of soil particles on its surface, it has been observed the blinding phenomenon and the absence of piping in the three investigated cases. These results were in good agreement with the geometrical approach. SEM images of the upstream face, cross-section and downstream face of the geotextile after long-term filtration tests confirmed the results of the experimental and the geometrical analysis.

Hydraulic applications: Canals, reservoirs and dams

Evaluation of the hydraulic behavior of hydrophilic and hydrophobic geotextiles under hydrostatic pressure test

L.C. Rodrigues & D.M. Vidal
Aeronautical Institute of Technology, São José dos Campos, SP, Brazil

ABSTRACT: Geotextiles have been successfully applied in road works, performing several functions in granular layers. Geotextile structure and their hydrophobic/hydrophilic characteristics are of great relevance. The resistance of dry geotextiles to penetration by water, WPR, is one of the parameters employed to evaluate the hydraulic behavior of geotextiles in unsaturated media. The papers discuss the influence of additives used in the manufacturing process and the soil/geotextile interface in the resistance to water penetration by experimental tests. The tests conducted in this study indicate that products presenting hydrophilic behavior in virgin samples can show a hydrophobic behavior after light washing. The tests on the sample with an initial water penetration resistance indicate an increase of up to 373% after washing. The evaluation of the soil influence indicates that the phenomenon is also present in this condition, but the rate of water pressure increase affects the WPR.

1 INTRODUCTION

There are several years that geotextiles are inserted in granular pavement layers performing functions such as filtration, separation, and stabilization. They are also applied to protect pavement layers from increasing moisture content, acting as a capillary barrier.

Geotextile characteristics and long-term filtration tests are generally conducted in saturated conditions. Therefore, in most pavement situations, the geotextile remains for several periods in the residual moisture situation, remaining in the dry state. When rainfall occurs, and percolating water reaches the interface soil/geotextile, the hydrophobic or hydrophilic behavior of the geotextile becomes relevant.

Water stagnation in the geotextile is related to a phenomenon called Water Penetration Resistance (WPR). It depends on the geotextile fibers' chemical nature and structure (Lennoz-Gratin 1987). The WPR is evaluated by tests conducted in dry specimens according to EN 13562. These tests are generally conducted on specimens in the condition in which they left the factory. Avancini *et al*. (2020) discuss water penetration resistance and its determination.

Some researchers have indicated that products classified as hydrophilic could present a hydrophobic behavior after water percolation (Bouazza *et al*. 2006; Stormont *et al*. 1997). Vidal *et al*. (2014) observed that a hydrophilic geotextile presented 6 mm WPR after a slight washing. In fact, in diverse fabric manufacturing stages, additives are employed to increase the efficiency of the process, reduce friction, and protect the fibers.

In addition, it is also essential to evaluate the effect of percolation occurring through the adjacent soil layer. This paper discusses the factors influencing water penetration resistance from experimental results assessing the influence of geotextile washing to remove surfacing additives and tests in a system soil/geotextile.

2 INFLUENCE OF WATER PENETRATION RESISTANCE IN PAVEMENT DESIGN

The paving designs must consider the various processes by which water can interfere with their behavior. Some of the situations associated with the presence of water in the soil are illustrated in Figure 1. In addition to the influence of the water table, infiltration processes due to rainfall or thawing must be considered.

Figure 1. Different ways in which water can act on paving layers.

Water can penetrate through cracks and micro-cracks of the asphalt overlay during rainy periods and infiltrate into the base course until it reaches a geotextile acting as a separator or stabilizer. In this case, the influence of a few centimeters of water accumulation should be evaluated and may or may not be relevant to the design. For example, traffic loads are likely to increase the pore pressure in the saturated sheet, causing localized flow toward the drain, eliminating the problem, especially since base courses are generally quite permeable.

Water can also approach the base or subbase layer by flowing capillarity through the subgrade, even when a drainage system is in place to ensure the lowering of the water level. In this case, a geotextile layer with hydrophobic behavior could prevent the advancement of water, if the loads imposed by traffic cannot raise the pore pressure to the point where the penetration resistance is exceeded.

When the geotextile is applied to perform the filtration function in deep drainage trenches to lower the water level, the accumulation of a few centimeters of water generally does not significantly affect the system's behavior.

3 HYDRAULIC BEHAVIOR OF UNSATURATED GEOTEXTILES

3.1 *Hydrophobic x hydrophilic characteristics*

The surface of polymers has characteristics that interfere with their relationship with other substances. For example, polymers such as polypropylene and polyester have hydrophobic characteristics, i.e. water molecules are not attracted to the apolar groups of the polymer (Atkins & Jones 2007). Most geotextiles are made up of these polymers and therefore possess hydrophobic characteristics.

However, polymer treatment techniques can cause changes in the surface properties of polymers that favor surface interaction and adhesion with other substances (Gilliam 2015). For example, oils are essential additives in the fiber spinning and fabric manufacturing stages of textile fiber processing. These additives are used to reduce the fibers' friction and

protect their surface during manufacture. Often these oils lead the virgin geotextile to exhibit hydrophilic characteristics. Therefore, most of these oils tend to leach out with the passage of water, which makes the hydrophilic characteristic temporary (Bouazza *et al.* 2006; Stormont *et al.* 1997; Vidal *et al.* 2014).

The research seeking processes to permanently alter the surface characteristics of fibers and filaments of the most commonly used polymers, PET and PP, to hydrophobic behavior has grown with the increased use of these polymers in the textile industry. However, the most sophisticated processes have shown a return to hydrophobic behavior over time (Tarig *et al.* 2022).

3.2 *Water Penetration Resistance (WPR) tests*

Lennoz-Gratin (1987) described a test procedure for evaluating the resistance to water penetration in dry specimens. The first French standard (AFNOR NF G 38020) was published in 1988 and established a test procedure with a rate of increase of water pressure of 10 mm/min, defining the WPR as the highest recorded value.

Since 1981 there is a method for determining the WPR of textiles, including those with low permeability - ISO 811 (ISO 2018) - in which the water pressure is applied from below the specimen and much higher pressures (up to 2m H_2O) can be achieved. The accuracy starts at 5 mm, too high for geotextiles for which the accuracy should be 1 mm.

In 2000, the European standard EN 13562 replaced the AFNOR standard, with some changes in the procedure, as the rate of increase of water pressure of (100 ± 5) mm/min (same minimal rate of ISO 811). The water pressure may be applied from below or from above the specimen. The pressure, in millimeters, at water appears in continuous droplet form through the specimen's opposite face, and the maximum water pressure achieved shall be recorded.

The standard does not discuss a procedure to evaluate the presence of hydrophilic substances on the surface of the fibers or filaments, recommending performing the test on dry geotextile and avoiding manipulation of the specimen in such a way as not to alter its structure. Thus, the test is usually performed on the sample in the condition in which it comes from the industry.

4 TESTS TO EVALUATE THE INFLUENCE OF ADDITIVES

4.1 *Materials and methods*

For this research, two nonwoven needled-punched geotextiles in cut fiber were selected, with hydrophobic/hydrophilic behavior estimated through reaction to water droplets dripped onto the surface. The geotextile samples were denominated NW1 and NW2.

An apparatus similar to the one outlined in Figure 1 was employed for the water penetration resistance tests with the following modifications:

- a scale and a video camera were placed inside the transparent cylinder to better visualize the water pressure on the exposed surface of the geotextile,
- another video camera was installed below the cylinder to a continuous record of the geotextile underside,
- a cylinder with an area of 165 cm^2 was used instead of 100 cm^2 as required by the standard so that the water column height values obtained are for comparison purposes and cannot be used as an index property.

The influence of additives that could induce a hydrophilic behavior was evaluated in tests performed according to EN 13152 on specimens in the received condition and after washing.

Each specimen was weighed and had its mass per unit area evaluated. After weighing, the specimens were submitted to the water penetration resistance test in virgin condition (as received from the manufacturer). All tests were performed by evaluating the behavior of the inner face of the roll.

The specimens of sample NW1 were separated into two groups. The first group was washed in filtered water, and the second group was washed in filtered water plus a non-ionic surfactant (5 ml/l) and again washed in filtered water.

For this washing, the specimens were immersed until saturation and submitted to a sequence of emersions/immersions carefully performed so as not to cause changes in the structure. The washed specimens were then left to dry in the laboratory until weight constancy and submitted to the water penetration resistance test.

The specimens of sample NW2 were washed only with filtered water.

4.2 Results

Table 1 summarizes the results of the water penetration resistance tests performed, where h_{inic} is the height of the water column at the appearance of the first drop and h_{max} is the height of the maximum water column observed on the specimen. Figure 2 shows illustrative images of the tests at maximum water pressure.
Table 1. Results of tests to evaluate the additive influence.

sample		m.u.a* (g/m²)	Virgin h_{init}(mm)	h_{max}(mm)	Washed with filtrated water h_{init}(mm)	h_{max}(mm)	Washed with water+surfactant h_{init}(mm)	h_{max}(mm)
NW1	PET	298 ± 27	0	0	28 ± 3	31 ± 1	24 ± 3	29 ± 3
NW2	PP	330 ± 49	12 ± 4	15 ± 3	59 ± 8	71 ± 6		

*mass per unit area (ISO 9864)

(a) Bottom-face view   (b) Upper-face view

Figure 2. Example of images recorded at maximum water pressure.

4.3 Discussion of the results

The WPR tests realized on virgin specimens of NW1 geotextile did not indicate resistance to water penetration, as expected. However, the results of the specimens washed with filtered water plus surfactant showed no advantage in washing with the surfactant, perhaps due to a

low rinsing efficiency. For this reason, the second sample was washed with filtered water only.

The additives that altered the surface characteristics of the fibers were quickly leached out by washing with filtered water, suggesting that a few cycles of water passage would lead to a hydrophobic condition. The washing of specimens of sample NW2 presenting hydrophobia in the test with the material in the condition received from the factory showed that even products with hydrophobic behavior may have increased resistance to water penetration after saturation and drying cycles.

No relationship between the mass per unit area and the WPR has been observed, leading one to believe that the phenomenon is more affected by surface conditions. The sample whose component polymer is polypropylene showed much higher resistance to water penetration than the sample whose polymer is polyester.

5 TESTS TO EVALUATE THE INFLUENCE IN SOIL/GEOTEXTILE SYSTEMS

5.1 *Materials and methods*

The influence of a hydrophilic porous medium in contact with a hydrophobic geotextile surface was evaluated in two steps. The first one considers the effect of the rate of water pressure increase on the geotextile surface, as generally, this rate would tend to be less than 100 mm/min in flow occurring in unsaturated soil. For this purpose, tests considering the proposal of the previous standard, which indicated a rate of 10 mm/min, were adopted to evaluate this effect.

For the tests with soil at the interface, a simple apparatus was developed to allow a first evaluation of the influence of soil/textile contact.

The materials used in the tests were a nonwoven needle-punched geotextile with polyester filaments, a hydrophobic material, and ground quartz, a hydrophilic material. The selected ground quartz presents uniform grain size (coefficient of uniformity, CU, equal to 1.4), and is composed by particles passing #20 (<0.85mm), being 85% with a diameter less than 0.78 mm and 10% with a diameter less than 0.47 mm.

WPR tests were conducted on the nonwoven geotextiles with two rates of water pressure increase: (100 ± 5) mm/s and (10.0 ± 0.5) mm/min, to evaluate the influence of the water pressure increase in the water penetration resistance.

The apparatus employed in the test with soil is composed of a lower chamber for the soil specimen and a system of clamps to fix the geotextile specimen. The area of the geotextile exposed to water pressure is the same as in the WPR test. A water reservoir at a constant level provides an upward flow and a piezometer placed below the geotextile interface allows for monitoring the rise of the water pressure in the soil near the interface. Video cameras monitored the piezometer and the top surface of the geotextile.

A thin layer of cotton placed at the bottom of the lower chamber allows a uniform distribution of penetrating water. Cotton was chosen because it is a hydrophilic material as the ground quartz. The particulate material is uniformly displaced in the lower chamber with a funnel until it exceeds the interface level. The excess soil is removed using a rigid ruler to guarantee full contact between the geotextile and the soil. After fixing the geotextile specimen, the assembly is placed on the support to be connected to the water supply reservoir, which is positioned to maintain the water level 80 mm above the lower level of the geotextile. Figure 3a shows the device's schema.

5.2 *Results*

The water penetration tests conducted on the nonwoven geotextiles indicate a mean value of (30 ± 2) mm in the tests with a rate of water pressure increase of (100 ± 5) mm/s, and

(a) Scheme of tests
(b) Water pressure below the geotextile
(c) Water emerging on the geotextile surface

Figure 3.   Views of the soil-geotextile test.

(25 ± 3) mm in the water penetration tests conducted at a water pressure increase of (10.0 ± 0.5) mm/min.

Two tests were conducted in the system soil/geotextile, presenting a similar behavior. Water started to appear on the top face of the geotextile about 90 minutes after the start of the water supply. The piezometer indicated a water column height of 20 mm above the underside of the geotextile when water emerges on the geotextile surface. Figures 3b and 3c show pictures of the tests in the system soil/geotextile obtained when the water begins to appear on the geotextile surface.

5.3   *Discussion of the results*

Tests conducted to determine the water penetration resistance, WPR, at different rates of water pressure increase showed that the filling speed proposed in EN 13562:2000 implies a value 20% higher than the value obtained with the test performed at the rate indicated in the AFNOR NF G 38020:1988.

Obtaining a higher value for this parameter probably aims to evaluate the behavior under critical conditions. However, it is interesting to know the behavior for situations where water accumulation occurs more slowly, as it usually occurs in cases where the water percolates through the soil.

The soil-geotextile system tests showed that water accumulation on the surface also occurs when water percolates through the unsaturated soil. The 20 mm of water height above the underside of the geotextile observed during the soil tests shows, in this case, a lower value of water penetration resistance than that observed in the WPR tests, even in the lower rate of water pressure increase, which was 25 mm.

6   CONCLUSION

The raw material and structure provide the hydrophobic characteristic and prevent water from penetrating the pores of the unsaturated geotextile unless a positive pressure equals or exceeds the water penetration resistance occurs.

Tests measuring the water resistance penetration, WPR, of nonwoven geotextiles show that water flow can modify this property. A hydrophilic product can be transformed in hydrophobic, and a hydrophobic product can significantly increase its WPR, being observed with an increase of 373%.

Tests performed at different rates of increasing water pressure indicated a 20% reduction in WPR when this rate is reduced from 100 to 10 mm/min. The influence of the rate of

increase of the applied pressure is relevant because this rate can be directly linked to the variation of the medium's permeability.

The tests with hydrophilic soil confirm that the penetration resistance persists even with the presence of soil at the geotextile interface. The values measured in the tests performed show a reduction in the resistance of the isolated geotextile, probably due to a reduction in the rate of pressure increase that becomes controlled by the soil permeability.

Research to evaluate the influence of soil particle intrusion on geotextile structure will be carried out in future work. However, a reduction of the water penetration resistance could occur, but there is no expectation of eliminating it. The tests performed have shown that the surface effect is very significant, and it would be difficult that the particles could form continuous columns able to conduct water from one geotextile surface to another.

ABSTRACT: Geosynthetic Clay Liners (GCL) are widely used in sealing applications throughout the world. In applications with constant water heads - such as artificial ponds, rivers, canals, etc. - the permeation rate through the GCL is of vital importance to the performance of the whole structure and the allocated function. A proper design must consider all potential sources of water loss in the designed application. This includes also the performance of overlaps or the combined effect of multiple sealing layers. Some factors are sometimes misinterpreted, underestimated or not considered.

The presented paper will focus on two major topics, each affecting the performance of geosynthetic sealing systems with special focus on geosynthetic clay liners (GCL). The impact of these effect is to be illustrated on exemplary calculations for virtual projects. The quantification of these effects will result in recommendations that shall help to anticipate unfavorable situations for the operational phase of a project already in the design stage. This shall contribute to a better overall understanding of GCL and help to avoid preventable design errors. An outlook shall summarize the further efforts envisaged by the authors to provide a simple tool to allow calculation of permeation rates for GCL or complete barrier systems.

1 INTRODUCTION

1.1 *Motivation*

Geosynthetic barriers – and as a focal point of this paper geosynthetic clay liners (GCL) in particular – are established as sealing elements for applications with constant water head. Regardless, there are various examples where factors, which are of important influence for the overall performance of such products, are not being considered or underestimated in the design stage of a project. Some of these impacts may not be obvious even to the experienced designer of lining systems. This can lead to higher permeation rates as considered in the design, consequently resulting in water tables falling short of the level that is being considered in the design. This may be crucial for applications where a sufficient permanent supply of water is essential. Examples for such structures are fire ponds, water channels (especially in hydropower applications) or irrigation facilities.

When problems with insufficient water tables occur, the sealing component – in the given cases the GCL – is often falsely claimed as unreliable, although misconceptions can be prevented by a better knowledge of the subject matter and an according choice of suitable products.

Figure 1. Typical application with high importance of precise hydrological balance: Fire ponds.

The presented paper intends to increase the knowledge on potential conditions that have impact on the permeation rate and to quantify the effect of one selected factor. The consequence of using different GCL thicknesses for the back-calculation of the hydraulic conductivity k_f from laboratory tests and subsequently the calculation of the permeation rate shall be illustrated on a fictious project.

1.2 *Method*

For the quantification of permeation rates of GCL it is common to refer to the results of laboratory tests (ASTM D5887; DIN EN 16416). The hydraulic conductivity is derived from the test results by the measured flow and the thickness of the permeated specimen.

The common calculative approach to derive the permeation is carried out by application of Darcy´s law (Darcy 1856), in this paper considered in the form of:

$$Q = k_f \cdot i \cdot A \tag{1}$$

where Q = Volumetric flow [$m^3 \cdot s^{-1}$]; k_f = Hydraulic conductivity [$m \cdot s^{-1}$]; i = hydraulic gradient [-]; A = Area [m^2]

2 NECESSARY CONSIDERATIONS FOR CALCULATING GCL PERMEATION

2.1 *General considerations*

GCL are established as sealing component for environmental protection applications, e.g., serving as single lining systems for non-hazardous landfills in accordance to the European Council Directive on the landfill of waste (1999). In such applications, usually no permanent water tables are to be considered on the sealing systems and the resulting permeation rates measured in lysimeter trials for GCL with sodium powder bentonite are virtually zero (Bluemel *et al.* 2010).

However, the use in applications with permanent hydraulic head demands for closer examination of the expected permeation rates.

The calculative approach is already mentioned in 1.2. The hydraulic conductivity k_f is a decisive factor in the calculative approach. The hydraulic conductivity k_f derived from laboratory tests may however be altered in the field by various effects. It must be taken in mind that this is valid for all mineral sealing components. The most significant of these effects for hydraulic applications are:

- Root penetration
- Ion exchange
- Dehydration
- Frost/Thaw

None of these effects can be assumed to be a general influence on every project but must be considered specifically by project boundary conditions.

2.2 *Specific considerations*

2.2.1 *Impact of thickness for calculation of permeation rates*

The thickness of the GCL is necessary to backcalculate k_f from the measured index flux q resulting from the laboratory tests (ASTM D5887; DIN EN 16416). The thickness is essential to calculate the hydraulic gradient i in equation (1). It is defined as:

$$i = \frac{(h_w + t)}{t} \qquad (2)$$

where h_w = hydraulic water head [m] – usually 1.5 m in ASTM D5887; and t = thickness of the GCL

With the measured index flux q (volumetric flow per area, Q/A, [$m^3 \cdot m^{-2} \cdot s^{-1}$]), all other parameters of equation (1) aside from k_f are defined, and the thickness can either be measured or assumed. A common assumption is t = 1 cm thickness for a swollen GCL. Under cell pressure in laboratory tests, the actually measured thickness may vary – depending mainly on the area weight of bentonite – between 0.5 and 1 cm. It is possible to use either assumed or measured thickness for the backcalculation of k_f.

While the k-value of a product may be backcalculated under consideration of the laboratory thickness and published in a data sheet, designers tend to use the "common assumption" for the thickness of a swollen GLC by t = 1 cm to calculate project specific permeation rates, regardless of the actual product thickness which would be expected under the project specific load and saturation conditions. The following calculation example in table shall illustrate that it may lead to unsafe results when k_f values backcalculated with measured thickness t < 1 cm during index flux testing are used to derive permeation rates of GCL in designs where the common approximation of t = 1 cm is used to derive the hydraulic gradient.

The example shows that – under the consideration of the given data – the assumption of a swollen GCL thickness of t = 1 cm may lead to underestimation of permeation losses in a lined water basin when the k-value has been evaluated considering lower thickness from live measurements during the index flux test. Given that all other conditions are coherent with the laboratory test, the variation of thickness between backcalculation of k_f (measured thickness t = 0.006 m) and permeation calculation (common assumption t = 0.01 m), the losses are 1.66-fold higher when considering the realistic thickness.

It remains however possible to use the assumption of t = 1 cm for the calculation of permeation rates in cases where the k_f has been derived from laboratory tests with exactly that thickness. In this case, the results will remain safe with respect to the thickness considered in the calculation.

Table 1. Calculation example for permeation rate through a GCL.

Measured index flux [$m^3 \cdot m^{-2} \cdot s^{-1}$]	$3.0 \cdot 10^{-9}$	
Measured thickness [m]	0.006 (6 mm)	
k_f, backcalculated [$m \cdot s^{-1}$]	$1.2 \cdot 10^{-11}$	
Calculative approach for water permeation: Q = $k_f \cdot i \cdot A$		
Assuming a basin with depth of 1.5 m and an		
Area of A = 10,000 m^2		
Considered thickness [m]	0.006 (realistic)	0.01 (common assumption)
Hydraulic gradient i [-]	251	151
Calculative permeation Q = $k_f \cdot i \cdot A$ [$m^3 \cdot s^{-1}$]	$3 \cdot 10^{-5}$	$1.8 \cdot 10^{-5}$
In other numbers for illustrative purpose:	2592	1559
daily loss [$l \cdot d^{-1}$]		

2.2.2 *Impact of overlaps*

While some impact factors on the permeation rate apply for all GCL in the same way, the overlapping technique differs by product and can hence make an influence on the overall GCL performance in terms of permeation.

This is due to the differing overlapping techniques featured by the individual manufacturing processes. While some products feature overlaps that are pre-impregnated with bentonite powder which is automatically dosed onto the cover geotextile in the manufacturing process, other products require for manual application of bentonite in the overlap areas. Sometimes, marking trolleys are used. Even with good craftmanship and clean manual implementation of bentonite for overlaps, the latter method remains prone to inhomogeneous distribution of the applied bentonite and thus to inconsistency of the conductivity of the overlaps.

With this subject matter being identified as one major impact for permeation calculations, respective recommendations can be made to quantify the impact of the GCL overlaps (see chapter 3.2.2).

3 RECOMMENDATIONS WITH RESPECT TO PERMEATION CALCULATIONS

3.1 *General recommendations*

Chapter 2.1 named effects that may have an impact on GCL permeability. Consecutively, the GCLs performance in the field, e.g., the permeation rate, may significantly differ from predictions if these predictions were solely based on calculations that consider laboratory values.

The listed effects under chapter 2.1 can usually be countered by constructive measures which are described in respective guidelines such as GRI-GCL5. One of such measures could be the implementation of sufficient soil covers against adverse effects on permeability caused by desiccation or freeze/thaw.

Advanced products such as multicomponent GCL, such as GCL with polyethylene coating, can also effectively prevent effects of desiccation, root penetration or ionic exchange (Egloffstein *et al.* 2013).

If these effects cannot be prevented, it is necessary to quantify the impact of the effect on the permeation rate and consider this in permeation calculations. As an example, the effect of ionic exchange on GCL permeability has been researched and also quantified in Egloffstein (2001).

3.2 *Specific recommendations*

3.2.1 *Recommendations concerning thickness in permittivity calculations*

With respect to the issue explained in chapter 2.2.1, the authors recommend to not deliberately choose $t = 1$ cm as thickness for the swollen GCL. Although this is safe for cases where k_f is back-calculated under assumption of $t = 1$ cm from the measured flow in laboratory tests (ASTM D5887; DIN EN 16416), the calculation becomes unsafe for k_f derived by using the measured thickness in the laboratory test. It is to be recommended to look at also the index flux value of a GCL product and not only to consider the k_f value from the data sheet.

The key to achieve reliable results is in this case the knowledge on this crux and correct interpretation of data.

3.2.2 *Recommendations on overlap permittivity*

Similar to the preceding recommendations, there is no general fixed safety factor for the consideration of overlap permittivity in permeation calculations of GCL lined hydraulic structures. Such calculations should consider the specific product properties. In many cases, GCL manufacturers are able to contribute laboratory results on the permeability of their

product specific overlapping technology. Such results can be considered in overall calculations of specific products.

Furthermore, multicomponent GCL overlaps can be sealed with butyl adhesive tape or in certain cases even welded. This can prevent any potential seepage path for water in overlaps of GCL used in sealing systems with constant water head.

4 CONCLUSION AND OUTLOOK

Within this paper, the authors have identified effects that leave an impact on the permeation of GCL and/or on the results of permeation calculations.

While some of those effects can be countered by constructive measures, others are inherent with the calculative approach which is generally being used when permeation rates are calculated.

The identification of these effects allows designers of hydraulic structures with permanent water table to prevent misconceptions when doing permeation calculations and thus evaluating the sealing efficiency of the products. Recommendations are given how to avoid underestimation of hydraulic losses.

The further roadmap on this subject matter envisages the development of a new software tool. This tool shall allow to calculate permeation losses under consideration of the potential effects that may impact the result while guiding the user in giving recommendations how to prevent hydraulic losses effectively. The software shall also include permeation calculations for composite liners under consideration of the calculative approach that is presented by Touze-Foltz *et al.* (1999). The final aim is to allow the fast and easy choice of a system that provides for the necessary impermeability under consideration of project specific requirements, while at the same time anticipating potential influences on the hydraulic conductivity of a barrier system. At the same time, the prognosis of leachate rates as presented in Rowe (2012) could be implemented with the software tool.

ABSTRACT: This paper presents the results of implementing erosion control techniques with geosynthetics on Brazilian Hydroelectric Power Plants (HPPs) reservoirs. Different erosion control techniques were applied in 2016 in two experimental units installed in the margins of the Porto Colômbia and Volta Grande HPPs. The performance of the analyzed sections was assessed qualitatively using a performance matrix that collected and summarized data over a monitoring period of four years. The performance was also assessed by differential bathymetry studies performed in 2016 and 2020 in the HPPs margins. This work highlights the benefits of implementing geosynthetic materials in margin erosion control techniques, taking advantage of its properties, ease of installation and durability, and evidence the importance of monitoring the techniques to know the long-term performance. The erosion control technique with Geomat in a roll showed the best results in all the analyzed sections.

1 INTRODUCTION

Problems arising from erosive processes constitute the main environmental impact in the operational stage of most reservoirs of HPPs. The problems reflect in the loss of arable, urban and forest areas, water quality, and the reduction of the volume and the useful life of the reservoirs, among other aspects.

The margins of water bodies are subjected to erosive processes and massive mobilization of sediments due to the dynamic environment (Biedenharn *et al.* 1997). The variables that have the most significant influence on the intensity of erosion are: topography, origin and soil composition of the margin and bed of water bodies, as well as the qualitative and quantitative aspects of the vegetation associated with local hydraulic conditions (height of waves and wind speed) (Fischenich & Allen 2000).

Edge protection measures can be grouped into three categories: vegetative systems, inert elements, and mixed (or soil bioengineered) systems, where these categories are often used together (USACE 1998; USDA 2015). Using soil bioengineering techniques represents the alternative with the lowest environmental impact on local conditions. In addition, its use favours aesthetics, aquatic and soil biota, and the microclimatic conditions of the water body. Also, it acts in the retention of pollutants, which would otherwise reach the water body.

The objective of any erosion control project should be to stabilize soils and manage erosion economically (Theisen 1992), where the choice of the appropriate control method is imperative for the success of erosion control operations on the banks of hydroelectric reservoirs.

Geotechnical studies carried out within the scope of Research and Development Projects of the National Electric Energy Agency of Brazil (ANEEL) showed that the soil on the banks of the reservoirs of the HPPs Porto Colombia and Volta Grande is prone to erosion. Two experimental units were selected to evaluate the implementation of bioengineering works for erosion control in the HPPs. In this work, three types of treatments that were applied in the experimental units are presented. The treatments were: Gabion box in Geogrid, Geomat in roll, and sack gabion and mattress in geogrid.

2 METHODOLOGY

2.1 *Study area*

The Porto Colombia and Volta Grande HPPs are located in the Rio Grande basin on the border of São Paulo and Minas Gerais states of Brazil (Figure 1). Different Erosion Control Techniques (ECTs) were applied using geosynthetics (geomat, geotextile and geogrid). The present study presents the results of monitoring three ECT installed in HPP Porto Colombia (PC) and HPP Volta Grande (VG). The first treatment is the Gabion box in Geogrid (ECT1), the second gabion sack and mattress in geogrid (ECT2), and the third Geomat in a roll (ECT3). The experimental units installed (with an approximate area of 150 m^2) are shown in Figure 2.

Figure 1.   Location of the Porto Colômbia (PC) and Volta Grande (VG) HPPs.
Figure 2.   Experimental units of HPPs Porto Colombia (PC) and Volta Grande (VG) treated with different Erosion Control Techniques (ECTs).

2.2 Geosynthetics

For this work, two geosynthetics were used: Geogrid (for gabion box and mattress) and Geomat. The Geogrid present the following characteristics: tensile strength of 16 kN/m and aperture dimension of 46 mm in the machine direction (MD), and tensile strength of 28 kN/m and aperture dimension of 64 mm in the cross direction (CD).

The Geomat has a mass per unit area of 563 g/m^2, puncture resistance of 0.38 kN, and tensile strength of 3.93 kN/m and 1.33 kN/m in the MD and CD, respectively.

2.3 Performance evaluation of the techniques

The monitoring of each experimental unit's sections occurred periodically, with monthly visits from 2016 to 2020. The performance of the techniques installed in each section used six performance variables, and a score (ranging from 0 to 3), as done in the works of Galvão et al. (2018), Aparicio-Ardila et al. (2021) and da Luz et al. (2021). The variables (performance matrix) are shown in Table 1. The six variables are: erosive spots/toe integrity on reservoir bank (V1), vegetative cover growth (V2), final structural integrity (V3), need for maintenance (V4), landscape integration/aesthetics (V5), and regrowth native vegetation top of the section (V6). The qualitative evaluation was performed 2 and 4 years after the installation of the ECTs.

Table 1. Performance matrix.

Variable	Score	
V1-Erosive spots/ toe integrity on reservoir bank	0	High
	1	Intermediate
	2	Low
	3	Inexistent
V2-Vegetative cover growth	0	Bare (<30%)
	1	Low vegetative cover (30 to ≤ 50%)
	2	Average vegetative cover (>50–≤ 70%)
	3	High vegetative cover (>70–100%)
V3-Final Structural Integrity	0	Serious damage (>30% of the total)
	1	Average damages (10–30% of the total)
	2	Low level of damage (<10% of the total)
	3	No damage
V4-Need for maintenance	0	High (>de 5 times)
	1	Average (3 to 5 times)
	2	Low (1 – 2 times)
	3	No need
V5-Landscape Integration/ aesthetics	0	No integration with local landscape
	1	Integration with local landscape after 2 years
	2	Integration with local landscape after 4 years
	3	Integration since the startup
V6-Regrowth Native vegetation top of the section	0	Absence of native flora
	1	Presence of 1–3 native species
	2	Presence of 3–5 species
	3	Presence of more than 5 native species

An initial bathymetry study was carried out in 2016 and other in 2020 at the end of monitoring. The bathymetry study was carried out following the regulations of Brazilian entities such as the ANA (Brazilian National Water Agency), ANEEL (Brazilian Electricity Regulatory Agency), and Law 12.334/2010 (2010).

3 RESULTS AND DISCUSSION

3.1 *Performance matrix*

The results obtained after evaluating the performance variables are shown in Figure 3 for each ECT for 2 (2Y) and 4 (4Y) years. The total scores for the analyzed periods (2 and 4 years) remained constant in all the units. After two years of installation, it is observed that the treatments that presented the best performance were located in the HPP VG. These were ECT2 (gabion sack and mattress in geogrid), followed by ECT3 (Geomat in a roll). On the other hand, all the ECTs installed in the HPP PC showed similar performances (ranging between 12 and 13 of total weight) in the two analyzed periods. ECT1 did not present integration with the local landscape in any HPPs. Analyzing the results qualitatively, ECT3 (Geomat in a roll) was a good performance in both HPPs.
Figure 3. ECT performance comparison: a) Gabion box in Geogrid (ECT1), b) gabion sack and mattress in geogrid (ECT2) and c) Geomat in a roll (ECT3).

3.2 *Differential bathymetry differential*

The average cross profiles of the bathymetry performed in the years 2016 and 2020 for each experimental unit are shown in Figure 4.

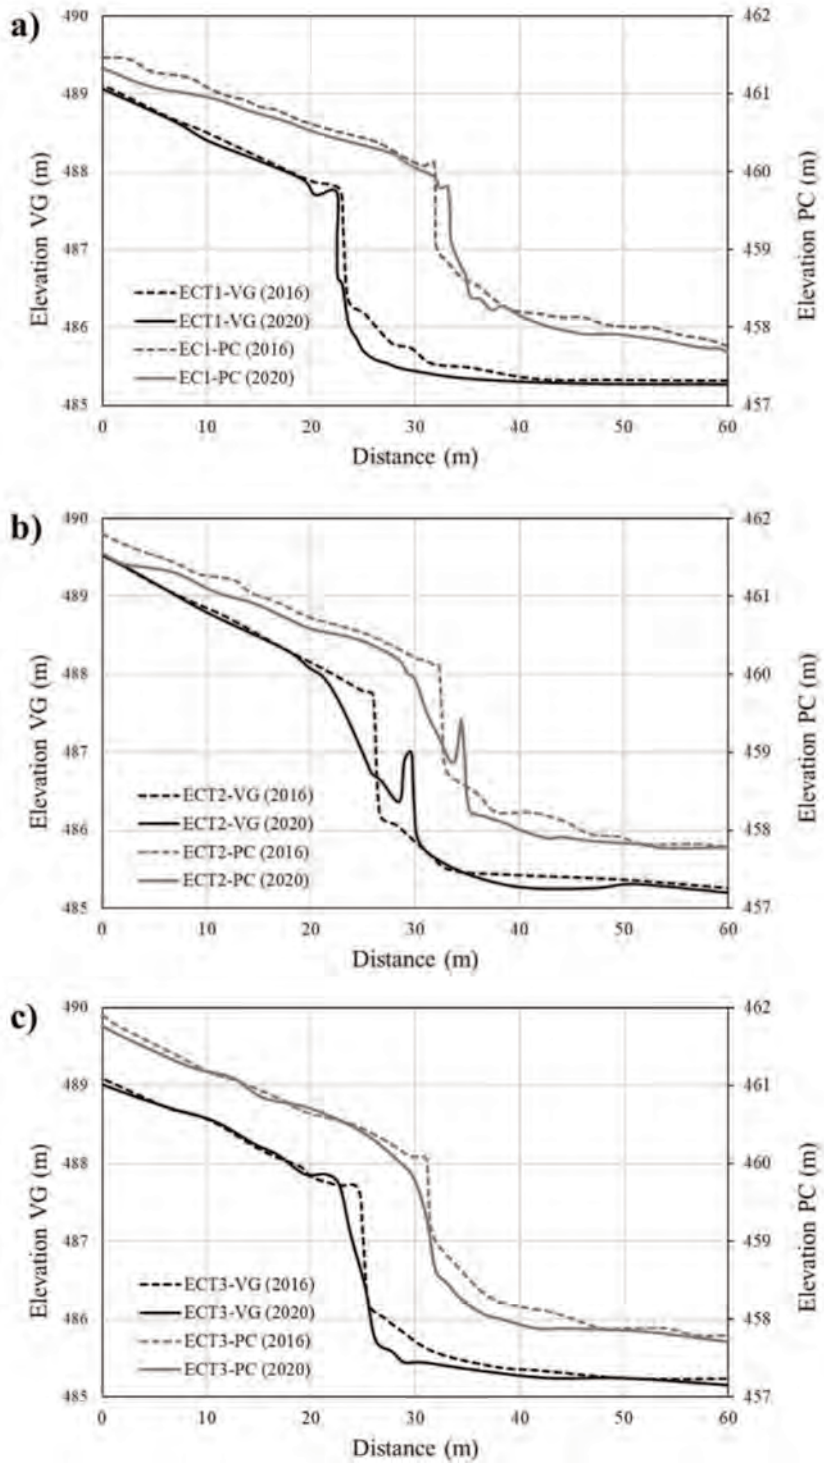
In the analysis of differential bathymetry (Figure 4), it is observed that there was a movement of material in all the experimental units. The sediments were redistributed in the ECT1-VG section, as observed in Figure 4a. On the other hand, in the experimental PC unit where the same treatment was installed (ECT1), the sediments were transported to the HPPs reservoir. Differential bathymetry of ECT2 in both units (VG and PC) showed similar behavior, indicating that there was rolling off the gabion sack. Analyzing the experimental units where ECT3 was installed, sediments transport was observed. However, considering that ECT3 does not have the same rigidity as the other two treatments (ECT1 and ECT2), the sediment movement is acceptable. According to Latapy *et al.* (2019), vertical errors can be induced during bathymetric occurrences due to waves at the margins, which may be responsible for random elevation variations.


Figure 4.   Differential bathymetry: a) EC1, b) EC2 and c) EC3.

4 CONCLUSIONS

Considering the qualitative performance and the differential bathymetry, the ECT3 treatment (Geomat in a roll) was the one that presented the best performance during the monitoring. Also, ECT3 took less time and was easier to install than other treatments.

The qualitative parameters adopted contributed to evaluating the treatments applied to mitigate erosion processes. Using the qualitative analysis matrix helps define the most effective erosion control techniques on the banks of reservoirs.

An innovative "Geo-carpet" system as a countermeasure against local scour at bridge piers: Small-scale test results

A. Galli & A. Radice
Politecnico di Milano, Milan, Italy

ABSTRACT: Local scour around bridge piers is one of the most diffused causes of failure for river bridges since it considerably modifies the geometry of the riverbed around the foundation. Countermeasures have been proposed in terms of both bed armoring and flow-altering devices. In this field, the use of Geosynthetics can provide innovative solutions, with environmental, economic and technological benefits compared to more traditional approaches. In the paper some flume experiments, run in clear-water flow conditions on a circular pier in a homogeneous granular riverbed, are described. The tests included four runs where the area around the pier was covered with innovative "Geo-carpet" systems made by plastic nets with different mesh size, and one reference test on an unprotected pier. The results, at least for a single hydro-dynamic condition, showed the efficiency of the Geo-carpets on the reduction of the scour depth and volume, and pave the way to future experiments investigating different geometries and flow conditions (including live-bed scour).

1 INTRODUCTION

River currents may induce relevant scouring effects around bridge piers, especially during flood events. Local scour is particularly detrimental for bridge stability, since it remarkably modifies the local geometry of the riverbed, with possible exposition of the foundation systems. Hydraulic research has shown that the scour process is related to the three-dimensional junction flow developing close to an obstacle that emerges from the river bed. From a geotechnical point of view, this implies a reduction of the confinement effect around the pier's foundation and, in extreme cases, of the subgrade reaction of the soil. Evident consequences are the reduction of the structural performance of the foundations (in serviceability conditions) and, potentially, the loss of its overall bearing capacity (in ultimate limit states). Possible countermeasures have been developed since many years (Lagasse *et al*. 2009), following two main ideas: either disposing massive objects on the riverbed around the pier (the so-called "bed-armoring" techniques), or by properly modifying the water flux in the proximity of the pier ("flow-altering" techniques).

Examples of bed armoring countermeasures are riprap (Figure 1a), gabions and gabions mattress (Figure 1b), and structural frames (Figure 1c). In countermeasures of this category, Geosynthetics may be employed as containers for rubble or gravel, thus constituting the so-called "geo-containers" described in Heibaum (2000) and sketched in Figure 1d. Flow-altering countermeasures may be instead realized, among others, by installing protecting collars (Figure 2a), by adding sacrificial piles upstream of a pier (Figure 2b), or by disposing ad hoc sloping plates, founded on mattress tubes or geocontainers (Figure 2c).

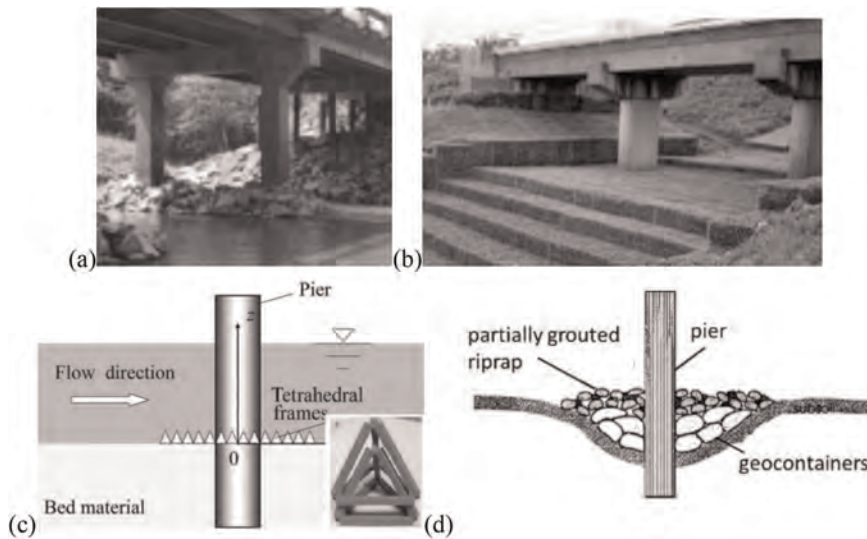
The aforementioned bed-armoring countermeasures provide in general an efficient protection against scouring, but the use (and the proper disposition) of massive objects often requires non-standard technological skills and large economic budgets. Furthermore, the


Figure 1. Examples of bed-armouring countermeasures: (a) riprap (from Froehlich 2013); (b) gabions and gabion mattress (Craswell & Akib 2020); (c) structural tetrahedral frames (from Tang *et al*. 2009); (d) geocontainers (Heibaum 2000).

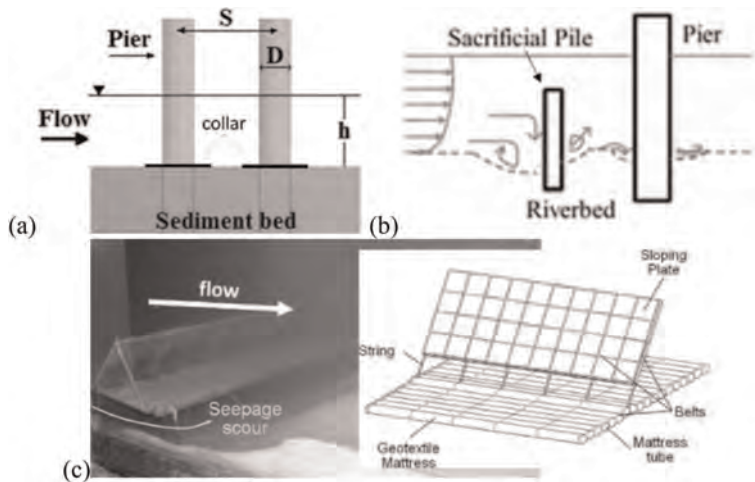

Figure 2. Examples of flow altering countermeasures: (a) protecting collars (from Memar *et al*. 2020); (b) sacrificial pile (Wang 2017); (c) example of sloping plates (from Xie *et al*. 2019).

flow-altering countermeasures require advanced manufacturing skills and site-specific design optimizations (e.g. depending on the characteristics of the flow), and their use cannot yet be considered a standard solution for engineers. In both cases, the cited limitations may result in (i) non-optimal design of the countermeasure, (ii) delayed installation, (iii) difficulty in maintenance and refurbishment (or complete substitution) after important flooding events. Experimental investigation on the use of nonwoven Geotextiles as protecting collars has also been developed for research purposes by Nouri Imamzadehei *et al*. (2016; Figure 3),

Figure 3. Photographs of experiments using a geotextile collar as a pier scour countermeasure (Nouri Imamzadehei *et al.* 2016).

revealing a relevant potentiality in reducing and delaying the scour process, at least at the laboratory scale.

In the present study, an innovative bed-armoring technique was tested in small-scale flume experiments. In particular, the use of grid membranes anchored to the riverbed was explored, and its effect on the scour evolution was analysed. This innovative solution, which could be referred to as "Geo-carpet", could be of particularly interest for large scale applications, since it would allow rapid and economic installations, without the need of dealing with massive objects or complex structural elements.

2 EXPERIMENTAL FACILITY AND PROCEDURES

The experiments were run at the Hydraulics Lab "LIF" of the Politecnico di Milano, using an open flume (Figure 4a) with rectangular cross section, length of 5.8 m, width of 0.4 m, and bank height of 0.16 m. A recess section (2 m long) allowed the formation of local scour holes. The flume was equipped with an electro-magnetic flow-meter for flow discharge and a tail-water regulation to set the flow depth. A 0.03-m layer of sediment was present along the entire flume. Lightweight sediment was made of Polybutylene Terephthalate monodisperse quasi-spherical particles, with equivalent diameter $d = 3$ mm and unit mass $\rho = 1270$ kg/m^3.

Clear-water conditions were considered throughout the experimental campaign. Preliminary runs were performed to determine the threshold discharge for a water depth of 0.08 m, following the method proposed by Radice and Ballio (2008) who quantitatively associated incipient sediment motion to a dimensionless sediment transport rate per unit width of 5.6×10^{-5}. The threshold discharge was 0.091 m^3/s. All the scour experiments were then run with a water depth of 0.08 m and a flow rate equal to 0.95 times the threshold one (i.e. 8.65 litre/s). It is in fact well known that largest scour values are induced in clear-water experiments with a flow rate close to the threshold one (see e.g. Franzetti *et al.* 2022). The cylindrical pier had a telescopic structure: the outer part, buried in the sediment bed, was a Polyvinyl Chloride thin pipe, while the inner part was a Plexiglas cylinder. The inner part could slide within the outer one and was manually lifted at the beginning of the test. Since the diameter of the pier (external diameter $D = 0.06$ m) was a small fraction of the flume width, no constriction scour was observed during the experiments.

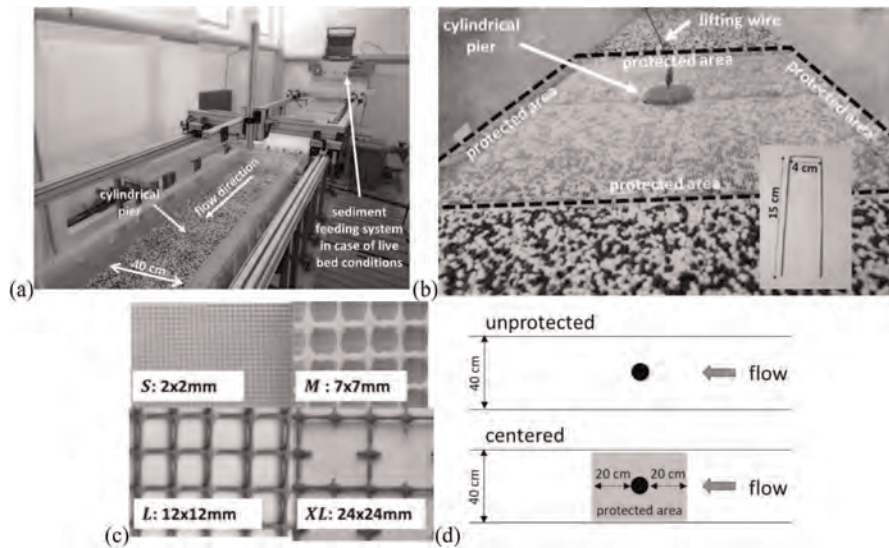
During the experiments, an area around the pier was protected with a net, anchored to the bed by means of "U-shaped" steel nails (Figure 4b) buried into the granular bed all along the border of the protected area. Several tests were run varying the mesh size of the nets. Four different mesh sizes s were employed (ranging from 2×2 mm to 24×24 mm, Figure 4c; corresponding runs are named S, M, L, and XL in the following). Consistently with the purposes of the present work, the grids were considered to behave as axially rigid membranes, but with negligible bending stiffness. Two different test configurations were considered (Figure 4d), representing the case of an unprotected pier (hereafter, named U), and


Figure 4. Experimental setup: (a) overview of the flume test facility; (b) detail of the placement of a net, anchored with "U-shaped" nails along its borders and around the pier; (c) detail of the nets used in the tests; (d) configurations of tests for unprotected pier and with the Geo-carpet in place.

that of a pier with a centred protection (20 cm both upstream and downstream). Thus, the present manuscript describes 5 tests: one on the unprotected pier, and four employing a centred protection.

The preparation of the flume consisted in (i) scraping the sediment bed to make it on average flat, (ii) spraying the bed surface with water to avoid particle uplifting by water during flume filling, (iii) installing the net over the protected area (except for the unprotected test). The test was then started by (iv) filling the flume with a small flow rate to avoid undesired sediment motion, (v) achieving the desired flow condition (flow rate 8.65 litre/s) with the pier completely buried in the sediment bed (to prevent initial unwanted local scour), and (vi) manually lifting the inner part of the pier to trigger the scour process. In this way, the beginning of a test was precisely determined. All the experiments lasted for 6 hours. During an experiment, point-wise scour measurements were taken with a manual point gauge. For the unprotected test (U) and for the cases where large meshes have been employed (L and XL, enabling the passage of the point gauge), measurements were repeatedly taken at different times. For smaller mesh sizes (runs S and M), on the contrary, scour measurements were taken only at the end of the test, after removing the net.

3 RESULTS AND DISCUSSION

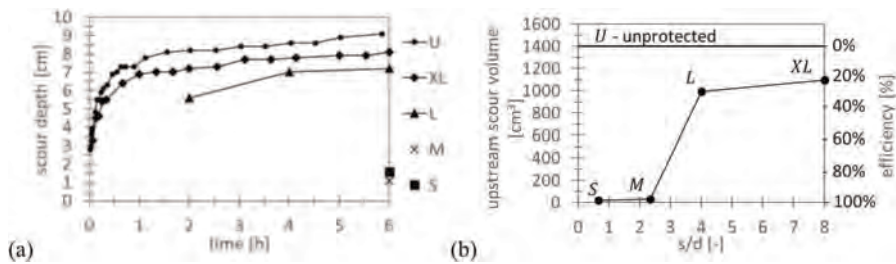
The results of the tests have been summarized in Figure 5a in terms of maximum scour depth and of its temporal evolutions (for runs U, L, and XL; for runs M and S, only the final 6-hours values have been measured). In particular, for run U the scour depth progressively increased with time, with a final maximum depth of 9.1 cm near the pier. The area interested by the scour in this case was about 930 cm^2 (approximate extensions equal to $5D \times 5D$ in the longitudinal and transversal direction, respectively, with respect to the flume axis). Runs XL and L showed similar temporal evolutions, although with lower final values of the maximum scour depth, witnessing how nets characterized by mesh sizes s remarkably larger than the


Figure 5.   Measured scour: (a) temporal trends of the spatially-maximum scour depth; (b) 6-hours scour volume measured between the upstream edge of the scour hole and the cross section at the pier axis, for increasing s/d mesh size ratios.

grain diameter d may also contribute in reducing scouring effects. Runs M and S, on the other hand, showed significantly reduced values of the final scour depths (about 1–1.6 cm) with respect to the unprotected configuration U.

These results are qualitatively confirmed also by the measurements of the upstream scour volumes, measured between the upstream edge of the scour zone and the flume section at the pier axis. For run U, the upstream scour volume was 1400.41 cm^3, whilst values of 19.5, 29.3, 996.1 and 1095.3 cm^3 for experiments S, M, L, and XL, respectively, have been obtained (all the values are referred to the end of the tests). These scour volumes, however, do not reflect the same quantitative performances in reducing the maximum scour depth observed in Figure 5(a): for run S, for example, being the grid "impermeable" to grain passage ($s/d = 0.67{<}1$), particles just rearranged themselves beneath the grid around the pier, but they could not be removed by the water flux. Beyond the protected area, moreover, a diffuse erosion zone appeared. Thus, the Geo-carpet in this case was highly effective in reducing the local scour phenomenon, at least in the vicinity of the pier, but some down-stream scour appeared. Similarly, for run M (although characterized by $s/d = 2.33{>}1$) a good efficiency in reducing the scour effects can be observed. For runs L and XL, on the contrary ($s/d = 4$ and 8, respectively), an evident scour hole was formed, because the grains could escape the net cells. In order to have a clear depiction of the scour volume reduction at the pier, Figure 5(b) shows the values of the measured upstream scour volumes as a function of the s/d ratios. For the sake of clarity, the data are also interpreted in term of proportional scour volume reduction with respect to the unprotected case, thus providing a quantitative indication of the global efficiency of the Geo-carpets against scouring. Three-dimensional reconstructions of the final scour pattern are finally depicted in Figure 6, for runs M and XL as representative cases.

Figure 6.   Three-dimensional scour pattern for runs M and XL.

Almost perfect efficiency (near 100%) was obviously observed for $s/d = 0.67$ (run S) because the Geo-carpets, as already mentioned, are in this case "impermeable" to grain passage and, owing to their negligible bending stiffness, only allow for a grain redistribution over the protected area. However, very high efficiency (about 97%) was also obtained for $s/d = 2.33$ (run M). This can be probably due to the arise, at the local level of each mesh of the grid in contact with the surrounding grains, of an "arching effect" allowing for a redistribution of the shear stresses (induced on the grains by the water flux) against the grid wires. These latter provide then and additional confining effect on the grains constituting the riverbed, that hinders the scour process. From a micromechanical point of view, the arching effect consists in a substantial reduction of the characteristic length controlling the phenomenon. For the unprotected case, in fact, the characteristic length can be assumed to coincide with the clear width of the flume (i.e. 40 cm, minus the diameter of the pier) that corresponded to 113 times the particle size. When the Geo-carpets were installed, on the contrary, the controlling characteristic length coincided with the mesh size s, i.e. one or two orders of magnitude less than the former. Further quantitative analyses on the arching effect are beyond the purposes of the present paper but, from a practical point of view, it is here observed that such an effect would be beneficial, allowing also the use of relatively large mesh sizes, without the need of necessarily install Geo-carpets impermeable to grains. When the mesh size was further increased (runs L and XL), a progressive reduction of the efficiency was observed as the scour volume tended asymptotically to that for the U run, that can be considered as a case corresponding with $s/d \to \infty$.

4 CONCLUSIONS

The paper described the main results of some original small-scale flume tests, aimed at studying innovative mitigation measures for local scour around bridge piers. In particular, the idea of a new "Geo-carpet" system was tested as a possible bed armoring intervention, realized by disposing a geogrid layer directly on the on the riverbed around the model pier, and by fixing it into the granular layer. This solution proved to be effective (at least in the tested hydraulic conditions) in reducing both the maximum scour depth around the bridge pier and the total scour volume. Such effect is of course maximized if geogrids "impermeable" to grains (i.e. with a mesh size smaller that the grain diameter) are employed; however, relatively high efficiencies in scour reduction are also observed in case of mesh sizes significantly larger than the diameter of the grains. A micromechanical justification of this results is related to the arise of an arching effect at the local level of each mesh in contact with the riverbed, redistributing the stresses on the surrounding grains and locally increasing the confinement on the granular layer.

Further experimental and theoretical researches are still needed both on scientific (e.g., influence of live-bed conditions) and technological aspects (placement techniques, possible pretensioning action imposed to the grids, design optimization, . . .) and, before real scale on site applications, several additional points need specific investigation. For example, durability and efficacy issues of the chosen polymer (e.g. aggressiveness of chemical substances, possible damages to the geogrids from materials transported by the river flow, influence of polymer weight with respect to buoyancy force, . . .) need to be carefully tested. In Authors' opinion, however, such Geo-carpet systems could represent an innovative field of application for Geosynthetics, enhancing the use of traditional geogrids and promoting research towards new solutions. Geo-carpets will potentially represent a rapid and cost-effective solution to mitigate the scour phenomenon, with evident structural and environmental benefits in terms of protection of the infrastructure.

technicians of the LIF Lab at PoliMi for supporting the design and realization of the experimental tests.

ABSTRACT: Fabric formed concrete revetments are being applied in several fields of application. This can be erosion protection, sealing, mechanical protection or as ballasting element for e.g. pipelines. These applications require different performances of these concrete mattresses. Despite the long history of more than 50 years, there are still unknown technical parameters in terms of concrete filled geotextile mattresses. This paper will therefore explain the contribution of concrete mattresses to the tensile strength of concrete, which has been carried out at the University of Applied Sciences in Münster. In addition the applicable ice load as well as the hydraulic roughness of the examined concrete mattresses will be demonstrated. Finally a brief introduction into reference applications highlights the relevance of concrete mattresses in hydraulic engineering.

1 CONCRETE MATTRESSES

1.1 *Components*

Concrete mattresses consist in general of a geotextile top and bottom layer, filled with highly fluid concrete. There are mattresses available with vertical spacers to control the thickness and mattresses with filter points. The thickness of the last mentioned will be controlled by the size, shape, and pattern of the filter point (cf. Figure 1, left). Mattresses without filter points can be applied for both applications, erosion protection and sealing (cf. Figure 1, right), whereas mattresses with filter points cannot be used as a sealing element. Their application is limited to erosion protection, or in special cases, as ballast or mechanical protection element e.g., pipelines or membranes.

1.2 *Installation*

Thanks to its textile character, the concrete mattresses can be assembled into panels, fitting to the geometry of the structure to be sealed or protected. The empty panels with an approx. unit weight of 400 g/m^2, will be rolled out on the prepared structure, temporarily fixed on the crest, and filled with concrete. For several reasons, the panel size should not exceed 1000 m^2. Therefore, using industrial zippers to connect panels to each other is a standard procedure.

Figure 1. Concrete mattress with: Filter points (left); Vertical binders for constant thickness (right).

To get the mattress filled in a proper manner, preferably self-compacting concrete with a maximum grain size of 8 mm should be used. Prior to the installation of a concrete mattress with filter points, it´s highly recommended to apply a nonwoven layer underneath the mattress, as permanent erosion protection needs to be guaranteed.

1.3 Design

In comparison to other types of revetments, there is no need to design a fabric formed concrete revetment (FFCR) according to single stone failure, as they are coherent revetments.

There are several design approaches for FFCR available in literature. The most common ones are BAW (1993), DWA (2012), Pilarczyk, K. W. (2009) and FHWA (2009). Above them, several physical tests were executed in order to quantify the performance of concrete filled concrete mattresses. Some of them are described in chapter 2.

1.4 Typical applications

Concrete mattresses are typically applied for sealing or erosion protection of canals, erosion protection of overtopping sections, sealing of ponds and berth protection. Furthermore, concrete mattresses can be used to mechanically protect and ballast e.g. pipelines.

One of the biggest advantages of concrete mattresses is their ability to be filled underwater. This enables the system to be installed while the hydraulic structure is operating.

Especially for the application on overtopping sections, it´s a huge advantage, that concrete mattresses with big filter points can be vegetated. This allows the system to aesthetically fit into the landscape.

Thanks to its textile character, the system adapts to the subsoil, which avoids cavities occurring underneath the revetment.

Due to the coherency of the system, the overall thickness of a FFCR is much thinner compared to a classical revetment, which contributes to a reduction in carbon footprint and cost.

2 PHYSICAL TESTS

2.1 4-point bending tests on concrete filled geotextile mattresses

At the University of Applied Sciences in Münster, 4-point bending tests have been executed on concrete filled geotextile mattresses. To be able to compare the results, concrete slabs with

the same thickness and concrete characteristics were produced and tested in the same manner. For each test, 3 specimens with a size of 2 m × 1 m × 0,2 m were produced. All in all four slab-types were examined:

1. Unreinforced concrete slab
2. Fiber-reinforced concrete slab
3. Concrete mattress filled with concrete (Incomat Standard)
4. Concrete mattress filled with fiber-reinforced concrete (Incomat Standard)

For the fiber-reinforced concrete, alkali resistant glass fibers were used. The glass fibers were added to the concrete, before filling the concrete into the mattress. This did not influence the fill-ability of the mattress in a negative manner. An investigation of the fiber distribution in the concrete shows an equal distribution of the fibers over the entire cross section.

Figure 2 shows the overview of the averaged ultimate loads of the different specimens tested. The comparison of the results shows a significant contribution of the textile formwork to the load bearing capacity of the system by approx. 40 %. It turned out, that using fiber-reinforced concrete significantly increases the maximum load bearing capacity in both cases: with or without textile formwork. More Details on these tests are presented in Wilke, Derksen, Ebbert, Harnisch (2020).

Figure 2. Overview of the averaged ultimate loads of the different specimens tested. Marker: Scatter of results.

Figure 3 shows a closeup of the load displacement curves of selected specimens of each type. They show a typical behavior of unreinforced systems. After the concrete cracks, the force suddenly drops down to the load being carried by the textile formwork. In this case the residual load bearing capacity is mainly provided by the lower layer of the textile formwork. The comparison of the displacement of the concrete slabs (green and brown curve) to the concrete filled geotextile mattresses shows (other curves), that the integrity of the mattress is not destroyed. This means that the concrete is still being kept together by the textile formwork. The total displacement carried by the textile formwork in this test is approx. 160 mm. This is a huge advantage, as the revetment would stay in place even after the concrete has fully cracked. An unreinforced concrete slab would have fallen apart.

2.2 Ice load testing

Harsh environmental environments require erosion protection as well. Consequently, at the Samara State University of Architecture and Civil Engineering, the ice load capacity of concrete mattresses was investigated. As a test setup, 3 concrete mattress sections (Incomat
Figure 3.   Closeup of the load displacement curves of selected test specimens.

Flex) with thicknesses of 10 cm, 20 cm and 30 cm were installed at the embankment of the Saratov reservoir. The monitoring took place in the winter of 2014/2015. In that winter, ice thicknesses of up to 0,69 m were measured. Table 1 shows the relevant climate related information. Within 24 h, the max. temperature difference recorded was 16°C, with a max. water level difference of 1 m.

Based on the in-situ sections and additional laboratory tests, an equation, following Gost-Standard SP 38.13300.2012 (2012), has been developed:

$$h = \frac{\gamma_n \cdot A \cdot N^{0,55}}{K_M}$$

with: h = thickness of concrete mattress; N = max. ice impact; γ_N = safety factor; A = empirical factor and K_M = factor considering the increased stability compared to unreinforced concrete slab revetments.

Table 1.   Summary of the recorded climate and ice data.

	2014		2015			
	Nov.	Dec.	Jan.	Feb.	Until March 10th	After

2.3   Concrete mattresses as erosion protection on overtopping sections

The basics to design concrete mattresses for erosion protection on overtopping sections have been derived at TU Vienna. The tests have been performed for concrete mattresses with filter points installed in a physical model. As the model needs to be scaled with a factor of 1:4, the Froude model law has been applied to convert the size of the physical model as well as the results. The Froude model law has been chosen, as it is usually being applied for scaling free water surface models. Wilke et al. (2012) reported these tests in their publication.

Its main conclusions are as follows:

– max. discharge ≥ 2.0 m³/(s*m)
– flow velocity ≥ 10 m/s
– proper toeing in at all edges (crest, toe and lateral)

where the discharge is given in m³/s per linear meter of crest length.

A comparison to other structures is shown in Table 2. It's clearly shown, that the concrete mattresses can carry much higher discharges and can be applied in a wider range of slope inclinations.

Table 2. Comparison of different overtopping section revetments [1]LfU BW (2004); [2]Tschernutter (2010).

Revetment type	Max. slope (1:n)	Maximum discharge (m³/(s*m))
Pitched stone[1]	6	≤ 1.0
Rip-rap[1]	4	≤ 1.0
Geosynthetic gabions[1]	4	≤ 1.0
Mastix asphalt[1]	6	≤ 1.0
Grass paver[1]	6	≤ 1.0
Soil solidification[1]	4	≤ 1.0
Concrete mattress[2]	2.5	≥ 2.0

To integrate the concrete mattress into the environment, a thin layer of soil can be installed on top of the mattress. The bigger the filter points of the mattress are, the better the interaction between soil and mattress will be. Greening with site adapted vegetation will establish good stability of the soil layer. In case of a heavy overtopping event, the soil layer is tolerated to erode, as the concrete mattress will take over the permanent erosion protection.

2.4 *Hydraulic roughness of concrete mattresses*

As concrete mattresses are often applied as an additional sealing layer on top of a deteriorated sealing layer, it's crucial to know their hydraulic roughness, in order to be able to calculate the water level in accordance with a minimum required discharge in an existing hydraulic structure.

At the Institute of Hydraulic Engineering and Water Resources Management (IWW) at RWTH Aachen University the hydraulic roughness of a real-scale Incomat Standard concrete mattress was determined. Due to the full dynamic similarity of the real-scale tests, these results are unaffected by scale effects and can be transferred to comparable applications. For this purpose, the bottom of the flume was lined with geotextile concrete mat elements, resulting in a total length of 24 m and a width of 1 m. Before installation of the mattress in the flume, first the roughness of the flume and the roughness of the empty geotextile mattress were quantified. During the investigation, several inclinations (I = 0.000 – 0.002) and discharges (Q = 200 – 400 l/s) were tested, resulting in mean flow velocities in a range of v = 0.9 – 1.5 m/s. More detailed information of this tests can be taken from Derksen (2017).

Based on the flow tests carried out, the mean equivalent sand roughness of the geotextile concrete mat of the type Incomat® Standard was determined to be $k_s = 0.0039$ m and corresponds to a Strickler coefficient of $k_{st} = 66$ m¹ᐟ³/s. The reciprocal of k_{st} represents the Manning's coefficient n.

Compared to Pilarczyk 2000, who published hydraulic roughness ranges for different types of mattresses, the roughness for constant thickness mattress measured by Derksen (2017) is laying on the smoother end of the range given.

3 REFERENCE PROJECTS

3.1 *Overtopping section (Picheldorfer Bach, Austria 2011)*

To protect Oberaich (close to Bruck an der Mur) against flood events, caused by extreme storm events, several protectional hydraulic structures were built. One of them is a flood retention pond, whose overtopping structure is integrated into the dike of the river Mur. The overtopping structure mouths in the river Mur.

To protect this structure in case of an overtopping event, a concrete mattress with big filter points has been installed. In total 3 panels of approx. 550 m^2 each, connected by industrial zippers, has been laid out and filled with concrete. After the concrete hardened, a soil layer has been installed and finished with vegetation.

Thanks to the greening with site adapted vegetation, the overtopping section perfectly fits into the landscape.

Figure 4. Concrete mattress: after installation (left); after being vegetated 2 years later (right).

3.2 *Canal sealing (Mittlerer Isarkanal, Germany 2013)*

The Mittlerer Isarkanal is a concrete sealed canal, which discharge of 150 m^3/s it supplies 7 hydro power plants with a total annual output of 130 MW. After more than 60 years of operation some sections needed to be remediated, as the concrete sealing layer was deteriorated. For several reasons, the installation needed to be carried out without emptying the canal. As underwater installation is common practice for concrete mattresses, it has been decided to apply them as new sealing layer. The concrete thickness of 10 cm decreases the size of the flow cross section. Thanks to the low hydraulic roughness (cf. chapter 2.4), the concrete mattress doesn't limit the required discharge.

To guarantee a successful installation, prefabricated panels of up to 1000 m^2 have been used for installation. The parts to be installed on the embankments were rolled in advance. The installation was carried out by the help of a pontoon (cf. Figure 5, left). In the first step, the concrete mattress on the bottom of the canal was filled from the pontoon. Afterwards, the concrete mattresses to be installed on the approx. 12.5 m long embankments, got unrolled and filled from the crest of banks. Diver support guaranteed a successful installation.

Thanks to the above-described follow up, the installation rate was up to 3000 m^2/day. The right side of Figure 5 shows the situation after installation.

Figure 5. Canal sealing: during installation from pontoon (left); after installation (right).

4 CONCLUSION

Concrete filled geotextile mattresses are used for more than 50 years in different applications. Their performance has been proven by many different tests e.g. 4-point bending, overtopping stability, ice load tests or hydraulic roughness, just to name the 4 of them introduced in this publication. For sealing applications, impermeable, constant thickness mattresses with a low roughness should be preferred. Erosion protection is guaranteed by both types, with and without filter points, but as mattresses with filter points can be vegetated, they should be preferred for applications like erosion protection of overtopping sections.

ABSTRACT: The world population increases decade after decade straining global food demand. During this time drought becomes more accentuated thus irrigation must become more efficient. Many irrigation canals are built of soil with a poor waterproofing quotient and concrete sections which, after 15 years or less, meet seepage through cracking. Geosynthetic lining is the solution. The main challenges for irrigations districts when lining canals are that during construction canals are taken out of service, this paper will illustrate these processes. It is important that the choice of material enables efficient installation in diverse weather conditions, is economically competitive and can withstand time when left exposed to the elements with an easy maintenance component. Through case studies, this paper demonstrates that bituminous geomembranes (BGM) meet and exceed these challenges. The paper reviews briefly the characteristics of BGM as uniquely qualified for usage when lining canals: low thermal coefficient, a low Manning coefficient, a density greater than 1, and proven longevity when left exposed. Thanks to their flexibility and bituminous properties that can be connected to any surface. Case studies presented in this paper highlight the BGM specific properties. In Romania, renovation of irrigation canals, in North America, BGM began a partnership with the Roza Irrigation District (USA), to line a complete irrigation scheme reservoir and irrigation canals throughout the Columbia River Basin, in Chile rehabilitation work on canals supplying water for a small irrigation scheme, in India and in France.

1 INTRODUCTION

Thousands of miles of canals move billions of cubic meters of water annually. Most of these canals are built of material ranging from soil to concrete. Water losses through bottom and side leakage and associated economic losses are an important concern for owners and operators. Lining canals or building recovery systems are the solutions used to control water losses, especially since summers are getting hotter and drier and water resources are becoming scarcer. We could observe that engineering is not well enough informed about geomembrane performances and continue to line canals with concrete or clay. Five years after completion, the rate of satisfactory projects has been known to drop significantly due to poor project design.
Figure 1. a. Peru: San Lorenzo, longitudinal crack / 1.b. Tajikistan: Fergana Valley, effect of frost-heave.

A lined canal system Figure 2a. Llangollen Canal (UK), and Figure 2b. Canal de Provence (France), when properly operated and maintained, are more efficient in many aspects of operation because of a higher conveyance capacity.

Figure 2. a. Llangollen Canal (UK) / 2.b. Canal du Provence (France).

The other major challenge when making canals watertight is taking the canal out of service during construction. Typically, this type of work is performed during winter with the possibility of delay due to weather and the associated cost. The choice of materials that are easy to install in diverse weather conditions (humidity, snow, rain, wind) maintaining an economically competitive advantage, and one that will withstand the test of time as an exposed lining system is a crucial component. Through case studies, this paper demonstrates that bituminous geomembranes (BGM) can meet these challenges with a long durable life even when directly exposed to UV, offering an ease of maintenance and repairs and supplying a very viable technical and economical option for lining canals. Furthermore, the manufacturer provides an in-situ training in all aspects of the installation process.

2 TECHNICAL CHARACTERISTICS OF BGM

2.1 BGM structure

The product's main structure is based on a non-woven polyester geotextile which is completely impregnated by elastomeric bitumen, with a glass fleece inside to help its manufacture

Figure 3. BGM structure.

Table 1. Summary of some physical and mechanical properties of a BGM 4.00 mm thick, the most common used in efficiency waterproofing.

Properties		Standard	Unit	BGM	Commentary
Physical properties	Thickness	ASTM D 5199	mm	4.0	BGM is thicker and heavier than any other liners making it more resistant to wind uplift or flotation and consequently requires less ballast to keep it in place. It can be placed in most weather conditions and since the seaming is by torching, humidity is not an issue.
	Density	ASTM D 1505	g/cm^3	1.276	
	Surface mass	ASTM D 5261	kg/m^2	4.85	
Mechanical properties	Tensile Stress at Break	ASTM D 7275 4073	kN/m	27	Due to its important thickness and its enclosed geotextile, BGM is far more resistant to puncture than the other liners and thus require less bedding and can be placed over very coarse granular fill without the threat of being damaged. Also, since the tear resistance of BGM is very high, this liner is less vulnerable to mechanical damages during in situ transport and placement.
	Tensile Elongation at Break	ASTM D7275	%	60	
	Tensile-Tear Resistance	ASTM D 4073	N	825	
	Puncture Resistance	ASTM D 4833	N	530	
Thermal Stability		ASTM D 1204	%	<0.1	Approximately 100 times lower than PE liners, BGM doesn't produce wrinkles or waving when temperatures vary onsite.
Friction Angle		ASTM D 5321	°	32	BGM friction angle is much higher than other liners and is therefore easier to install on deep slopes and safer for installation crews.

by strengthening the product at a temperature of 180°C. On top of the structure is sand to enhance UV resistance and provide traction for installation workers. On the bottom is an anti-root film to prevent permeation of any vegetation roots through the liner. The BGM Geomembrane is produced in France under severe QC/QA control. the BGM factory is ISO-9001, and the Geomembrane is CE (European Standards) and ASQUAL (France) certified. The ASQUAL certification includes the auditing of the production line as well as the Geomembrane performance.

The BGM compounded with elastomeric bitumen can be installed to a temperature of −40°C and is therefore more suitable to be used in cold weather countries like Canada, North of USA, North and East of Europe or in altitude. Product is manufactured in 4 thicknesses ranging from 3.5 to 5.6 mm.

2.2 BGM specific advantages in irrigation watertightness

The technical characteristics of BGM namely those unique for use in lining canals:

– No wrinkles as BGM has a low thermal coefficient,
– A low Manning coefficient allowing the passage of more water for a same cross-section of the canal,
– Longevity even when exposed more than 60 years and more than 300 years buried as proven by nuclear laboratories in France and USA,
– A density (1,276) greater than water, enabling an economical option as BGM can be installed in canals while water is flowing. Panels can be welded underwater using a specific mastic to provide weld under water by a phenomenon of vulcanization,

- Can be connected to any type of surface: concrete see Figure 4 entry of a concrete siphon, steel or HDPE pipe.
- Local personnel and maintenance teams of an irrigation district or of any local installer can be trained in-situ by a manufacturer's monitor, keeping installation costs very low,
- Mechanical resistance: due to its enclosed geotextile, BGM is very resistant to puncture (530 N or more). The hydrostatic puncture and the resistance to puncture by aggregates (1550 kPa and 25 kN respectively) are thought to be much higher than other liners like PE. From an economical point of view, this liner will require no protection (use of Geotextile) on one or both sides. BGM is therefore much more resistant during construction and maintenance work.

3   CASE STUDIES

Case studies presented in this paper highlight the specific property of BGM that was the decision factor in the choice.

3.1   *In Romania*

Romania has some secondary canals requiring renovation. BGM was used for re-lining:

- Original concrete irrigation canal (see Figure 7): principal canal with concrete panels 2,5 m by 1,2 m with a slope 50% and width 18 m canals,
- And, at the terminal part, earth canals.

In certain parts (see Figure 6), due to the high damage of the concrete lining the concrete slabs will be removed and will be constructed as earth canals with BGM lining with a thickness of 4.0 mm or even 4.8 mm.

Figure 6.   concrete for canals some years after due to unstable soil underneath.

Figure 7.   Wasteway No.5 Regulation Reservoir, feeding Yakima and Roza Districts Irrigation canals.

3.2 *In North America:*

3.2.1 *California State (USA)*
Two of the three leaking sections of the Caspa District canal in Wyoming, USA, were repaired with BGM in 1992 and 1994 respectively. The third, slightly larger (80,000 m^2) section was repaired in 1995 by the canal operator's own highly trained employees.

3.2.2 *Washington State (USA)*
In 2005, BGM began its partnership with the Yakima district (Washington State, USA) for providing a watertight solution year after year of old irrigation canals. The project was intended to provide irrigation services to the many farms and agricultural regions of the Yakima Valley (best cherries for USA). In 2016, there was an extension of this cooperation to the Roza Irrigation District for lining the Wasteway No.5 Reregulation Reservoir outside of Sunnyside, Washington State on the West Coast of the United States (See Figure 7).

   The project is expected to conserve roughly 10 million cubic meters of water each season. It was completed by the end of August ensuring permitting a large storage of water in autumn and winter. This ability to sustain schedule was due to the complete absence of wrinkles permitting the installers and welders to work without any delay even during warm season. This reservoir is completely and permanently monitored by a certain number of piezometers,

   Water is pumped from the Columbia River. There are 3 main irrigation districts in this region that work in cooperation with dozens of smaller regional irrigation districts of which the Roza Irrigation District belongs. In the last 17 years, BGM has been used to line irrigation canals throughout the Columbia River Basin with successful projects in Naches-Selah, Quincy, Moses Lake, Wenatchee, Yakima and Ellensburg. All these districts appreciated the robustness of BGM, the fact it is able to be installed in low temperature, it can be installed by internal teams after training by a manufacturer representative giving greater flexibility in the use of their teams.

3.3 *In Latin America: Chile*

The Elqui River and Tributaries Board of Control (Junta de Vigilancia del Río Elqui y sus Afluentes, JVRE), administers 121 irrigation canals in Elqui Province in north-central Chile to irrigate an area in the order of 200 km^2 and the Rio Choapa Board of Control (Junta de Vigilancia del Rio Choapa) administers more than 660 km of canals to irrigate more than 220 km^2 of land in central Chile. The area covered by these districts which produce grapes, citrus fruits, avocados, and vegetables for export – is a very dry area where water is a scarce resource, meaning canals need to be lined to avoid water loss. The Rio Choapa and the Rio Elqui irrigation districts decided to look for alternatives to concrete liners to reduce costs. As a result of these search efforts, more than 62,000 m^2 of irrigation canals in these two districts were lined with a 3.5 and 4 mm thick BGM. These canals were lined at a cost of about 30% less than a concrete lining and have been operating successfully with a longer lifespan than with concrete in this unstable soil.

Figure 8.   a. Irrigation canals in Chile: Rio Elqui / 8.b. Irrigation canals in Chile: Rio Choapa.

It is worth noting that in smaller canals where the perimeter is less or equal than the width of the BGM roll, construction joints are less frequent and thus the deployment of the liner is very fast.

Reasons for choice of BGM:

– Resistance to UV and longevity in exposed conditions,
– Ability to be fixed to concrete,
– High friction angle permitting animals to walk across,
– Low Manning coefficient,
– A lot less expansive and faster to deploy than a conventional concrete lining.

3.4 *In India*

The Pench Left Bank Canal, located in central India, brings water from the Pench River to the region's crops. The original canal consisted of a concrete lining that was collapsing due to clay swelling underneath. In a state where water resources are becoming scarcer over the years, the Nagpur Water Resources Department decided to re-seal the canal using a long-lasting geomembrane (see Figure 9). A BGM 4 mm thick was laid on the substrate and anchored at the head of the slope. Works both started in June 2019 and 2022 and were scheduled to be completed before the monsoon season. BGM could be installed so quickly that the entire projects (2019 phase) finished in 15 days at an average of 2,200 m^2 laid and welded per day. The customer needed a strong, flexible geomembrane. They chose BGM for its ability to withstand:

– Substrate settlement,
– The region's extremely high temperatures.

Figure 9.   a. Irrigation canals in India – before / 9.b. Irrigation canals in India – during installation.

3.5 *In France: Canal de Provence*

The Canal de Provence supplied water to 116 cities in the south-east of France which represents around 3 million inhabitants, the irrigation of 80,000 hectares of agricultural land and feeds more than 8,000 industries. They water originates in the Alps (Figure 10).

Figure 10.   Canal de Provence in the French Alps.

Figure 11 below shows a typical section of its channels. The width at the bottom is between 2.7 and 3.0 meters. The width in the upper region can be from 10.0 to 17.2 meters. The depth is between 2.4 and 3.6 meters. On each side, there are 2 tracks of 2 m. asphalted for assuming the maintenance and security. The slopes are between 27 and 34°.

Figure 11.   Cross-section type of the Canal de Provence.

Canal de Provence could note that their network suffers from pathologies of geotechnical origin (dissolution of gypsum or clay in the presence of water from leaks) which induce displacements of the ground. The main objective of conveyance efficiency was to reduce the risk of geotechnical disorders caused by infiltration. The pre-feasibility studies consisted of a catalogue of canal renovation techniques. Subsequently, a dozen companies were consulted based on creating a competitive dialogue. The choice fell on the implementation of a thick BGM weighted in raft of a concrete slab. BGM was chosen for the following reasons:

– Sealing coating that does not adhere to the support and allows centimeter displacements of the support to be resumed,
– BGM has a high surface mass allowing installation in high speedy wind (Venturi effect in canals). In addition, the welding system allows installation in wet or hot weather,
– Sandblasted on upper face offering adhesion to allow the ascent of fallen animals or humans in the canal (high friction angle). Thickness sufficient to resist blows of hooves for animals,
– Robustness even exposed confirmed by feedback from several decades in similar situations,
– Without expansion, the geomembrane is in permanent contact with its support, no wrinkles, slowing down the current. The Manning coefficient stays consistent,
– It can be welded and then fixed by rulers and fasteners at the head of the joffers to overcome the impossibility of making anchor trenches,
– Exposed at the level of the joffers, due to its great UV resistance.

To ensure the supply of users downstream of the works, the interventions were carried out in successive sections of 200 meters in length allowing the implementation of a bypass (see Figure 12).

Figure 12.   Dewatering work on a section without interrupting water circulation.

4 CONCLUSION

BGM since its inception of manufacturing in a factory (1974) has become a very famous geomembrane being employed and appreciated on every continent due to its robustness, its ability to be installed and left exposed with an expected lifespan of more than 20 years and to be installed by any team of any district after onsite training by a manufacturer's representative. The overall cost of the lining system should be considered for the entire project cost for comparison, inclusive of subgrade preparation, no need of geotextile to protect a thinner and less robust geomembrane, eliminating difficulties induced by windy conditions due to its high unit mass, maintenance and installation costs are reduced by employing internal teams.

Effect of tailings fines content on leakage though circular geomembrane holes overlain by saturated tailings

J.-Y. Fan & R. Kerry Rowe

Department of Civil Engineering, GeoEngineering Centre at Queen's-RMC, Queen's Univ., Kingston, ON, Canada

ABSTRACT: Coupled physical and hydraulic experiments are conducted to quantify leakage through circular geomembrane holes with diameters of 10 mm, 20 mm, and 50 mm. Three different tailings, fine-grained tailings with fines content of 90 % and d_{10} of 1 μm (denoted as T1), silty sand tailings with fines content of 30 % and d_{10} of 20 μm (denoted as T2), silty sand tailings with fines content of 20 % and d_{10} of 40 μm (denoted as T3), are examined. The effective stress and pore pressure in the tailings above geomembrane and remote from the hole are ~170 kPa and ~350 kPa, respectively. It is shown that leakage through geomembrane hole is proportional to the hole radius (and not the area) for each type of tailings, and highly dependent on the fines content of the tailings. For example, the leakage for T2 and T3 tailings are 1.8-fold and 65-fold greater than that for the T1 tailings, respectively, for a given hole size. The practical implications are discussed.

1 INTRODUCTION

Increasingly the design and operation of tailings storage facilities (TSFs) involves the use of a geomembrane (GMB) liner to reduce seepage from the facility into the surrounding environment and/or reduce the hydraulic gradient within the embankment and the foundation (Lupo & Morrison 2007; Rowe 2020; Rowe & Jefferis 2022; Touze *et al.* 2008). Due to the low hydraulic conductivity of tailings, the GMB liner system for TSFs commonly comprises a single GMB liner even though the hydraulic head within the facility can exceed 100 m (Touze *et al.* 2008). The GMBs used in mining applications are most commonly either made from high-density polyethylene (HDPE) or linear low-density polyethylene (LLDPE) with a typical thickness of 1.0 to 2.5 mm (Rowe *et al.* 2013; Touze *et al.* 2008). With these GMBs, the leakage is effectively limited to flow through holes in the GMB that most commonly arise either during construction (including during placement of material over the GMB) or subsequently due to stress cracking (Giroud & Bonaparte 1989a, 1989b; Giroud 2016; Fan & Rowe 2022c, 2023; Rowe 1998, 2005, 2012, 2020).

Leakage through a circular GMB hole overlain by saturated tailings and underlain by a highly permeable subgrade has been recently examined (Badu-Tweneboah & Giroud 2018; Fan & Rowe 2022a, 2022b; Rowe *et al.* 2017; Rowe & Fan 2021, 2022). Analytical equation predicting leakage through a circular GMB hole with diameter of *2r* (*r* is hole radius) overlain by saturated tailings was proposed based on the Rowe-Booker equation (Rowe & Booker 2000) by Rowe and Fan (2021) as:

$$Q = \frac{H}{\frac{1}{\xi} + \frac{1}{\Omega}} \tag{1}$$

where

$$\Omega = \{4 + [2.455 + 0.685 \tanh{(0.6 \ln(r/T))}]r/T\}rk_2 \qquad (2)$$

$$\xi = \pi r^2 k_1 / t \qquad (3)$$

where H is the water head above the GMB, T is tailings thickness, t is GMB thickness, k_1 is the hydraulic conductivity of tailings within the GMB hole and k_2 is the hydraulic conductivity of tailings overlying the GMB. For the cases that the hole is filled with fully consolidated tailings, $k_2 = 1.1\ k_1$. Based on the proposed equation, factors (e.g., GMB hole size, water head, consolidation stress, subgrade gradation) affecting the piping and internal erosion through GMB defects have been investigated by Fan and Rowe (2022b).

The characteristics of tailings vary greatly and are highly dependent on the ore type, mineralogical composition, the physical and chemical processes used to extract the metals. The presence of fines particles (<75 μm) within tailings notably affected the compressibility and permeability of tailings (Fan et al. 2022) and may potentially impact leakage through any GMB defects. Thus, the objective of this paper is to investigate the effect of tailings fines content on leakage through circular holes in a geomembrane overlain by saturated tailings.

2 EXPERIMENTAL INVESTIGATION

2.1 Tailings

Three different tailings, fine-grained tailings with fines content of 90 % and d_{10} of 1 μm (denoted as T1), silty sand tailings with fines content of 30 % and d_{10} of 20 μm (denoted as T2), silty sand tailings with fines content of 20 % and d_{10} of 40 μm (denoted as T3), were examined (Figure 1). T1 was originated from a copper-zinc mine located in the south of Portugal and samples were collected immediately downstream of a thickener thickened using a flocculant. T1 (pyrite tailings) had a high acid generation potential and a specific gravity of 3.6 - 3.7. According to the Unified Soil Classification System (USCS), the sample could be described as a low plasticity clay (CL). Additional tailings details may be found in Lopes et al. (2013) and Fan and Rowe (2022a). T2 and T3 were both cyclone sand originating from a copper mining facility in British Columbia (Canada) without being thickened. The tailings

Figure 1.   Grain-size distributions of fine-grained tailings (T1), silty sand tailings with 30% fines (T2), and silty sand tailings with 20% fines (T3) (Notes: T1 was first tested by Fan and Rowe (2022a), T2 was first tested by Rowe and Fan (2021, 2022), T3 was first tested by Fan and Rowe (2022b)).

had a similar specific gravity of ~2.65 and were both classified as silty sand (SM) based on the USCS classification. More information on T2 was given by Rowe and Fan (2021, 2022), and on T3 by Fan and Rowe (2022b).

2.2 Geomembrane and subgrade

Two types of smooth GMB, LLDPE with thickness of 1 mm beneath T1 and HDPE with thickness of 1.5 mm beneath both T2 and T3 were tested (Table 1). Circular holes with diameters of 10 mm, 20mm, and 50 mm, respectively, were pre-punctured in the center of 590 mm- diameter GMB specimens. Highly permeable subgrades with hydraulic conductivity k of at least three orders of magnitude greater than that of overlying tailings were investigated. The subgrades satisfied the filter compatibility criterion by Foster and Fell (2001) and the erosion category for the overlying tailings were all assessed to be no erosion.

Table 1. Measured leakage (L/day) through circular geomembrane holes of various sizes with a similar loading condition of effective stress and pore pressure in the tailings remote from the hole of ~170 kPa and ~350 kPa, respectively.

Tailings	GMB type	GMB thickness (mm)	Hole diameter (mm)		
			10	20	50
T1[a]	LLDPE	1	0.4	0.8	2.5
T2[a]	HDPE	1.5	0.5	1.6	4.3
T3[a]	HDPE	1.5	29	–	142

[a]Note: Leakage was first presented by Fan and Rowe (2022a) for T1, Rowe and Fan (2021, 2022) for T2, Fan and Rowe (2022b) for T3. The test measuring leakage through 20 mm diameter hole overlain by T3 was not conducted.

2.3 Test apparatus and procedure

Coupled physical and hydraulic experiments performed in this study were conducted in the same rigid cylindrical steel test cell with an inside diameter of 590 mm and height of 500 mm as that used by Rowe and Fan (2021, 2022). The cell was filled from the bottom up as follows: geocomposite drain, subgrade with a thickness of ~200 mm, GMB with a central defect, saturated tailings slurry with initial solids content of ~70% and final thickness of ~200 mm after consolidation.

2.4 Measured leakage

Leakage test was conducted with a combination of $\sigma_v \approx 520$ kPa and $u \approx 350$ kPa. During the experiment, leakage through the GMB hole gradually came to an equilibrium as tailings consolidated, the steady leakage in Table 1 and Figure 2 for each test was adjusted to 20 °C based on the temperature of the collected leakage. Test results show that leakage through geomembrane hole was closed to be proportional to the hole diameter and not the hole area for each type of tailings. For example, increasing hole diameter from 10 mm to 20 mm, there was a 1.9-fold increase in leakage for T1 tailings and a 3-fold increase in leakage for T2 tailings, and there was a 6.1-fold, 8.3-fold, and 4.9-fold increase in leakage when increasing the hole diameter from 10 mm to 50 mm for T1, T2, and T3 tailings, respectively. For a given hole size, the leakage for T2 and T3 tailings were 1.8-fold and 65-fold greater than that for the T1 tailings, respectively, showing the highly dependent of leakage on the fines content of tailings, especially for tailings with relatively smaller fines content (e.g., 20%).
Figure 2. Comparison of the measured leakage with three different tailings above the GMB and a highly permeable subgrade (filter compatible and no piping occurred) beneath the GMB at the effective stress and pore pressure in the tailings remote from the hole of ~170 kPa and ~350 kPa, respectively (Notes: leakage was first presented by Fan and Rowe (2022a) for T1, Rowe and Fan (2021, 2022) for T2, Fan and Rowe (2022b) for T3).

3 DISCUSSIONS AND PRACTICAL IMPLICATIONS

3.1 *Effect of fines content on leakage*

k is highly dependent on the fraction of smaller size particles within a soil, e.g., k was linearly correlated with $d_{10}{}^2$ based on Hazen equation. Besides d_{10}, fines content is also a parameter that is commonly used when describing tailings. This is because both parameters highlight the importance of smaller size particles to k. In the following description, fines content is used to illustrate the effect of smaller size particles on leakage through GMB hole.

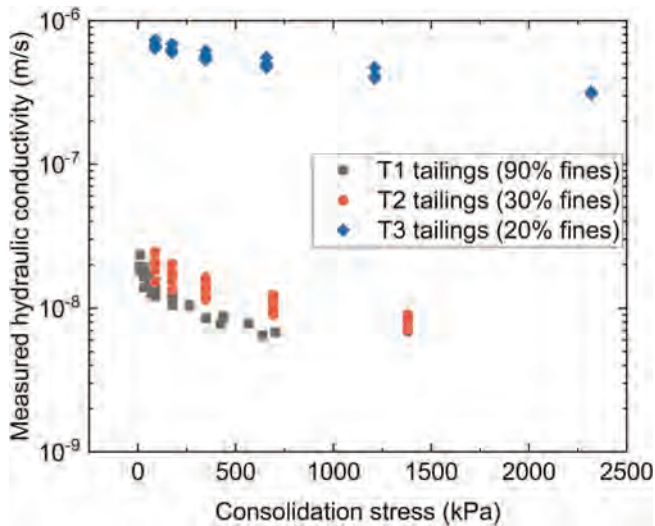
The relationship between consolidation stress and k of tailings tested was obtained using the stress-dependent permeameter (Fan *et al.* 2022). Results shows that k of tailings was highly dependent on its fines content (Figure 3). For example, at the same consolidation stress, there was an average of 1.5-fold increase in k when decreasing fines content from 90% to 30%, and there was a 30- to 60-fold increase in k when decreasing fines content from 30% to 20%, although the representative grain sizes for T1 was much finer (over an order of magnitude less) than those for T2 (Table 1). Fan *et al.* (2022) investigated the influence of fines content on the compressibility and permeability of tailings with a range of fines content from 0% to 100% by adding fines into or moving out of the host silty sand tailings with initial fines content of 18%. Results show that the same increment of fines from 12% to 30% and from 30% to 48% resulted in an approximately 8-fold and 2.5-fold decrease in k, respectively, and k remained constant when increasing fines content from 48% to 100%. Thus, a similar (around 2.5-fold variation) leakage through any GMB defect with the same hole size could be expected when the GMB is overlain by 30% and 100% fines tailings, whereas a sharp increase in leakage may be observed when reducing fines content from 30% to nil. This is caused by the effect of fines content on the involvement of the fines (<75 μm) and coarse ($\geq$ 75 μm) portions within soil skeleton under compression, and its impact on the specific surface of the mixture, as described by Fan *et al.* (2022).


Figure 3. Measured hydraulic conductivity of three tailings via the stress-dependent permeameter by Fan *et al.* (2022) (Notes: hydraulic conductivity was first presented by Fan and Rowe (2022a) for T1, Rowe and Fan (2022) for T2, Fan and Rowe (2022b) for T3).

Internal erosion and piping are a significant cause of failure and accidents affecting embankment dams (including tailings dam). Increasing the subgrade coarseness from the filter compatible subgrade presented herein to a filter incompatible poorly graded gravel subgrade, piping through GMB defects with diameters of both 10 mm and 50 mm was easily initiated when the GMB was overlain by T3 tailings (Fan & Rowe 2022b); whereas no piping was observed when the GMB was overlain by T1 tailings, even with a 72 m water head above the GMB (Fan & Rowe 2022a).

This is because a greater hydraulic disturbing force arose from a higher leakage when the GMB was overlain by a more permeable T3 tailings relative to T1 tailings.

Due to the localized concentration of head loss within a distance of $10r$ from the GMB hole center when the tailings are placed directly above the GMB, a feasible way of minimizing leakage through any GMB defect could be to place the tailings slurry with high fines content first (i.e., bottom layer) prior the placement of low fines content tailings (i.e., top layer). The thickness of bottom layer after consolidation should be enough if it is close to $10r$ (e.g., layer thickness > 0.05 m for r of 5 mm and 0.25 m for r of 25 mm). Further increasing its thickness has negligible impact on leakage. Moreover, tailings with fines content $\geq 30\%$ is sufficient for minimizing leakage and preventing the piping potential due to its low k.

3.2 *Reliability of leakage prediction*

Leakage through circular GMB defect with diameter of 10 mm, 20 mm, and 50 mm, respectively, were calculated using the modified Rowe-Booker equation (eq. 1; Rowe & Fan 2021, 2022). The ratio of observed leakage (Table 1) relative to the predicted leakage for the three tailings examined herein was generally within 10% (Figure 4), illustrating the suitability of the modified Rowe-Booker equation. Thus, the modified Rowe-Booker equation gives good predictions for a range of hole diameters and tailings.
Figure 4.   Comparison of the observed and predicted leakage for ranges of hole sizes and tailings types showing a good prediction of the proposed analytical equation.

4   SUMMARY AND CONCLUSIONS

Experiments were conducted to quantify leakage through GMB holes from the overlying three different tailings with fines content of 90%, 30%, and 20%. The influence of fines content on leakage was examined. For the specific conditions and materials examined, the following conclusions were reached:

(1) Leakage through GMB hole was highly dependent on the fines content. There was a notable drop in leakage if increasing fines content from 20% to 30%, but the drop was less significant for an increase in fines content from 30% to 90%. A feasible way of minimizing leakage could be to place the tailings slurry with high fines content first prior the placement of low fines content tailings.
(2) Placing tailings with fines content $\geq$ 30% directly above the GMB was sufficient for minimizing leakage and piping potential for the cases examined.
(3) The modified Rowe-Booker equation gave a good prediction for leakage through circular GMB hole with a range of hole diameters and tailings types examined.

Leaks detection of earthwork dam with geomembrane lining system by an active technique using optic fibers

G. Stoltz, S. Nicaise, L. Peyras & N. Chaouch
INRAE, Aix Marseille Univ, RECOVER, Aix-en-Provence, France

C. Guidoux & M. Boucher
GeophyConsult, Chambéry, France

ABSTRACT: This article presents the development of an active optical fiber device to address the issue of leak detection, and to allow operators to monitor the performance and safety of mountain reservoirs sealed with geomembrane lining systems. The device includes a fiber integrated into the geomembrane lining system and devices to heat and auscultate the fiber. The results shown that the active method has been successfully applied in a representative INRAE demonstrator. In particular, it has been shown that the technique is capable of locating without false positives or negatives a leak with a flow rate greater than or equal to 0.05 l/s and placed upstream of the optical fiber.

1 INTRODUCTION

The performance of geomembranes for sealing hydraulic structures such as basins or reservoirs no longer needs to be demonstrated. However, despite the robustness of geomembranes, the presence of leaks through them is possible. From some assumptions about frequency of holes per square meters, Giroud and Bonaparte (1989) gave some assessments about the leakage rates through a geomembrane liner. These leaks may appear during the construction of the hydraulic structure or during the service phase of the hydraulic structure. Leaks from construction work may be due to welding defects or damage to the geomembrane. They can be drastically avoided by a rigorous quality assurance construction program and by applying weld quality control methods (vacuum bell method, pressurizing the central channel method, etc.) and electrical leak detection methods such as the use of the water lance method/water puddle method electric broom (Müller 2007; Touze *et al.* 2021). During the operation phase of the structure, leaks may appear due to the application of static loads by puncturing aggregates in contact with the geomembrane (below or above it), or else by the application of dynamic loads (eg a falling block) on an exposed geomembrane. In the case of an exposed geomembrane, the location of a leak can be done visually (if the basin is empty) or with an electrical geophysical method (if the basin is filled). In the case of a geomembrane covered with a layer of granular materials, the detection and location of a leak that appeared during the service phase of a basin is less obvious by the methods mentioned above. However, there are basins for which it is important to detect and locate a leak very quickly to ensure safe use of the structure. This is for example the case of altitude reservoirs which are the type of structure targeted by the study of this article.

Hill or altitude reservoirs are hydraulic works mainly dedicated to the production of artificial snow (main purpose of altitude reservoirs) and / or intended for irrigation (main purpose of hill reservoirs). Other applications are possible such as the production of

hydroelectric power, the supply of drinking water, as well as for the practice of leisure fishing. The storage capacity of altitude reservoirs is variable, ranging from modest capacities (less than 20,000 m^3) to significant capacities for altitude structures (greater than 150,000 m^3). The RISBA project (2013 - 2015), "Risks of high altitude dams", has shown that the majority of recent or planned reservoirs have an average capacity of around 100,000 m^3 (Boutry *et al.* 2014). In France, the height of the embankments (i.e. the difference between the crest and the natural terrain) of the altitude reservoirs is between a few meters up to a maximum of 19.95 m, which, compared to their storage capacity, theoretically corresponds to administrative classes C and D. In Italy, in the Aosta Valley, almost all these types of structures have backfill heights comprised between 10 m and 15 m. Even if the size of the altitude reservoirs is modest compared to large dams, given the severe meteorological conditions in winter at an altitude above 1800 m (Peyras & Meyriaux 2009) and their potential impact in the event of failure, these structures are frequently administratively upgraded (transition from theoretical class C to class B).

Regarding the design of the altitude reservoirs, with the exception of the oldest ones, the majority of these structures have a geomembrane lining system (GLS). In addition to the geomembrane which ensures the waterproofing function, this type of device comprises several layers each providing one or more functions such as the support structure (on which the geomembrane is set and having functions of protection and drainage of the geomembrane) and the structure protection, overlying the geomembrane, which has a role of protecting the geomembrane against external mechanical stresses. A full description of GLS can be found in Peyras & Meyriaux (2009).

In general, the presence of a leak in the structures described above is detrimental and, in extreme cases, can seriously affect the stability of the structure. Thus, to ensure the stability and ensure the durability of the structure over the long term, any leak must be located and repaired. In the case of a covered geomembrane, generally by a multi-decimetric granular layer, the presence of a leak is dramatic because it is necessary to remove the entire layer of aggregates to access the geomembrane and perform the visual inspection and reparation. It is then obvious that this operation is long and potentially detrimental for the geomembrane because the machine which will remove the granular cover layer can itself damage the geomembrane again.

In this context, a specific action on the development of a simple and robust method for locating leaks was carried out within the framework of action WP3.4.1 of the European research project Interreg Alcotra called RESBA, "resilience of dams d 'altitude', started in 2017 and bringing together French partners (INRAE and the University of Savoie Mont Blanc) and Italian partners (Piedmont and Aosta Valley region, Polytechnic School of Turin). This action consisted of testing the active method by optical fiber, in an optimal configuration for this type of structure. Although the method is already operational (for example Guidoux *et al.* 2019 tested successfully a close method on a concrete experiment dam), there are currently no altitude reservoirs equipped with such a device. This observation can be explained by several possible reasons: lack of knowledge of the technique by the administrator of altitude reservoirs, absence of a demonstrator at the site level, negative prejudice concerning the difficulty of transport and the cost linked to the heating generator to take away in mountainous context, etc.

To demonstrate the performance of the method under conditions close to a real structure, the method was implemented through geophyConsult on the experimental basin of the INRAE site in Aix-en-Provence. Three main questions were particularly investigated:

– What is the minimum (heating) power to be supplied for optimum leak detection?
– What is the minimum leakage rate detected for minimum heating energy? This question is particularly linked on the one hand to the detection criterion, i.e. the temperature difference which can only be explained by the presence of an anomaly (i.e. a leak), and, on the other hand, at the distance of the leak relatively to the positioning of the optical fiber;
– Is the system as efficient in hot period (summer) as in cold period (winter)?

2 BACKGROUND OF THE ACTIVE METHOD BY OPTICAL FIBER

2.1 *The active method*

From the first leak detection experiments using fiber optic temperature measurements carried out from 1995, it appeared that the visualization of raw measurements only usually did not allow to identify leaks correctly. Indeed, many factors other than leaks influence the temperature of a soil: the geological nature of the soil, the relative position of the fiber with respect to the air or the upstream reservoir, or even the proximity of crossing structures. The development of methods for analyzing temperature data by optical fiber therefore quickly turned out to be a major challenge in making this technology operational.

The active method or Heat Pulse Method (HPM) Dornstadter J. & Heinemann (2010) is mainly used in cases where the optical fiber must be installed in an environment whose temperature is directly influenced by the water in the reservoir (even with no leakage). It refers to the realization and use of temperature measurements within an optical cable installed near the reservoir and previously heated by the Joule effect using electrically powered copper wires (see Figure 1).

Figure 1.   Optical cable used for the active method.

The needed electrical power - typically 5 to 10 W/m - depends on the conductivity of the soil, the heating time and the aimed temperature increase. In the presence of a leak in the vicinity of the cable, the convection generated by the flow will cause a lower rise in the temperature of the cable (see Figure 2).
Figure 2.   HPM principle.

2.2 Interpretation and outcomes

The interpretation of the measurements is based on the comparison of the measured values of dT with a reference value of dTREF. Through calibration tests in the laboratory or on site with controlled leaks (Perzlmaier 2007), it is possible to quantify the flow velocity for a range of Darcy's velocities between 10^{-5} and 10^{-3} m/s. The leak detection radius around the optical cable using this method is often less than for passive approaches, in the range of 15 to 20 cm. The means required for heating make this method more difficult to operate on measurement lengths of ten kilometers or more.

As some technical parameters may vary from one heating to another (the injected electrical power, the heating time, the evolution of the outside temperatures), the raw dT profiles are systematically readjusted, by adjusting their average and their standard deviation to those of a reference measurement. The dT values of a given heating are then subtracted from the dT_{REF} values recorded at the same positions during the reference heating. A measurement is thus obtained at any point of the cable which is strictly speaking the detection parameter of the active method, to which a detection threshold depending on the field conditions (spatial variability characteristic of the cable used) is applied. This methodology is called SACRE (as for Surveillance Active par "Centrage et Réduction avec Etat-zéro" in French, Active Monitoring by Centering and Reducing with Reference-State).

3 MATERIAL AND METHOD

3.1 Design and realization of the experimental basin

For the experiments, a basin already existing at INRAE's site of Aix-en-Provence was completely redesigned in order to fit the topic of the research (Figure 3). The embankment delimiting the basin is 23m long and 10m wide; it is made of local clay, which Plasticity Index is 17 and hydraulic conductivity is 10^{-9}m.s^{-1}. The dike is 2.5m high, so the water head is about 2m.

In 2019, we added a new GLS to the structure: first, a Draintube® drainage geocomposite made up of mini-drains with a diameter of 20mm spaced 2m apart is installed directly on the
Figure 3.   View of the experimental basin.

soil; drains are parallel to the slope and connected to a central gravel drain that allows evacuating water supplied by the leaks. Then, a 1mm thick polypropylene geomembrane placed above the geocomposite ensures the waterproofness.

Fourteen artificial leaks cross the geomembrane and bring water between the two geo-synthetics; water is collected by the mini-drains. Each leak is connected to the water supply through a garden hose; water is directly pumped into the basin to have the same temperature as the basin water. The leaks reproduce the potential geomembrane damages, and are located on the basin in order to study the influence of sun exposure and their relative position to the mini-drains. Sensors and valves are used to control and measure pressure and flow rate of the leakage water.

3.2 Instrumentation of the basin

The purpose of this basin is to process real-scale measurements with controlled conditions. Therefore, we have installed a large panel of instrumentation inside out of the embankment (Figure 4).

3.2.1 The leaks

The leaks are part of the instrumentation and the reservoir is composed of fourteen leaks. Each leak is connected to a garden hose and pierce artificially the geomembrane (Figure 5). Water from the basin supplies directly the leaks using a pump (Lowara BGM9). The leaks allowed the water to pass through the geomembrane, then the water will be collected by a mini-drain in the Draintube® drainage geocomposite and led down to the bottom of the basin.

Leaks are spread through the surface of the basin in order to study the influence of the sun exposure and their relative position to mini-drains.

3.2.2 The actives optical fiber

The optical fiber is composed of a measurement cable and a compact optical interrogator device (Sensornet Oryx). During the second campaign, this interrogator was kindly loaned by EDF through geophyConsult. In this experiment, the optical fiber is associated with few copper cables rolled along the length of the cable (Figure 1). The copper cables were used to heat up the optical fiber; this combination, which allows the fiber to contrast clearly with its environment, is called the active optical fiber. The electrical power injected during the heating operations was recorded with an energy consumption meter (Voltcraft Energy Logger 4000F), placed upstream of the heating device.

Figure 4.   Instrumentation plan, view of the basin from above.

Figure 5.   Leaks insertion system.

During the measurement campaigns, the active optical fiber was used as a temperature sensor with a spatial resolution of 1 m and a 5 minutes acquisition frequency. The active optical fiber is located at the bottom of the basin under the drainage geocomposite (Figures 4 & 6).

The detection of a leak by the optical fiber corresponds to a calculation of the temperature difference measured in the vicinity of the optical fiber in the absence of a leak with that measured in the presence of the leak. This parameter is denoted ΔdT. The criterion for detecting a leak, corresponding to a measured thermal anomaly, was set at 0.3°C. For the purpose of quantification, the detection intensity (°C.m) is calculated, which corresponds to the area under the curve ΔdT along the linear optic fiber.

Figure 6.   Localization of the active optical fiber.

3.2.3   *Measured and controlled parameters*
Temperature and water content probes located downstream of the leaks (Figure 4) are used to confirm fiber optic measurements. Three temperature sensors (Probe 107 Campbell Scientific) were used to measure the temperature of the water near the leaks (Figure 4).

Ten water content probes (CS650 Campbell Scientific) were installed to detect the water streaming down from each leak. A CR1000 data acquisition system (Campbell Scientific) recorded the set of data from temperature and water content under a 1-minute acquisition frequency.

The incoming pressure (Jumo Dtrans p30 type 404366 sensor) and the flowrate (Kobold MIK 5NA 55 E L443 sensor) of each leak are controlled with a valve placed upstream and recorded during the experiments with a USB-6001 data acquisition card (National Instrument).

3.3 *Experimental campaign*

The experimental basin was subjected to two experimental campaigns of 5 days of measurements: the first was carried out from October 11 to 21, 2019 and the second from February 10 to 14, 2020. The objective of these two campaigns was on the one hand to test the performance of the device during two periods when the outside temperatures are different and, on the other hand, test the robustness of the device over time, on the scale of a research project. During the injection campaigns, five injection flow rates (0.005 - 0.01 - 0.02 - 0.05 - 0.1 l/s), 5 heating powers (2 - 4 - 6 - 8 - 10 W/ml) and three distances injection point - heating cable (0 - 1.6 - 3.0 m) were tested. Each of the heating powers has been the subject of a reference measurement, that is to say a measurement of temperature rise in the vicinity of the optical fiber and the heating cable, in the absence of leaks.

4   RESULTS AND DISCUSSION

It has been shown that all the leaks with a flow rate greater than or equal to 0.05 l/s and placed upstream of the optical fiber at the base of the backfill have all been detected. With the detection criterion of $0.3°C$, and with a heating power greater than or equal to 4 W/m, no false positives were detected.

No significant impact of heating power on leak detectability was observed. In other words, a leak detected with a power of 8 W/m was also detected with a power of 2 W/m. However, the use of a low power induced false positives caused by the too low temperature contrast induced by the heating. Consequently, a minimum power of 4 W / m is recommended.

Increasing detection intensities were observed with the injected flow rates (Figure 7). At equivalent flow rate, the detection intensities decrease if the distance between the leak and the measurement cable increases, in line with the fact that the leakage speed decreases along

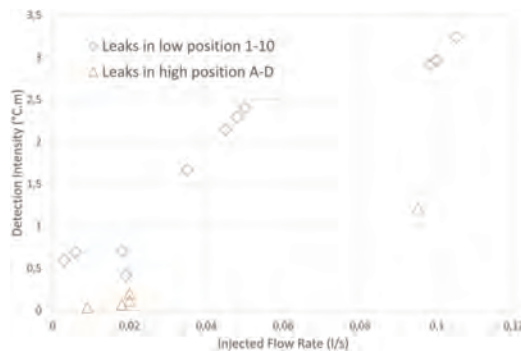

Figure 7.   Detection intensity as a function of the injected flow rate.

the propagation of the leak (diffusion in the drainage geocomposite). Thus, on a real site, it is recommended to install optical fibers at several sides of the basin, with a spacing which will depend on the desired level of leak detectability.

5 CONCLUSION

The purpose of this article was to implement a method for locating and detecting leak in GLS via an optical fiber positioned just under the geomembrane. In the fiber optic cable is integrated a copper cable to heat the environment close to the fiber. This heating makes it possible to create a thermal contrast and to evaluate more precisely the zones of leaks compared to all the normal zones, that is to say without leaks. This device finds all its interest in critical basins, as is the case for high-altitude reservoirs. This device has been successfully applied in a representative INRAE demonstrator.

It has been shown that the technique can locate without false positives or negatives a leak with a flow rate greater than or equal to 0.05 l/s and placed upstream of the optical fiber. However, as the level of leak detectability depends on the distance between the leak and the optical fiber, the sizing of the optical fiber network to be positioned in the structure will be a key step in the performance of the device.

ABSTRACT: The paper presents the results of tests on a family of products for erosion control on river/channel banks: geomats reinforced with double twisted steel wire meshes or with polypropylene geogrids; and reinforced geomats combined with geocontainer mattresses. The allowable resistant shear stress and allowable water velocity have been evaluated by testing in a flume according to ASTM D6460. Two different experimental campaigns have been carried out, to evaluate the performance of products both in unvegetated and vegetated conditions, both at short and at long flow duration. The analysis of test results allowed to define the surface of allowable shear stress vs the elapsed time t (years) from installation and the duration of flow D (hours). The procedure for getting the design curves of allowable shear stress vs flow duration at different times t is illustrated. The obtained charts allow the design according to the principles set in ISO 18228-8.

1 INTRODUCTION

Erosion on river/channel banks is produced by the shear stresses applied by the stream. The water flow produces shear stresses on bottom and side banks, proportional to water depth and velocity. Shear stresses can produce erosion by removing soil particles and excavating progressively deeper into the channel bottom and sides, which can be protected by lining with specific geosynthetics.

According to ISO 18228-8, the design and selection of geosynthetics for protecting river/channel banks require performance tests, in unvegetated and vegetated configuration, to assess the limit values of water velocity and shear stress. The paper aims to present the results of tests on a family of erosion control products: geomats reinforced with double twisted steel wire meshes or with polypropylene geogrid; and reinforced geomats combined with geocontainer mattresses. The obtained charts allow the design according to the principles set in ISO 18228-8.

2 TESTED PRODUCTS

The research involved two families of erosion control products for protection of river and channel banks: Maccaferri Macmat-R are three-dimensional erosion control geomats

composed of UV stabilized synthetic fibres extruded either onto a double twisted steel wire mesh or a Polypropylene (PP) geogrid, as shown in Figure 1, left and centre.

Maccaferri Reno Mattresses Plus are units manufactured from double twisted hexagonal woven steel wire mesh, made of PoliMac®-coated and Galmac-coated steel wire (Figure 1, right). The base, diaphragms, side and ends of each unit are manufactured from one continuous panel of mesh. The base is folded onto itself at regular intervals to form double diaphragms that are secured with spirals at the production facility. To ensure better packing of the fill and improve the hydraulic performances of the mattresses, the units are supplied together with vertical ties (X-Ties) connecting the base panel to the lid and to be installed on the site. The geocontainer mattresses, available with height h of 17, 23, 30 cm, are filled with stones at the project site to form flexible and permeable, monolithic structures. Maccaferri Macmat-R and Maccaferri Reno Mattresses Plus are even combined to form the Maccaferri Combo Reno Mattresses Plus, shown in Figure 2, where Macmat R is placed as the top lid of Reno Mattresses Plus.

Figure 1.   Maccaferri Macmat-R geomats reinforced with double twisted steel wire mesh (left) or a polypropylene (PP) geogrid (centre); Maccaferri Reno Mattresses Plus (right).
Figure 2.   Maccaferri combo Reno Mattresses Plus.

3   EFFECTS OF VEGETATION

A significant number of studies, both field and simulated studies, demonstrated that vegetation coverage effectively reduces water-induced soil erosion.

The general goal of geosynthetics for erosion control is to protect the soil from erosion, either indefinitely or until vegetation can establish itself.

Permanent erosion control and revegetation mats (PERMs) provide erosion control, aid in vegetative growth, and eventually become entangled with the vegetation to provide reinforcement to the root system. It is evident that the best performance in erosion control on river / channel banks can be achieved when the vegetation root system is reinforced by a specifically engineered geosynthetic, like a reinforced geomat, installed as a turf reinforcement mat (TRM).

The erosion control geosynthetic shall afford protection and reinforcement of the vegetation root system immediately after installation, while being open enough to allow the robust growth of vegetation within few weeks.

4 ALLOWABLE RESISTANT SHEAR STRESS

The allowable resistant shear stress τ_{all} of reinforced geomats can be evaluated by testing in a flume according to ASTM D6460.

Tests on different products and different conditions were carried out at the Utah State University (UTAH) in the years 1995 and 1996, before the ASTM D6460 test protocol was published.

Tests were run until either 60 hours or critical conditions (excessive erosion or sudden geomat failure), but with no pre-defined failure criterion.

In the years 2019 - 2020 a new research program was carried out at Colorado State University at Fort Collins (CSU).

Table 1 highlights the products tested at UTAH and at CSU.

Figure 3 shows the comparison of vegetation growth at different stages within the same product.

Table 1. Products tested at UTAH and at CSU.

Research	Product	Weight (g/m^2)	Thickness (mm)	Void Index (-)	Geomat Geometry
Utah (1996)	Macmat R/6	550	10	> 90 %	Random
CSU (2020)	Macmat R1 6822G0	450 ± 30	16 ± 4 (at 2 kPa)	> 90 %	Random
Utah (1996)	Macmat 10 / 20	550 / 650	10 / 20	> 90 %	Regular (biconic)
CSU (2020)	Macmat R1 05rs	400 ± 30	15 ± 2 (at 2 kPa)	> 90 %	Random
Figure 3. Pictures of Macmat 6822G0 at different vegetation growth in the CSU testing program.

5 TEST PROCEDURE AND RESULTS

5.1 *Test conducted by Colorado State University*

Test conducted by Colorado State University between 2019 and 2020 both on unvegetated and vegetated MacMat-R afforded the following results:

– Full revegetation was obtained in only 6 weeks.
– In 6 weeks the performances (Limit shear strength and Limit Velocity) reached what traditional erosion control solutions achieve in 1 year.
– 6th week performance achieved 60 % of 1 year measured performance.

The performance of geosynthetics in erosion control on river / channel banks depend on two main factors:

– The development of vegetation, which is increasing along the elapsed time t (years) from installation;
– The duration of flow D (hours): the performance is decreasing at increasing flow duration.

Figure 4 qualitatively shows the dependence of the allowable shear stress from the time t and the flow duration D. The surface in Figure 4 can be cut with a plane parallel to the time t axis, thus obtaining the chart of the allowable shear stress vs the flow duration D at a given time t, that is isochronous curves, as shown in Figure 4; if the surface is cut with a plane parallel to the flow duration D axis, then the chart of the allowable shear stress vs the time t for a given flow duration D, that is isoflood curves, is obtained, as shown in Figure 4.

To increase the shear resistance in unvegetated conditions a biotextile (BTX) can be placed below the Macmat-R, but it was noted that the BTX improves the performance only at t = 0.

5.2 *The importance of light penetration*

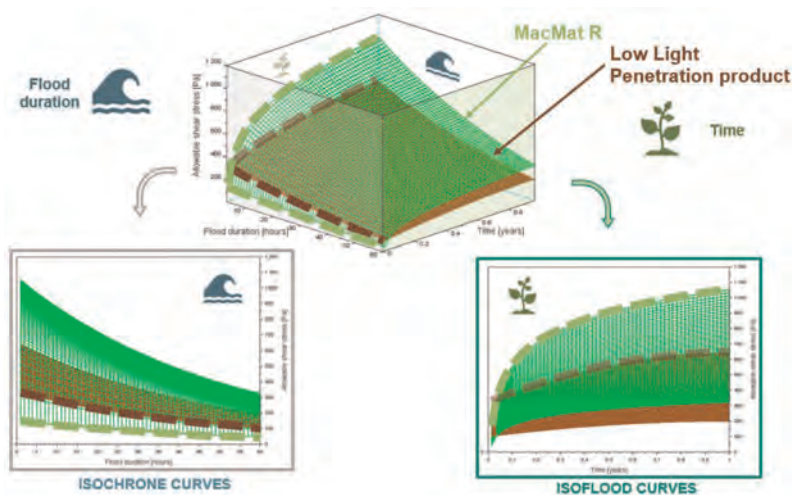
It is important to note that Maccaferri Macmat R affords a very open structure of the geomat (hence with high light penetration and void index), which allows a very fast vegetation growth in comparison with other products with a dense structure (hence with small light penetration and void index): therefore the allowable shear stress τ – time t – flow duration D surface for Maccaferri Macmat R is above the surface for denser products after few weeks of vegetation time t, as shown schematically in Figures 4 and 5, which clearly show that a lower light penetration (for denser products) would allow a higher performance only at t = 0, while a higher light penetration (for Macmat R) affords a higher performance over time.


Figure 4. 3-D pattern of the allowable shear stress vs the time t and the flow duration D, from which isochronous curves and isoflood curves are derived.
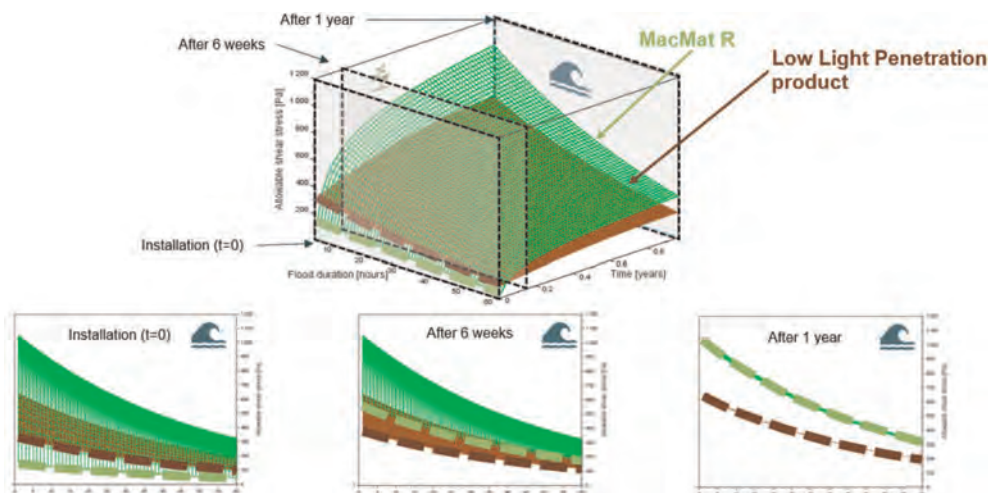

Figure 5. Effect of light penetration on the performance of vegetated reinforced geomats on channel banks.

5.3 *Analysis and results*

The procedure for getting the design curve of allowable shear stress vs flow duration in unvegetated and vegetated conditions is the following (see Figure 6):

– Step 0: get the experimental curve of allowable shear stress vs flow duration in vegetated and unvegetated conditions. An exponential regression line is interpolated from the experimental results (UTAH) in vegetated condition up to 60 h flow duration, and the performance at 1 hour (for vegetated conditions) or to 0.5 hours (for unvegetated conditions) is derived. These ones represent the experimental curves of allowable shear stress τ_{all} vs flow duration.
– Step 1: get the characteristic curve in vegetated and unvegetated conditions. Due to the different test protocol, a conversion coefficient Cc needs to be computed as the ratio between the limit shear stress for 1 hour flow duration (for vegetated conditions) or to 0.5 hours (for unvegetated conditions) at UTAH and the actual value obtained at CSU:

$$Cc_{vegetated} = 1296\ Pa\ /\ 1053\ Pa\ =\ 1.23 \tag{1}$$

$$Cc_{unvegetated} = 794\ Pa\ /\ 140\ Pa\ =\ 5.67 \tag{2}$$

This allows the trend up to 60 hours (observed at UTAH) to be extended also to tests at CSU, thus obtaining the characteristic curves of allowable shear stress τ_{all} vs flow duration in vegetated and unvegetated conditions. The characteristic curves are unfactored, hence these curves shall be considered as the reference performance of geomats (vegetated and unvegetated).
– Step 2: get the design curves in vegetated conditions. An overall Reduction Factor ($RF_{tot,veg}$), with values ranging from 1.30 to 3.0, according to ISO/TR 18228-8, is applied to the characteristic curve (obtained at Step 1) to obtain the design curves. The applied value of $RF_{tot,veg}$ defines the design area (see Figure 6, where $RF_{tot,veg} = 2.3$ has been evaluated as applicable).

It has to be noted that the difference in experimental results between Macmat 6822G0 (reinforced with double twisted steel mesh) and Macmat R105 (reinforced with

polypropylene geogrid) can be considered as negligible. Therefore, the design curves in Figure 6 apply both to Macmat 6822G0 and Macmat R105.

Moreover, the analysis of a large number of tests (over 60 test certificates were compared) performed on geomats according to ASTM D6460 with vegetation at 6 weeks growth stage provides statistical evidence that the performance at 6 weeks is equal to 60 % of the performance at 1 year vegetation growth (which can be considered as the fully vegetated stage), in agreement also with the pattern shown in Figures 4 and 5.
Figure 6.   Experimental, characteristic, and design curves of allowable shear stress vs flow duration in vegetated condition.

Therefore, if required, the allowable shear stress of Maccaferri Macmat R with vegetation at 6 weeks growth stage, $\tau_{all,\ 6\ weeks}$, can be conservatively evaluated by applying a Reduction Factor $RF_{6\ weeks} = 1.67$ to the allowable shear stress at 1 year vegetation growth, $\tau_{all,\ 1\ year}$, from Figure 6.

The chart of allowable shear stress vs flow duration can therefore be used to get the conditions of unvegetated MacMat R, Macmat R at 6 weeks vegetation, and Macmat R at 1 year vegetation.

The allowable velocities of Maccaferri Macmat R reinforced geomats have been obtained from the same tests in a flume according to ASTM D6460. Table 2 provides the limit velocity V_{all} for Maccaferri Macmat R erosion control products.

5.4   Extension to Maccaferri Combo Reno Mattresses Plus

Based on the same tests in the flume according to ASTM D6460, the design areas for Reno Mattresses Plus 30, 23, 17 have been obtained, as shown in Figure 7. Being mattresses filled with stones, such design areas have to be considered in unvegetated conditions.

As said, Maccaferri Combo Reno Mattresses Plus (Figure 2) are made up by the combination of Maccaferri Macmat R and Maccaferri Reno Mattresses Plus.

Hence the performance of Maccaferri Combo Reno Mattresses Plus can be evaluated also in the vegetated conditions, by simply applying the superposition of effects between the performance of Macmat R in vegetated conditions (from Figure 6) with the performance of Maccaferri Reno Mattresses Plus, as shown in the design chart in Figure 7.

Table 2. Limit velocity V_{all} for Maccaferri erosion control products.

| Sample ID:	Macmat R16822G0	Macmat R105rs	Macmat R16822G0 +BTX	Mamat R16822G0	Units
Limit velocity	3.22 0.98	3.47 1.06	> 30 > 10	> 28.02 > 8.54	ft/s m/s

Figure 7. Design chart for Maccaferri Reno Mattresses Plus.

6 CONCLUSIONS

The results of tests on a family of erosion control products have been illustrated: geomats reinforced with double twisted steel wire meshes or with polypropylene geogrid; and reinforced geomats combined with geocontainer mattresses.

Two different experimental campaigns have been carried out, in order to evaluate the performance of products both in unvegetated and vegetated conditions, both at short and at long flow duration. The allowable resistant shear stress and allowable water velocity have been evaluated by testing in a flume according to ASTM D6460.

The analysis of test results allowed to define the surface of allowable shear stress vs the elapsed time t (years) from installation and the duration of flow D (hours). This surface can be cut with a plane parallel to the time axis, obtaining the chart of allowable shear stress vs flow duration at given time t; or cut with a plane parallel to flow duration axis, obtaining the chart of allowable shear stress vs time for a given flow duration.

The procedure for getting the design curves of allowable shear stress vs flow duration at different times t from the 3-D surface has been illustrated.

The obtained charts allow the design according to the principles set in ISO 18228-8.

ABSTRACT: Geotextile tubes are a technology used in different sectors, such as water supply and sanitation, mainly in the final stage, to dewater the sludge generated in wastewater and water treatment plants. This paper presents geotextile tubes at the beginning of the water supply system (i.e. catchment). This paper shows a large-scale remediation project that used geotextile tube dewatering technology to desand the stream where part of the water catchment of São Carlos city – (São Paulo, Brazil) is carried out. This paper aims to present the system's hydraulic performance and the geotextile degradation. The effluent quality throughout the operation was monitored. Granulometric distribution at different heights of the filter cake is presented to better understand the deposition of particles inside the geotextile tube during the dewatering process. Decreases were observed in the geotextile's tensile strength and permittivity properties after application.

1 INTRODUCTION

The process of inadequately occupying urban watersheds can cause surface erosion and siltation in water bodies due to the accumulation of sediments. Among the consequences of silting up water bodies is a reduction in the volume of water, shortages in the water supply and intensification of floods. Dredging is the most common form of environmental remediation for sediment accumulation (Lawson 2008). Geotextile tubes filled with dredged material provide an innovative and cost-effective alternative to traditional techniques due to their simplicity and flexibility. These structures can even be used for erosion prevention due to their stability against erosive forces (Fowler *et al*. 1994).

Geotextile tubes are manufactured from geotextiles with high tenacity, durability and small pore openings. Geotextile tubes are made with reinforced seams, forming permeable structures with the property of draining the material with which it is filled. Sludge dewatering application using geotextile tubes were first used in the 1990s. The general dewatering process using geotextile tubes comprises three steps: containment, dewatering and consolidation (Lawson 2008). The containment step involves pumping the waste into the geotextile tube. In the dewatering stage, a geotextile tube can receive several filling cycles. After the system reaches the maximum height stipulated in the design (first filling), the system loses water through forced filtration, drainage and evaporation (Müller 2018). It should be noted that after the first filling cycle, the maximum height of the system is no longer reached.

The performance of geotextile tubes depends on an extensive source of variables that can be classified a priori as hydraulic, mechanical and durability. Heilman *et al*. (2003) state that

trial and error is a common design method in projects with geotextile tubes, as the known design methods do not fully represent the complexity of the systems.

For geotextile tubes, Leshchinsky *et al.* (1996) highlight the use of four safety factors: factors related to creep over time; seam resistance; installation damage; and durability. Validating the sizing methods found in the literature for geotextile tubes, and determining appropriate safety factors, requires carrying out full-scale tests. This is due to the fact that in these tests, significant differences are observed regarding the requests imposed on the geotextile (Silva *et al.* 2021).

The present study presents the hydraulic performance of a geotextile tube installed to desand the Monjolinho stream, part of the water catchment of São Carlos city – (São Paulo, Brazil). Geotextile samples were collected at the end of the service life to assess its degradation. Sediment samples were also collected at the consolidation phase for geotechnical analysis. The main aim of this study is to provide information that contributes to understanding the geotextile tube's behavior in sediments dewatering applications. Moreover, this study investigates the deposition of sediment particles inside the geotextile tube during the dewatering and consolidation process.

2 METHODOLOGY

2.1 *Study area*

The city of São Carlos, in the state of São Paulo – Brazil, is supplied by surface sources (Monjolinho and Ribeirão do Feijão stream) and ground sources from 28 deep wells that draw water from the Guarani aquifer. At the water treatment plant, 35.3 million m^3 of water is produced, where 16% of the water comes from surface catchment from the Monjolinho stream. Problems in the drinking water supply operation resulting from the sediment transport of the Monjolinho stream forced the rapid execution of a remediation project. A geotextile tube was used for desanding the stream. Geotextile tubes are a technology widely used in the sanitation sector, known for their ease of installation and efficiency in dewatering. Figure 1 shows the location where the geotextile tube was installed.

Figure 1.   Geotextile tube location (21°59'11.85''S; 47°52'32.14''W).

2.2 *Materials*

The geotextile tube was manufactured from woven polypropylene geotextile, with the following characteristics: apparent opening of 0.343 mm, tensile resistance in the machine direction (MD) of 78.2 kN/m, and 106.5 kN/m in the cross direction (CD). The geotextile

tube meets Sabesp's technical specification (NTS 301 2015), which establishes reference values for the dewatering application. The geotextile tube (Figure 2) was 10 m wide and 15 m long with a maximum height of 2.3 m (indicated by the manufacturer). The tube was installed on a dewatering platform, consisting of a High-Density Polyethylene geomembrane (1.00mm), and a draining geocomposite with a double layer of 200 g/m^2 nonwoven geotextile. The draining geocomposite was used to replace the layer of gravel and the layer of nonwoven geotextile of 300 g/m^2 suggested in the NTS 301 (2015). The stream sediments were pumped into the tube with a pump of 100 m^3/h. The percolate from the tube was returned to the stream through a channel. A Parshall gutter was installed in the channel to measure the outflow (Figure 2). The sediments had a specific gravity of 2.74 g/cm^3 and a grain size distribution of 88.8% sand, 4.9% silt, and 6.3% clay.

Figure 2.   Geotextile tube.

2.3   *Monitoring*

The percolate quality was monitored over the dewatering time, periodic collections were carried out, and turbidity was measured, as shown in Figure 3a. In this study, the dewatering phase was completed prematurely due to problems with pump availability. In the Consolidation phase, 17 days after the last filling, geotextile and sediment samples were collected (Figure 3b). A reference sediment sample was collected directly from the stream bed. Specific gravity and granulometry tests were performed on each sediment sample. Tensile strength tests, seam strength tests and permittivity tests were carried out on the exhumed geotextile according to ISO 10319 (2015), ISO 10321 (2008) and ASTM D 4491 (2020), respectively.

Figure 3.   Sample collection. a) percolated collection, and equipment used for turbidity measurement. b) geotextile exhumation and sediment sampling.

3 RESULTS AND DISCUSSION

3.1 Hydraulic performance

Monitoring was carried out for approximately 110 consecutive days. However, due to problems with the pump operation, only fillings were carried out for 56 days. During this period, approximately 156 m³ of sediments were stored. Moreover, a maximum height of 1.40 m was reached at the central point of the tube (39% lower than the expected height). The inlet flow was measured using an ultrasonic meter, and it was observed that the pump worked at a maximum of 70% of its capacity. The decrease in pump flow may be associated with the presence of the sediment that forced the flow's transport. Due to the limited availability of the ultrasonic flow meter, only readings were taken during three periods, and the recorded values "Measurements" are presented in the graph in Figure 4. The maximum output flow, measured in the Parshall flume, was 40 m³/h.
Figure 4.   Inlet flow measurements performed at different periods.

The importance of compatibility between the pump capacity and the volume available inside the geotextile tube can be observed. In this remediation project, the tube dimensions were selected according to the expected storage volume (offered by the manufacturer), and the pump capacity was not verified. This indicates that the design was made according to trial and error, as Heilman *et al.* (2003) mentioned.

3.2 Sediment distribution

The specific gravity was 2.57 g/cm³, 2.70 g/cm³ and 2.68 g/cm³ for the bottom, center and top samples (Figure 3b), respectively. Figure 5 presents the granulometric distribution of the samples collected at the bottom, center and top of the Geotextile tube and the reference sample. It can be observed that the curves of the bottom and top samples showed similar behavior with percentages in the sand fraction close to 50%. In the granulometric curve of the center, it can be observed that the fraction of sand was higher, close to 77%.

Figure 5 shows that the reference sample collected directly from the stream bed does not represent the material dredged by the pump, which had high variability. The sediments pumped to the geotextile tube were pumped directly from the stream, involving operational variations such as suction height and stream dynamics affected by environmental conditions (rain and wind).

For this specific study, a sedimentation pattern cannot be identified, as the pumped material was not homogeneous. It did not come from an equalization tank. The granulometric distribution in the different heights of the geotextile tube depended on the pump
Figure 5.   Particle size distribution curve of the sediment samples.

operation, which explains the different granulometric distributions in the three analyzed points (bottom, center and top).

Turbidity is an indirect measure of the amount of sediment/particles passing through the geotextile tube (Aparicio-Ardila *et al*. 2020). During the monitoring, it was observed that the turbidity after dewatering decreased, ranging from 600-700 NTU (Nephelometric Turbidity Units) values to 200-300 NTU. This indicates that the water returned to the stream (percolated) had a better quality.

3.3   Degradation

Table 1 presents the geotextile tube property results after the dewatering application. As expected, a decrease can be observed in all the properties in the exhumed sample compared to the virgin one, in which the exhumed sample was exposed for 110 days. After exposure, this behavior was observed in other applications where the geotextiles were exposed to the weather conditions, such as Carneiro *et al*. (2018) in marine environments, Aparicio-Ardila *et al*. (2021a) in the application of erosion control and Aparicio-Ardila *et al*. (2021b) in weathering panels.

Table 1.   Geotextile virgin and exhumed properties and variation regarding the virgin sample.

Properties	Test Method	Virgin	Exhumed	Variation (%)
Tensile strength per unit CD (kN/m)	ISO 10319 (2015)	106.5	95.2	10.6
Tensile strength per unit MD (kN/m)	ISO 10319 (2015)	78.2	73.8	5.6
Seam tensile strength CD (kN/m)	ISO 10321 (2008)	75.5	52.86	30.0
Permittivity (s^{-1})	ASTM D 4491 (2020)	0.35	0.27	22.9

The mechanical degradation measured by the tensile strength of the geotextile and the seam showed a more significant decrease in the resistance of the seam indicating the importance of the quality of the seam for the dewatering application. Another essential characteristic evaluated was the hydraulic performance, measured by the permittivity. Permittivity presented a more significant decrease when compared in percentage terms with the resistance of the geotextile.

4 CONCLUSION

A trial-and-error process is not a design method. Using geotextile tube technology requires preliminary planning and testing to take advantage of the application's potential fully. Despite the operational limits for the execution of the presented environmental remediation project, the technology contributed to the solution of the operational problem in the catchment and returned water with better quality to the stream. Identifying a sedimentation pattern is impossible when the pumped material is not homogeneous.

Durability of exposed PVC-P geomembranes used for rehabilitating the upstream face of dams

D. Cazzuffi
CESI S.p.A., Milan, Italy

D. Gioffrè
Department of Civil Engineering and Architecture, University of Pavia, Italy

ABSTRACT: This contribution presents the recent results of an ongoing research on the long-term behaviour of a PVC-P geomembranes installed on the upstream face of masonry and concrete dams. In the last 30 years, starting from sometime after the dam rehabilitation with this type of geosynthetics, the exposed PVC-P geomembrane were sampled periodically and tested in laboratory. Material properties measured at the laboratory were compared with the ones obtained from test on virgin samples, when available. The sampled geomembranes have been subjected to physical and mechanical tests and the results interpreted with reference to the variation of plasticizer, tensile characteristics, foldability at low temperatures, and specific mass. In particular, the decrease in plasticizer content resulted in a slightly increase of the geomembrane rigidity, i.e. higher modulus and tensile strength and lower strain at failure. The experimental program allowed to study the evolution of the properties of the geomembrane over the years enabling the assessment of the residual life of exposed geomembranes installed on the upstream face of dams.

1 INTRODUCTION

Geomembrane systems are one of the most sustainable rehabilitation technologies for dams. Geosynthetic barriers have been used as alternative solutions not only to mitigate the deterioration processes in existing dams, but also to prevent the onset of seepage-induced degradation in new dams, and as the main hydraulic barrier, particularly for embankment dams, in cases where low-hydraulic conductivity soils are not readily available (Cazzuffi 1987).

The use of geosynthetics as water barriers is one of the numerous uses of geosynthetics in hydraulic and geotechnical applications of geosynthetics. The use of geosynthetics in dams represents a major application of the geosynthetics since "dams have a particular status due to their impact on the environment and on safety", as pointed out by Heibaum *et al*. (2006).

While the concept of using geomembranes in dams instead of conventional "low permeable" materials (e.g. clay, cement concrete (hereafter simply called concrete) or bituminous concrete) derived, among other considerations, from the successful use of geomembranes in canals and reservoirs, the credibility of synthetic materials in dams had been established by the good performance of embedded PVC waterstops in a very large number of concrete dams worldwide. In those dams, waterstops play an essential role in preventing water seepage through joints that are indispensable to accommodate concrete expansion and contraction. A geomembrane placed on the upstream face of a dam or inside a dam can be considered,

from a conceptual viewpoint, as one wide waterstop sealed at the abutments and at the bottom of a dam.

The most pioneering applications of PVC-P geomembranes, employed to rehabilitate concrete and masonry dams, were in the alpine regions in Europe, at more than 1500 m elevation. In particular, this contribution focuses on eight large concrete and masonry dams, all in the Italian Alps, that were rehabilitated with this technology in the 1980s and 1990s. In all of these dams, the PVC-P geomembrane was left exposed to the environment, which is quite demanding at such elevation in terms of resistance to UV rays, freeze-thaw cycles, extremely low temperatures, and high daily and seasonal temperature variations.

The rehabilitation of dams consisted in the application of a geocomposite on the upstream face. This geocomposite was formed by a geomembrane layer, placed externally and having a barrier function, and by a geotextile layer, placed internally with a mechanical protection and drainage function. The geocomposite usually covers the entire upstream face of the dam and the most common installation method consists of vertical strips of about 2.00 m wide, fixed to the dams by means of batten strips held by anchor bolts (Scuero & Vaschetti 1996). The geotextile component protects the geomembrane from the mechanical damage caused by irregularities in the dam upstream face; it also contributes to reduce the creeping or sagging of the geomembrane along the quasi-vertical dam face.

In this paper, PVC-P geomembranes installed on the upstream face of dams are evaluated using results of a wide experimental campaign still ongoing (Cazzuffi & Gioffrè 2018; Cazzuffi & Gioffrè 2021a). The results of the experimental tests carried out on samples retrieved directly at site integrated the data obtained in the research and contributed to monitor the variation over time of the characteristics of the PVC-P geomembranes in service; moreover, the additional tests presented here helped to confirm the methodology already employed in (Cazzuffi & Gioffrè 2021b) to predict the lifetime of the geomembrane.

2   LONG-TERM BEHAVIOUR OF GEOMEMBRANES IN DAMS

The durability of geomembranes is based on their weathering properties, and on their resistance to specific loads during service, such as extreme temperatures, frost, freeze/thaw, ice, impacts by floating debris and boats, wind and waves, fauna and flora, vandalism etc. (Hsuan *et al.* 2008).

Not all geomembranes have the same behavior due to their different chemistry, basic ingredients, and manufacturing process; For these reasons it is important when considering dam projects to either select an existing geomembrane or to design a new one that can best perform according to the type of environment in which it will be used, and that can provide an adequate durability for the required application.

The behavior in service of geomembranes is commonly predicted using standard accelerated ageing tests. However, these tests, although accelerated, still require too much time for providing an effective indication on the long-term behavior of geomembranes.

The most practical way to ascertain if a geomembrane will resist to the environmental loads expected in a dam project in the long term, is to retrieve samples of the same type of geomembrane already in service in a similar environment , for a period of time that should be as long as possible, ideally as long as the required service life of the geomembrane in the considered dam. Tests are then performed on these samples to determine to which extent their properties have changed during service. Testing of the physical and mechanical properties of the exhumed samples indicates if the geomembrane properties at the time of the test are within acceptable limits, and extrapolation allows the determination of the expected remaining service life. This approach has been adopted in Italy (Cazzuffi 1987; Cazzuffi & Gioffrè 2020, 2021b), using data from several concrete and masonry dams rehabilitated with exposed PVC-P composite geomembranes.

3 REHABILITATION OF CONCRETE AND MASONRY DAMS

The analysis of the long-term behaviour of the geomembranes presented in this paper has been conducted studying the performance of several samples of geomembranes, installed in the '80s and '90s, and retrieved from the upstream face of eight large concrete or masonry dams in the Italian Alps (Cazzuffi 1996; Cazzuffi *et al.* 2010; Scuero & Vaschetti 2009, 2017), where most of the pioneering applications of PVC-P geomembranes to rehabilitate concrete dams were located.

The dams considered (Figure 1) were built in the '30s (only one in the '50s) and are characterized by several common features, so that it is possible to make some considerations that are acceptable for all of them. It is important to highlight that these areas are characterized by a very changeable weather, responsible for sudden changes in temperature, with consequent heat loads which play an important role in the durability of the dam and its materials.

Figure 1. Location map of the dams considered in the paper.

For all these 8 dams, the PVC-P geomembrane was left exposed to the environment, which at such elevation is quite demanding in terms of resistance to UV rays, freeze-thaw cycles, extremely low temperatures, and high–daily and seasonal–temperature excursions.

Between 1980 and 2000, all of the upstream faces of the 8 dams here considered were rehabilitated with the application of a geosynthetic layer in order to restore their initial watertightness.

The rehabilitation was performed by installing an exposed two-layers composite geomembrane, formed by: i) a plasticized polyvinyl chloride (PVC-P) geomembrane; ii) a polyester (PET) or polypropylene (PP) needle-punched nonwoven geotextile. In just one case an extra layer of high-density polyethylene (HDPE) geonet was added. Given its very low coefficient of permeability, the geomembrane was installed to ensure the barrier function of the upstream face.

The geotextile layer was installed to fulfill two main functions:: i) anti-puncturing function, through the regularization of the surface on which the geomembrane is laid down; ii) drainage function, as it avoids the accumulation of water between the geomembrane and the dam face; this happens as a result of the generation of a high-transmissivity plane which allows water to flow by gravity into a special collector.

In all of the cases presented here, the geomembrane is always coupled with another geosynthetic; therefore in the following we will refer to the entire waterproofing system as composite geomembrane, as this is the layer providing the barrier function we want to analyze in this paper.

4 EVALUATION OF THE RESIDUAL LIFE OF EXPOSED GEOMEMBRANES

In order to evaluate the variation over time of the characteristics of the PVC-P geomembranes installed on the eight dams here considered, a good number of samples have been taken after the geomembrane application and all of them have been subjected to the same type of tests.

Samples were retrieved both above and below the water table level and in different parts of the upstream face, with the aim of studying the different behaviour of the same geomembrane under different conditions of exposure.

When determining the life expectancy of a geomembrane it is important to identify the more critical portion of the upstream face, as the first failure will affect negatively the whole waterproofing system. Therefore, here we present the results of the tests made on samples taken above the water level, as this is the area which suffers most from the direct exposure to atmospheric agents. The results obtained are thus referred to as the worst case scenarios for each geomembrane and this helped us to conduct a precautionary analysis of the geomembrane durability.

All the samples taken from the dams upstream faces have been tested at the Geosynthetics Laboratory of CESI S.p.A. in Milano, Italy. These tests allowed the comparison among different samples during the degradation process of the geomembranes. The cases of Camposecco and Ceresole Reale are particularly significant, as for these dams the test results on virgin samples are available. The analyses conducted for these cases are, therefore, more valuable as the knowledge of the materials initial condition allows the reconstruction of the entire life behaviour of the geomembrane.

Before the tests, samples were prepared by separating the geotextile layer from the geomembrane. Only the tests made on the geomembrane layer (Table 1) will be discussed in the following.

Table 1.   Laboratory tests and reference standards.

Test	Reference standard
Plasticizer extraction	EN ISO 6427
Nominal thickness	EN 1849-2
Volumic mass	EN ISO 1183-1
Hardness (Shore A)	EN ISO 868
Cold flexibility	EN 495-5
Dimensional stability	EN 1107-2
Tensile properties	EN ISO 527-3

The results obtained show a constant small decrease of the plasticizers' content (Figure 2a), while temperature of cold flexibility rises with time; moreover, dimensional stability grows longitudinally and declines transversally in the years.

Mechanical parameters show that the geomembrane get stiffer over time (Figure 2b), with a growth of tensile strength and a reduction of the correspondent strain, both in the longitudinal and in the transversal direction.

Long-term performance of PVC-P geomembranes depends on several aspects referred to exposure environment and polymer and additive formulations. The service life of PVC-P geomembranes can be predicted based on experimental results. Through a careful monitoring of the variation over time of the characteristics of the PVC-P geomembranes in service, it was possible to define a methodology of lifetime prediction for the geomembrane installed in dams when the results on virgin samples are available. In particular, the plasticizer content plays a fundamental role in terms of variation in physical properties of the PVC-P geomembranes (Giroud 1995; Giroud & Tisinger 1993).

In order to evaluate the most critical service life of the PVC-P geomembrane, two approaches can be used: (1) the curve of plasticizer content versus time is extrapolated until the end-of-service-life plasticizer content is reached; or (2) the plasticizer content data points are converted into plasticizer loss ratio data points and the curve of plasticizer loss ratio versus time is extrapolated until the extrapolated plasticizer loss ratio is equal to end-of-service-life criterion expressed in terms of plasticizer loss ratio.

Giroud (2021) proposes, for the end-of-service-life criterion, a plasticizer content value of 17.5% for PVC-P composite geomembranes bonded to a nonwoven needle-punched geotextile (which are the most frequently used in the considered dams). This value was based on laboratory tests (Luciani *et al.* 2019, 2020) and on data collected from monitored structures,

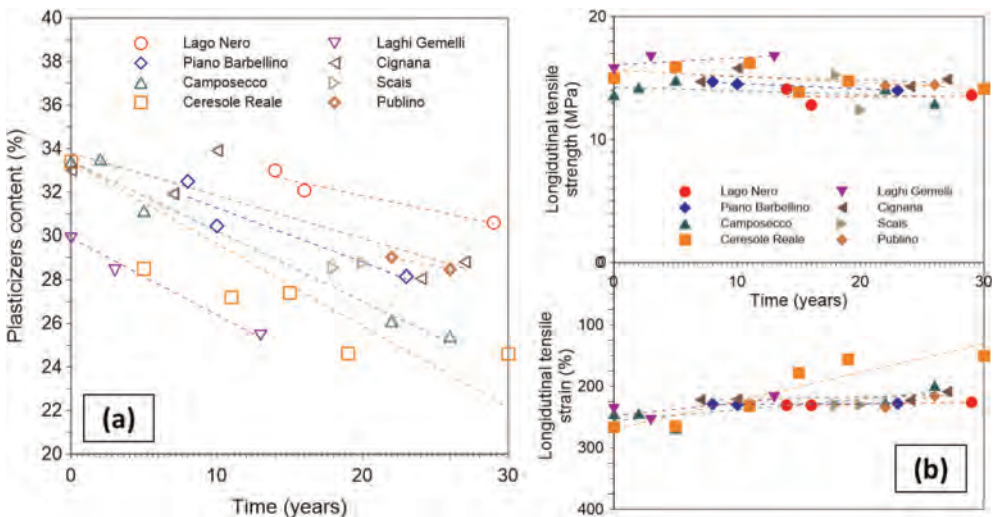
According to approach (1), which used the curve of plasticizer content versus time, Figure 3a and Figure 3b show the lifetime assessment of exposed PVC-P geomembranes for Ceresole Reale and Camposesso dams, respectively.Vertical lines in Figure 3a and 3b show that the lifetime assessment of the exposed geomembranes for Ceresole Reale dam and Camposecco dam, assuming a linear decrease of plasticizer loss ratio over time, are approximately 42 years and 48.5 years in terms of plasticizer content criterion, respectively.


Figure 2. Test results: (a) Plasticizers content vs time; (b) Longitudinal tensile strength and strain vs time.
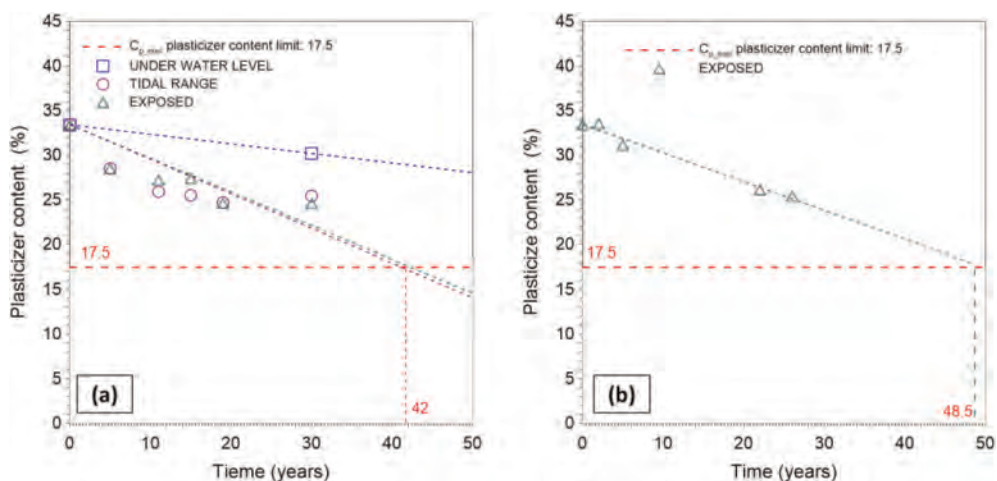

Figure 3. Lifetime assessment of exposed PVC-P geomembranes: (a) Ceresole Reale dam; (b) Camposecco dam.

5 CONCLUSIONS

The range of possible applications of geomembranes as water barriers in dams is quite wide. In fact, geomembranes can be applied to all types of dams, either in new construction or for in rehabilitation, both in dry conditions or underwater.

Long-term behaviour of a PVC-P geomembranes installed on the upstream face of masonry and concrete dams have been discussed in this paper, particularly in dams where test results on virgin samples are available.

Data on the performance of dams rehabilitated using geomembranes have been provided. These data show a remarkable performance of composite geomembranes in dams, even when the geomembrane component is exposed to atmospheric agents.

ABSTRACT: Four laboratory models filled with aggregates with fractions 0–32 mm were prepared in a special laboratory box with dimensions of 1000 x 1000 x 600 mm. Three models were fitted with a geogrid, which, together with the aggregates, formed a mechanically stabilized layer (MSL), 100, 150 and 200 mm in thickness, while one model, without a geogrid, served as a reference model. A new-generation – multiaxial – geogrid was used for the experiments. The models were loaded with a static force of up to 100 kN with the aim of finding out the differences in the magnitude of lateral pressures acting on the laboratory box wall. The experiments revealed principal reductions in the horizontal pressures in the mechanically stabilized layer compared to non-stabilized aggregates. The greatest reductions were recorded at the geogrid level, nevertheless, a significant reduction in horizontal pressures is manifested throughout the entire MSL. The intensity of the aggregate confinement in the geogrid is related to the reduction in horizontal pressures and quantified as a parameter enabling the evaluation of the efficiency of mechanical stabilization of aggregates by geogrids – the Confinement Efficiency Factor (CEF).

1 INTRODUCTION

A mechanically stabilized layer is formed as a result of the interaction of a stiff geogrid with aggregates. The aggregate grains penetrate into the geogrid holes leaning against its ribs thus causing their mutual interlocking. The grains confined in the holes are strongly immobilized. As a result, the whole layer shows considerably higher stiffening that the original aggregates and is mechanically stabilized. Byun *et al.* 2018 and Lees & Clausen (2019) assumed that the aggregates confined in the geogrid behave as a composite with qualitatively different mechanical properties compared to individual used components (geogrid and aggregates). The mechanical stabilization mechanism of aggregates by a geogrid has been characterised in professional literature, e.g. Rakowski & Kawalec (2009) and Horníček & Rakowski (2017). The quantification of the mechanical confinement effect, however, still remains an open question.

The paper focuses on the quantification of this confinement effect on the basis of conducted laboratory experiments involving the monitoring of horizontal pressures exerted by

aggregates onto the laboratory box wall. The comparison of the horizontal pressures detected in the mechanically stabilized layer with a variable geogrid position versus non-stabilized aggregates allowed deriving the factor indirectly quantifying the aggregate confinement intensity in the geogrid.

A new generation of stiff monolithic geogrids labelled multiaxial geogrids was first used in the experiments.

2 EQUIPMENT AND STRUCTURE OF LABORATORY MODELS

2.1 *Description of models*

A universal laboratory box with dimensions 1000x1000x800 mm where the backfill height reached 500–600 mm was used for the laboratory modelling (Figure 1). Four models marked M–0 to M-III (Figure 2) were designed and assembled. All models contained a compacted layer of aggregates (crushed stone mixture) with fractions 0–32 mm, 400 mm in thickness, with a load-bearing capacity on the surface of the layer of min. $Ev_2 = 100$ MPa pursuant to the ČSN 72 1006 standard.
Figure 1. General scheme of the laboratory model.
Figure 2. Vertical profiles of models M-0, M-I, M-II, M-III.

Subsequently, another layer of the same aggregates, 200 mm thick, was placed and compacted in Model M-0, where no geogrid had been fitted and which, therefore, served as a reference model for mutual comparisons. In the other three models, the 400 mm thick aggregate layer was overlaid with a multiaxial geogrid (Figure 3) and, successively, a crushed stone mixture layer with fractions 0-32 mm, 200 mm thick after compaction (Model M-I), 150 mm thick after compaction (Model M-II), or 100 mm thick after compaction (Model M-III). The compaction time was selected proportionally to the thickness of the layer over the geogrid.
Figure 3.   Multiaxial geogrid.

2.2   *Loading*

The models were subjected to continuous vertical loading with a hydraulic press, the exerted force ranging within 0–100 kN. The force was transmitted onto the model structures via a part of a polymer sleeper with dimensions of 880x250x150 mm, which had been placed in the middle of the upper surface. This represented a maximum stress at the lower sleeper area of 454 kPa under loading by the highest exerted force.

2.3   *Measurement, recording and evaluation of horizontal pressures*

The measurement of horizontal pressures was conducted using the configuration displayed in Figure 4. The sensor itself was a special foil (Tekscan Pressure Mapping Sensor 5315), containing over 2000 sensels with a raster of 1 x 1 cm, where each sensel allows the recording of the corresponding earth pressure. This flexible foil 43 cm in height and 48 cm in width was fixed onto the inside lateral wall of the laboratory box in a position corresponding to the longitudinal axis of the placed sleeper section. To protect the foil from the aggregate sharp edges a protective layer of unwoven geotextile was used. The signal from the foil is recorded by a reader and transmitted to a laptop using special software for data recording (data logger) as well as the subsequent processing of the measured data.
Figure 4.   The scheme of horizontal pressure recording.

The evaluation software defined a special interest zone on the foil surface area in the form of 8 vertically arranged strips, 50 mm high and 150 mm wide, situated so that the projection of the sleeper's longitudinal axis would intersect the centre of each strip. This arrangement allowed detailed evaluation of the area 150 mm in width to a depth of up to 400 mm from the surface of the structure. In each of the 8 strips, the average lateral pressure coming from 75 sensels was evaluated in relation to the exerted vertical force. Taking into account the maximum grain size of the aggregates of 32 mm, the granularity of the sensels on the foil enables a very reliable accuracy of the evaluation of horizontal pressures in the strips spaced 50 mm from each other. A finer subdivision is technically feasible, however, the imprints of individual grains would be difficult to interpret in this case.

3 MAIN OBSERVATIONS FROM EXPERIMENTS

The up-to-now known interlocking mechanism assumes the reduction of horizontal pressures in aggregates versus standard aggregates. The aim of experimental works was to find out how much the lateral pressures in MSL are reduced in comparison to non-stabilized aggregates. Figure 5 displays the lateral pressures in Model M–0 as they were measured in individual strips from top to bottom, from s5 to s40, for the case of the maximum sleeper loading, i.e. 100 kN. The lateral pressure values show a gradual uniform decrease in the downward direction, except for Strip s10, where a significantly lower pressure was recorded, most likely due to a specific local configuration of aggregate grains.
Figure 5.   Lateral pressures in model M–0 (kPa).
Figure 6.   Lateral pressures in M–I vs M–0 (%).
Figure 7.   Lateral pressures in M–II vs M–0 (%).

Figure 8.   Lateral pressures in M–III vs M–0 (%).

Figures 6–8 present the results reached in Models M-I to M-III expressed as percentages of the pressure recorded for the reference model M–0 without a geogrid under maximum loading by the press of 100 kN. The geogrid position is marked by a dashed line.

In model M-I (Figure 6), a noticeable reduction in lateral pressures is evident in all strips, except the bottommost one. The pressure at a level of 5 cm over the geogrid (s20) amounted to 14.6 % of the value measured in the model without a geogrid, i.e. it reached a reduction by 85.4 %. The reduction in the adjacent above situated strip (s15) is lower amounting to 32.7%. A remarkable fact is that the strips more distant from the geogrid (10–20 cm) showed a significant reduction in the lateral pressure again (74.4% and 75.6%). A significant reduction in pressures is also recorded under the geogrid ranging from 30.4% to 54.0%. The high value of the mutual ratio in the s40 level (217%) is due to the low base value in Model M-0 (2.4 kPa). In the M-1 model, a value of 5.1 kPa was measured at the same level, which is in good relation with the value of 5.6 kPa in the s35 level.

In Model M-II (Figure 7), the pressure reduction values in the strips over the geogrid are nearly identical to those in Model M-I. The reductions under the geogrid, on the other hand, are lower than those measured in M-I amounting from 30.9% to 46.9%, which, however, still represents significant reductions. Model M-III (Figure 8) shows a similar trend, with a 74 % reduction directly over the geogrid, which is subsequently decreased to 52.8%. The reduction under the geogrid is noticeable, too. In all models fitted with geogrids, the lateral pressures onto the laboratory box wall recorded in the geogrid position were practically zero, which testifies to the high rate of the composite immobilization at this level. The summary results are presented in Table 1.

Table 1. Confining efficiency factor (CEF%) for studied models.

Layer/Model	M-I	M-II	M-III
Top layer	75.1	76.7	52.7
Geogrid layer	85.4	85.4	74.0
Total MSL	75.6	64.3	54.7

4 INTERPRETATION OF OBSERVATIONS

Significant reductions in lateral pressures in the models with geogrids versus the model without a geogrid manifest the existence and the effect of strong confinement of the aggregates in the geosynthetic apertures. This is a convincing confirmation of the principle and the mechanism of mechanical stabilization of aggregates. The most pronounced reductions are measured in the immediate vicinity of the geogrid. Also, the reduction in the first layer from the top, which is situated just below the cover (asphalt, concrete, rail bed) in a real structure is of considerable importance for the durability of the cover. The lower the deformability of the base layer, the lower the probability of fatigue deformation in the cover.

The pressure reduction percentage in a mechanically stabilized layer compared to the reference model without mechanical stabilization has been designed as the Confinement Efficiency Factor (CEF). This parameter quantifies the confinement or stabilization efficiency of a mechanically stabilized layer. CEF can be evaluated for a specified layer thickness or for the entire MSL defined, in our case, as 10–20 cm over and 10 cm under the geogrid.

5 CONCLUSIONS

The conducted laboratory experimental works allow formulating the following conclusions:

- The innovative method of measuring and recording the pressure of aggregates onto the laboratory box wall has been proven highly effective.
- Significantly lower horizontal pressures were measured in the mechanically stabilized layers than in the non-stabilized aggregate. This has confirmed the existence of the confinement and immobilization mechanism of aggregate grains in the geogrid holes, and thus the overall principle of mechanical stabilization.
- The next generation of multiaxial geogrids has proved efficient in the mechanical stabilization of aggregates.
- The Confinement Efficiency Factor (CEF) has been designed, which is defined as the percentage reduction in lateral pressures in a respective layer compared to non-stabilized aggregates. CEF is recommended for use as a parameter to quantify the confinement intensity and the degree of stabilization in mechanically stabilized layers.
- The greatest reduction in lateral pressures was observed at and in close vicinity to the geogrid level; however, all the monitored mechanically stabilized layers generated lower horizontal pressures throughout the profile.
- As a result, the horizontal deformations of the stabilized layer are reduced. The lower deformability of the stabilized layer under the top cover of transportation structures (asphalt, concrete, ballast) contributes to the extension of its service life.

Geosynthetics wrapped tire derived materials as drains for liquefaction mitigation

Y. Hu & H. Hazarika
Kyushu University, Fukuoka, Japan

S.P.G. Madabhushi & S.K. Haigh
University of Cambridge, Cambridge, UK

ABSTRACT: Liquefaction has been responsible for tremendous damage in historical earthquakes Some liquefaction countermeasures have been developed to prevent such damage, in which drainage method is one of the effective techniques. However, sustainable and low-cost technique is still needed for existing buildings. On the other hand, gravel-tire chips mixture (GTCM) as an alternative drainage enhancing geosynthetics, has been introduced recently. A new design of liquefaction mitigation technique has been proposed in this study. It utilizes GTCM as materials of drains installed around the buildings. A series of 1–g model shaking table tests were conducted to evaluate the performance of the technique in this research. The results indicated that excess pore water pressure beneath the building was dissipated through GTCM drains effectively during the shaking. The liquefaction-induced settlement of the building was controlled to a significantly low level. GTCM drains show effectiveness in reduction of liquefaction potential for existing buildings.

1 INTRODUCTION

In Japan, the total number of end-of-life tires produced was 86 million, which was about 1 million tons by weight in 2020, according to the report by JATMA (Japan Automobile Tyre Manufacturers Association 2021). The majority of these waste tires (65%) are either burned for energy or dumped on the ground. Thermal recycling, on the other hand, is detrimental to the atmosphere because it emits more CO_2 than other recycling methods. In order to promote waste tire recycling and reduce CO_2 emissions, the use of industrial by-products in cascaded form (returning on different products) has gained popularity in recent years (Hazarika *et al*. 2018). As an example, scrap tire-derived materials (STDMs) have been utilized as geosynthetics in recent years, considering their low-carbon-release characteristics and other advantageous material characteristics including lightweight, excellent vibration absorption capability, and high permeability. Such characteristics offer an alternative application for other conventional materials in applications including drainage, landfill leachate removal, soil reinforcement, and so on.

On the other hand, one of the earthquake-induced hazards, liquefaction, has become much more frequent in recent years, especially in Japan. The damage due to such hazard was observed over a wide area following the 2016 Kumamoto Earthquake (Hazarika *et al*. 2017), which highlighted the value of taking preventive steps to protect buildings and facilities by reducing ground settling and lateral spreading. Furthermore, sustainable and cost-effective disaster mitigation efforts are desperately needed in most developing countries, where infrastructure growth is still in its infancy. The main problem is striking a balance between

the cost and the increased environmental impact of any infrastructure project. A new technique, which utilizes a layer of tire chips as the horizontal inclusion under the foundation of residential housing, was developed in response to the demand (Hazarika *et al.* 2008). As a new geosynthetics, the pure tires were then replaced by gravel tire chips mixture (GTCM) material, since it can provide sufficient bearing capacity to the foundation (Hazarika *et al.* 2016, 2020). However, these mentioned techniques, as well as most of the other liquefaction countermeasures, are developed for new constructions. Very few techniques have been developed for existing buildings to mitigate liquefaction.

Drainage method is one of the effective liquefaction countermeasures, that has been widely used in practice. The principal objective is to relieve the excess pore water pressure generated during the earthquake before they reach high values that can finally cause liquefaction (Brennan & Madabhushi 2006). The performance of the drains underneath structures has been investigated most recently (Garcia-Torres & Madabhushi 2019). Considering the performance of GTCM in horizontal reinforcing inclusion mentioned before, it could be possible to utilize this material in vertical drain method as well.

In this paper, a new technique called GTCM drainage system has been proposed as shown in Figure 1. The main purpose is to dissipate the generated excess pore water through these prefabricated drains installed around the existing building during the earthquake. The liquefaction potential of the foundation can be therefore reduced, as well as induced settlement. A series of model tests were conducted using 1-g shaking table. With dynamic loading applied, the development of excess pore water pressure in the foundation and the progress of settlement was observed to evaluate the effectiveness of this drainage technique in mitigating liquefaction.

Figure 1.   Principle of GTCM drains technique.

2   MATERIALS AND EXPERIMENTS

2.1   *Materials used*

Three raw materials were used in this research, including tire chips, gravel and Toyoura sand. Tire chips were supplied by a local company from recycling scrap tires. The waste tire was firstly shredded by a special shredding machine into various sizes with a shape of square and an aspect ratio of 1:1 (width to length), approximately. And then, those tire chips with the size of 4 mm were selected by sieving. Gravel with a similar grain size was mixed with selected tire chips as GTCM material. The volumetric fraction of gravel is 50%, since increasing the gravel fraction would result in the decreasing liquefaction resistance of the mixture (Pasha *et al.* 2018). While adding more tire chips, the shear strength of the mixture

would be smaller (Pasha *et al.* 2019). Toyoura sand is a Japanese standard sand used as the foundation for the research. Table 1 shows the properties of GTCM and Toyoura sand.

Table 1. Properties of materials in use.

Material	G_s	Dry density (g/cm³)	ρ_{max} (g/cm³)	ρ_{min} (g/cm³)	D_{50} (mm)
Toyoura sand	2.640	1.506	0.976	0.611	0.160
GTCM	1.910	1.022	1.036	0.842	4
Figure 2. Test model on the 1–g shaking table.

2.2 *Model tests*

The 1g shaking table tests were conducted using the shaking table facility at the geo-disaster laboratory of Kyushu University. Models were constructed in a transparent Plexiglas soil box with dimensions of 1800 mm, 400 mm and 850 mm, as shown in Figure 2. Soil-structure-fluid interaction can be simulated using the scaling law proposed by Iai (1989). Since this research involves liquefaction-induced damage to structures, it is the most suitable similitude relationship. Throughout these tests, considering the size of the soil box on the shaking table, a geometrical scaling factor of 1:32 was set based on this law.

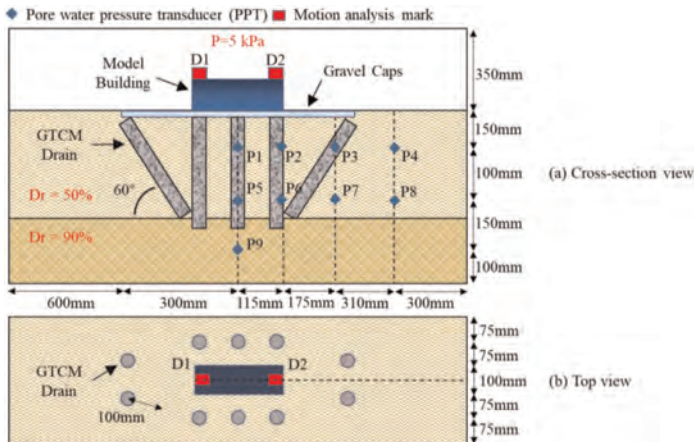
Depending on whether GTCM drains were installed in the foundation or not, two cases of 1–g shaking table tests were performed. In Case 1, four parallel arrays of prefabricated GTCM drains with a diameter of 50 mm and height of 300 mm were installed vertically around the four sides of the residential building from the surface level up to the bottom of the loose sandy layer and extended into the hard layer. The distance between the center of two neighboring drains is 100 mm. The vertical drains along the short side of the model building were then replaced with four GTCM drains inserted at 60 degrees diagonally in Case 2. A shallow foundation of a structure with a bearing pressure of 5 kPa, represented by a rectangular block of brass material, with a cross-sectional area of 230 mm by 100 mm in model scale, was set upon the soil. In addition, there was a thick layer of gravel with 2 cm in depth between the model building and GTCM drains. A sinusoidal acceleration of 300 Gal with a frequency of 4 Hz and duration of 10s was applied to the model. Several pore water pressure transducers were set in the location shown in Figures 3–4. Two motion analysis marks were located on two sides of the model building.


Figure 3.   Layout of model test Case 1.

Figure 4.   Layout of model test Case 2.

3   RESULT AND DISCUSSION

3.1   *Settlement*

The model building suffered settlement due to the deformation of the loose sand foundation. Through motion analysis, the time history and trend of the building settling in both two cases are obtained and drawn out in Figure 5. As can be observed, both buildings initiated a speedy settling subsequent to the start of seismic loading in two cases. In Case 1, the maximum settlement during the earthquake is 39.03 mm at D1. While at the other side (D2), the displacement is recorded as 40.91 mm. The rotation due to the uneven settlement is about 0.468°. Compared to Case 1, the building suffered less settlement in Case 2, as shown in Figure 5b. The maximum displacement recorded is 37.45 mm at D1 and 32.32 mm at D2, resulting in a rotation of 1.28°. Take the average settlement in the center of the building as a reference, the vertical-inclined combined system in Case 2 has an improvement in protection efficiency by 14.6% over vertical-only drains in Case 1. In addition, a significant settlement was also observed in the ground around the buildings, as well as free field areas. Of

particular concern is the wedge areas formed between the vertical drains and inclined drains in Case 2. On the basis of these phenomena, it is reasonable that though the GTCM drains technique successfully mitigated liquefaction during the earthquake, unignorable foundation settlement still happened under bearing pressure from the heavy building itself and soil consolidation.

Figure 5. Time history of settlement in (a) Case 1 and (b) Case 2.

Figure 6. Time history of Ru in Case 1.

Figure 7. Time history of Ru in Case 2.

3.3   *Excess pore water pressure*

Figures 6–7 show the time history of the excess pore water pressure ratio, defined as $R_u = u_{\text{expp}}/\sigma'_{vo}$ recorded by PPTs at each location inside the sandy layer (shown in Figure 3). In Case 1, with vertical GTCM drains installed around the building, the excess pore water was dissipated during the shaking. Due to the combined effect of compaction from the bearing pressure, the Ru value is smaller at P1 than at P3 and at P4. The generation of pore water pressure was limited by the drains nearby after the initial speedy increase at P2 as well. The higher value of Ru is only obtained at P4 and P8, located at the free field away from the building and drains.

A similar situation happened in Case 2, except the Ru value reaches 1 at P4 and P8 respectively, which indicates liquefaction happened. However, since the five vertical GTCM drains along the short side of the building were replaced with two inclined drains, and fewer drainage surrounded, it is reasonable that the excess pore water pressure ratio was much higher at P4, P7 and P8 compared to Case 1. Despite that, the change of the configuration of GTCM drains from vertical only to a vertical-inclined combined system does not affect the core function in mitigating liquefaction for the existing building. In addition, considering that liquefaction did not happen beneath the building, the recorded displacement could have resulted from the consolidation of the loose sandy soil.

4   CONCLUSION

When GTCM drainage system is applied, excess pore water can quickly dissipate through the GTCM drains from the foundation to the soil surface. As a result, the risk of liquefaction beneath the existing structures would be reduced. Compared to the vertical-only GTCM drains system, the proper combination of inclined drains could improve the resistance of buildings toward liquefaction-induced settlement. Although the drainage capacity might be reduced accompanied by a slightly elevated risk of liquefaction in the free-field areas around the building, the core function remains effective. The technique, thus, is expected to have great potential in the cost-effective seismic design and retrofitting of structures. If adequate design guideline is established, the developed liquefaction mitigation technique could be applied for upgrading (retrofitting) the existing structures that run the risk of damage during devastating future earthquakes.

ABSTRACT: The engineered turf cover has gained significant acceptance in the past decade as a final cover for environmental closure of waste containment facilities. When compared to a traditional soil cover, the major advantages of the engineered turf cover include faster construction, improved cover slope stability, enhanced runoff water quality, and reduced post-closure maintenance costs. After a waste containment facility is closed, the large surface area can be beneficially used for development of a solar farm. The engineered turf cover provides a stable foundation for solar panels. This paper presents an overview of the engineered turf cover. Case studies are provided to demonstrate field performance of the engineered turf cover and applications of renewable solar energy development.

1 INTRODUCTION

A final cover system is the critical component of environmental closure of waste containment facilities, such as municipal solid waste (MSW) and industrial waste landfills, coal combustion residual (CCR) units, brownfields, etc. It isolates the underlying waste, preventing its exposure to the environment, and protecting human health and safety. It minimizes infiltration of precipitation into the waste and reduces leachate generation. For a waste containment facility that generates gas (e.g., an MSW landfill), the final cover also improves landfill gas collection efficiency and reduces fugitive gas emissions.

The past decade has seen a significant increase in the use of the engineered turf cover to close various types of waste containment facilities. The engineered turf cover is a 3-component system consisting of, from bottom to top, a structured geomembrane, an engineered turf, and a specified infill (Figure 1).

Figure 1. Illustration of engineered turf cover: system components (left) and typical cross section (right).

The structured geomembrane, which is made of high-density polyethylene (HDPE) or linear low-density polyethylene (LLDPE), serves as the hydraulic barrier to encapsulate the waste and prevent infiltration of precipitation into the waste. The engineered turf is made of HDPE synthetic grass blades tufted into a double-layer polypropylene (PP) woven geotextile backing. Its main function is to protect the underlying geomembrane from ultraviolet (UV) exposure and wind uplift. The specified infill has a minimum thickness of 0.5 inches (13 millimeters [mm]) and is a granular material that meets technical specifications for the grain size distribution, angularity, and specific gravity (Zhu *et al.* 2021). It is placed inside the synthetic grass blades to cover the geotextile backing and provide ballast for wind uplift protection.

Compared to a traditional soil cover, the engineered turf cover does not require the vegetative and protective soil layers that typically have a minimum total thickness of 2 feet (0.6 meters [m]). By removing the soil layers, the engineered turf cover provides a reliable closure solution that is not dependent on weather, soil, or vegetation conditions. It enables site owners and operators to overcome long-standing challenges of soil erosion, geotechnical instability, and post-closure maintenance associated with traditional soil covers (Zhu *et al.* 2019). Other advantages include faster construction and less environmental impact (e.g., avoidance of land disturbance, clean runoff, and reduction in carbon emissions) (Joshi 2023). Based on the results of extensive outdoor UV longevity tests, the service life of the engineered turf cover is projected to be more than 100 years, provided it is installed and maintained properly in accordance with design drawings, engineering specifications, and post-closure care requirements (Scholl *et al.* 2023; Zhu *et al.* 2021).

2 ENGINEERED TURF COVER CASE STUDY

2.1 *Project background*

The Mississippi Phosphates Corporation (MPC) site is located in Pascagoula, Mississippi, US. The MPC produced diammonium phosphate fertilizer from the late 1950's through December 2014, when it declared bankruptcy. In August 2013, approximately 39 million gallons (approximately 150,000 m^3) of acidic wastewater was discharged to the nearby Bayou Casotte, resulting in a large quantity of fish kill, closing of the bayou, and subsequently, violation of the Clean Water Act. The United States Environmental Protection Agency (US EPA) formally added the MPC site to the Superfund National Priorities List (NPL) in January 2018 (Zeller 2019).

The US EPA planned to close the East Gypsum Stack as a part of the site remediation. The stack contains the phosphogypsum, which is the by-product of fertilizer production from phosphate rocks. The area of the stack to be closed is about 170 acres (69 hectares [ha]). The US EPA selected the engineered turf cover, ClosureTurf®, as the final cover after conducting a detailed value engineering study. Compared to a traditional vegetative soil cover that would include a 2-foot (0.6-m) thick soil layer and a geomembrane layer, the engineered turf cover was expected to save an estimated US$6 million in the 30–year life cycle of the project, including US$4.6 million on construction costs and US$1.4 million on post-closure operation and maintenance costs. In addition, using the engineered turf cover was expected to eliminate approximately 42,700 truck trips required to haul the cover soil and save expenditures related to on-going water treatment because of quicker installation (Zeller 2019). Prior to the closure, the US EPA was spending on average US$1 million per month to treat the acidic contact water in-situ with lime.

2.2 *Final cover construction*

Construction of the engineered turf cover was divided into 3 phases, which started in September 2019 and completed in March 2023. Selected construction photos are shown below.

Figure 2.   Engineered turf cover construction at the Mississippi phosphates corporation gypsum stack, a US EPA superfund site.

2.3   *Field performance*

Due to its close proximity to the coast, the site has frequently experienced storms since the installation started. Tropical Storm Cristobal was a tropical cyclone that developed in the Gulf of Mexico and made landfall in the US over southeastern Louisiana on June 7, 2020. The wind and precipitation data collected at two weather stations were analyzed to evaluate the field performance of the engineered turf cover installed at the MPC site. One station is located on the site and the other station is located 2.5 miles (4.0 kilometers [km]) southwest from the site.

The site experienced rainfall from June 6 to 8, 2020, with the most severe weather conditions experienced on June 7. In total, the site received 7.62 inches (194 mm) of rain during a period of 53 hours, with the maximum hourly intensity of 3.00 inches/hour (76.2 mm/hour) and total daily precipitation of 6.26 inches (159 mm) on June 7. The peak wind gust was recorded as 42.3 miles per hour (68.1 km per hour) on June 7. The recorded precipitation and wind speed data are plotted in Figures 3 and 4, respectively.

Figure 3.   Recorded precipitation at the MPC site during tropical storm cristobal.
1696

Figure 4. Recorded wind speed at the MPC site during tropical storm cristobal.

One year later, Hurricane Ida made landfall in the US over southeastern Louisiana on August 29, 2021. The MPC site experienced rainfall from August 29 to 31 with the most severe weather conditions experienced on August 30. The site received 7.29 inches (185 mm) of rain for a period of approximately 48 hours, with the maximum hourly intensity of 3.54 inches/hour (89.9 mm/hour) on August 30. The maximum 24–hour rainfall was 5.64 inches (143 mm) on August 30. The peak wind gust was recorded as 35.3 miles per hour (56.8 km per hour) on August 30.

The areas that were installed with the engineered turf cover at the time of Tropical Storm Cristobal and Hurricane Ida were about 50 and 100 acres (20 and 40 ha), respectively. The site was inspected after both events. No significant infill movement or damage to the engineered turf cover was observed. Because the runoff from the engineered turf cover area was no longer in contact with the gypsum waste, it was discharged directly offsite without treatment. The total savings on wastewater treatment cost were estimated to be around US $400,000 for these two storm events.

3 SOLAR ENERGY DEVELOPMENT

3.1 *Beneficial reuse of waste containment facilities*

After a waste containment facility is closed, the large space can be beneficially used for development of a solar farm to provide a clean source of renewable energy. Using a closed waste containment facility can prevent disturbing a farmland or a natural greenfield at another place. The facility already has infrastructures built at the site, for example, the access roads, stormwater management system, security fences, electricity connection system, etc. Therefore, construction of a solar farm on a closed facility saves costs. Development of green energy is also a demonstration of the site owner's commitment to sustainability, which can help improve public relationships. Furthermore, the solar farm can generate revenue to offset site operation and maintenance costs, transforming the waste containment facility from a post-closure care liability into a renewable energy asset.

3.2 *Traditional solution*

The traditional solar solution utilizes a vegetative soil cover for closure and a racking-supported photovoltaic (PV) solar panel system for solar energy generation. The racking

system is usually supported by heavy concrete foundations to protect the solar panels and racking system from uplifting and overturning by wind loads. The concrete foundations are installed directly on top of the final cover. Pile foundations are usually not used due to penetration of the final cover barrier layer (e.g., geomembrane, clay, and/or geosynthetic clay liner [GCL]). In most cases, installation of solar panels is limited to the top deck due to stability concerns and construction difficulties associated with installing solar panels on side slopes of the waste containment facility.

The major challenges with the traditional solar solution are related to soil erosion, maintenance, and impact on final cover performance. Rainwater falls off the edges of panels and hits the ground as a concentrated flow. The impact force can cause erosion of the soil cover along the drip line. As a result, soil erosion affects runoff water quality and increases maintenance and repair costs. It can undermine the concrete foundations for the solar panels and integrity of the final cover system too. To control soil erosion, it is important to establish good vegetation on the final cover and perform regular maintenance and repairs, as necessary.

On the other hand, overgrown grasses, weeds, and plants need to be trimmed because they affect not only the final cover performance, but also the solar panel efficiency by blocking the sunlight with shadows. Because of narrow access between solar panels, the vegetation must be cut manually, requiring intense labor work for large sites. In addition, workers need to operate equipment carefully to avoid cutting cables and conduits or damaging solar panels. Last but not the least, potential impact of loading from heavy concrete foundations and gravel leveling pads on the performance of final cover needs to be evaluated during engineering design and monitored after construction, because it can create differential settlement that may cause localized ponding of stormwater.

3.3 *Engineered turf solution*

The engineered turf cover provides a more favorable solution to address the above-mentioned challenges regarding solar energy development on a waste containment facility. It is a stable foundation that is not subject to soil erosion. It requires minimal maintenance, i.e., no mowing, fertilizing, or revegetation. Since vegetation overgrowth is no longer a concern, a low-profile solar panel system can be installed directly on the engineered turf cover, which causes less impact on the final cover system than the traditional solar panel system. Case studies of solar farms installed on engineered turf covers are provided in the section below.

3.3.1 *Case Study #1 – MIRA Landfill, Hartford, CT, US*
The MSW landfill is located in Hartford, Connecticut and owned by the Materials Innovation and Recycling Authority (MIRA). Thirty-six (36) acres (14.6 ha) of the engineered turf cover, ClosureTurf, was installed on the landfill in 2014. A one-megawatt (1–MW) solar electricity generating facility was constructed on top of the engineered turf cover within a 5–acre (2–ha) area of the landfill top deck (Figure 5a). At its peak capacity, the solar facility can generate enough electricity to power about 1,000 homes per day. The solar panels are supported by a racking system ballasted with concrete blocks (Figure 5b).

(a). Solar panels installed on top deck   (b). Solar panel system

Figure 5.   Engineered turf cover and solar panels installed on MIRA landfill, Hartford, CT.

3.3.2 Case Study #2 – Cranston Sanitary Landfill, Cranston, RI, US

The Cranston MSW landfill in Rhode Island is a formal US EPA Superfund site owned by the Cranston Sanitary Landfill Remedial Action Group. A total of 22 acres (8.9 ha) of the engineered turf cover, ClosureTurf, was installed on the landfill in 2015. A 3.5–MW community solar farm was installed on top of the engineered turf cover in 2021. It has turned the site that is otherwise undevelopable into a renewable energy resource, as an example of brownfield redevelopment. The solar project consists of more than 9,700 ground-mounted solar panels. The solar panel frames are ballasted with concrete blocks for wind uplift protection (Figure 6).

Figure 6. Community Solar farm installed on engineered turf cover at the Cranston Sanitary landfill, Cranston, RI.

3.3.3 Case Study #3 – A confidential CCR impoundment, Southeastern US

This solar project features the solar power generation system, PowerCap^{TM}, installed on a CCR impoundment capped with the engineered turf cover, ClosureTurf. PowerCap is custom-designed for direct installation on the engineered turf cover. It does not require penetrations through or mechanical connections to the engineered turf cover. The system consists of friction strips connected to the bottom of the solar panel rails, which provide interface friction and maintain stability of solar panels on slopes.

The solar project was completed in January 2019. It consists of 120 flush-mounted solar panels with a total capacity of 39 kilowatts installed on a 3 Horizontal to 1 Vertical (3H:1V) side slope of the closed CCR impoundment (Figure 7). Recent field inspection conducted in December 2022 indicated that after almost four years, the solar power generation system had performed well, as expected. There were no signs of impact on the performance of the underlying engineered turf cover by the solar power generation system.

Figure 7. PowerCap installed on engineered turf cover at a confidential CCR impoundment, Southeastern US.

4 CONCLUSIONS

The engineered turf cover provides a viable solution to overcome long-standing challenges faced by traditional soil covers of waste containment facilities, including soil erosion, geotechnical instability, and post-closure maintenance. It also provides a stable foundation for a solar farm that is constructed to beneficially use the otherwise undevelopable space for power generation. A combination of the innovative environmental closure and solar power generation technologies can transform waste containment facilities (e.g., MSW and industrial waste landfills, CCR units, brownfields, etc.) from long-term liabilities to renewable energy assets.

New GCL composite vertical anti-seepage technology and its application

Xie Shiping, He Shunhui, Zhang Jian & Zheng Yongya
Tianjin Zhonglian GeLin Science and Technology Development Co., Ltd., Tianjin, China

ABSTRACT: Geosynthetic Clay Liner (GCL) composite vertical anti-seepage barrier technology introduces GCL into the field of vertical anti-seepage and combines with low-permeability wall to form a composite anti-seepage system. GCL was laid vertically one or both sides of the excavated trench. GCL panel is factory fabricated to ensure easy fast and accurate vertical installation at site, GCL can be standard, multicomponent, or even polymer enhanced to cope with site specific leachate. Backfill can be mixture of soil-bentonite, cement-bentonite or soil-cement-bentonite. Compared with conventional rigid anti-seepage wall, it improves the overall performance in terms of wall permeability, integrity and durability, and it is more cost-effective than its counterpart HDPE vertical barrier. GCL anti-seepage barrier technology has been used in landfill, industrial pollution site and mine waste site remediation successfully, and well-received as a suitable candidate for immediate protection and containment assurance in China.

1 INTRODUCTION

Currently, solid waste landfills leakage and accidents in chemical storage facilities around the world pose potential threat to the soil and groundwater of the surrounding environment, thereby, the urgent treatment measures are needed to prevent contaminant migration (Khandelwal A 1998; Peng C.H. 2020; Rowe R.K. 2004; Sangam H.P. 2001a). The storage amount of urban waste in China exceeded 8 billion tons (Yuan C. 2017). During the 13th Five Year Plan period of China, 803 landfills projects were built according to the data of National Development and Reform Commission in 2016, many of them were found leachate release to the surrounding environment. With the increasingly stringent requirements of environmental protection, many existing landfills sites require effective technical measures to impede pollutants migration and reduce damage to the surrounding environment. The vertical cut-off wall, as an effective method, has been gained widespread acceptance across the world (Bohnhoff G L 2013; Park M G 2011; Sangam H P. 2001b; Xie H 2018). It is one of the important aspects to use vertical anti-seepage barrier to control and remediate landfill leakage.

Conventional rigid vertical anti-seepage technology is mostly developed from the cut-off wall used in water conservancy projects (Zhen S L 2017). It is known that concrete was widely applied in cut-off walls, but the leakage often happened due to the weak joints of adjacent wall sections and cracks in the walls induced by stress concentration. In addition, for the cement mixing pile, the permeability coefficient of the single-row piles is typically within 10^{-5} cm/s. Some literatures revealed that the impervious performance of the cut-off walls constructed with cement, even with good construction management, can only reach as low as 5×10^{-7} cm/s (Johnson AI 1985), which still cannot meet 1×10^{-7} cm/s–regulated by Chinese specifications.

As a commonly used high-performance horizontal lining material, Geosynthetics Clay Liners (GCLs) are widely applied in water conservancy, environmental protection and other fields (LI X 2005), because of its low permeability (less than 5×10^{-9} cm/s), self-sealing and self-healing properties. Therefore, the use of GCL in the vertical anti-seepage wall can not only effectively overcome the shortcomings of the conventional cut-off walls, but also provide a new solution for vertical anti-seepage engineering.

2 AN INNOVATIVE GCL COMPOSITE VERTICAL ANTI-SEEPAGE BARRIER

An innovative GCL composite vertical anti-seepage barrier, consisting of fabricated GCL panel (hereinafter referred to as composite component) and backfill wall material, is a new type of composite vertical anti-seepage solution, as shown in Figure 1. Firstly, locating the wall and excavating the trench until the designed depth, secondly, GCL is laid vertically along one or both sides of the trench, and then the wall material is backfilled in the trench to form a composite cutoff wall, working as an anti-pollution and anti-seepage barrier. On the other hand, GCL greatly improves the anti-seepage performance of composite structure, and the multilayer structure enables the composite barriers to cope with different kinds of leachate.

Figure 1.   The schematic diagram of GCL composite vertical anti-seepage barrier.

In order to facilitate the vertical installation of GCL composite component, auxiliary components were attached to the GCL panel as shown in Fig 2. It can be seen clearly that the GCL composite component is equipped with a support plate and counterweight groove at the bottom of GCL panel, and the top of GCL panel is fixed on a steel roll core, with overlapping lines marked on both sides. GCL composite component can be vertically laid in a straight and controlled state with the cooperation of unwinding machinery, horizontal hammers, counterweights, etc. During installation steel-made joint box is used to prevent debris from entering the overlapping area.

Figure 2.   Schematic diagram of GCL composite component.

The U-shaped counterweight groove is filled with counterweight blocks, composed of clay and bentonite, driving GCL panel downwards steadily. After pouring wall materials into the trench, the counterweight block can absorb water and swell in a limited space, and seal the gap at the bottom of the trench, thereby avoiding permeation at the bottom of the wall.

3 DESIGN OF GCL COMPOSITE VERTICAL ANTI-SEEPAGE BARRIER

3.1 GCL selection

According to the site specific contaminate and impermeability requirements, the type of GCL and the number of layers of GCL were determined. Usually standard GCL that comply with GRI-GCL3 specification is compatible with MSW landfill leachate and can be selected for this kind of application. Otherwise, if the landfills site gets lightly polluted and contains critical chemicals, multicomponent GCL or GCL with polymer modified bentonite should be options. In any case, product permeability test with site leachate is necessary and subsequent work can be carried out only after the verification test result is qualified. In addition, increasing the layers of GCL, namely, installing on both sides of the trench, can further improve the wall anti-seepage performance. Usually the GCL panel penetrates into the natural aquiclude no less than 1m so as to form a closed barrier system. At the top of the wall, the panel is folded and terminated with pour of concrete.

3.2 Wall backfill material selection

The environmental protection requires high anti-seepage performance of the vertical barrier wall, so the wall type generally selects low permeability walls such as soil-bentonite wall, cement-bentonite wall and plastic concrete wall. In addition, under the premise of ensuring that the permeability coefficient of the wall is not greater than 10^{-7} cm/s, the wall can also be designed as a low permeability reactive wall by adding adsorbent reactive materials such as activated carbon, zeolite, and diatomite to the low permeability wall for specific pollutants to enhance the wall's adsorbent reactive capacity for pollutants.

The selection of GCL type and wall backfill material should be assessed comprehensively according to the actual site situation so as to meet the design target both technically and economically.

3.3 GCL composite components connection

The typical roll width of GCL composite component is 5–6m. The overall anti-seepage performance partially depends on the connection quality between panels. Adjacent GCL composite component should be overlapped by a minimum of 45cm with the assistance of special construction technology and equipment as shown in Figure 2.

GCL composite components are marked with an overlap line that is 50cm away from the edge of the GCL composite component (see Figure 2). Construction personnel can clearly know the overlap position and ensure that the overlap width is not less than 45cm. A special steel joint box with a width of 50cm and length of 55cm is designed and inserted into the trench of width 60cm to prevent the backfill wall materials and construction debris from entering the overlap area to ensure the overlap construction quality. In addition, bentonite paste is applied in the seam area while the panel is lowered down into the trench. Large scale test by Zhejiang University has verified the seam permeability has the same order of magnitude with the GCL panel (Zhan L T et al. 2021).

4 ENGINEERING CASES—ENVIRONMENT REMEDIATION OF DONGCHENG LANDFILL SITE

4.1 Background

Dongcheng landfill site at Jinghai District Tianjin China was originally a pond, filled with municipal solid waste about 800,000m³. It was not constructed in accordance with landfill hazard-free regulations, no lining system was in place at the beginning. This informal landfill site gradually became a pollution source, which contaminated the surrounding atmosphere, soil, surface water and groundwater severely, posed threats to the living conditions and health of the local residents, resulted in increasingly prominent social problem (Figure 3a). The local government finally made the decision to remediate the landfill site. Considering the environment remediation target and requirement of anti-seepage grade, it was finally decided to apply on-site remediation method–cover lining + vertical barrier–to break the connection between the waste dump and surrounding environment, control the contaminant migration.
Figure 3.   (a) waste dump (b) GCL composite vertical anti-seepage barrier layout.

4.2 Design

The selection of appropriate vertical barrier system depends on the nature of the contaminant and site engineering geology and hydrogeology conditions. Thus a technical comparison was made between concrete cut-off wall, HDPE vertical barrier, and GCL composite vertical anti-seepage barrier, it was concluded that GCL vertical composite barrier system is technically superior over the two others to meet the primary target of the remediation. Therefore, from the overall consideration of safety, reliability and economic factors, it was recommended to apply "GCL+ cement-bentonite mixture" composite vertical barrier technology around the old landfill area. As shown in Figure 3b, the anti-seepage barrier is about 1500m long with an average depth of about 15m and a wall thickness of 600mm. The wall bottom is inserted into aquiclude 1.2m, and wall design permeability coefficient is less than 1×10^{-7}cm/s. Lab permeability test with GCL sample, selected for the project, and site leachate showed that they are completely compatible (Figure 4).

Figure 4.   Effect of landfill leachate on permeability of GCL.

4.3 *Construction and engineering effect*

Bentonite grout was injected into the trench while it was excavated by hydraulic pressure grab bucket. Then GCL composite panel was installed on the side wall of the trench away from pollutants, followed by the pour of cement-bentonite mixture by underwater conduit and finally formation of the GCL vertical barrier. Because the width of GCL composite panel was 6m, it was required to excavate 6m for the first trench section, and 5.5m for the consecutive ones. A portion of fine and coarse aggregate was added to the backfill mixture to improve the wall performance, among which the 28-day compressive strength $\geq$ 0.3MPa, and the permeability of cement-bentonite backfill is in the order of 10^{-7} cm/s magnitude. See Figure 5 for construction process.

Figure 5. Construction of GCL composite vertical anti-seepage barrier: (a) Trench excavation, (b) Laying of GCL composite component, (c) Dropping down the joint box, (d) Pouring wall materials.

Inspection of site drilling core sampling and subsequent monitoring results indicated that GCL vertical barrier has excellent anti-seepage performance, and permeability coefficient can reach as low as 10^{-8} cm/s. According to the inspection report of the monitoring wells established outside of the waste dump one year after the completion of the vertical barrier, the contaminant migration is not further aggravated, and there is a trend of gradual improvement.

5 CONCLUSIONS

The permeability of GCL composite vertical anti-seepage barrier is less than 1×10^{-7} cm/s, which meets the environmental requirements of China. The wall can be designed and GCL can be selected for specific pollutants, and the multi-layer structure can cooperate with each other to cope with more complex engineering situations. The fibers and pores on the surface

of GCL make it tightly secured with the wall material to form a composite vertical impervious structure. By adopting the lap connection method for easier construction, the specially developed construction tools and construction technology can effectively ensure the lap effect and make the joint have excellent anti-seepage performance.

GCL composite vertical anti-seepage barrier has been applied in some projects. Engineering practice shows that this novel technology has excellent impermeability and chemical compatibility and is a rising vertical anti-seepage solution for comprehensive treatment of polluted sites.

ABSTRACT: An experimental study was conducted on the manifestation of organic contaminant-reactive geosynthetic liner for preventing the spread of contaminated groundwater. The polymer which has absorb oil highly and self-swelled was selected for the organic pollutant reactive geosynthetic barrier. This polymeric material has composited with nonwoven and film woven by needle punching process as GCLs. The geosynthetic oil absent liner prepared was immersed in organic pollutant material (TPH and TCE) for 24 hours and the permeability coefficient was evaluated (ASTM D5887). The permeability coefficient of the geosynthetic oil absent liner immersed in TPH and TCE was resulted in 7.3×10^{-8} cm/s and 1.1×10^{-8} cm/s, where the value of $\alpha \times 10^{-2}$ cm/s for the normal water as a control test. It was confirmed that the geosynthetic oil absent liner showed an orderly behavior that could sufficiently perform the role of a liquid barrier to prevents the spread of contaminated groundwater.

1 INTRODUCTION

Recently, pollution accidents due to the outflow of organic pollutants are frequent. It takes time to install a barrier system after the occurrence of an outflow, and the spread of pollutants appears extensively by that amount. Rather than taking post-measures against the leakage of organic pollutants, a solution to reduce damage by minimizing the spread of pollutants through appropriate pre-measures are required. Vertical barrier systems such as sheet piles and geomembranes seriously disturb the flow of groundwater in the blocked area and are not suitable as a precautionary measure.

When pre-installed under normal conditions, it does not affect the flow of groundwater, but when an organic pollutant spill occurs, it is necessary to think about a new liquid barrier system that selectively adsorbs only organic pollutants from the contaminated groundwater and performs the liquid blocking liner.

In geosynthetic clay liners (GCLs), which are typical reactive liquid barriers, bentonite selectively adsorbs water and swells to perform water barriers. GCLs have liquid barrier features by securing watertightness in the GCLs layer by fixing and constraining bentonite

particles that show a swelling behavior to water with upper and lower covers. A geosynthetic oil absorbent liner, applying similar concept, that forms a liquid barrier by fixing and constraining polymer particles that selectively adsorb organic pollutants can be designed. When this geosynthetic oil absorbent liner meets groundwater contaminated with organic pollutants, it selectively absorbs organic pollutant components and swells. A liner that forms a liquid barrier can be expected.

In this study, a prototype of a geosynthetic oil absorbent liner using oil-absorbing resin that selectively reacts and swells to organic pollutants was manufactured and its permeability coefficient was evaluated to prevent the spread of groundwater contaminated with organic pollutants. The feasibility of geosynthetic oil-absorbent liner was experimentally confirmed.

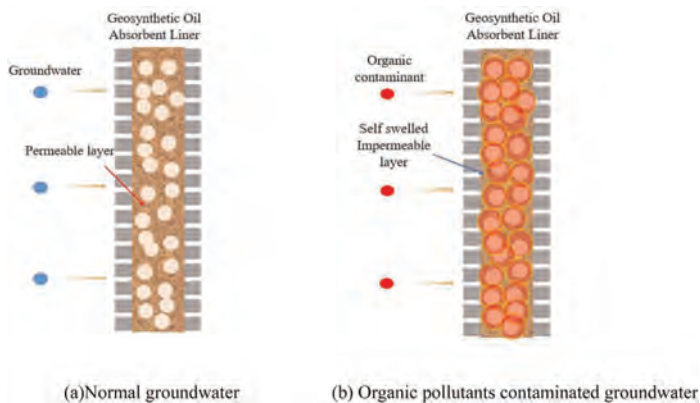
2 A CONCEPTUAL APPROACHE

2.1 *The liquid barrier by selective absorption and definitions*

The geosynthetic oil absorbent liner has the same structural feature as GCLs, and the sorbent resin in the central layer does not show swelling behavior under normal groundwater, but forms a gelation layer which shows a liquid barrier through adsorption &self-swelling of organic pollutants in contaminated groundwater. Therefore, in steady state groundwater, the geosynthetic oil absorbent liner shows a permeability coefficient between 10^{-2} cm/s and 10^{-1} cm/s and does not affect the flow of groundwater. Thus, geosynthetic oil absorbent liner can be defined as follows: A composite geosynthetic which has a permeability coefficient of 10^{-2} to 10^{-4} cm/s under normal groundwater conditions, that allows groundwater flow, but when it comes into contact with an organic pollutant, it shows a permeability coefficient of less than 10^{-7} cm/s within 24 hours.

As shown in Figure 1, the mechanism that shows the liquid barrier performance of geosynthetic oil absorbent liner is as follows. First, it encounters contaminated groundwater, and polymer resin particles adsorb organic pollutants and self-swell to be gelled. This resin particles gelled fill the space in the center layer of the liner and blocks the liquid flow path, thereby exhibiting the liquid barrier. At this time, the permeability coefficient is 10^{-7} cm/s or less.

As shown in Figure 1, the liquid barrier performance mechanism of the geosynthetic oil absorbent liner absorbs organic contaminants when it comes into contact with contaminated groundwater and fills the space of the center layer of the liner through self-swelling-gelling behavior to block the liquid movement path. It exhibits performance as a barrier, and at this time, the permeability coefficient is 10^{-7} cm/s or less, which is the standard for water-repellent performance.



(a)Normal groundwater   (b) Organic pollutants contaminated groundwater

Figure 1.   The liquid blocking mechanism of geosynthetic oil absorbent liner.

2.2 Material characteristics required

The oil absorption characteristics and gelation behavior of the oil absorption resin used in the proposed geosynthetic oil absorbent liner determine the liquid barrier performance. Oil absorption properties are determined by the resin's unique molecular structure, chemical reactivity and powder particle size, and reactivity with organic pollutants. Oil absorption characteristics are defined in terms of swelling degree (g/g), that can be expressed the ratio (Equation 1) of mass change of resin immersed in organic pollutants solution for a certain period (24 hours or 48 hours recommended).

$$swelling\ degree = \frac{W2 - W1}{W1} \tag{1}$$

where w1 = weight of unabsorbed resin; w2 = weight of absorbed resin.

Figure 2 shows a photograph of the polynorbornene resin used in this study, immersed in TCE solution for 24 hours. As shown in the photo, it can be confirmed that the oil-absorbing resin has sufficiently gelled through oil absorption and swelling. The required swelling degree of the oil absorbent resin shows a value of 20–50 depending on the organic pollutants in contact. According to previous studies, it can be seen that the network-structured polyolefin resin with divinylbenzene as a functional group shows high oil absorption around 50 (g/g). This means that the oil-absorbed resin exhibits swelling behavior with sufficient volume change. Polynorbornene-based resins used in this study are also known to exhibit high oil absorption of about 30–50(g/g).

Figure 2.   The organic pollutants absorption and gelation behavior of polynorbornene resin.

2.3 Manufacturing the prototype geosynthetic oil absorbent liner

The prototype of geosynthetic oil absorbent liner used in this study is a mat type product, which is a composite of polypropylene staple fiber nonwoven fabric (300g/m2) and polypropylene film woven using needle punching technique, and polynorbornene is put in the center layer about 2.5kg/m^2(Figure 3).

Figure 3.   The prototype geosynthetic oil absorbent liner.

3 EXPERIMENTALS AND DISCUSSIONS

3.1 *Experimental*

To evaluate the liquid barrier properties of geosynthetic oil absorbent liners, the permeability coefficient of the prototype was evaluated by applying the hydrostatic head method of ASTM D5887, which is used to evaluate the permeability coefficient of GCLs. First, the geosynthetic oil absorbent liner specimen was pretreated by immersing in a solution of organic contaminants for 24 hours. Considering the initial stage in which high-concentration organic pollutants were spilled, it was attempted to determine whether the liquid barrier performance could be achieved within 24 hours. The organic pollutants used were TCE (trichloroethylene) and TPH (diesel), respectively. The test procedure was carried out in the same way as that of general GCLs.
Figure 4.   A test setup of geosynthetic oil absorbent liner.

3.2 *Results and discussions*

3.2.1 *Results*

After about 24 hours of pretreatment, the permeability coefficient of the obtained geosynthetic oil absorbent liner showed a value lower than 10^{-7} m/s as shown in Table 1, confirming that the liquid barrier performance was sufficiently introduced in both organic pollutant conditions. When looking at the cross section of the prototype after pretreatment, it was confirmed that the oil absorption resin layer in the center was sufficiently swollen to form a liquid barrier layer. On the other hand, in the general groundwater condition before pretreatment, the permeability coefficient of $10^{-2} \sim 10^{-4}$ cm/s, which is similar to sandy soil, was resulted.

Comparing the values of the permeability coefficient before and after pretreatment, it can be confirmed that the geosynthetic oil absorbent liner exists as a permeable layer under normal groundwater conditions, but the liquid barrier performance is achieved by contacted organic pollutants. It can be judged that the barrier performance varies depending on the amount of organic pollutants contacted and absorbed.

3.2.2 *Discussions*

(a) concentration of organic pollutants

In the experiment, TPH and TCE stock solutions were applied. This assumes that a high concentration of organic pollutants is introduced into the groundwater at the initial stage of the oil spill accident. However, at low concentrations, the amount of organic contaminants required to form the barrier layer is insufficient, so it is expected that it will take a long time for oil absorption and swelling, and additional research is needed.

(b) pretreatment conditions

The 24-hour pre-treatment applied in the experiment is the condition for the rapid introduction of liquid barrier performance, and more reliable barrier performance was confirmed when 48 hours as standard in ASTM D5887 was applied through the pre-treatment preliminary test. In addition, since oil absorption and swelling behavior are

chemical reactions, it was confirmed through preliminary experiments that the pre-treatment temperature affects the test results.

(c) rebleeding

Sufficiently absorbed resin causes rebleeding (the behavior of discharging oil-absorbing substances) over time, but it is judged to be very insignificant compared to the initial excessive spill of organic pollutants. For what kind of behavior occurs in the actual field, it is necessary to check the behavior and performance through field test construction.

(a) retrieved specimen (TCE)   (b) retrieved specimen (TPH)
Figure 5. Retrieved Test specimens of geosynthetic oil absorbent liner.

4 CONCLUSIONS

An experimental study was carried out to confirm the feasibility of a geosynthetic oil absorbent liner that can be applied to minimize the spread of contaminated groundwater in the early stage of an accident in which organic pollutants spilled. As a result, the following conclusions could be drawn.

1. the permeability coefficients of the proposed prototype pretreated for 24 hours in TCE and TPH assuming organic pollutants were 1.1×10^{-8} (cm/sec) and 7.3×10^{-8} (cm/sec), respectively. All of them were confirmed to satisfy the criteria as a liquid barrier layer.
2. It was confirmed that the oil-absorbing resin used showed sufficient oil absorption and self-swelling properties for organic pollutants.

Although the experimental results were conducted under limited conditions, the proposed geosynthetic oil absorbent liner is seemed to be applicable to minimize the initial outflow of groundwater contaminated with organic substances. It was confirmed that additional studies on the long-term behavior of liquid barrier and the field performance.

Electrokinetic geosynthetics, electro-osmosis constitutive model and numerical modelling

Y.F. Zhuang*
School of Civil Engineering, Wuhan University, Wuhan, P.R. China

ABSTRACT: Electro-osmosis was discovered more than 200 years ago. Quite a lot of phenomena discovered in that early stage of research are still attractive up to now. It seemed that research on electro-osmosis had been suspended for a while since 1950s∼1970s. It may be because both mechanism and engineering application of electro-osmosis are very complicated. However, in the past decade, there were quite a lot of breakthroughs on electro-osmosis technique. One among those was Electrokinetic Geosynthetics (EKG), a new category of geosynthetics which provides corrosion proof electrode; another one was smart DC power supply. To some extent, these breakthroughs make large scale application of electro-osmosis possible. They tackle the challenge of power demand and energy consumption not only for electro-osmosis but also for all electrokinetic related techniques in geotechnical and geoenvironmental engineering and these techniques are still evolving. This paper presents latest progresses on EKG and its application in large scale electro-osmotic dewatering and consolidation. Novel numerical modeling based on energy level gradient theory was carried out to model the field test of electro-osmotic consolidation using EKG. Comparison between calculated results and field test results is used for validation and further improvement of the numerical modelling program. The energy level gradient theory is a novel constitutive model that may help understanding of not only consolidation issue but also mechanism of unsaturated soil. Research presented in this paper is interdisciplinary and encouraging for further research.

1 INTRODUCTION

1.1 *Electro-osmosis*

Phenomenon of electro-osmosis was firstly reported by Ferdinand Friedrich Reuss in 1807, while the first publication on electro-osmosis was in 1809 (Reuss 1809). Although this phenomenon was firstly discovered in soil, it has been applied in many different areas, such as chromatographic analysis, microfluidics technology and biochips. These applications are at micro level, which aim at precise control of fluids in micro, nano or molecular scale. At micro level, the double layer model by Helmholtz is well accepted as a fundamental model to interpret the mechanism of electro-osmosis.

Electro-osmosis has applications also at macro level, such as sludge dewatering, soft ground consolidation, contaminated soil remediation, REE mining and so on. For these applications, Helmholtz's double layer model helps little for engineering design. It is because that knowing mechanism of fluid movement in micropores is not enough for predicting electro-osmosis behavior at macro scale. Therefore, theories which can be used for

---

*Corresponding Author: zhuang@tsinghua.edu.cn

engineering design of electro-osmosis need to be developed for different macro applications as mentioned above. At macro level, one of the most known theories is Esrig's theory (Esrig 1968). This is a theory to describe dewatering and variation of pore water pressure during electro-osmotic consolidation. However, electro-osmosis theories at macro level are generally insufficient for carrying out a feasible engineering design.

1.2 *Electrokinetic geosynthetics (EKG)*

The concept of EKG was firstly presented by Jones *et al.*, in 1996 (Jones *et al.* 2022; Nettleton *et al.* 1998). The idea was to make geosynthetics electrically conductive so that electrokinetic phenomena of soil can be combined with the traditional functions of geosynthetics. This concept is very inspiring for inventing a new category of geosynthetics for application of electrokinetic (EK) technique in various kinds of engineering. According to the concept, it seems that there are many flexible ways to create new EKG products; only need to make geosynthetics electrically conductive. However, it took longer time than expected to develop mature and mass-producible EKG products. The difficulties lie in many aspects and here are some of them based on the experiences of the author.

1. New products need to be clearly defined with details of function, design, materials and application scenarios; it is more than saying to make traditional geosynthetic electrically conductive.
2. Need a reason for the market to potentially accept the product so that manufacturer will have motivation to build a line to manufacture some samples for a trial and keep on evolving according to the experiments from bench scale to in-situ scale.
3. The materials planned to be used shall be available at a reasonable cost. In the area of geosynthetics, the materials especially refer to polymers, namely, electrically conductive polymers for EKG.
4. Technique of manufacturing the product shall be fully developed.

This paper presents state-of-art EKG technology based on the development history of E-board and E-tube, which are currently mass-producible EKG in China. The difficulties encountered, the solutions and the problems to be addressed will be presented and discussed.

2 E-BOARD AND E-TUBE

2.1 *Electrically conductive polymers*

Electrically conductive polymers were discovered in 1970s and the Nobel prize in chemistry 2000 was awarded jointly to Alan J. Heeger, Alan G. MacDiarmid and Hideki Shirakawa "for the discovery and development of conductive polymers". It has been decades since the discovery of conductive polymers and they have been widely used in areas like semiconductor materials or electrostatic eliminator. However, if they are going to be used to make geosynthetics, reasonable balance among electrical conductivity, strength, flexibility, machinability and cost shall be considered. This is actually the first difficulty we encountered when developing EKG.

From the year that the author noticed the concept of EKG in 2000 to the year that first sample was made, it has been about 3~4 years (Zhuang 2005). At this stage, the resistivity of EKG was 0.064 Ω·m. Theoretic analysis shows that resistivity of EKG should not be higher than the magnitude of $10^{-3}\Omega$·m, while there was no electrically conductive polymer with this resistivity commercially available in the market. We felt that this idea has strong potential but not commercially feasible at that time, so we put it on the shelf until we decided to develop raw material of the conductive polymer. The first success of developing the raw material was in 2011 (see Figure 1).
Figure 1.   Raw material of electrically conductive polymer with resistivity of of $10^{-3}\Omega\cdot m$.

2.2   EKG for dewatering and consolidation

At the first stage, namely, during 2000 to 2005, many trials were carried out and the purpose was to verify the possibility of using conductive geosynthetics as substitution for metal electrodes in electro-osmosis. At the second stage, after the adequate raw material of conductive polymer had been developed, we started to consider the definition of a specific EKG product.

E-board is the first mass producible EKG, which was achieved in 2012 in China (Zhuang *et al*. 2012). E-board was designed for dewatering and consolidation application. The reason that E-board was the first product that manufacturer willing to try was the huge usage amount of PVD (billions of meters per year in China) and the intense competition of PVD that extremely squeezed the profit margins. The appearance of E-board is similar to that of PVD only that the polymer is conductive (see Figure 2(a)). Besides this, two copper wires embedded in the bumpers of E-board are characteristic design of the E-board. This design is important for better distribution of electric current, although the polymer is conductive; furthermore, the wires is important for connecting the E-board to the power supply.

E-board was chosen as the first specifically defined product to develop also because the first generation of a new product should not deviate too far from the recognition of the products that people are already familiar with. People will not need a car to have 6 wheels. However, after E-board evolved to be mature, E-tube was designed for similar but different focus of dewatering purpures. Photos of E-tube is shown in Figure 2(b). E-tube was design for providing a better vacuum system for dewatering (Zhuang *et al*. 2014; Zhuang 2022) and a better leachate collection system for EK mining applications.

(a) E-tube   (b) E-tube

Figure 2.   EKG for dewatering and consolidation.

Generally, two major difficulties of manufacturing E-board and E-tube was as follows.

1. Difficult to balance conductivity and physical properties.

The goal of $10^{-3}\Omega\cdot m$ resistivity was difficult to achieve. Better conductivity was accompanied by lower strength and poorer flexibility. Besides the resistivity of the raw polymer materials, a method is also need for evaluation of the final product of EKG, because the manufacturing process, especially the extruding process, will change the conductive property of EKG. Now the measurement method has been proposed for E-board and E-tube (Zhuang et al. 2021). The resistivity of $10^{-3}\Omega\cdot m$ and duration of three months for minimum are now the basic requirements of quality control of EKG.

2. Difficult to embed the wires inside the polymer.

Copper has larger density than that of polymer. When the polymer is melted, copper tends to sink at the bottom. Therefore, a specially designed extruding machine shall be built in order to enclosed copper wires tightly in the right place (the bumper) inside the EKG.

3 SMART DC POWER SUPPLY

3.1 *Energy consumption*

Comparison of energy density in Figure 3 shows that energy consumption of electro-osmotic consolidation under steady voltage is much higher than that of consolidation by surcharge preloading. Surcharge preloading along e~logp curve is the lower limit of consolidation energy consumption (Zhuang 2005; Zhuang et al. 2015). The fact that electro-osmotic consolidation currently has higher energy consumption than that of preloading is an issue that restrains its application. However, it could be seen in another hand as an issue that has high volume of optimization.

The electric energy is consumed by hydrolysis, producing heat, electrochemical reaction and ion transportation, etc. besides dewatering and consolidation. It is not possible to prohibit these energy consumptions but it is possible to lower them if optimized strategy of electric field application is adopted.

(a) Energy density under electro-osmosis   (b) Energy density under surcharge preloading

Figure 3.   Energy density under electro-osmosis and reloading consolidation (Gui 2022).

3.2 *Power requirement*

Power requirement is a more important issue than energy consumption for application of electro-osmotic consolidation in large scale. For large scale consolidation, usually thousands of square meters at the same time, electric current can be unacceptable high if a constant voltage is simply applied in the field.

The solution to tackle this problem is roll-polling program (Zhuang et al. 2015; Zhuang 2021). It is this novel technique that makes large scale application of electro-osmotic consolidation possible.

Solution for the above two issues is to invent smart DC power supply (see Figure 4). And the roll-polling program is the core of the smart DC power supply. The smart DC power supply can lower the energy consumption to less than 1 kW·h/m^3 and power requirement to less than 0.005kW/m^3. We have the idea to further reduce the power requirement to a half by redesigning the smart DC power supply.

4 ENERGY LEVEL GRADIENT THEORY

Energy level gradient theory uses energy density as a substitution of stress for analysis of dewatering and consolidation (Zhuang 2005; Zhuang *et al.* 2015). Energy density has the unit as stress, namely, kJ/m^3 = kPa, while electric energy is easy to monitor and calculate during electro-osmosis. This theory provides formulas for electro-osmosis design as follows.

Electric current can be described by formula (1)

$$I = (I_0 - I_\infty)e^{-at} + I_\infty \tag{1}$$

Where I is electric current intensity during electro-osmotic dewatering (A); I_0 is initiate electric current intensity (A); I_∞ is levelled off electric current intensity (A); t is time (s); a is time factor (s^{-1}).

Electro-osmotic dewatering can be described by formula (2)

$$Q = \frac{k_q v(I_0 - I_\infty)}{a^2 \Delta x^2}(1 - e^{-at}) \tag{2}$$

Where Q is accumulative volume of electro-osmotic dewatering at time t (m^3); t is time (s); k_q is flow rate coefficient (m^2·Pa^{-1}·s^{-1}); v is voltage (V); I_0 is initiate electric current intensity (A); I_∞ is levelled off electric current intensity (A); a is time factor (s^{-1}); Δx is distance between anode and cathode (m).

Final dewatering of electro-osmosis can be described by formula (3)

$$Q_\infty = \frac{k_q v(I_0 - I_\infty)}{a^2 \Delta x^2} \tag{3}$$

Where Q_∞ is total volume of dewatering (m^3); k_q is flow rate coefficient (m^2·Pa^{-1}·s^{-1}); v is voltage (V); I_0 is initiate electric current intensity (A); I_∞ is levelled off electric current intensity (A); a is time factor (s^{-1}); Δx is distance between anode and cathode (m).

5 NUMERICAL MODELLING

Formulas (1) ~ (3) are simplified formulas for electro-osmosis design. The precise differential equations of energy level gradient theory are as follows (Zhuang 2005; Zhuang *et al.* 2015).

$$\begin{cases} \nabla \vec{q} = k_E \dfrac{\partial E_s}{\partial t} \\[2mm] \vec{q} = k_{qx} \dfrac{\partial(E_f - E_s)}{\partial x}\vec{i} + k_{qy} \dfrac{\partial(E_f - E_s)}{\partial y}\vec{j} + k_{qz} \dfrac{\partial(E_f - E_s)}{\partial z}\vec{k} \\[2mm] \nabla E_f = \dfrac{k_{ex}}{k_{qx}}\dfrac{\partial v}{\partial x}\vec{i} + \dfrac{k_{ey}}{k_{qy}}\dfrac{\partial v}{\partial y}\vec{j} + \dfrac{k_{ez}}{k_{qz}}\dfrac{\partial v}{\partial z}\vec{k} \\[2mm] G = f_G(w) \\[2mm] \vec{j} = G \cdot \nabla v \\[2mm] w = w_0 - \dfrac{\gamma_w}{\gamma_{ds}}\displaystyle\int_{E_{s0}}^{E_{st}} k_E dE_s \end{cases} \tag{4}$$

Where $\bar{q}$ is vector of water flow rate (m·s^{-1}); E_s is energy density level (J·m^{-3}); t is time (s); k_E is energy coefficient (Pa^{-1}); $\triangledown$ is Hamiltonian operator; E_f is energy density level of the applied energy filed (J·m^{-3}); k_{qx}, k_{qy}, k_{qz} is flow rate coefficient along coordinates of x,y,z, respectively (m^{-2}·Pa^{-1}·s^{-1}); i,j,k is unit vector along coordinates of x,y,z, respectively; k_{ex}, k_{ey}, k_{ez} is electrical permeability along coordinates of x,y, z respectively (m^2·v^{-1}·s^{-1}); G is electric conductivity of soil (Ω^{-1}·m^{-1}); w is water content of soil (%); $f_G(w)$ is function of water content, which shall be determined via experiment; j is vector of surface density of electric current (A·m^{-2}); γ_{ds} is unit weight of dried soil (N·m^{-3}); w_0 is initial water content of soil (%); E_{s0} is initial energy density level of soil (J·m^{-3}); E_{st} is energy density level of soil at the t moment (J·m^{-3}).

An example of numerical modeling using this constitutive model of energy density analysis is shown as follows (Sayami 2021).

A soil model of 3m×6m×3m (breadth×length×height) was used. The dimension of electrodes was 5mm×100mm×3m. Parameters used in modeling are as follows.

p_C = preconslidation pressure (Pa) = 4kpa
γ_{ds} = unit weight of dried soil(N/m^3) = 760 N/m^3
γ_w = unit weight of wet soil(N/m^3) = 980 N/m^3
C_C = compression index (dimensionless) = 0.3865
e_o= e_C = Void ratio corresponding to p_C (dimensionless) = 2.6

Meshing of the model is shown in Figure 4. One of the modeling results is shown in Figure 5.

Figure 4.　Meshing of the model (Sayami 2021).

Figure 5.　Electric potential contour line after 500 hours of consolidation (Sayami 2021).

6 CONCLUSIONS

This paper provides a review of the development of new category of geosynthetics, namely EKG, from concept to mass producible produces and their application in field. Limited to the allowance of pages, this paper cannot dive into very specific details of the topics, but the references listed in this paper can help for further understanding. Major conclusions are as follows.

1. E-board and E-tube are two kinds of relatively mature EKG products which are mainly used in electro-osmotic dewatering and consolidation. The important characters of these EKG materials are that they have two copper wires embedded in the electrically conductive polymer and the quality control for the EKG is that resistivity not higher than $10^{-3}\Omega$·m and duration of conductivity not less than three months.
2. To lower the power requirement is as important as lower the energy consumption and the key of achieving these purposes is developing of smart DC power supply. Roll-polling

program is the core of the smart DC power supply. Based on this technique, the energy consumption can be lower to less than 1 kW·h/m^3 and power requirement can be lower to less than 0.005kW/m^3.

3. Energy level gradient theory is developed and applied for the design of electro-osmosis in engineering scale. The key thought of this theory is using energy density as key a parameter that substitute the stress, because in electro-osmosis electric energy is easier to monitor and calculate compared to stress, e.g. pore water pressure or suction.

4. Simplified formulas of the energy level gradient theory can be used for design, while precise differential equations can be used for numerical modeling.

Innovative installation method of geotextile tubes in deep waters

J.M. Soh & S.H. Chew
National University of Singapore, Singapore

Y.C. Tan, H.M.A. Yim, J.W.A. Quek, D.J. Lim & S. Kee

ABSTRACT: Geotextile tubes are commonly used as revetments and breakwaters in coastal protection structures, where most are in relatively shallow waters. A common installation method involves dropping the filled geotextile tubes from split bottom hopper barges onto the seabed in a free-fall manner. However, this method may not be suitable in deep waters because of the lack of accuracy in its placement subjected to harsh waves and current conditions. This paper critically evaluates an innovative installation method that can be done in deep waters (i.e., water depth 20–40 m) that promise adequate placement accuracy, speedy installation, and cost effectiveness. This method makes use of a high-capacity floating crane barge to lower fully filled geotextile tubes from a barge onto the seabed. A trial of this method was conducted in Singapore to construct an underwater geotextile tube bund. Monitoring sensors were installed on the geotextile tubes to monitor the effectiveness of this installation process. In addition, shape accelerometer arrays were installed beneath the geotextile tubes to monitor the ground settlement and accuracy of installation. Results from instrumentation data and observations show that the high-capacity crane barge is an effective method for the installation of geotextile tubes in deep waters of 20–40 m range.

1 INTRODUCTION

Geotextile tubes are commonly used as revetments and breakwaters in coastal protection structures. Most of these structures are in relatively shallow waters with depths of less than 20 m. During construction, there are several methods of installing the geotextile tubes. When it is to be installed along the shoreline, the empty geotextile tubes can be laid in their desired positions, before infill material is pumped into them. In relatively shallow waters up 20m, a common method is to drop the fully filled geotextile tubes in a "free-fall" motion from a split bottom hopper barge onto the seabed (Figure 1(a)) (Lawson 2008). These methods will not be suitable in deep water conditions. For example, geotextile tubes in the "free-fall" method are susceptible to the influence of currents, thus affecting accuracy of placement. For deep water conditions, there are custom-made designs to specially install geotextile tubes, such as NEREIS (Figure 1(b)).

Figure 1. Installation methods: (a) "Free-fall" dropping of filled geotextile tube (Pilarczyk 2000); (b) NEREIS custom designed geotextile tube installation barge (Kamada 2010).

Systems such as the NEREIS are custom-made and are used for the specific site applications, and are less likely to be used for other applications (Kamada 2010). This prevents cost-sharing with other projects, and thus potentially contributing to the high installation costs. Thus, there is a need to search for a new method to install geotextile tubes in water depths of around 20–40m in a cost-effective, fast, and accurate manner.

2 INNOVATIVE INSTALLATION METHOD USING HIGH-CAPACITY CRANE BARGE

This paper evaluates the feasibility of using a high-capacity crane barge to lower filled geotextile tubes from a flat top barge onto the seabed. There are 2 key components required for this installation method: (1) High-capacity crane barge; and (2) Geotextile tube lifting frame. The lifting frame ensures that the lifting force from the crane barge is uniformly distributed along the filled geotextile tube. This will minimize bending and uneven lifting of the geotextile tube during lifting and lowering process. The geotextile tube is connected to the lifting frame using a sacrificial geogrid. Once the geotextile tube is lowered onto the seabed, the geogrid sheet will be cut by divers. To ensure accuracy of placement, GPS sensors were installed at two ends of the lifting frame. An illustration of this installation method and the lifting frame setup is shown in Figure 2.

Figure 2. Installation using high-capacity crane barge (left) and lifting frame with geogrid setup (right).

3 SITE TRIAL SETUP

A site trial was conducted using the high-capacity crane barge method. A total of six filled geotextile tubes were lowered onto the seabed with a 600-ton high-capacity crane barge to form a bund. During the field trial, two key factors were investigated: (1) Effectiveness of the lifting frame in ensuring uniform distribution of forces across the length of the filled geotextile tube during lifting and lowering; and (2) Accuracy of placement of geotextile tubes in water. The geotextile tubes were approximately 20–22 m in length and 6.5 m in width when filled and were made from high strength polypropylene geotextiles with ultimate tensile strengths of 200 kN/m in both Machine Direction and Cross-Machine Direction. Three of the six geotextile tubes were instrumented with strain gauges along its Longitudinal Direction (LD), Circumferential Direction (CD) and Diagonal Directions (DD), as illustrated in Figure 3. Two Shape Accelerometers Arrays (SAA) were also installed (shown in

Figure 3.

Figure 4) to monitor the settlement beneath each layer of geotextile tubes and the accuracy of placement.

Finally, wireless pore pressure sensors were mounted on the exterior of the geotextile tubes to monitor the vertical movement of geotextile tubes when the geotextile tubes were lowered into the water, by tracking the depth of the geotextile tubes. Figure 5 illustrates the installation sequence for the geotextile tube bund. Figure 6 shows how the lifting frame is used to lift the geotextile tube, while Figure 7 shows the lifting and lowering process for a filled geotextile tube.

4 SITE TRIAL RESULTS

Figure 8 shows the strain gauge readings from instrumented geotextile tube B2 during the lifting and lowering process. Strain was converted to tensile force (kN/m) using the tensile force-strain relationship of the geotextiles. The initial values of tensile forces were the tensile forces induced during the infilling stage of geotextile tubes prior to the lifting operation. It was observed that the tensile forces experienced by geotextile tube started to change when the tube was lifted off the ground. Tensile forces remained constant during the whole period the tube was in the air, as well as during the whole lowering process. Tensile forces started to change again when the geotextile tube touched the seabed, until the geotextile tube was fully settled on the seabed.

The largest changes in tensile force during lifting operation was observed to occur in the Circumferential Direction (CD) of the tube, with value ranging from 5 to 20 kN/m at

Figure 8. Selected strain gauge readings of tube B2 during lifting and lowering process.

various locations. Tensile forces in the LD and DD direction experienced very minor changes of only up to 8 kN/m. This was likely due to the deformation of the geotextile tube in its cross-section, which is CD direction, during lifting. It could also be observed that some CD readings decreased (e.g., CD5 experienced a 20 kN/m decrease in tensile force), while others increased (CD1 experienced an increase of 15 kN/m). This was likely due to the difference in positions of the strain gauges on the geotextile during the lifting process as illustrated in Figure 9. The CD strain gauges at the top of the geotextile tube (e.g., CD5) experienced a decrease in tensile force because the geotextile tube "compressed" upwards, while the strain gauges at the bottom (e.g., CD1) experiences additional tensile force as it was stretched.

Strain gauges in LD direction experienced minimal changes in tensile forces during lifting and lowering, which indicated the lifting frame's ability to maintain uniform tension in the longitudinal direction of the geotextile tube, and prevented any sagging of the tube.

Similar trends were also observed in instrumented geotextile tubes M2 and T1. Overall, the lifting frame had shown to be effective in ensuring sufficiently uniformed distribution of forces throughout the geotextile tube during the lifting and lowering process.

The wireless pore pressure sensors attached on the exterior of geotextile tubes were used to monitor its movement when it was lowered into the water. Figure 10 clearly shows a second round of maneuvering the geotextile tube after it was first lowered, i.e., after the geotextile tube was first lowered onto the top of middle layer of geotextile tubes, it was then re-lifted, and its position adjusted before it is lowered again into its final position. This demonstrated

Figure 9.   Deformation of geotextile tube during lifting.

Figure 10.   Movement of tube T1 during the lowering process.

Figure 11.   Bottom layer geotextile tube positions based on SAA1 settlement profile.

Figure 13.   3D bathymetry survey result after the geotextile tube bund had been completed.

an advantage of the crane system, where adjustment of the tube position could be made until it was in the desired position.

Shape Array Accelerometers (SAA) were useful in determining the positions of geotextile tubes as the settlement profiles could be analysed. SAA1 readings showed the settlement profile immediately below geotextile tubes B1, B2 and B3 as illustrated in Figure 11. In addition, SAA1 readings also showed that geotextile tubes B1, B2 and B3 were installed with gaps between them. After the installation of all 3 geotextile tubes which formed the bottom layer, the gaps were filled with Cement Mixed Soils (CMS). Bathymetry surveys were also conducted after various construction milestones to verify the accuracy of placement. Figure 12 shows bathymetry survey (plan view) of the geotextile tubes from the bottom layer after they were installed, and results showed good agreement with the estimated geotextile tube positions obtained from SAA1 readings. Figure 13 presents the 3D bathymetry survey

results after the completion of the geotextile tube bund, and showed that the geotextile tubes were well aligned in the longitudinal direction.

5 CONCLUSION

The objective of this paper was to evaluate the feasibility of a simple method to install geotextile tubes in deep waters of about 20–40 m. Conceptual studies were done on an innovative new method using commercially available high-capacity crane barges coupled with an innovative lifting frame. The installation method was tested under a full-scale site trial. During the lifting of the geotextile tube, strain gauge data showed that the specially designed lifting frame was able to ensure uniformed distribution of lifting forces on the geotextile tube without any sagging observed along the longitudinal direction. The high-capacity crane was also able to lower the geotextile tubes with good accuracy due to the GPS system mounted on the two ends of the lifting frame. It was further demonstrated from both the SAA data and hydrographic survey results that the geotextile tubes were installed with adequate placement accuracy, and that the whole bund could be well positioned using this method of installation. In conclusion, the high-capacity crane coupled with the special lifting frame system is a viable and economical method for installing geotextile tubes in deep waters of 20–40 m.

ABSTRACT: Recently, prefabricated vertical drains (PVDs) and deep cement mixing (DCM) columns have been combined to improve the soft soil ground under embankment. This not only significantly improves the shear strength in soft soil ground but also increases the rate of consolidation. The present study develops a simple two-dimensional (2-D) plane-strain numerical model of the DCM columns and PVDs improved soft ground under embankment. The geometry of the PVD and DCM column in equivalent 2-D model were obtained from the concept of same area replacement ratio, while the equivalent horizontal permeability of soft soil and DCM columns surrounding PVD was deduced from the matching of the total volume of water to be discharged in an axisymmetric model and the total changes in flow in a plane strain. Subsequently, the proposed method was applied to the Huai-Yan embankment in China, in which was used the combined method for ground improvement. The results of settlement and lateral displacement obtained from the proposed model were in good agreement with the observed data and results obtained from previous solution.

1 INTRODUCTION

It is well-known that deep cement mixing (DCM) columns and prefabricated vertical drains (PVD) have been used widely to improve soft soils under embankment construction (Chai & Carter 2011; Horpibulsuk *et al.* 2012; Lorenzo & Bergado 2003). To prevent excessive settlement and increase the bearing capacity of soft soil, DCM columns were placed into soft soil ground. PVDs were typically installed by a steel mandrel into soft ground to accelerate consolidation process of soft soil ground (Hansbo 1981; Nguyen & Kim 2018; Rujikiatkamjorn *et al.* 2013).

DCM columns are typically installed in soft soil layer to reduce the large deformation and differential settlement between the structures and the adjacent road constructions (Chai & Carter 2011). However, when DCM columns were partially penetrated in soft soil (floating improvement), a high excess pore water pressure can be accumulated in the unimproved soft clay layer. This can result in large residual settlement in the post-construction stage and a lengthy consolidation period (Liu & Rowe 2015). This point is a disadvantage in the case of DCM column improvement.

Prefabricated vertical drains (PVD) are typically used to accelerate consolidation of soft soil by reducing the length of the drainage path in ground. Thus, the settlement of PVD-improved soft soil ground was mostly completed during the construction period, resulting in reducing the post-construction settlement. Because the construction time is limited, the PVD method can consider for a cost-effective means of construction of embankment on the soft deposits. However, when the PVDs was improved solely in the soft soil deposits, the ground bearing capacity cannot be significantly enhanced as the case of improvement by DCM columns. The horizontal displacement at toe of embankment occurs largely. Therefore, the slope stability of the embankment can be reduced as the filling height increases.

To increase the slope stability of soft ground during construction and accelerate consolidation, the combination of PVD and DCM columns has been applied recently. The profile of composite foundation is shown as Figure 1. This is also a cross-section of bridge approach embankment in the Northern suburb of Shanghai in China. It can be seen that this method allows a large spacing of DCM columns and PVDs and a possible application of floating DCM columns in ground improvement. Therefore, the combined method can apply for embankment constructed over soft deposit and save the construction cost (Xu et al. 2006; Zhang et al. 2006).
Figure 1. Cross-section of test embankment on composite foundation.

According to the advantages of the combined method, this objective has been attended in recent years. However, there are very limited of the numerical analysis for consolidation analysis and investigation of soil arching of composite foundation of PVDs and DCM columns. Therefore, aim of this study is to present a simple two-dimensional (2-D) plane-strain numerical model of the composite foundation under embankment. The geometry of the structures and the equivalent horizontal permeability of composite foundation is deduced in a plane strain. Subsequently, the proposed model is applied to and the field case of Huai-Yan embankment in China.

2 NUMERICAL MODEL

2.1 *Equivalent width of DCM column and vertical drain*

The width of PVD and DCM column in 2-D plane strain model was typically converted from situ condition. In this study, the width of PVD and DCM column in plane strain model

was obtained from matching the area ratio between the axisymmetric unit cell and the 2-D model (Nguyen *et al*. 2018, 2022), as follows:

$$b_w = C \frac{d_w^2}{S} \tag{1}$$

$$b_{DCM} = C \frac{d_{DCM}^2}{S} \tag{2}$$

where b_w and b_{DCM} are the equivalent width of PVD and DCM column in the equivalent 2-D model, respectively. C value depends on the installation pattern, i.e., $C = \pi/4$ for square pattern and $C = \pi/2\sqrt{3}$ for triangle pattern; d_w and d_{sc} are the diameters of PVD and DCM column, respectively; S is spacing of PVDs and DCM columns. In this study, the spacing of PVDs and DCM columns is the same.

2.2 *The equivalent hydraulic conductivity*

To obtain an equivalent hydraulic conductivity of PVD-installed soft soils, Nguyen *et al*. (2018) carried out the assumption that the total change in the flow in the plane strain model is equal to the total volume of water to be discharged of in-situ case for a given consolidation period. The equivalent horizontal hydraulic conductivity in 2-D model of the PVD-installed soft soil as follows:

$$k_{hp} = \frac{1}{4} \frac{S}{2} \frac{\pi k_h}{\mu \ln 2} \tag{3}$$

where S is the spacing to the adjacent PVDs or DCM columns; k_h is the horizontal hydraulic conductivity of soil and μ is the factor considering the effects of PVD spacing, smear zone and well resistance, which were described in Hansbo's solution (Hansbo 1981), as follows:

$$\mu = \ln \frac{n}{s} + \frac{k_h}{k_s} \ln(s) - \frac{3}{4} + \pi \frac{2H^2 k_h}{3q_{wa}} \tag{4}$$

where $n = D_e/d_w$, in which D_e is the diameter of unit cell and d_w is the equivalent diameter of the drain; $s = d_s/d_w$ in which d_s is the equivalent diameter of the smear zone; k_s is the horizontal hydraulic conductivity of the smear zone; H is the drainage length and q_{wa} is the discharge capacity of PVD in the axisymmetric model.

To consider the influence of DCM columns in the composite foundation, the modulus of elasticity of DCM wall in 2-D plane strain model is deduced by matching the flexural rigidity of SC column in field condition and SC wall in the equivalent plane strain (Nguyen *et al*. 2022).

$$E_{DCM}^w = \frac{3}{16} \frac{E_{DCM} d_{DCM}^4}{b_{DCM}^3} \tag{5}$$

where E_{DCM} is modulus of elasticity of DCM in situ condition.

3 CONSOLIDATION ANALYSIS OF COMPOSITE FOUDATION

3.1 *Numerical model setup and geotechnical parameters*

This section carries out a consolidation analysis of composite foundation under Huai-Yan highway embankment at stations K19 + 688–K19 + 798. The subsoil was improved by combination of DCM columns and PVDs. Both of DCM columns and PVDs were installed

in a triangular pattern at a spacing of 2.2 m and depth of 13 m, in which radius of DCM columns is 0.25 m (Ye *et al.* 2012). The profile of subsoil was detailed in Ye *et al.* (2012). It was summarized in this study as follows: the top layer is a brown clay with 1.5–2.0 m thick; the second layer is soft soil with 10.3–12.0 m thick. The soft soil is underlain by the relatively hard clay. The thickness of subsoil layers is assumed to be constant at stations for simple analysis. The height of embankment is 4m from two stages in the filling process. The first step was filled with 2.0m of embankment in 50 days, followed by 75 days for dissipation of excess pore pressure. The second 2.0m embankment was applied in 50 days in last stage. The unit weight of filling material is 20 kPa. The cross-section of Huai-Yan embankment is presented in Figure 2.

Figure 2. Cross-section of composite foundation under test embankment in Huai-Yan highway (Nguyen *et al.* 2022).

In this section, the consolidation analysis of composite foundation is performed through the present 2-D plane strain model. The behavior of subsoil layers was modeled by the modified Cam-Clay (MCC) model (Roscoe & Burland 1968). This has been widely used to model mechanical behavior of soft clay with elastoplastic model for clayey soil. Sand layers including embankment fill material and DCM walls were treated by the Mohr-Coulomb model. The equivalent permeability of soft soils and elastic properties of DCM columns in 2-D plane strain model are calculated as the above equations and presented in Table 1. The properties in Table 1 is collected from the previous studies (Nguyen *et al.* 2022; Ye *et al.* 2012). The mean of properties is as follows: E is modulus elastic; υ is Poisson's ratio; λ and κ are compression and swell index in MCC model, respectively; γ is unit weight of material; k_h and k_v is horizontal and vertical permeability of materials.

Table 1. Geotechnical properties of materials in numerical analysis.

Materials	E (MPa)	υ	κ	λ	e_0	γ (kN/m³)	k_h (m/day)	k_v (m/day)	k_{hp} (m/day)
Clay	–	0.3	0.008	0.08	0.6	18	8.64×10^{-5}	8.64×10^{-5}	2.9×10^{-5}
Soft clay	–	0.3	0.02	0.2	1.7	15.5	2.8×10^{-4}	1.4×10^{-4}	4.7×10^{-5}
Hard clay	–	0.3	0.005	0.05	0.7	19.5	2.8×10^{-4}	1.4×10^{-4}	4.7×10^{-5}
Fill material	25	0.2	–	–	–	20	0.1	0.1	–
DCM wall	80	0.2	–	–	–	20	8.64×10^{-6}	8.64×10^{-6}	–

Figure 3 presents the geometry and finite element (FE) mesh for the composite founda-tion. A 15-node triangular element was used. Because PVDs depth was shortly installed within a depth of 13 m, the factor of well resistance can be ignored in this study. Therefore, PVD can simulate as drainage element in numerical analysis (Hird *et al*. 1992). The dis-placement boundary condition was as follows: the vertical displacement and horizontal displacement were fixed at the bottom of the model, and horizontal displacement was fixed at the right and left boundaries. Drainage boundary was applied at the top surface and bottom of the model.

Figure 3.   Geometry and mesh properties in numerical analysis.

3.2   *Results and discussion*

Figure 4 shows the comparisons of settlement results between the predicted results obtained from the numerical analysis and the measured data. The previous solution (Ye *et al*. 2012) is also carried out to compare with the present analysis. Generally, the proposed solution provides a good agreement with the field data. The numerical results are also consistent with the results of field data and the proposed solution. The settlement result from solution of Ye *et al*. (2012) is overestimates the monitoring data and the present analysis. Ye *et al*. (2012) considered an analytical model with a single DCM column enclosed by surrounding soil and PVDs is simplified as a drainage ring. Therefore, effect of well resistance of vertical drainage is ignored. It can be seen that the proposed model is useful for the consolidation analysis of composite foundation of DCM columns and PVDs.

Figure 4.   Comparison of settlement results obtained from numerical model and previous solution.

Figure 5 shows the numerical results of the lateral displacement at the toe of the embankment after the construction process (i.e., 175 days). The results show that the profile shape of lateral displacement of the two cases with and without PVD is also similar. However, the lateral displacement of subsoil when PVDs are not improved is considerably larger than that with PVDs. These results could be explained that the PVDs can improve the stiffness of the soil at early stage due to consolidation process. The increase in rate of consolidation of soft soil induced by PVDs enhanced the shear strength development in composite foundation, thereby decreasing the lateral displacement under embankment for case with PVD.
Figure 5. Numerical results of lateral displacement at toe of embankment for cases with and without PVD.

4 CONCLUSIONS

This paper proposed an equivalent plane strain model of composite foundation of PVDs and DCM columns. The equivalent horizontal permeability and dimensions of DCM and PVD in an equivalent plane strain model is provided. Effects of smear zone due to PVD installation is also considered. The proposed solution was applied to analyze consolidation behavior of soft ground improved by the combined method under Huai-Yan highway embankment in China. The results obtained from the proposed solutions are in good agreement with the measured data. The present model can use to predict consolidation behavior as settlement and lateral displacement of soft ground improved by a combined method of DCM columns and PVDs.

Performance of nonwoven geotextile tubes in a water treatment plant

S.T.S. Paranhos, M.A. Aparicio-Ardila & J. Lins da Silva
São Carlos School of Engineering (EESC), University of São Paulo (USP), Brazil

ABSTRACT: Two nonwoven geotextile tubes were installed at the Bela Vista Water Treatment Plant in Nova Odessa, Sao Paulo, Brazil, to receive sludge from the decanters monthly washing. The first geotextile tube had its filling cycles performed with fresh sludge, and the second, with the addition of flocculant polymer. The tubes were monitored during the filling and emptying cycles, and in the consolidation period, obtaining some hydraulic and mechanical characteristics. For hydraulics characteristics, the performance improvement was evaluated by applying flocculant polymer concerning the sludge dewatering and evolution of the solids content. Concerning the mechanical characteristics, the strains mobilized in the nonwoven geotextile were obtained and discussed.

1 INTRODUCTION

Factors such as an increasing population, economic development and shifting consumption patterns have increased global water use by six times over the past 100 years and continues to grow steadily at a rate of about 1% per year (Unesco 2020). To accompany this growth, Water Treatment Plants (WTPs) play a significant role providing treated water to the population but producing more and more sludge. The main characteristic of WTP sludge is a material with fine grains and high moisture content that is difficult to dispose of and needs to be dewatered (Aparicio-Ardila *et al.* 2020). Geotextile tubes have been used in the sanitation sector as an alternative technology for dewatering since the 1980s (Fowler *et al.* 1996).

In an overview of this technology, geotextile tubes in dewatering applications comprise the containment, drawdown, and consolidation stages. The first stage (containment) involves filling the tube by pumping fine-grained material into the system. The drawdown stage involves the drainage of excess free water (where there is a volume reduction). The last stage (consolidation) also has a volume reduction due to the drainage and the weight of the material inserted in the tube (Kim & Dinoy 2021). The first and second stages can occur more than once, depending on the number of filling cycles specified in the project and the volumetric capacity of the geotextile tube.

Geotextile tubes can be manufactured from woven or nonwoven geotextile or a combination of both. The choice of fabrication material must be made based on the hydraulic and mechanical performance of the geotextile. Hydraulic performance refers to a solid's retention, effluent quality and other hydraulic requirements. Mechanical performance analyzes the relation of stresses and strains mobilized in the geotextile and the geometric configuration of the geotextile tube cross-section during filling.

Most studies developed with geotextile tube design are based on mechanical performance and consider low-strain materials for encapsulation (woven geotextiles) (e.g., Cantré 2002; Silva *et al.* 2021). Testing and analytical modeling of tubes made from woven geotextile for the dewatering process was studied by many authors (e.g., Aparicio-Ardila

et al. 2020; Müller & Vidal 2019; Ratnayesuraj & Bhatia 2018). Few studies have evaluated the feasibility of using only nonwoven geotextiles for manufacturing tubes, such as Aparicio-Ardila *et al.* (2020) and Bourgès-Gastaud *et al.* (2014). Despite the promising results of using nonwoven geotextiles, they refer only to hydraulic performance on a reduced scale.

The present article was motivated by gaps regarding nonwoven geotextile tubes' hydraulic and mechanical performance. This paper presents the monitoring of the geotextile tube while filling and draining cycles. It also presents the evolution of solids content in the consolidation period, and strains of two full-scale tests with tubes made from nonwoven polyester geotextile and filled with WTP sludge, with and without polymer addition to the sludge.

The objectives of this article are: (1) to present and discuss the strain data read in the field, (2) to present and discuss the volume variation while filling and draining cycles, (3) to analyze the difference in evolution in solids content with and without the use of flocculant polymer.

2 MATERIALS, EQUIPMENT AND METHODOLOGY

2.1 *Materials*

The experimental data were obtained by installing two full-scale geotextile tubes at the Jardim Bela Vista WTP located in Nova Odessa, State of São Paulo, Brazil, to receive the sludge from the monthly washing decanters. The geotextile tubes were 10 m long and 9.2 m in perimeter and were made of nonwoven polyester geotextile. The geotextile presents a mass per unit area of 612 g/m^2, tensile strength per unit width of 35 kN/m at the cross direction and 28 kN/m at the machine direction, with respective elongation of 89% and 85% in each direction, seam tensile strength of 26.54 kN/m and an apparent opening size of 52 μm.

The nonwoven geotextile tubes (GT1 and GT2) were manufactured from two rectangular geotextile layers of equal sizes, overlapped, and closed at the perimeter by two double seams. Regarding the tests, they were positioned in a draining cradle in the shape of a pool comprising draining geocomposite and PVC geomembrane.

Concerning the sludge, the specific gravity of the grains (δ) and granulometric analysis are, respectively, 2.4 g/cm^3 and 0.5% sand, 16.5% silt, and 83.0% clay. The inherent variability of the sludge should be mentioned and is reflected in the characteristics of the sludge of each test (Table 1), such as Sludge Solids Content (SSC) and the sludge-specific weight (Υ). GT1 was filled with sludge in nature, and GT2 was filled with the addition of a cationic polymer C8396, also used in Aparicio-Ardila *et al.* (2020).

Table 1 summarizes the information already presented about the experimental setup and the number of filling cycles, pump flow rate and monitoring technologies that will be described next.

Table 1. Settings used for the GT1 and GT2 tests.

Test	SSC %	Υ kN/m^3	Flocculant Polymer	Number offilling cycles	Pump flow rate–Cycle l/s–number	Monitoring Technologies
GT1	2.01 ± (1.79)	9.93	None	4	16–1, 2, 3, 4	US, DWS
GT2	3.42 ± (1.34)	10.01	C8396	5	2,8–1, 2 16–3, 4, 5	US, DWS

Standard deviations in brackets.

2.2 Monitoring technologies to collect geometry and deformation data

GT1 and GT2 were monitored using two technologies: Ultrasonic Sensor (US), which was fixed to a metallic structure that surrounded the base, and Draw Wire Sensors (DWSs), which were sewn directly onto the geotextile, 20 cm and 35 cm up to the seam, respectively for GT1 (Figure 1b) and GT2 (Figure 1c) on the top layer to measure the strain in the circumferential (cross direction of geotextile) and axial (machine direction of geotextile) directions (Figure 1a).

Figure 1. Site of DWSs. a) circumferential and axial directions of the geotextile tube, b) 20 cm up to the seam in GT1, and c) 35 cm up to the seam in GT2.

2.3 Monitoring technologies to collect volume variation and solids content

In GT1, a 16 l/s flow rate pump was installed to operate the four filling cycles performed. Moreover, in GT2, the choice of using two different pumps with different flow rates (the first with 2.8 l/s and the second with 16 l/s) resulted in the need to adopt one more filling because the first two fillings failed to reach the maximum height. The volume variation during filling cycles could be computed by:

- measuring the volume pumped to the geotextile tubes.
- estimating the retained internal volume, made through extrapolation of the cross-section geometry in three dimensions. The cross-section was calculated using the method proposed by Cantré & Saathoff (2011).
- dewatered volume calculated by the difference between the pumped and retained volume.

The method put forward by Cantré & Saathoff (2011) included the non-linear-elastic behavior of nonwoven geotextiles in a method based on membrane theory, which was proposed by Plaut and Suherman (1998). This procedure was done by adding a calculation step to the iterative method. With each new iteration, the previously constant perimeter increased in length due to the strain. Then, a new equilibrium was established, and the circumferential stress was recalculated. The incremental of admensional stress between two iterations was used as the stopping criterion.

After completing the filling and draining cycles, the consolidation phase was analyzed through the retained volume. A weekly collection plan of sludge samples was carried out to monitor the evolution of the solids content inside the geotextile tubes.

The collection plan was based on the division of the tube into four quadrants (Q1 to Q4) and each quadrant into four regions: corners (CO), center (CE), lateral edge (LE) and transverse edge (TE), as shown in Figure 2. This distribution was determined to collect representative samples from equidistant regions, without, however, having the influence of open areas in previous collections. Small windows were opened in the upper part of the geotextile tube to access the different regions, and the sludge samples were extracted using fractions of PVC tubes. Subsequently, the average solids content of each sample was determined.
Figure 2.   Location of quadrants and regions for sample collection.

3   RESULTS AND ANALYSES

3.1   *GT1 full-scale test*

The data collected by the US and DWSs were correlated using a time scale (Figure 3a). On this time scale, with time in days, the maximum circumferential stress occurs concomitantly with the maximum filling height in each cycle and decreases over the days during dewatering. It was observed that the strain of the material continued in the 24 hours following the end of each filling. It reached an increase in strains with a magnitude of less than 1% in all four cycles. This behavior is similar to the creep process due to the maintenance of the applied pressure. In this period, the filling height remained close to the maximum.

The maximum fill height recommended by the manufacturer for a geotextile tube with the dimensions used in this study is 1.30 m. The first filling was a height variation of 1.52 m and a strain of 18.6% in the circumferential direction and 15.1% in the axial direction. Due to dewatering, a reduction of 1.19 m in the height was observed after a week, associated with a geotextile shrinkage of 6.9% in the circumferential direction and 2.1% in the axial direction, that is, reaching strains of 11.7% and 13%, respectively in relation to the beginning of the test. In the second cycle, a maximum height of 1.33 m and strain in relation to the beginning of 22.2% and 18.3%, respectively, were reached for the circumferential and axial directions. From this cycle onwards, the strains between filling and dewatering were closer.

This behavior points to some possibilities: there was a gradual loss of material resilience or an accommodation of the geotextile and consequently of the DWS when the tube empties as the cross-section assumes a flatter shape. Moreover, the width increases due to the spread of the material contained in the geotextile tube (Shin & Oh 2003).

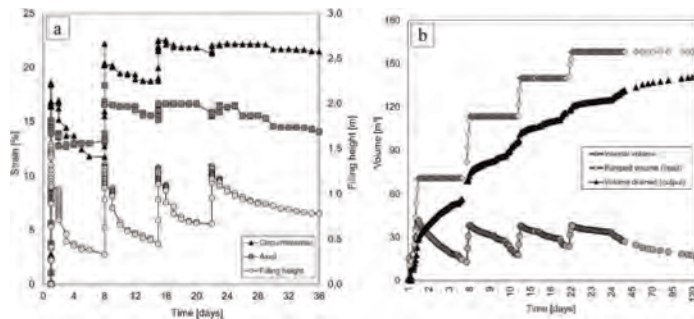
Figure 3b presents the volume variation during cycles and consolidation periods. Totaling the pumped, internal, and drained volumes for GT1, we have: 158 m^3, 15 m^3 (retained after the consolidation period) and 143 m^3. According to the manufacturer, the volumetric capacity of GT1 is 45 m^3, thus it was able to receive it in 4 filling cycles 3.5 times its capacity. During the first filling, 71 m^3 were pumped (approximately 1.6 times its volumetric capacity), which means the initial instant drainage was efficient. In the next cycles, with increased solids retained inside the geotextile tube, the remaining free storage volume is reduced, and the formation of the filter cake makes the drainage slower. In the last filling, the instantaneous drainage was so slow that the pumped volume was similar to the volumetric capacity available.


Figure 3. GT1 test. a) circumferential and axial strain during cycles obtained with DWSs and filling height obtained with US. b) volume variation during filling and draining cycles and consolidation period.

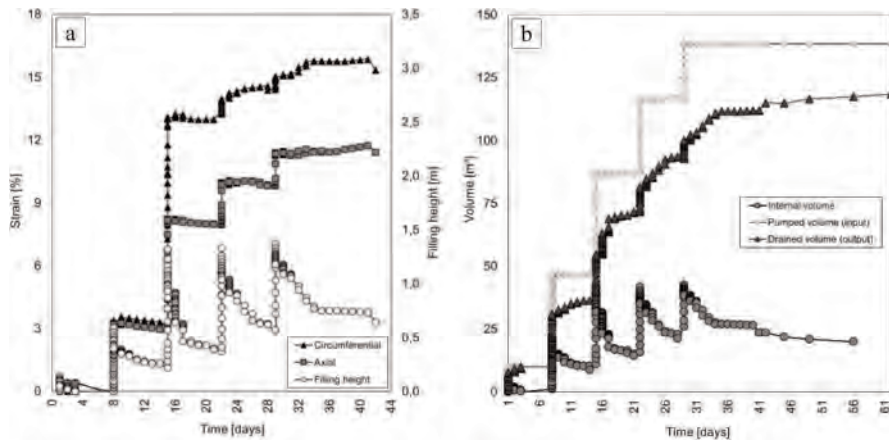
3.2 GT2 full-scale test

The data collected by the US and the DWSs were correlated using a time scale and are shown in Figure 4a. The lower flow pump kept the geotextile tube with a low fill height in the first two cycles. When changed to the higher flow pump after the third cycle, it was possible to reach the maximum planned height (in this case, 1.30 ± 0.07 m). For cycles 3, 4 and 5, the maximum heights were 1.32 m, 1.33 m and 1.37 m, respectively. In the moments with maximum height, the strains read in relation to the beginning of the test were 13.2%, 14.2% and 15.1% in the circumferential direction and 8.2%, 10.1% and 11.5% in the axial, respectively, for cycles 3, 4 and 5. These data reaffirm the hypothesis that each new filling exerts an additional effort on the material, resulting in more significant strains.

According to the DWS readings, the axial and circumferential strains were very close in the first two filling cycles. These data need to be analyzed with caution, as the readings may indicate the influence of short geotextile tube (where the non-establishment of the plane stress state is). Alternatively, it can indicate the accommodation of the material. When the tube starts to be filled, the geotextile is not completely stretched, and the pumping pressure agitates the geosynthetic.

The main difference between the GT1 and GT2 tests, compared to the maximum fill height, is in the first cycles: in GT1, the maximum height occurred in the first filling, leading to a large initial strain, while the last three cycles presented heights close to 1.30 m. In GT2, the first two cycles had low filling heights (0.14 and 0.59 m) due to the characteristics of the pump. After changing the pump, the following three cycles reached a height close to 1.30 m. It is likely that this initial difference led to the reading of the retraction between cycles 1 and 2 in GT1 and the absence of the retraction in GT2. Despite a small increase in strains between readings (according to height variation), it can be considered that they stabilized in cycles with a height of 1.30 m in GT2, as occurred in GT1. It can be observed in GT2, as well as in GT1, that there was a continuous strain of the material, which never exceeded 1%, during the continuous 24 hours at the end of the fillings.

Figure 4b presents the volume variation during cycles and consolidation periods. Totaling the pumped, internal, and drained volumes for GT2, we have the following: 138.5 m^3, 20 m^3 (retained after the consolidation period) and 118.5 m^3. GT2 was able to receive 3.1 times its capacity in 5 filling cycles. The total pumped volume was smaller than the volume of GT1. However, the volume of solids retained inside the geotextile tube was 33% higher, which was justified by the solids content of the pumped sludge, which was 70% higher than that of GT2. The pumped volume was reduced throughout the cycles, but this reduction was smaller than that observed in GT1, indicating better instantaneous dewatering and less filter cake formation.


1737

Figure 4. GT2 test. a) circumferential and axial strain during cycles obtained with DWSs and filling height obtained with US. b) volume variation during filling and draining cycles and consolidation period.

3.3 Evolution in solids content with and without using flocculant polymer

Figure 5 shows the average solids content obtained in each collection performed for GT1 and GT2. The effects of using the flocculant polymer could already be seen in the sludge samples collected from the filling pipe: the separation of solid and liquid fractions was clear. This prior separation caused the dewatering to occur at an accelerated rate, with consequent evolution of the solids content in a period 3 times shorter when compared to GT2, disposed of for 34 days, with GT1, disposed of for 103 days to reach sufficient solids content for removal.

Another point that draws attention is the distribution of the solids content of the sludge in the geotextile tube: the center was the region with the lowest solids content (therefore, higher humidity) and the corners, which was the highest solids content throughout the entire evolution. The edges showed intermediate values. These results indicate that the regions with the largest exposure surface have a shorter dewatering time. Upon reaching a solids content of around 25%, the appearance of a solid and consistent sludge can be observed. Solid content that is considered appropriate for removal and sending to a landfill.

Figure 5. Comparison of the evolution of solids content between the two tests: GT1 (without using flocculant polymer) and GT2 (with the use of flocculant polymer).

4 CONCLUSIONS

The nonwoven geotextile deforms during the filling cycles, and the maximum strains are obtained concomitantly with the maximum heights. Upon reaching the maximum height, before starting the dewatering, a settling of the material was observed, similar to the creep behavior.

The maximum strain concerning the beginning of the GT1 test was 22.2% and 18.3%, respectively for the circumferential and axial directions and occur during the second filling. These strains are a quarter of the deformations found at the material's breaking point. Therefore, tensile strength and deformation properties offered by this type of geotextile were not shown to be a limiting factor in this study, indicating that its use should be further explored for the dewatering of WTP sludge. However, it is indicated that further studies should be carried out to determine the point of greatest mobilization of cross-sectional strains.

The presence of flocculating polymer directly influenced the dewatering conditions and the evolution of the solids content in the consolidation phase. GT2 showed an evolution of approximately three times faster than GT1.

Experimental investigation on a novel graphene-based geotextile under mechanical loading

H.T. Senadheera, A. Bouazza & J. Kodikara
Department of Civil Engineering, Monash University, Clayton, VIC, Australia

D. Gibbs
Technical, Research and Innovation, Geofabrics Centre for Geosynthetic Research, Innovation & Development, QLD, Australia

ABSTRACT: Traffic loading, temperature and moisture variations are the main external causes of distresses in pavements. Therefore, it is crucial to monitor pavement loading to facilitate operation, rehabilitation and maintenance of road networks. Current in-situ pavement monitoring methods, which use embedded sensors in the pavement, allow real-time supervision of the road health condition. However, these methods are destructive to the pavement while they can provide information at distinct locations only. Therefore, there is a deficiency in a method that allows spatially continuous monitoring in roads. In this research, a novel graphene-coated geotextile is evaluated for use in applications as a distributed sensor to detect pavement response and damage. In this study, tests were conducted to examine the piezoresistive response of the material by subjecting the geotextile specimens to tensile loading. The results showed a significant electro-mechanical behaviour with potential to be used in a vast range of applications in road infrastructure.

1 INTRODUCTION

Road rehabilitation and maintenance cost billions of dollars each year for federal and state governments. Cracking, rutting, wear and deflection are some of the most common pavement distresses. Traffic loads and environmental loads are the main external causes of road failure. Environmentally-driven deterioration in pavements can occur primarily due to temperature and moisture variations, which impact both long-term and short-term pavement performance. In addition, traffic congestion and vehicle overloading accelerate the deterioration of pavements. Therefore, it is important to monitor traffic and environmental loading in real-time, to regulate effective Pavement Management Systems (PMS). Consequently, it is also crucial to establish appropriate traffic management procedures to extend the service life of roads.

Currently, in-situ pavement health monitoring methods are used to obtain real-time information on pavement response in terms of stress, strain, moisture and temperature. Strain gauges, Linear Variable Differential Transformers (LVDTs), Fiber Optics (FO), moisture probes and thermocouples are few of many in-situ monitoring methods commonly used for structural health monitoring (SHM) of pavements (Wang *et al*. 2012). Inductive loops and Weigh-In-Motion (WIM) systems are two of the widely-used technologies by road agencies for traffic volume and mass surveys, respectively. However, most of these methods can only obtain measurements at distinct locations, which as a result incur large installation and maintenance costs.

In this research, a novel graphene-based geotextile is examined for use in sensing applications in roads. The geotextile, made conductive by applying a graphene coating, is currently used for liner integrity surveys in containment facilities. The research is aimed at expanding its existing applications and investigating its feasibility as a distributed sensor to capture pavement response.

In order to assess its feasibility as a sensor, the aforementioned graphene-coated geotextile was tested for its electrical behavior with applied tensile loading. This paper presents a background to graphene-based geotextiles and the results obtained from the characterization tests for the geotextile.

2 GRAPHENE

Graphene is a quasi-two-dimensional monolayer of Carbon atoms, arranged in a hexagonal lattice that forms a 2D honeycomb lattice plane. Due to this structural stability of graphene, although its thickness is only around 0.35 nm, it has a very high mechanical strength, which is about 100 times the strength of steel of same thickness. Graphene has three strong sigma-bonds in each lattice and one pi-bond which provides freely moving electron that results in its high electrical conductivity. (Zhen & Zhu 2018).

These favorable properties have made graphene a promising material in high-sensitivity sensing systems. For example, under mechanical strain, the electronic structure of graphene would be altered such that a bandgap is introduced into the material, resulting in significant electro-mechanical effect, i.e. piezo-resistive effect (Yang *et al*. 2018). Due to high flexibility, sensitivity and working range of graphene-based strain sensors compared to that of traditional metal-based or silicon-based strain sensors, many strain sensors have been fabricated for graphene transferred onto flexible polymer substrates (Li *et al*. 2012).

3 GRAPHENE-BASED NON-WOVEN GEOTEXTILE

A graphene-based geotextile was manufactured by Geofabrics Australasia by coating a non-woven geotextile with graphene. The integration of graphene makes the geotextile conductive and thus, is being used in leak detection applications in waste, containment and landfills (Aitchison *et al*. 2019). In liner integrity surveys in barriers by electrical inspection, a voltage is applied to the surface of the barrier and leaks are detected via a closed electrical circuit forming at the leak location. When the subgrade soil is dry or non-conductive, water is supplied to provide sufficient electrolytes. This is called as the water lance or water puddle method (Parra & Owen 1988). However, this method incurs high installation and transportation costs and also record false leaks due to the presence of water. Therefore, an alternative method using conductive geotextiles are being currently used to test lined systems for defects. A voltage is supplied to an inspection probe and when a leak is identified, current will flow into the conductive geotextile to form a closed circuit, generating a warning (Figure 1).

Figure 1.   Diagram of the arc testing method (ASTM D7953).

3.1 *Application of the graphene-based geotextile in pavements*

As explained in Section 1, there is still a deficiency of monitoring methods that enables spatially continuous monitoring within SHM of pavements. Therefore, the current study is aimed at investigating the properties of the said graphene-coated geotextile for applications in pavement hydro-thermo-mechanical load monitoring as a spatially continuous sensor.

The graphene coating on the geotextile forms a conductive paths network on the synthetic fibers of the geotextile. When subjected to external loading, the conductive paths deform, distort and then break with increasing load (Park *et al*. 2002). These changes occurring to the conductive paths of the graphene coating manifests as a change in electrical resistance of the geotextile. Due to the conductivity of the material, this change in electrical property can be measured and reliably related with the applied load. Thus, it can be potentially used for field applications taking advantage of its distributed sensing capability.

3.2 *Mechanical load testing on the graphene-based geotextile*

A series of tensile tests were conducted to characterize the electrical behavior of the graphene-based geotextile with applied mechanical loading. The geotextile was subjected to tensile loading until failure and its electrical resistance was measured simultaneously. The objective was to examine the correlation between the mechanical strain and change in electrical resistance of the graphene-based geotextile under tensile loading.

In order to examine its reliability and sensitivity as a sensor, the Gauge Factor (GF) was calculated (Avilés *et al*. 2018), which is the slope of the linear relationship between the relative change in electrical resistance and the applied strain (Equation 1).

$$GF = \frac{\left(\frac{\Delta R}{R_0}\right)}{\varepsilon} \tag{1}$$

where, R_0 is the initial electrical resistance of the sensor corresponding to the unstrained state and ε is the applied strain.

Figure 2 shows the relative resistance change (dR/R_0 (%))–strain (%) relationship obtained by the tensile tests. The study deals with applications in road infrastructure, hence, strains only up to 10% were used for further investigation. The experimental results indicated that the material shows a consistent and significant electro-mechanical response for the range of strains 0 to 10%.

Figure 2.   Relative resistance change vs strain data obtained by the tensile tests.

The obtained data was fitted into a linear curve to calculate the slope, i.e. the gauge factor (GF) for each specimen. The obtained GFs by the repeated tests were in the range of 11 to 15, indicating a notable electro-mechanical response in the geotextile.

4   CONCLUSIONS AND FUTURE RESEARCH

The notable relationship between the electrical resistance and tensile loading obtained from the laboratory tests ascertain its potential as a distributed sensor for use in pavements, with special focus on detecting pavement damage, such as excessive deformation i.e. rutting. Further testing is to be carried out to simulate traffic loading conditions and to determine how the graphene-based geotextile behaves under actual field conditions. Moreover, a suitable field monitoring technique needs to be established in order to utilize this geotextile in practical applications.

Future transport infrastructure will consist of smart roads, where they will be equipped with smart materials and technologies providing network capability. It is expected that the graphene-based geotextile will contribute to developing new tools and techniques to pavement health monitoring and vehicle management in the context of smart road infrastructure.

Invention of a new geosynthetic drainage sheet to optimize hydraulic and mechanical performance for extreme geotechnical applications

R. Kroh & H. Zanzinger
SKZ–German Plastics Center, Würzburg, Germany

F. Lotz
University of Applied Sciences Würzburg-Schweinfurt, Würzburg, Germany

ABSTRACT: Especially in landfill lining systems and mining, the compressive loads on the sealing system and the overlying drainage system are enormous. They must be absorbed by the geosynthetic drainage systems without damage and without compromising hydraulic performance, i.e. sufficient water flow capacity.

Newly developed, integrally manufactured geosynthetic drainage sheets (GDS) made of high-density polyethylene (HDPE), which are based on a new, patented process, are being tested in laboratory trials on specimens produced in the laboratory. In particular their short-term compressive behavior and their water flow capacity under high compressive stresses with soft bedding were investigated. The results of the novel GDS are also compared with laboratory-made geonet structures. While geocomposites with geonet drainage cores suffer very severe losses in water flow capacity under the influence of surcharge and even more so under the influence of soft bedding, drainage geocomposites made of the novel GDS show a much smaller decrease and better performance than conventional products.

Weaknesses of biplanar geonets with regard to compressive behavior under the influence of compressive loads as well as a reduction of hydraulic effectiveness with ribs running obliquely to the slope are specifically circumvented by appropriate selection and size of the waterway grooves of the GDS running in the machine and cross-machine direction.

1 INTRODUCTION

Geosynthetics with the main function of drainage are state of the art in various areas of civil engineering, e.g. road, tunnel, landfill, or mining construction. When installed, the drainage systems must be able to drain water or any kind of liquid penetrating from the ground with as little pressure loss as possible for the entire period of use. (Koerner 2007; Rüegger & Hufenus 2003)

In applications with high compressive loads, e.g. in landfill lining systems or mining, the drainage systems must show high mechanical resilience, i.e. the drainage structure must not fail due to the compressive stress. The ability to collect and drain water (water flow capacity) must be guaranteed for any given time to avoid failure of the drainage system and thus of the entire application.

Nowadays drainage systems consisting of geonet structures (GNT) in combination with geotextiles are used at high compressive loads. Compared to drainage systems consisting of structured or randomly arranged monofilaments, or dimpled geomembranes, drainage

systems consisting of GNT show little compression with high absorption of compressive stress. (Müller *et al.* 2008)

Nevertheless, failure of the drainage structure can still be observed at enormous compressive loads, especially in biplanar GNTs. This so called "roll-over" effect describes the twisting of the upper ribs of the GNT in relation to the ribs below under high compressive load and shear stress. This leads to a reduction in the cross-section required for the water flow. In practice, this means a reduced water flow capacity for the geosynthetic drainage system, which in the worst case can cause the drainage function to fail. (Yeo & Hsuan 2007)

A new, patented process describes the integral manufacturing of a geosynthetic drainage sheet (GDS). In the following, "integral" is used to describe production from a single plate-shaped base body. In the simplest case, grooves (longitudinal direction, MD "machine direction") and counter-grooves (transverse direction, CMD "cross-machine direction") are introduced into an extruded, plate-shaped base body with the aid of embossing rollers (see Figure 1). These grooves are formed by material displacement, which leads to opening passages at the crossing points of the grooves and counter-grooves.

The integral production results in massive support structures within the GDS. These support structures can largely absorb enormous mechanical loads, in particular compressive and shear loads. The GDS is highly dimensionally stable, which means that a failure in stability of the drainage core can be avoided. Sufficient water flow capacity can be guaranteed at all times. This manufacturing process is characterized by a high degree of flexibility. For example, the geometry of the grooves and counter-grooves can be varied regarding the available cross-section for water drainage. In general, the thickness and width of the GDS are exclusively linked to the selection of the extrusion tool used. GDS with a width of several meters and a flexibly selectable sheet thickness are conceivable. The polymers can also be flexibly selected thanks to the extrusion process. It is also conceivable that in addition to the conventionally used polymers such as PE, PP, PA or PS, other types of polymers such as wood-plastic composites (WPC), biopolymers or recycled plastic materials can be processed. (Zanzinger 2020)
Figure 1. Manufacturing of a geosynthetic drainage sheet (GDS). (1) Extruder; (2) Plate-shaped base body; (3) Embossing roller 1; (4) Embossing Roller 2; (5) GDS.

GDS, according to the manufacturing process described above, and the mechanical and hydraulic advantages postulated with them are so far of a purely theoretical nature. This work is intended to represent a first practical examination of this topic, by manufacturing GDS specimens based on the process illustrated in Figure 1 and by comparing their short-term compressive behavior and their hydraulic performance to nowadays used GNT.

2 EXPERIMENTAL PART

GDS and GNT specimens were manufactured on a laboratory scale by machining HDPE panels with the dimension of 200 mm x 200 mm x 8 mm. The characteristic grooves were brought in using suitable milling tools. With GDS specimens, the grooves and counter-grooves were arranged at an angle (α) of 90° to another, derived from the manufacturing process shown in Figure 1. With GNT specimens, grooves and counter-grooves were brought in at a characteristic angle of 60°. Additionally, GNT with an angle of 90° were manufactured. The depth of the grooves was $d_1 = d_2 = 4 – 4.5$ mm for all test specimens (Figure 2a).

Figure 2. a) Schematic illustration of the GDS and GNT specimen geometry. b) GDS specimen with nonwoven geotextiles draped on the top and bottom.

The manufactured GDS and GNT specimens were draped (adhesive) on the top and bottom with mechanically bonded nonwoven geotextiles made of PP with a mass per unit area of 264 g/m^2 (Figure 2b).

The available cross-section for water drainage in direction of water flow (A_{Drain}) was determined by multiplying the cross-section of one groove (A) with the number of grooves in direction of water flow.

The mass per unit area (m_A) of the specimens was determined according to EN ISO 9864. The short-term compression behavior was determined using a universal testing machine according to EN ISO 25619-2.

The water flow capacity was determined with a specially manufactured apparatus according to EN ISO 12958-1. For soft/soft bedding, foams (10 mm thick) were placed between the pressure and base plates and the test specimen.

Table 1. Overview of the manufactured GDS and GNT specimens.

Test specimen	Width of grooves b [mm]	Number of grooves in direction of water flow	Radius of the rounded area of GNT R_{GNT} [mm]	Angle between grooves and counter-grooves α [°]	Available cross-section for water drainage in direction of water flow A_{Drain} [mm^2]	Mass per unit area[1] m_A [g/m^2]
GDS1	5.03	18	–	90	413	3940
GDS2	5.97	18	–	90	466	3411
GDS3	7.98	15	–	90	569	2826
GDS4	10.07	15	–	90	688	1699
GNT1	8.05	15	2.5	60	550	2175
GNT2	8.02	18	2.5	90	554	2302
GNT3	8.03	18	1.5	90	681	1848

3 TEST RESULTS AND EVALUATION

3.1 *Short-term compressive behavior of GDS and GNT specimen*

In Figure 3a the short-term compressive behavior of GDS and GNT specimens is presented graphically.

For the same compressive stress, the GNT specimens show a significantly higher compression than GDS specimens. While GNT specimens have a typical circular rib geometry, the ribs of GDS specimens are characterized by a rectangular shape and a flat contact area. The compressive stress can thus be absorbed over a larger contact area compared to the circular rib shape. The solid material is compressed directly at the support structures of the GDS, causing the compressive stress-compression curve to rise rapidly. The more massive these support structures are and the larger their number is within the drainage structure, the faster the rise of the compressive stress-compression curve occurs and the better the compressive resilience is.

The higher percentage compression of the GNT specimens can also be explained with the help of the circular rib geometry. In the rounded area, initial deformations can occur as the compressive stress increases. Further on, the circular rib geometry is deformed, while at the same time solid material is compressed in the support structures of the GNT specimens. The slope of the compressive stress-compression curve increases but is flatter than the compressive stress-compression curves of the GDS specimens. Thus with increasing compressive stress, the difference in compression between GDS and GNT increases.

3.2 *Water flow capacity of the GDS specimens as a function of specimen geometry*

In Figure 3b water flow capacity at 20 °C for the four different GDS specimens at two different compressive loads and a hydraulic gradient of i = 1.0 is shown graphically. Testing was carried out under soft bedding conditions, to simulate an intrusion of soil-material into the grooves of the GDS under compressive load.

With increasing groove width and thus larger available cross-section for water drainage in direction of flow (Table 1), the water flow capacity increases. At a groove width of 8 mm, it passes through a maximum and then decreases. At high compressive loads, the maximum is shifted to smaller groove widths. This behavior is equally observable for small and large hydraulic gradients. It can be demonstrated, that at a lower compressive load and a sufficiently large cross-section for water drainage in direction of water flow, intrusion can be compensated. However, this behavior becomes invalid with an increasing compressive load, as intrusion comes even more into effect. GDS specimens with smaller groove widths show significantly smaller decrease in water flow capacity as a result of increasing compressive load under soft bedding conditions than GDS specimens with larger groove widths and thus larger cross-sections for water drainage in direction of flow. Therefore, a trend towards smaller groove widths is clearly evident under extreme compressive loads and soft surrounding soil material.

Figure 3. a) Compressive stress-compression curves of GDS and GNT specimens. b) Water flow capacity at 20 °C of GDS specimens as a function of groove width at compressive loads (p) of 100 kPa and 500 kPa and a hydraulic gradient (i) of 1.0 (soft/soft bedding).

3.3 *Comparison of the water flow capacity of GDS and GNT specimens*

Figure 4a shows the water flow capacity of GDS and GNT specimens under different compressive loads. As in section 3.2, the soft/soft bedding simulates the intrusion of soil-material into the grooves of the GDS and GNT specimens.

Looking at the water flow capacity of the specimens in a soft/soft bedding situation at a compressive load of 100 kPa and comparing it with the values of the test specimens in a hard/hard bedding situation, significant differences between GDS and GNT can be observed. The effect of the nonwoven geotextile layers being pressed into the free spaces of the grooves is clearly more pronounced with the GNT specimens. The absolute difference in the water flow capacity between the hard and soft bedding situation of GDS specimens is approx. 0.7 l/m*s on average for the same compressive load. For comparable GNT specimens, this is between 1.2 l/m*s and 2.1 l/m*s and is thus greater by a factor of 1.7 to 3.0 than for the GDS specimens. This effect is even more noticeable with increased compressive load. With a comparable groove width, GDS specimen show a significantly lower influence of the non-woven geotextile layers being pressed into the free spaces of the grooves and counter-grooves under compressive load. This can be explained by the different geometry of the grooves. The rounded areas in the GNT grooves (Figure 2a) clearly contribute to higher intrusion of the geotextile layers, while the rectangular-shaped grooves of GDS specimens can counteract intrusion to a higher degree. This advantage is of great importance with regard to use under extreme compressive loads. The water flow capacity of GDS can be maintained for a longer period of time as the compressive load increases.

A further difference becomes apparent when comparing the water flow capacity of the GDS specimen with the characteristic groove arrangement of 90° with the GNT specimen with a typical arrangement of 60°. When the grooves were arranged in the direction of water flow, the GNT specimen with a groove arrangement of 60° showed a significantly better water flow capacity than the comparable GDS specimen, as water could be conducted through the grooves of the test specimen on the upper and lower sides. This represents an advantage of GNT over GDS. However, when grooves were arranged perpendicular to the direction of water flow, the GNT specimen showed a significant decrease in water flow capacity, whereas the GDS specimens hardly showed any differences (Figure 4b). The groove arrangement of 90°, derived from the manufacturing process, proved to be advantageous. GDS therefore showed good properties for a flexible application with regard to the installation direction.

In case of the typical GNT specimen, grooves and counter-grooves are arranged perpendicular to the direction of water flow at an angle of 120° to each other. This results in long flow paths for the drainage of water within the grooves. In a given time, less water can flow through the grooves and counter-grooves of the GNT specimen. The water flow capacity decreases drastically.

Figure 4. a) Comparison of the water flow capacity of GDS and GNT at different test conditions regarding the bedding situation and the compressive stress (i = 1.0) b) Comparison of the water flow capacity of GDS and GNT as a function of the installation direction (p = 100 kPa, i = 1.0, hard/hard).

4 CONCLUSION

For the use of geosynthetic drainage systems under enormous compressive load, such as in mining or landfill construction, GNT-based drainage systems are currently state of the art.

GDS described in this paper represent an alternative and can be produced flexibly and integrally in a combined process of extrusion and embossing of the drainage structure by material displacement.

In this study GDS and GNT specimens were manufactured and tested with regard to their short-term compressive behavior and their water flow capacity under compressive load.

The investigation shows that GNT specimens exhibited greater deformations at the same compressive stress than GDS specimens with comparable geometry. The rectangular shape of the grooves of the GDS specimens represents an advantage in terms of compressive behavior. Due to the solid support structures with a flat contact area, the compressive stress can be absorbed better and with less deformation.

Also differences in the hydraulic performance of the drainage structures investigated can be shown. GDS specimens reveal good properties for a flexible application with regard to the installation direction, while GNT specimens exhibit a significantly reduced water flow capacity when installed perpendicular to the direction of water flow.

In addition to the flexible application, GDS specimens have significant advantages in water flow capacity when tested in soft bedding conditions. The effect of the nonwoven geotextile layers being pressed into the cross-section of the grooves and counter-grooves is clearly less noticeable with GDS specimens than with comparable GNT specimens. The percentage decrease in water flow capacity of the GNT specimens is, depending on the pressure load, higher by a factor of 1.7 to 3.0 than with comparable GDS specimens.

In terms of material consumption, the more solid GDS specimens have higher masses per unit area compared to the GNT specimens investigated. However, the choice of a small groove width proves to be indispensable in order to maintain the water flow capacity under enormous compressive loads. Increased material consumption is therefore unavoidable. Only a reduction of the thickness can reduce the material consumption, but this also reduces the available cross-section for water drainage in direction of water flow and thus the water flow capacity.

The trends determined in this work with regard to short-term compressive behavior and water flow capacity indicate that GDS can be a promising alternative to conventional GNT-based drainage systems. The advantages of GDS over GNT can be demonstrated, particularly in extreme geotechnical applications with enormous compressive loads. In addition to the promising mechanical and hydraulic properties, the patented manufacturing process represents a further advantage. GDS can be manufactured on a large scale for specific applications. The geometry of GDS can be adapted according to the goal and benefit of the application and in terms of economic efficiency.

A study on the electrical properties of copper-functionalized graphene oxide in cement mixture

Jin Kim, Jae Hyun Jeon, Ji Yoon Kim, Jong Yeong Lee & Jung Geun Han
Chung-Ang University, Seoul, Korea

ABSTRACT: In this study, we intend to apply the electrical properties of graphene to cement mixture. When the resistance value is approximately 4 kiloohms. This value is a resistance value that hardly conducts electricity. An attempt was made to impart electrical properties to cement mixture by mixing Functionalized Graphene Oxide with copper with excellent electrical properties to the cement mixture. The cement mixture specimen, which had previously exhibited a resistance value of more than 4 kiloohms, showed a value of less than 1 kiloohms when functionalized graphene oxide was mixed. The purpose of this study is to determine the amount of cracks that have occurred in cement mixture by using electrical properties that are four times improved compared to the existing specimen when electricity flows through cement mixture. Cement mixture showed a trend of increasing resistance value according to cracking. This was used to formulate resistance values according to the amount of cracks and to evaluate the long-term lifespan and quality of cement mixture.

1 INTRODUCTION

Graphene is one of the thinnest, strongest, hardest and flexible materials discovered to date with respect to strength, thermal and electrical properties. Among them, by focusing on the electrical properties of graphene, it is used in various industrial fields such as displays, batteries, and semiconductors(Abbasi *et al*. 2016; Al-Dahawi *et al*. 2016; Lee *et al*. 2008; Ren & Chen 2014). In particular, in the field of civil engineering, various studies are being conducted, such as trying to assign electrical properties by mixing graphene with cement composites. Baoguo Han *et al*. (2007) conducted a study to assign electrical properties by mixing carbon fibers with cement paste. Therefore, in this study, 'Functionalized Graphene Oxide' was added to cement paste to give electrical properties and analyze it.

In addition, basic research was conducted to use the electrical characteristics as monitoring techniques such as quality control of concrete structures.

2 MATERIALS

Graphene is a two-dimensional structure with dense carbon atoms with a thickness of 0.335 mm, and is composed of a sp2 hybrid carbon allotrope with a single atom thickness of 0.1 nm – 0.5 nm. The bond length between carbon and carbon atoms arranged in a hexagonal honeycomb structure is about 0.142 nm, and these layers are easily dispersed because they are bonded to each other by weak Van Der Waals forces(Novoselov *et al*. 2004; Tiwari & Syvaarvi 2015).

In this study, Graphene Oxide (GO) was produced using a sulfuric acid according to the 'Modified Hummers Method' using graphite powder(Graphite powder, natural, universal

grade, −200 mesh, 99.995%, Sigma-Aldrich). Since the 'Modified Hummers Method' oxidizes graphite while decomposing it by a chemical method through oxidation, many functional groups including oxygen are generated on the surface. In addition, since single-layer graphene has a large surface energy, various molecules or ions can be adsorbed and desorbed. Therefore, the electrical properties can be controlled through chemical functionalization, which is affected by the type and concentration of adsorbed molecules. These properties indicate the possibility of using graphene as a sensor (Kim 2013).

In this study, Functionalized Graphene Oxide (Cu-GO) was prepared by copper, which is used in electric wires and electronic products to imorove the electrical properties of graphene (Gariono N. *et al.* 2021). SEM imaging, XRD analysis, and FT-IR were performed to confirm functionalization. SEM imaging was performed as shown in Figure 1. It was confirmed that Cu, which was attached to the functional group of graphene in a spine form, covered the surface, indicating the success of functionalization.

(a) Surface of Graphene Oxide (GO)

(b) Surface of Graphene Oxide Functionalized with Copper (Cu-GO)

Figure 1.   Confirmation of functionalization by SEM.

Through the XRD results in Figure 2., it can be confirmed that Cu-GO was successfully functionalized through the 2θ value that does not appear in GO (Figure 2(a)).

(a) GO

(b) Cu-GO
Figure 2.   XRD pattern of GO and Cu-GO.

Finally, through the FT-IR results (Figure 3), GO O-H peak (3392.18cm−1), C=O peak (1723.3cm−1), Sp2 C=C peak (1577cm−1), C-O peak (1156.2cm−1) −1) was confirmed. O-H peak (3337.7 cm−1), Sp2 C=C peak (1622.3 cm−1), and C-O peak (1149.9 cm−1) of Cu-GO were confirmed. A new 3436.8cm−1 peak, which was not shown in GO, was derived, confirming that copper ions are functionalized with O-H functional groups.

(a) GO (b) Cu-GO

Figure 3.   FT-IR of GO and Cu-GO.

3   TEST AND RESULT

3.1   *Electrical properties of cement paste mixed with Cu-GO*

To evaluate the electrical properties of cement paste, the specimen was prepared and the electrical resistance value was measured. The specimen to which nothing was added (Test-Normal) and The specimen to which 0.01% of Cu-GO was added relative to the weight of cement (Test-Cu-GO) were prepared. To measure the electrical resistance, copper electrodes were inserted at both ends of the specimen as shown in Figure 4 and measured using a digital multimeter(3244–60, HIOKI, JAPAN). If a crack occurs when electric current is flowing in the structure Figure 5, The strength of the electric field increases. As the strength of the electric field increases, the potential difference increases and the electrical resistance increases accordingly. Therefore, it can be confirmed that the electrical resistance increases as the crack occurs. This was used to measure the electrical resistance that changes according to the amount of cracking in the concrete, and by using this, a basic experiment was conducted to develop a monitoring technique for the durability and quality of the concrete structure
Figure 4.   Cement paste specimens used in the experiment.

As above, the cross-sectional area (S) of the specimen was 2500 mm^2 and the height was 50 mm, and the electrical resistance value measured through Equation 1 was converted into specific electrical resistance.

$$\rho = R \times S/l$$

ρ : SpecificElectricalResistance(Ω cm)
R : Cross $-$ SectionalArea(cm^2)   (1)
S : ElectricalResistance(Ω)
l : Length(cm)

The specimen used in the experiment was cured in water at 23°C temperature for 28 days and then the electrical resistance value was measured in a completely dry state. The measured electrical resistance values are shown in Table 1.

Table 1. Electrical resistance and specific electrical resistance of cement paste.

	Electrical Resistance(Ω)	Specific Electric Resistance(Ω-m)
Test-Normal	2645	132.3
Test-Cu-GO	1269	63.5

As a result, it can be confirmed that the specific electrical resistance of the cement paste was reduced by more than two times when Cu-GO was added.

3.2 Electrical properies according to cracks

If a crack occurs when electric current is flowing in the structure Figure 5, The strength of the electric field increases. As the strength of the electric field increases, the potential difference increases and the electrical resistance increases accordingly. Therefore, it can be confirmed that the electrical resistance increases as the crack occurs. This was used to measure the electrical resistance that changes according to the amount of cracking in the concrete, and by using this, a basic experiment was conducted to develop a monitoring technique for the durability and quality of the concrete structure

Figure 5. Potential difference due to crack occurrence.

For the measurement of electrical resistance according to cracks, the specimen was mounted on the UTM(Universal Testing Machine, HJ–1295, Heungjin Testing Machine, KOREA) as shown in Figure 6, and then a load was applied to induce failure. The electrical resistance was measured from loading to failure, and the electrical resistance according to the vertical displacement of UTM during the process is shown in Table 2.

(a) Before Crack   (b) After Crack

Figure 6.   Method of measuring electrical resistance according to the occurrence of cracks.

Table 2.   Electrical resistance and specific electrical resistivity according to vertical displacement.

|	Vertical Displacement(mm)	Electrical Resistance(Ω)	Specific Electric Resistance(Ω-m)
Case 1	0	2,602	130.1
	0.4	2,850	142.5
	1.0	3,255	162.8
	Failure	25,347,000	1,267,350
Case 2	0	1,273	63.7
	0.4	1,338	66.9
	1	1,612	80.6
	1.5	1,713	85.65
	Failure	23,870,000	1,193,500

The electrical resistance measured before load applied was the same as the electrical resistance of the specimen measured in 3.2, and then the electrical resistance increased as cracks occurred. It can be seen that the electrical resistance for each case continues to increase with a difference of about 2 times. When Cu-GO was mixed, the strength of the specimen increased, so that the vertical displacement just before failure increased from $1mm$ to $1.5mm$, and the specific electrical resistance just before failure increased by 40% compared to the state before cracking.

4   DISCUSSION

In this study, electrical properties were imparted to non-conductive cement composites using functionalized graphene oxide. A basic study was conducted to evaluate the durability of cement structures using these electrical characteristics. Basically, the cement mixture containing Cu-GO reduced electrical resistance more than twice as much as normal specimens. Through this, it was confirmed that the electrical properties of the cement composite were improved. Next, the change in electrical resistance was measured according to the crack using UTM. As a result, it was confirmed that the electrical resistance value also increased as the crack amount increased. It is hoped that this concept can be used as a basic study to evaluate the durability and quality of cement structures.

ABSTRACT: Finnish Transport Infrastructure Agency (Finland), Norwegian Public Roads Administration (Norway) and Swedish Transport Administration (Sweden) have asked Sintef (Norway) to prepare and manage the writing of guidelines on the Use of GeosyntHetics in Nordic conditions. The Rough project (RecOmmendations for the Use of GeosyntHetics in Nordic conditions) has been organized to collect all existing information and provide missing data. The corresponding work is presented in this communication: it focuses on the behaviour of geosynthetics during installation in Nordic conditions. The work is organised in two parts: (1) a full-scale on-site experiment in Kemi (Finland) on installation under Nordic conditions for the applications with functions reinforcement/stabilisation, filtration, drainage; and (2) considering the difficulty of the realisation of similar on-site experiment for sealing, it has been decided to realise a literature study associated with a synthesis of the state of the art for sealing.

1 INTRODUCTION

A common system for specification and certification of geosynthetics, NorGeoSpec, has been in operation in the Nordic countries since 2002. Experiences have revealed a lack of relevant requirements related to the installation and function of geosynthetics in a cold climate especially when temperature are largely below 0 °C. A development project ROUGH (RecOmmendations for the Use of GeosyntHetics in Nordic conditions) has been established to identify special requirements for geosynthetics to ensure technically and economically optimal solutions in country-specific climates and soils. Traffic Authorities in Finland, Sweden and Norway, research institutes, universities and a group of producers participated in the project.

1.1 Nordic conditions

Climatic conditions in the Nordic countries are challenging. Continuous pressure to increase the efficiency of heavy transport and reduce the climate impact of transports has led to the maximum permissible weights of heavy vehicles, especially in Finland and Sweden, being clearly higher than in the rest of Europe.

During the coldest winters, freezing index in inland Norway, northern Sweden and northern Finland may easily exceed 60,000 Kh (2,500 Kdays), which corresponds to a frost penetration depth of more than two meters in typical subgrade conditions. The frost penetration generally may result in considerable frost heave imposing deformations, stresses and deterioration of the road structure. In order to avoid the adverse effects of frost, high-quality road-and railway structures in the Nordic countries must be built including thick non-frost-susceptible structural layers or with frost insulation layers. Accordingly large amounts of blasted rock and crushed rock aggregates are used in construction works. Typically, the frost insulation layer is placed with a separation geotextile on the subsoil and with a road superstructure of 60–150 cm above. One of the essential special features of these artificially produced blasted rock materials and crushed rock aggregates are the sharp edges of the particles, which poses an obvious risk of damage to other materials installed next to them, such as geosynthetics. The combination of soft subsoil and sharp-edged rock fill material imposes also considerable deformations and stress of the structure and the material. This risk is exacerbated by the need to use heavy vibratory compaction equipment to compact angular crushed rock particles.

The most typical applications of geosynthetics in Nordic road construction projects are related to filtration and separation of soil layers. In particular, these functions are needed on thinly built lower-class roads, where the risk of mixing of structural layer materials and subsoil is high, especially during the thawing phase of seasonal frost in spring. Other typical uses are related to access during the construction period and include strengthening the lower part of road embankment and ensuring the operation of drainage structures.

1.2 Existing guidelines

In the Nordic countries there are several guidelines or recommendations which help to take into account the possible damage of geosynthetics during installation. Nevertheless, experiences have revealed a lack of relevant requirements directly related to installation and function of geosynthetics in cold climate. Presently, different ways of considering installation damage existing systems exist in Nordic Europe. Most classification systems define the requirements based on 3 key parameters: strength of the subsoil (2 to 3 types), type of backfill (2 to 5 types, depending on size of particles and angularity), aggressivity of the installation method (2 to 4 types, depending on drop height and compaction technique).

Note that, if all these guidelines consider the typical Nordic in-situ soils, backfill and traffic conditions, until today, none of them consider the installation temperature as a parameter.

1.3 Objective and content of project

The objective of ROUGH project is specially to focus on cold temperature by using local soil conditions in the Nordic countries and local construction methods and typical aggregate materials. The project includes a survey of experiences, literature studies, laboratory investigations and a full-scale field test. Depending on the type of geosynthetics the main means implemented were:

1–a full scale on-site experiment in Kemi (Northern Finland) on installation under Nordic conditions for the applications with the functions reinforcement/stabilisation, filtration, drainage;

2–considering the difficulty of the realisation of a similar on-site experiment for sealing applications, it has been decided to realise a literature study associated with a synthesis of the state of the art for this function.

Long term behaviour like freeze/thaw action and traffic loading is obviously important for the function but is not included in ROUGH. (ROUGH project 2022)

2 PERFORMED WORK

2.1 Collect of experience and synthesis

A general review of the existing knowledge on damage during installation for geotextiles and related products has been realised and allowed to give the general principles of the evaluation of installation damage showing how it is considered in existing guidelines. In most cases, mainly the influence of installation on the integrity of the structure of the product and on its mechanical performances is considered.

The effect of the installation on product's hydraulic properties should also be taken in consideration, especially in Nordic conditions with freezing and thawing, or when the products are placed on soils with high water content, with high content of fines and/ or soils consisting organic matter (peat, mud). Similarly, the influence of the evolution of the hydraulic performance of the products (short and long term) has been very rarely studied and discussed considering their importance on freeze thaw cycles on the structural behaviour.

To succeed to completement some of these important missing information the realisation of the full-scale experiment on geotextiles and related products in Kemi was decided.

Considering the difficulty of the realisation of a similar on-site experiment for sealing applications, it has been decided to realise a literature study associated with a synthesis of the state of the art for this function. This work allowed to propose (1) general requirements for products used in sealing applications under Nordic conditions, including (a) impact of environmental conditions on design choices, considering (b) aspects related to raw material/ structure of products in different conditions: exposed applications, shallow cover and fully covered applications, (c) performance requirements for geosynthetic barrier including preservation of GBR's integrity during transportation and storage and possibility of unrolling the GBR in place under freezing temperatures, on frozen soil subgrade, without damaging them; (d) worker safety during installation; (e) welding to assemble or repair GBR and (f) installation of the soil cover on the GBR (when applicable), (2) specific installation requirements (project management, packaging, storage and handling, subgrade preparation, deployment, assembly) and (3) quality control (quality assurance strategy, conformance testing of geosynthetic materials, CQA Report).

2.2 Realisation of the field work

The test site was established along an ongoing construction project to upgrade the Highway 4 (E8/E75) (Northern Finland), close to the border to Sweden (see Figure 1). Altogether 13 products were installed covering the functions reinforcement/stabilization, filtration, and drainage. The products were installed as a part of a road structure and of a drainage ditch at an average temperature $-10\,°C$ (down to $-15\,°C$). The installation and compaction were carried out according to pre-determined procedures. The procedures for the extraction of the products had to be specially adapted to be able to remove the fill material on top of the geosynthetics, without creating added potential damages due to excavation. The tests provided valuable information on behavior and potential damage during installation of geosynthetics linked to temperatures below $0\,°C$.
Figure 1. Location of the field tests (Screenshot Google Maps) and temperatures during installation and recovery [°C].

2.2.1 *Reinforcement/stabilisation*

To obtain site realistic damage behaviour during placement and compaction of materials, specifications based on Finnish guidelines for road construction were used for the field conditioning. 7 reinforcement/stabilisation products were installed on top of the crushed-rock compacted sub-base. Then, the base layer consisting of 30 cm blasted rock 0/56 was placed. During installation no heavy equipment drove over the installed products. The tipping height out of the excavator bucket was approx. 1.0 m and the compaction was performed with a 12.6 t dynamic roller. During geosynthetic installation, upper crushed rock material had a temperature of approx. −6 °C and the base-course material about −12 °C. Figure 2 (left) shows the products before the base layer was placed. In order to minimize positional influences, each product was cut into half and installed at two different locations along the test field. The Figure 2 (right) shows the compaction process of the base layer: the aggregate layer was compacted was compacted with 5 passes with 12.6 t dynamic roller, in accordance with the Finnish road construction guidelines (InfraRYL Table T1).

Figure 2. Installed geosynthetic samples for reinforcement/stabilisation function. Compaction of base layer.

To avoid additional damage to the samples during the recovery of the geosynthetics, a vacuum/sucking lorry was used. The first 20 cm of the base crushed rock layer were removed by careful use of an excavator. The remaining 10 cm of the base crushed rock layer was successfully removed by the vacuum lorry. Figure 3 shows the process of recovering the geosynthetic products by sucking the material off the geosynthetics.

Figure 3. Vacuum lorry and system for sucking of material from the geosynthetics.

2.2.2 *Filtration*

Similarly for filtration, the effects of installation at low temperatures on the geosynthetics in a trench were checked. The 4 geosynthetics were placed directly on the local native soil which was frozen. The trench was filled with the same 0/56 crushed rock as for reinforcement/stabilisation which was compacted according to the Finnish road construction guidelines (InfraRYL Table T1). In order to take account of possible different loads when backfilling the trench, the drop height of the aggregate was varied (1.0 m & 2.0 m). In order to minimize positional influences, each product was cut in half and installed at two different locations along the trench. Filling aggregate crushed rock 0/56 mm had a temperature of approx. −6 °C and temperature of about −12 °C was recorded on the local native soil. After filling the trench, compaction was done with a vibration plate (Figure 4).

Figure 4.   Filtration trench: Backfilling and compaction of upper layer.

The products were then carefully removed according to same procedure as in paragraph 2.2.1. Tensile strength & strain and characteristic opening size were determined on virgin and retrieved samples.

2.2.3 *Drainage*

To obtain site realistic damage behaviour during placement and compaction of materials, specifications based on Finnish guidelines for road construction were used for the field conditioning. The 2 geosynthetic were placed directly on the frozen local native soil. Before installing the geosynthetic layer, temperatures of about −12 °C were recorded on the sub-grade layer. In order to minimize positional influences, each product was cut in half and installed at two different locations along the field test. After installation of the geosynthetics, a sub-base layer consisting of 30 cm crushed rock 0/56 was placed with a tipping height out of the excavator bucket of approx. 1.0 m. After installation, the sub-base layer was compacted according to the Finnish road construction guidelines (InfraRYL Table T1). During the compaction process the sub-base aggregate had a temperature of about −6 °C.

The vacuum/sucking lorry was used similarly as previously described to avoid additional damage to the samples during the recovery of the geosynthetics. Figure 5 shows the products before the top aggregate layer was placed and the sucking of the backfill aggregate above the products.

Figure 5.   Installed geosynthetic samples with drainage function and recovery of the drainage composites.

2.3 Laboratory work

In addition to the tests realized in laboratory on the field samples presented in 2.2, tests were performed on virgin samples at different temperatures. The virgin products' mechanical characteristics were tested at −20 °C, −10 °C, 0 °C and + 20 °C. The specimens were cooled down at least one hour before testing these characteristics. The cooling chamber was only opened to place a new specimen on the testing machine. After closing the door of the cooling chamber, the testing was started when the temperature inside the chamber reached the required temperature again.

The results of these tests at different temperature show that mechanical strength, tensile stiffness, and compressive strain is significantly increased with the reduction of the temperature (0 °C to −20 °C) when tested in the laboratory: e.g., with a reduction in temperature from + 20 °C to −10 °C, the average tensile strength of all products tested $\geq$ + 40 %. It shall be noted that similarly the surrounding soil mechanical properties increases under the same reduction of temperature.

Previous experiences from Nordic construction sites had shown significant damage on junctions on one type of geogrid. Accordingly, the project included an intention of developing a laboratory performance test to evaluate this type of damage.

Summary of laboratory tests performed for the different functions is presented in Table 1.

Table 1. Tests performed in laboratory.

Reinforcement/ stabilisation	characteristic(s)	sample tested	Temperature			
			−20 °C	−10 °C	0° C	20° C
Kemi	Tensile test (20 cm)	damage (in situ) (test)		x		(x)
		reference				x
Laboratory	Tensile test (rib & junction)	damage (dynamic impact)	x	x	x	x
		virgin	x	x	x	x

Filtration	characteristic(s)	sample tested		Temperature			
				−20 °C	−10 °C	0° C	20° C
Kemi	Tensile test (20 cm)	damage (in situ) (test)	Drop height 1.0 m		x		(x)
	Opening size (0_{90})		Drop height 2.0 m		x		(x)
		reference					x

Drainage	characteristic(s)	sample tested	Temperature			
			−20 °C	−10 °C	0° C	20° C
Kemi	Tensile (20 cm) Compression Waterflow capacity	damage (in situ) (test)		x		(x)
Laboratory	Compression strength/ strain a compression strain (1 MPa)	reference				x
		virgin	x	x	x	x

3 OVERALL CONCLUSIONS AND PLAN FOR IMPLEMENTATIONS

The ROUGH project allowed to bring the following important conclusions for the geotextiles and related products tested during the full-scale experiment, if they are correctly

designed for a positive temperature (e.g., + 20 °C) for the defined geotechnical conditions of installation (type of soils, drop height, compaction, etc.), no additional installation damage is observed on the essential characteristics when the products are installed under the same conditions at −10°C:

- tensile strength and tensile stiffness for reinforcement/stabilisation,
- robustness factor and characteristic opening size for filtration,
- water flow capacity for geosynthetic drainage composites.

The field test in Kemi did not reveal similar types of junction-damage on the grids installed as previously experienced. The susceptibility for this type of damage is likely to be heavily influenced by the polymer type and additives and the production procedure. The result from the ROUGH-project is valid for the geosynthetics tested during the full-scale experiment in Kemi and for the products of the same family (same production process, same polymer, same function).

The writing of Guideline on the "Use of GeosyntHetics in Nordic conditions" is now under process and should be published within the next months by the Nordic country's authorities.

Ganna Volodymyrivna Zhurba
Euroizol Geosynthetics LLC, Ukraine

ABSTRACT: The territory of the airport is located on the watershed of the two big rivers. At this object, loess soils have a predominantly solid and semi-solid consistency with small surface layers of refractory consistency to a great depth.

To ensure the stability of the embankment, the upper soil layers with minimal bearing capacity must be withdrawn at a depth up to 1.5 m. To ensure waterproofing and achieve the design value of the coefficient of subgrade reaction on the surface in 74 MN/m^3 under the designed airfield pavement is arranged a layer of stabilized soil and an additional layer of bentonite mats. To separate the concrete layers, use non-woven polypropylene thermally reinforced geotextile.

The paper presents the results of calculations of the design of the aerodrome pavement by the finite element method. It provides a rational decision for the design and comparative analysis with other structures.

1 INTRODUCTION

The use of geosynthetic materials effectiveness in the construction of highways and linear artificial structures is confirmed by many years of practice.

The relevance of their use has significantly increased due to the growing cost of production and logistics of traditionally used inert materials. The wide use of geosynthetic materials in road and airfield construction is caused by their high physical and mechanical characteristics: strength, resistance to the influence of climatic and hydrogeological factors, durability, and environmental safety.

2 REVIEW OF RESEARCHES

In Ukraine, loess soils are widespread mainly in the steppe and forest-steppe, where it is the parent base for chernozem. Loess soils occupy 65–70% of the territory and mainly on floodplain and watershed terraces of rivers and the airport is located on the watershed loess plateau of two large rivers.

The deepest layers of loess are in China, so existing problems with weak soils were solved using geosynthetics in such works [1].

J. Giroud, Ji Han, and L. Noirey laid the foundations for the use of geosynthetics in road and airfield structures [2–3]. The investigations of G. Zornberg gained a wide development of basic test methods [4]. The problem of construction on weak soils, particularly loess soils, has always existed. Its solution was dealt with by world scientists, achieving great success in these fields [5–7].

3 PROBLEM STATEMENT, THE GOAL AND THE TASKS

The problem with loess soils is their behavior in case of saturation with water. Soils change their physical and mechanical properties, and acquire subsidence properties. According to the SNiP 2.05.08-85Aerodromes, the allowable subsidence is no more than 2.0 cm during the entire period of operation (20 years). That is why ensuring the stability of the soil layers should be ensured by geosynthetic materials in view of their durability.

The total thickness of loess soils exceeds 30 m. Groundwater wasn't detected. However, pavement water collected on a large area and by a large number of communications make a potential threat to the breakthrough and wetting of the loess stratum and subsequent subsidence.

The northwestern part of the existing airport is characterized by a large number of water-bearing communications that are in poor condition. This is confirmed by the dome-shaped rise of the water-table in this area in comparison with the entire territory of the airport.

The purpose of this paper is to ensure the bearing capacity of airfield pavement on loess sediment soils by using geosynthetic materials.

In order to fulfill the set goal, the following tasks were selected:

(1) Determination of physical and mechanical properties, strength and deformation properties of soils, as well as the presence of physical and geological processes, phenomena and causes of their formation based on laboratory and field research data.
(2) Calculation of the coefficient of subgrade reaction of the soil base for the use of geosynthetic materials in various options.
(3) Calculation of settlement of airfield pavement under the main undercarriage of the calculated aircraft load from the waterproofing of the ground base.
(4) Development of solutions to ensure the bearing capacity of the airfield pavement and the embankment on weak loess soil stability using geosynthetic materials.

4 THE SOURCE MATERIALS CHARACTERISTICS

The source materials analyzed included obtaining the engineering and geological characteristics of the territory when the following types of work were carried out, such as collection, analysis, and summarization of past years' data and testing the area by the dynamic sounding method to determine the normative soil characteristics and compare them with the data of engineering and geological investigations. Characteristics of soils were determined (Table 1).

The main problem with the arrangement of the airfield pavement of the airport is their direct location on a thick layer of loess soils: GTS-3, light dusty clay loam, heavy with average depth of the occurrence is about 4.5 m, and the GTS-4, sandy loams, located below with average depth is about 8.0 m. These soils normally fall into the layers of soil that can be compressed (Hc) during airfield exploitation. Their initial subsidence pressure is estimated as 0.05 MPa on average for GTS-3a and for GTS-3b it's 0.10. The initial moisture content of subsidence for all four types of soils is 19%, which is much higher than the natural moisture content of these soils.

The total subsidence under the natural pressure of loess loam and sandy loam along the wells varies from 7.8 cm to 43.4 cm. The thickness of the subsiding layer varies from 9.7 m to 23.0 m

5 FIELD STUDIES OF THE SOIL BASE AND ESTABLISHING REQUIREMENTS FOR GEOSYNTHETIC MATERIALS

Field surveys of the upper part of the engineering-geological section state were carried out by the method of dynamic probing. The essence of this method is that during the sounding, soil's penetration resistance with the indicator (the tip) is determined, which is an assessment of their bearing capacity. In general, 28 boreholes were drilled to a depth of 4.50 m.

Based on the results of field surveys, the following conclusions were made:

(1) The surface layer of soil is represented by light dusty loam GTS-3, which is covered from the surface by a thin layer of fertile soil up to 1.0 m thick.
(2) The advantages of natural conditions, which ensure the semi-solid state of GTS-3 soil, which mainly constitutes the natural soil base of airfield pavement, have been revealed. Therefore, it is possible to limit its excavation only to a depth of 3.0 m from the surface to remove individual inclusions of soil layers of rigid plastic consistency.
(3) Before its compaction, the exposed surface must be plowed to a depth of 0.40...0.5 m and then mix it and compacted with the value of the compaction coefficient $K_u \geq 0.98$ (the density of the soil skeleton is not less than 1.80 g/m3). The following layers of GTS-3 soil, up to the base of the airfield pavement, should also be compacted to the value of the compaction coefficient $K_y \geq 0.98$ layer by layer (0.20 – 0.25 m) with a density of dry soil in the range of 1.80 – 1.85 g/m³.
(4) The normative characteristics of soils have been clarified, and a soil passport has been established.

To ensure the waterproofing properties of soils and their reinforcement, the use of geosynthetic materials is proposed. Their technical characteristics are given in Table 2.

6 THE COEFFICIENT OF SUBGRADE REACTION

Various options for ensuring the load-bearing capacity of the soil base by strengthening the soil or reinforcing it with geosynthetic materials were considered to obtain the coefficient of subgrade reaction K_{se} of at least 74.0 MH/m³ was calculated according to the formula:

$$K_{se} = \frac{K_{s1} + K_{s2} \cdot \alpha_2 + K_{s3} \cdot \alpha_3}{1 + \alpha_2 + \alpha_3},$$

(1)

where $\alpha_2 = \frac{t_2[1.6D_r-(t_1+0.5t_2)]}{t_1(1.6D_r-0.5t_2)}$; $\alpha_2 = \frac{t_2[1.6D_r-(t_1+t_2)^2]}{t_1(1.6D_r-0.5t_2)}$; K_{s1}, K_{s2}, K_{s3} – calculated values of the coefficient of subgrade reaction, MH/m^3, respectively to the first (counting from above), second and third base layers from homogeneous soils and materials in different conditions, including draining and heat-shielding layers; t_1, t_2 – the thickness of the first and second layers of the base, respectively; D_r – the conventional diameter of the circle of load transfer to the base m, is taken to be equal to 3.6 m for monolithic pavements calculated for non-categorical and I load categories.

Options for calculating K_{se} with a layer of artificial soil base strengthening with cement and bitumen emulsion and a granular base reinforced with geosynthetic materials are considered (Table 3).

The total thickness is 1.4 m. The coefficient of subgrade reaction: $K_{se\ nonreinf}$ = 65.4 MH/m^3, $K_{se\ reinfor.layer}$= 74.1 MH/m^3.

7 CALCULATION OF SETTLEMENT OF AIRFIELD PAVEMENT UNDER LOAD

Aircraft for calculations: Boeing 777-300ER with characteristics are: gross weight – 352.44 t; tire pressure – 1.52 MPa; load on the main gear – 1629.34 kN; calculated load on one wheel – 265.63 kN; footprint radius – 0.237 m; the depth of the active soil zone – 6.63 m; vertical compressive stress – 0.13 MPa. The number of wheels on the main gear $n_k = 4$. The distance between the tires: $y_i = 0.70$ m, $x_i = 1.30$ m.

Stress from the soil's own weight, taking into account the condition of reaching 10% of the active vertical load (1).

$$\sigma_{vv}(z) = 0.1 \cdot \gamma_{cp} \cdot z. \tag{2}$$

where, γ_{cp} is the specific gravity of the soil, taken as 20 kN/m^3.

By equating the formulas (1) and (2), possible to find the depth of the active zone value by the method of iterations.

Graphically, the depth of the active zone is located at the intersection of the changes depending on the total compressive stresses $\sigma_{z(z)}$ and stresses from self-weight $\sigma_{vv(z)}$ (1).

Measures to eliminate the subsidence properties of the soil should be provided depending on the fulfillment of the condition.

$$\sigma_{zp} + \sigma_{zg} \leq p_{sc}. \tag{3}$$

where σ_{zp} – vertical compressive stress in the soil from operational load; σ_{zg} – vertical compressive stress from the soil's own weight and airfield pavement; p_{sc} – initial settling pressure, which is determined according to GOST 23161-78.

If condition (2) is satisfied, compaction of the upper layer of the subsidence soil to the requirements of the standards should be provided. If $\sigma_{zp} + \sigma_{zg} > p_{sc}$, it is necessary, in addition to compacting the upper layer, to provide for measures to eliminate the properties of the settlement soil to a depth that ensures the satisfaction of the condition:

$$s_{sc} \leq s_u. \tag{4}$$

where s_{sc} – the vertical deformation value of the base caused by the soil settlement, which is determined with humidity w_p at the limit of rolling; s_u – the limit value of the vertical deformation, which is accepted according to the norms, is 0.02 m.

The obtained values of the theoretical settlement and the settlement are 1.92 cm, which is less than the permissible settlement of 2.00 cm. That is, the proposed construction with the arrangement of the soil-cement layer and the replacement of 1.50 m of loess subsidence meets the requirements for deformations.

8 DESIGN AND CALCULATION OF THE AIRFIELD PAVEMENT

To accomplish this task, the following steps were taken:

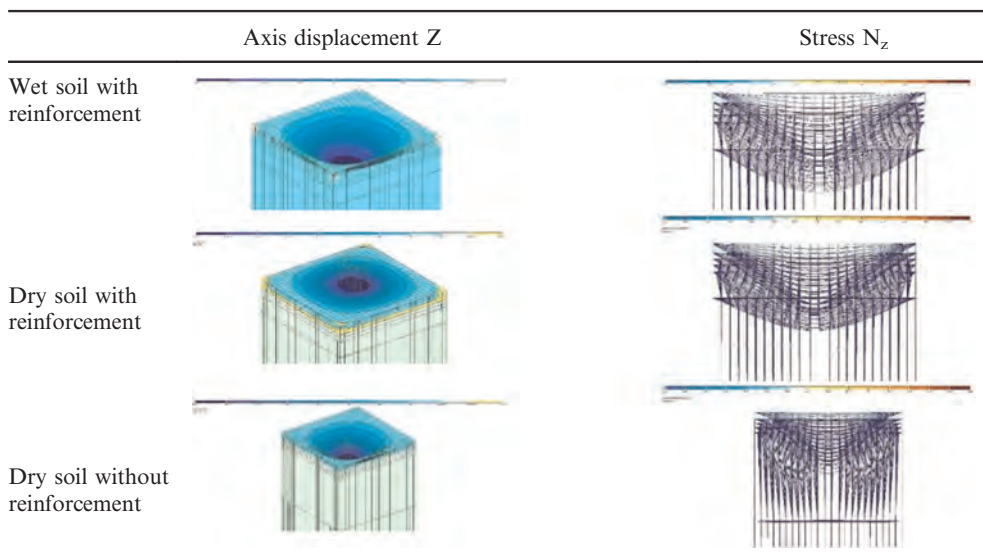
– development of variations for airfield pavement;
– calculations and comparative analysis of obtained results for the airfield surface;
– generating conclusions and directions for future researchers.

When choosing the optimal design version for the new airfield pavement, we were focused on ensuring such functions as ensuring the stability of high slopes on weak soils, ensuring the uniformity of the embankment settlement on weak soils and accelerating construction terms by using geosynthetic materials.

Structural solutions for use in strengthening the base soil reinforced with geogrid GM No 8 with a strength of 200/200 kN/m and waterproofing the base with bentonite mats GM No 4 for the high-speed runway pavement are recommended. Technical decision consists: Concrete class Btb 4.0/5.0, $t_1 = 0.40$ m; GM No 1 (to separate the layers of the concrete pavement); Concrete B 5.0/75, $t_2 = 0.30$ m; Sand cement with optimal mixture M 75, $t_3 = 0.20$ m; Soil cement M 40 mixed with a milling machine on site, $t_4 = 0.22$ m; Rubble – sandy mixture C-5, $t_5 = 0.24$ m, treated with a minimum amount of bitumen cationic emulsion (1.50%) or rubble – sandy mixture C-5 with pouring of bitumen emulsion on the surface with a consumption of 1.50 l/m^2; GM No 8; Soil (loam or sandy loam); GM No 4; Compacted ground base of airfield pavement.

To provide additional waterproofing and achieve the calculated value of the coefficient of subgrade reaction (k – value) on the surface of 74 MN/m^3, a layer of stabilized soil and the additional layer of bentonite mats with resistance to pH fluctuations are laid under the designed airfield pavement.

There are not any standards and norms for waterproofing with geosynthetics that are suitable specifically for airports' pavement. Therefore, it is necessary to rely on the EN 15382 standard for products used in transport infrastructure.

When comparing geomembrane GCL with conventional GCL, there are two parameters to consider: chemical stability and water resistance (according to the ASTM D 5887 standard).


The modelling of the stressed-deformed state of the airfield pavement and soil was made in several software packages. It is allowed to use a simplified mathematical model of the soil base, taking into account the fact that the proportionality coefficient between the positive deflection of the plate and the reaction of the base is a variable value and depends on the coordinates of the point of the middle surface of the pavement (node), in which the deflection and the reaction of the base are determined:

$$q(x^2 x^3) = -K(x^2, \quad x^3) \cdot w. \tag{5}$$

where $q(x^2 x^3)$ – reaction of the soil base; $K(x^2, \quad x^3)$ – proportionality factor function (the coefficient of subgrade reaction); w – positive deflection at the given point along the normal to the plate surface in the deformed state.

The results of stress-strain state calculations in the Lira CAD software complex are shown in Table 4.

Table 4.   The results of stress-strain state calculations.

	Axis displacement Z	Stress N_z
Wet soil with reinforcement		
Dry soil with reinforcement		
Dry soil without reinforcement		

9 CONCLUSIONS

According to the type of soil conditions, the site belongs to the second type due to subsidence. Therefore, when designing several measures are provided that exclude or reduce subsidence to acceptable limits, water protection and construction measures according to DBN A.2.2-1-2003.

Design method for rockfall protection embankments reinforced with geosynthetics

P. Rimoldi
Civil Engineering Consultant, Milan, Italy

N. Brusa
Tailor Engineering, Ferrara, Italy

ABSTRACT: Reinforced Soil Rockfall Protection Embankments (RS-RPE) reinforced with geosynthetics proved to be a safe measure for protecting people, structures and infrastructures from rockfall events, designed to absorb even very high impact energy (up to 30,000 kJ). RS-RPEs can be constructed in various shapes and sizes, with different reinforcements (geogrids, geotextiles, geostrips, steel wire meshes, etc.) and facing materials (wraparound, geocells, gabions, etc.). The Authors have developed a new analytical design method for RS-RPE which consider the effect of all the variables playing a role in the resistance to penetration on the uphill face and the resistance to extrusion on the downhill face, in order to finally compute approximate yet consistent values of the penetration depth and of the extrusion length; hence the designer can quickly try different solutions and finally select the best combination of design variables which afford to respect all design limits and Factors of Safety. Back analyses of full scale tests are used to validate the presented design method.

1 INTRODUCTION

In the present article, the Authors present an original design method for Reinforced Soil Rockfall Protection Embankments (RS-RPE) subject to high energy rock impacts, whose framework was previously defined by Rimoldi & Brusa (2021).

By using the proposed method, the designer can quickly set all the characteristics of the RS-RPE, including geometry, facing system on the uphill face, reinforcement properties and vertical distribution, in order to respect all the ultimate and serviceability limit state conditions.

2 FRAMEWORK FOR THE IMPACT ANALYSIS

The most critical part of the design procedure, and the most underdeveloped, concerns the dynamic analysis of the design impact, with the evaluation of the penetration depth on the hill side and the extrusion length on the valley side.

Referring to the available full scale tests and numerical models, the Authors propose the following framework for the optimised design of RS-RPE through the dynamic impact modelling:

- As the impact is an impulsive action by nature, the falling rock transfers the momentum of the motion to the embankment. The impulsive force that is instantly applied to the embankment depends on the mass, the shape and the velocity of the boulder, on the mass,

geometry, geotechnical properties and construction method of the embankment, and on the number, position, layout and technical characteristics of the reinforcing geosynthetics.

- The wave energy developed by the impulsive force applied to the embankment propagates in a quasi spherical shape; as consequence it means that below the rock footprint in the uphill face the soil is highly compressed, while above the impact footprint, the soil is subject to upward vertical stresses, which would lift the mass of soil above if reinforcement is not present.
- The soil mass adjacent to the rock impact footprint results in compression while, after a certain distance from the first contact point, the acceleration applied to the soil mass produces an outward horizontal movement equivalent to a downhill directed "tensile" force being applied to the soil; at the limit between the compressed and the "tensioned" zone, cracks are formed; the soil mass is therefore separated into two parts.
- The tensile and pullout resistance of the reinforcement contribute to resist the outward displacement.
- Reinforcement layers are able to "guide" the impact energy, so that the initial spherical shape is soon converted into a horizontal cone; outward displacements occur within this cone, leaving the remainder of the soil mass in place.
- Hence only the horizontal component of the impact velocity is relevant for the design of reinforcement.
- Reinforcement layers, made of geogrids, geostrips or geotextiles, can spread the impact load along the embankment axes in both transversal and longitudinal directions.
- The stresses generated by the impact wave energy have an important component in the direction parallel to the length of the embankment, beyond the compressed zone at the uphill face: this justifies the design option of placing reinforcement layers in such direction.
- The reinforcement layers are subject to high tensile forces, but the impulsive nature of the active force allows to not consider at all any creep effect in the reinforcements, and to consider a higher dynamic tensile modulus than the static one.
- Very strong and/or repeated impacts can produce very large outward displacements, which can bring to the pullout failure of the wrapping length of the reinforcement. Hence, this length shall be designed to be much longer than in static conditions; connection of the front face and back face reinforcement, that is a back-to-back design, is highly recommended.

Such evidence translates into the following rational assumptions:

- The downward vertical component of the impact load is resisted by the embankment fill and may have an effect only on the bearing capacity of the foundation and the global stability of the structure and of the downhill slope, while the upward vertical component of the impact load is resisted by the fill confined by reinforcement layers. As consequence, the soil mass involved in the impact-extrusion mechanisms is limited by the horizontal planes tangent at the top and bottom points of the impacting boulder (Figure 1.a), and laterally by two planes diverging from the boulder lateral limits according to an impact load spreading angle, α (Figure 1.b).
- The impacting boulder is assumed to have a spherical or cubic shape, e.i. dimension D (see Figure 1.b), that can be easily computed by equalizing the kinetical energy of the equivalent boulder to the given impact energy E_0:

$$E_0 = 1/2 V_m (\gamma_m / g) v_b{}^2 \tag{1}$$

where V_m is the volume of the boulder (assumed either as a sphere of diameter D or a cube with size D), γ_m is the unit weight of the boulder, v_b is the design impact velocity of the boulder, and g is the gravity acceleration.

The following assumptions are made for the compressed zone at the upstream face:

- Geosynthetic reinforcements cannot work in compression; hence, reinforcement placed in the direction of the impact ("transversal reinforcements") cannot contribute to penetration resistance.
- Only reinforcements placed along the axis of the embankment ("longitudinal reinforcements"), if present, can contribute to resist the impact load through the tensioned-membrane effect generated by the deformation of the reinforcement, like the cord of an arch (Figure 2.a). This effect can be considered also to increase the load spreading angle, α.
- The soil resists the impact load (see Figure 2.b) through its coefficient of viscous damping, C_s, and its elastic resistance with an overall elastic coefficient, K_{tot}, which is given by the sum of the elastic coefficient of the soil, K_s, and of the elastic coefficient of the geosynthetic reinforcements, K_g (as said, provided only by the longitudinal ones, if present).

Figure 1. The impact-extrusion mechanisms is limited by (a) the horizontal planes tangent at the top and bottom points of the impacting boulder and (b) by the lateral planes diverging according to the load spreading angle α; (c) the rock mass movement and RS-RPE deformations are contrasted by both the transversal and the longitudinal geogrids.

- The elastic coefficient of the soil, K_s, is assumed to be proportional to the Winkler modulus, M_w, of the compacted fill; while the elastic coefficient, K_g, provided by the longitudinal reinforcements, is assumed to be proportional to their ultimate tensile strength, T_u.
- The upstream facing system contributes to the elastic passive resistance through a facing coefficient, C_g, which modifies the elastic coefficient of the soil, K_s, and the coefficient of viscous damping, C_s.
- The coefficient of viscous damping, C_s, is assumed to be proportional to the damping ratio, ζ, of the compacted embankment fill or of the cushioning layer placed on the uphill face.

The values of the load spreading angle α and of the facing coefficient C_g should be evaluated from the results of full scale impact tests on RS-RPE of similar configuration to the one under consideration. Another way of setting α and C_g is to perform a back calculation of a known impact on the specific system under considerations, using the framework herein presented, where the parameters are modified by trials and errors starting from realistic initial values (see section 3).

If no specific full scale tests nor known impact events are available, the default values in Tables 1 and 2 are proposed: in Table 1 the load spreading angle α varies as a function of the reinforcement layout, of the number N_G of reinforcing layers within the height D of the diffusion cone (see Figure 1.a), and of the type of reinforcement (with open mesh allowing soil interlocking, like geogrids and steel wire meshes, or without open mesh, like woven geotextiles or geostrips). In Table 2 the facing coefficient C_g varies as a function of the cushioning capacity of the facing system, where the simple wrap-around facing system is assumed with $C_g=1.0$.

Facing system	C_f
Wrap-around	1,00
Gabions with coarse fill	1,50
Sand filled bags	1,30
Geocells	1,20
Tires	1,35

Taking into account the above listed assumptions, the penetration depth on the upstream face can be computed according to the method presented by Carotti *et al.* (2000), based on the theory of totally anelastic impact, through the lumped mass model made up by a 1-DOF (one degree of freedom) oscillator, characterized by a viscous damper and a spring (Figure 2.b), which undergoes a deformative cycle with angular frequency, ω. The lumped mass, m, of the 1-DOF oscillator is the mass m_s of the soil contained in the cone as previously identified (see Figure 1.a and 1.b) plus the mass of the boulder m_m. The masses m_s and m_m are equal to the respective weights W_s and W_m divided by the gravity acceleration, g. The equations for calculating the energy absorbed by soil deformation on the uphill side, E_p, and the transmitted energy, E_s (which produces the downhill extrusion), as shown in Figure 1.a, are the following:

$$E_0 \ = \ E_p \ + \ E_s \ = \ E_p \ + \ E_0 \cdot \ E_s / \ E_0 \tag{2}$$

$$E_s / \ E_0 \ = \ m_m / \ (m_m \ + \ m_s) \ = \ W_m / \ (W_m \ + \ W_s) \tag{3}$$

While the weight W_m is an input data from the risk analysis, the weight W_s can be easily calculated from the geometry of the problem (see Figure 1.a and 1.b).

Considering the viscous work of the 1-DOF oscillator during a deformative cycle, the maximum displacement of the 1-DOF oscillator, which is equal to the penetration depth, L_p, is:

$$E_p \ = \ 1/4(\pi \ \cdot \omega \cdot \ C_s \cdot L_p{}^2) \tag{4}$$

The circular frequency ω is calculated as:

$$\omega \ = \ (K_{tot} / \ m_{tot})^{0.5} \ = \ \left[g \ \cdot \ (K_s \ + \ K_g) \ / \ (W_m \ + \ W_s) \right]^{0.5} \tag{5}$$

The dumping coefficient of the soil C_s can be evaluated from the dumping ratio ζ of soil:

$$C_s = 2 \cdot \zeta \cdot (K_{tot} \cdot W_s/ g)^{0.5} \tag{6}$$

where ζ may be assumed, in this case of a single dynamic cycle and large strains, in the range $0.10 \div 0.20$ for granular soil, while if the cushioning system on the uphill face includes sand–rubber or gravel–rubber mixtures ζ may be assumed in the range $0.20 \div 0.30$; for geocell cushioning system ζ may be assumed equal to 0.02.

The 1-DOF oscillator model allows a calculation of the part, E_p, of the impact energy, E_o, which is dissipated to stop the boulder through deformation, while the residual energy, E_s, is assumed to spread downstream of the penetration depth, generating the tensioned zone that produces the extrusion on the valley side of the embankment (see Figure 2.a).

The following rational assumptions are made for the zone between the penetration depth and the downstream face:

- The fill resists the extrusion movement through its frictional stresses developed on the top and bottom horizontal surfaces of the extrusion cone, that is with the frictional forces S_t and S_b shown in Figure 1.a, given by the integral of the direct shear stresses τ_{ds} on the two surfaces, with:

$$\tau_{ds} = f_{ds} \cdot \sigma_v \cdot \tan\varphi_s \tag{7}$$

where f_{ds} is the direct shear factor considering the effect of first detachment friction under fast applied loads, σ_v is the vertical stress, and φ_s is the friction angle of the fill.
- The geosynthetic reinforcements confine the fill and increase the load-spreading angle, α, which depends on the type of reinforcement, on the number of reinforcements within the height of the extruded cone, and on the presence or not of the longitudinal reinforcements (Table 1).
- In the tensioned zone, the transversal reinforcement resists extrusion by pullout resistance between the downstream facing and the penetration depth, that is with the pullout forces F_{po} shown in Figure 1.a. The pullout resistance can be activated only if reinforcement is properly wrapped around the downhill face with adequate wrapping length or connected to facing elements, which can transfer the pullout force to the whole fill thickness between two consecutive reinforcement layers. The pullout force provided by each reinforcement within the height D of the diffusion cone is calculated as the integral of the pullout stresses τ_{po} on the length of reinforcement between the crater and the downhill face, with:

$$\tau_{po} = 2 \cdot f_{po} \cdot \sigma_v \cdot \tan\varphi_s \tag{8}$$

where f_{po} is the pullout factor for the specific reinforcement with the specific fill, σ_v is the vertical stress on the considered surface, and φ_s is the friction angle of the fill.

The total pullout force F_{po} is obviously the sum of the pullout forces provided by all reinforcement within the height D of the diffusion cone.

- Since pullout resistance cannot increase indefinitely and the extrusion length strongly depends on the reinforcement deformation, the pullout force shall be produced with limited tensile elongation; hence, the pullout resistance is assumed to be limited to the tensile strength at 2 % elongation, $T_{2\%}$ (kN/m), of the transversal reinforcements.
- Given the impulsive nature of the impact load and the consequent impulsive state of tension in the extrusion zone, a reduction factor for impulsive conditions, RF_{imp}, may be applied to the pullout force, which is calculated with the pullout factor, f_{po}, valid in static conditions. On the other hand, like for first detachment friction, under impulsive conditions the initial pullout resistance may be even higher than in static conditions, hence

RF_{imp} may be assumed to be > 1.0. Until full scale testing of pullout resistance under fast applied loads will confirm which is the real mechanism, it is prudent to assume that RF_{imp} is equal to 1.0.

- The residual energy, E_s, is assumed to be equal to the work done by the friction forces, S_t and S_b, and the total pullout force, F_{po}, which allows a calculation of the extrusion length, L_v, on the valley side of the embankment (Figure 1.a):

$$E_s = (S_t + S_b + F_{po}) \cdot L_v \tag{9}$$

Following the above described method, the impact analysis allows the setting of the required geometry of the embankment (see Figure 1.a), such as the height, H, the crest width, L_u, the slope angles on the mountain side, β_m, and on the valley side, β_v; and the required layout of reinforcement (type, strength, vertical spacing in transversal and longitudinal directions), by checking the following SLS (Serviceability Limit State) conditions, in order for the impacted embankment to be repaired with simple maintenance works:

- The maximum allowable penetration length shall be less than 50 % of the embankment width at the bounce height of the impacting boulder.
- The maximum allowable extrusion length shall be less than 20 % of the embankment width at the bounce height of the impacting boulder.

Once established with the dynamic analysis, such geometry and reinforcement layout shall be checked for internal, external and global stability under dynamic conditions, considering the accidental load of the impact force as an equivalent static force, F_{imp} (kN), applied horizontally in the centre of impact (Figure 3), calculated as the sum of the equivalent penetration force, F_p (kN), and of the equivalent extrusion force, F_v (kN), simply evaluated as energy / movement:

$$F_{imp} = F_p + F_v = (E_p / L_p) + (E_s / L_v) \tag{10}$$

Figure 3.   Evaluation of the equivalent static force.

3   BACK ANALYSES

3.1   *Trento test Nr 2*

Peila et al (2002) reports the results of full scale tests performed at the testing facility set up near Trento (Italy), shown in Figure 4.

Five tests were performed and we report the back analysis of test Nr 2, where the RS-RPE had the cross section shown in Figure 4: it can be noted that the RPE was built with wrap-around facing and that reinforcement was provided both in transversal and longitudinal directions. The test was performed by impacting a concrete boulder with weight of 87 kN. In test Nr 2 the translational velocity of the boulder at the moment of the impact was estimated as 31.3 m/s, and the kinetic energy of the block at the moment of contact was approx. 4,354 kJ. On the hill side a crater was formed with a maximum depth

of about 1 m, while on the valley side a large extrusion displacement of approx. 0.90 m was observed. All input data and calculations for the back analysis of Trento Nr 2 test are reported in Table 3.

Figure 4.   Test setup in Trento and cross section of the RPE built for test Nr 2 (modified from Peila *et al.* 2002).

3.2   *Maegawa test Nr 3*

Maegawa et al (2011) report about full scale tests that were carried out in a quarry in northern Japan. At the site, two feasible rock-slope lanes, 37 m high with a slope of 42°, are available for rolling concrete blocks down the slope, as shown in Figure 5. The concrete blocks were individually launched by a backhoe to roll down the slope.

Eight tests were performed and we report the back analysis of test Nr 3, where the RS-RPE had the cross section shown in Figure 5: it can be noted that the RPE was built with a cushioning system on the uphill face, made up of 0.8 thick layer of 150 mm high geocells filled with mixed granular soil, and that reinforcement was provided both in transversal and longitudinal directions. The test was performed by impacting a concrete boulder with weight of 170 kN. In test Nr 3 the translational velocity of the boulder at the moment of the impact was estimated as 14.4 m/s, and the translational kinetic energy of the block at the moment of contact was 1,763 kJ. On the hill side a crater was formed with a maximum depth of 1.727 m, while on the valley side the extrusion displacement of 0.239 m was observed. All input data and calculations for the back analysis of Maegawa Nr 3 test are reported in Table 3.

3.3   *Discussion of back analyses*

The results reported in Table 3 show that the proposed method is capable of excellent modelling of high energy impacts on RS-RPEs, since both the calculated penetration depth and extrusion length are within $\pm$ 5 % of the measured values.

Modelling of wrap-around facing system (test Trento Nr 2) allowed to set the following critical parameters:

Dumping coefficient of reinforced fill   Cs=   800   [kN·s/m]
Damping ratio of uphill facing system ζ=   0.10   [-]
Winkler modulus of reinforced fill   Mw=   8,000   [kN/m3]
Angle of spreading of the impact α=   45   [-]
Coefficient of facing resistance   Cf=   1.0   [-]

Modelling of the geocell facing system (test Maegawa Nr 3) has shown that with a cushioning system the correct crest width of the RS-RPE shall include the thickness of the cushioning system itself; moreover, geocell fill offers a "soft" cushioning layer, yet

it affords to widen the spreading angle of the impact, α; hence for such facing system the following critical parameters apply:

Dumping coefficient of reinforced fill	Cs=	200	[kN s/m]
Damping ratio of uphill facing system	ζ=	0.02	[-]
Winkler modulus of reinforced fill	Mw=	3,000	[kN/m3]
Angle of spreading of the impact	α=	55	[-]
Coefficient of facing resistance	Cf=	1.2	[-]

4 CONCLUSIONS

A new design procedure for RS-RPE has been described: the analysis of available full scale impact tests and numerical analyses allowed to develop an optimised and rational method for the dynamic analysis of RS-RPE under rock impacts.

The proposed method affords to calculate the penetration depth and the extrusion length caused by the impact of the design boulder, with its mass, velocity, bounce height, and kinetic energy, on a given layout of the RS-RPE.

The back analysis of full scale tests available in literature allowed to check that the method provides very precise and reliable results; moreover, the parameters for specific facing systems have been checked and validated.

A simplified displacement-based hybrid approach for the design of geosynthetic-reinforced earth walls

A. Galli

Department of Civil and Environmental Engineering, Politecnico di Milano, Italy

ABSTRACT: Design criteria for geosynthetic-reinforced earth walls are usually based on simplified limit equilibrium approaches, taking into account ultimate conditions both with respect to soil strength and reinforcements' resistance (tensile and pull-out). Convenient values of partial safety factors are then introduced to get a safe structural dimensioning. The stability of internal failure mechanisms is however based on the mobilization of soil-geosynthetic interface shear stresses and the reinforcement action should rather be computed as a function of the current internal displacements within the wall. In the paper a simplified displacement-based hybrid approach is introduced, combining traditional limit equilibrium analyses of internal failure mechanisms together with displacement controlled non-linear pull-out analyses of the reinforcements. A consistent relationship between the safety factor and the performance of the wall (i.e. façade displacement) can then be derived, providing the designers of an objective tool to optimize the design choices and to run consistent structural safety checks.

1 INTRODUCTION

Geosynthetic reinforced earth walls (GRE) or mechanically stabilized earth walls (MSE) are acknowledged as efficient and economic solutions for supporting e.g. excavations, soil backfills and artificial embankments. The rapidity of construction, the possibility of using (or re-using!) local granular materials and the capability of accommodating large differential settlements, make them highly competitive with respect to traditional concrete walls and significantly reduce their environmental impact (see e.g. Basu *et al*. 2015). Sustainability issues and long-term resilience requirements are moreover fundamental aspects, since GRE usually involve large soil volumes and are often intended as long-lasting (or even permanent) geotechnical structures (Galli 2022). In this perspective, efficient and accurate operational design approaches, are key issues. Advanced numerical approaches (e.g., among others, Saran & Viswanadham 2018), however, are still largely time consuming and require advanced theoretical and computational skills to the users. Standard design procedures (BS 8006 2010; FHWA 2001; EBGEO 2003), on the contrary, are often based on oversimplified limit equilibrium approaches and disregard any consideration about the structure's performance (e.g. the façade displacements). They cannot then be considered fully consistent with the requirements of sustainable design criteria. Recent developments have however been proposed, in static conditions, e.g. by Wang *et al*. (2021), explicitly computing the value of the required geosynthetic tensile stiffness for a GRE wall. In seismic conditions, moreover, Gaudio *et al*. (2018) evaluate the expected wall displacements (co-seismic displacements), by adopting the kinematic approach of limit analysis. As pointed out by Galli and di Prisco (2019) with reference to slope stabilizing piles, these methods could however underestimate

the structure displacement in low seismicity areas, or miss the triggering of co-seismic displacements.

In the present paper, a simplified approach is adopted for studying internal failure mechanisms of GRE walls. The method is defined as "hybrid" since it combines an ultimate limit state approach for wall's internal failure mechanisms, with a displacement-controlled approach for the non-linear pull-out behavior of the geosynthetics. Inspired by the design of passive slope stabilizing structures (Galli & di Prisco 2013; Galli *et al.* 2017; Kourkulis *et al.* 2012) the method allows then to link the global factor of safety of the wall to the amplitude of its façade displacement, through the progressive mobilization of the stabilizing action in the reinforcements. In the following, the method will be described, and some numerical results on a simplified wall geometry will be parametrically discussed.

2 DEFINITION OF A HYBRID METHOD

Equilibrium equations for slope stability analysis require the driving action E (usually, the self-weight of the soil mass plus the possible external loads) to be equilibrated by the ultimate soil shear strength, R, mobilized along the failure surface and by the ultimate stabilizing action, A, provided by the stabilizing structure. Limit Equilibrium Methods (LEM) usually assume that all these terms are evaluated at their Ultimate Limit State (ULS), irrespectively of displacement compatibility conditions. In a hybrid method, on the contrary, the stabilizing action A is explicitly considered to depend on the soil displacement U, associated to the considered failure surface F, through a "characteristic curve" (Galli & di Prisco 2013; Galli *et al.* 2017). This allows to consider not only ultimate but also Serviceability Limit State (SLS) conditions for the soil-structure interaction. The governing equilibrium equation can general be written as:

$$E^F = R^F_{ULS}/F_S + A^F(U^F). \tag{1}$$

where a global factor of safety F_S is introduced as reducing factor for the soil strength. Equation (1) clearly highlights how in a hybrid method ULS conditions for soil strength are combined to SLS conditions for the soil-structure interaction, and represent a link between the F_S for the failure surface F and the corresponding amplitude of soil displacement. By solving equation (1) for F_S for any possible surface F, a family of curves can be derived, whose minimum envelope represents the actual $F_S - U$ relationship for the wall. These curves cannot however be considered a prediction of the on site displacement of the wall for assigned working conditions, but they only provide the designer of a consistent displacement estimation with respect to the required stabilizing action. They can be employed to objectively and rationally optimize the design and to run the required structural safety checks. An application of such hybrid method to GRE walls will be briefly outlined hereafter and some applications to real-like design cases will be presented.

2.1 *Stability of wall internal failure mechanism*

Stability of GRE walls requires in general to verify both external (i.e. sliding, toppling and vertical bearing failure mechanisms) and internal failure mechanism, these latter typically being associated to the pull-out and tensile response of the geosynthetics. External failure mechanisms will be here disregarded (they are in fact associated to rigid-body movements of the wall) and the attention will only be devoted to internal failure ones. Several failure mechanisms are in general recognized in Literature (single or two-blocks failure mechanisms, log-spiral failure mechanism, complex mechanisms; see e.g. Gaudio *et al.* 2018). Without the loss of generality of the proposed hybrid method, however, in the following only single-block failure mechanisms will be considered for a wall height H and a façade

inclination β to the horizontal, defined by planar failure surfaces F with an inclination θ to the horizontal (Figure 1a).

In this context, the driving action E^F corresponds with the component of the soil weight W along the direction θ, whilst the soil strength R_{ULS}^F corresponds with the limit soil shear strength T_L along the failure plane. The stabilizing action $A = A(U_h)$ is instead represented by the sum of the horizontal components of the tensile action mobilized in the geosynthetic layers at the intersection with the sliding plane. Its numerical evaluation will be briefly discussed in the following section. By imposing the vertical and horizontal equilibrium for the soil mass, and the failure criterion for soil along the sliding plane (a simple purely frictional criterion with friction angle ϕ'), it is possible to derive an explicit relationship between the F_S and the mobilized value of the supporting action A, depending on displacement U_h:

$$F_S = F_S(U_h) = \tan\phi' \frac{W\cos\theta + A(U_h)\sin\theta}{W\sin\theta - A(U_h)\cos\theta}, \tag{2}$$

where W also depends on θ, and, owing to the assumed single-block failure mechanism, the soil displacement field U is uniform within the soil sliding mass, with the horizontal and vertical components equal to $U_h = U \cdot \cos(\theta)$ and $U_h = U \cdot \sin(\theta)$, respectively, and $U_v = U_h \cdot \tan(\theta)$.
Figure 1. (a) Single block failure mechanism for a GRE wall; (b) pull-out interaction between soil and geosynthetic.

2.2 Geosynthetic pull-out behavior

The term $A = A(U_h)$ of equation (2) can be computed once the soil-geosynthetic pull-out behaviour is modelled as a function of the horizontal displacement U_h of the soil mass. To this goal, N horizontal layers of geosynthetic are introduced, each layer being discretized in M nodes and $M - 1$ finite elements (Figure 1b). Each element is assumed to behave elastically, with a constant tensile stiffness J and no compression and bending stiffness. The local pull-out interaction of each node of the geosynthetic (identified by the indices i, j for the sake of simplicity is modelled by means of elastic-perfectly plastic relationships (with interface stiffness $k^{i,j}$ and limit shear stress values $\tau_L^{i,j}$), as a function of the nodal relative displacement between the soil and the geosynthetic, $U_h^{i,j}$ and $u_h^{i,j}$, respectively. The first node of each geosynthetic has been instead considered as rigidly connected to the wall façade. By collecting the values of the tensile stiffness of each finite element into a global stiffness matrix $\boldsymbol{J}$, all the nodal soil and geosynthetic displacements into vectors $\boldsymbol{U}_h$ and $\boldsymbol{u}_h$, respectively, the global equilibrium to the horizontal translation of the N geosynthetic layers can be written as:

$$\boldsymbol{J} \cdot \boldsymbol{u} = \boldsymbol{k} \cdot (\boldsymbol{U}_h - \boldsymbol{u}_h - \boldsymbol{q}^p). \tag{3}$$

The left-hand term summarizes the tensile elastic behavior of the reinforcements, whilst the right-hand term represents the mobilized interface shear stresses. The term $\boldsymbol{q}^p$ collects in particular the values of the permanent (i.e. plastic) relative displacements triggered in the

nodes. The numerical integration of this term is obtained by applying the piece-wise linear integration technique proposed by Cocchetti (2002). Extensions of such numerical procedure to (i) more complex failure mechanisms, (ii) non-linear pull-out interface relationships with strain hardening or softening and (iii) large displacement membrane behavior can also be implemented.

3 DISCUSSION OF A NUMERICAL EXAMPLE

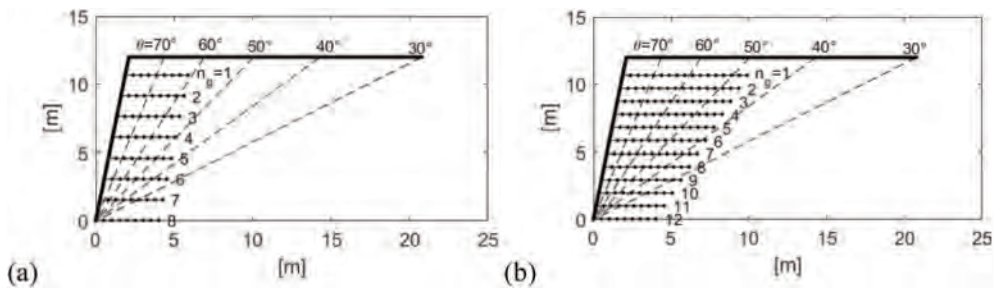
The hybrid approach outlined here above has been applied to the design of a GRE wall ($H =$ 12m and $\beta = 80°$). The soil is modelled as a uniform granular material (unit weight $\gamma =$ 20kN/m^3 and friction angle $\phi' = 30°$; zero pore water pressure is assumed). Two different geosynthetic disposals are considered, corresponding with a relatively weak and strong reinforcement, respectively. Disposal 1 consists of 8 equally spaced layers with a uniform length of 4 m (total cumulative length of 32m; Figure 2a), whilst disposal 2 of 12 equally spaced layers with a linearly decreasing length between 8 and 4 m (cumulative length of 72m; Figure 2b). In both cases, five failure surfaces are considered (angle $\theta = 30, 40, 50, 60$ and 70°), and the geosynthetic layers are discretized by means of finite elements 50cm long (64 and 144 finite elements for disposals 1 and 2, respectively), with a tensile stiffness $J =$ 1000kN/m. The limit values of the soil-geosynthetic interface shear stresses are computed according to a purely frictional law, depending on the effective normal stress on the geosynthetic. Pressure dependent effects have also been considered, by linearly decreasing the interface friction angle e from 38° to 30° between the top and the base of the wall, and by linearly increasing the interface stiffness from 555.6 kPa/m and 4950 kPa/m between the top and the base.


Figure 2.   Sketch of (a) disposal 1 and (b) disposal 2.

3.1 Evaluation of the characteristic curves

The characteristic curves $A = A(U_h)$ computed up to a maximum façade displacement $U_h =$ 50cm for the five considered failure planes both for disposals 1 and 2 are plotted in Figure 3a and b, respectively. The curves show a marked non-linear behavior for increasing values of U_h, with an increasing stiffness for increasing values of θ. For disposal 2, in particular, this effect is maximized for $\theta \geq 50°$, where no remarkable differences are observed among the characteristic curves since all the geosynthetics are activated.

3.2 Evaluation of system performance

The curves of Figure 3a and b can be numerically used in equation (3) to obtain the $F_S - U_h$ relationships, as shown in Figure 3c and d for disposals 1 and 2, respectively. The minimum

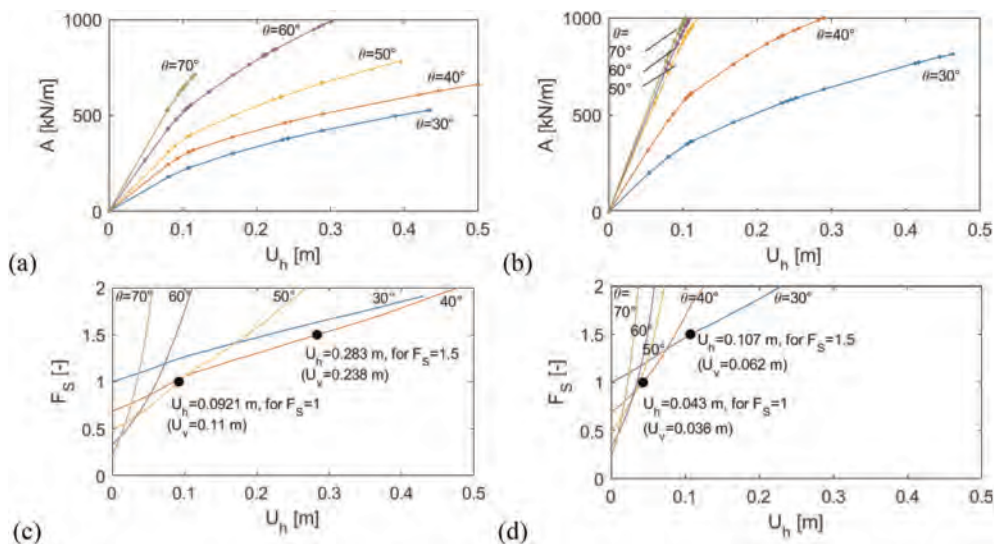
envelope of these curves represent the relationship describing the global performance of the wall, and they provide a useful displacement-based design tool for engineers. For a given geosynthetic disposal they allow in fact to estimate the displacement associated to the desired safety level, or, on the contrary, to optimize the choice and disposal of the reinforcements once design values of the safety factor and of the displacement are assigned.


Figure 3. (a-b) characteristic curves for disposals 1 and 2; (c-d) $F_S - U_h$ curves for disposals 1 and 2.

As an example, the two values $F_S = 1$ and 1.5 are highlighted, corresponding with a limit critical condition and with a usual "safe" design condition, respectively, for the internal stability of the wall. The results (represented as black circles) show that higher values of the F_S are associated to larger horizontal façade displacements, since higher values of the stabilizing action need to be mobilized. They also prove a marked difference in the system performance between the two chosen disposals (horizontal displacement of 92.1 and 283 mm for disposal 1, when considering $F_S = 1$ and 1.5, respectively; whilst 43 and 107 mm for disposal 2). The envelope of $F_S - U_h$ curves allows even to highlight the critical failure mechanism associated to each safety level, and, then, to retrieve an estimation of the possible extension and the entity of vertical settlement U_v of wall crest. In case of disposal 1, for example (Figure 3c) the critical failure mechanism changes from $\theta = 50°$ (for $F_S = 1$), to $\theta = 40°$ for ($F_S = 1.5$), with vertical settlements of the wall $U_v = 110$mm and 238mm, respectively; corresponding extensions of the failed zone vary instead from about 7.95m and 12.2m, respectively, from the wall crest. Similar considerations can be derived also for disposal 2 (Figure 3d; values are reported in the figure). As already outlined, however, these values cannot be considered a prediction of the on-site displacement of the wall. They only allow for an objective and rational method to compare different design solutions and, as it will be shown in the next section, to run consistent safety checks on the tensile geosynthetics behavior.

3.3 Estimation of tensile action in the geosynthetics

The numerical integration scheme briefly described in §2.2 permits also to evaluate the tensile internal action in the geosynthetic layers, once a consistent estimation of the horizontal

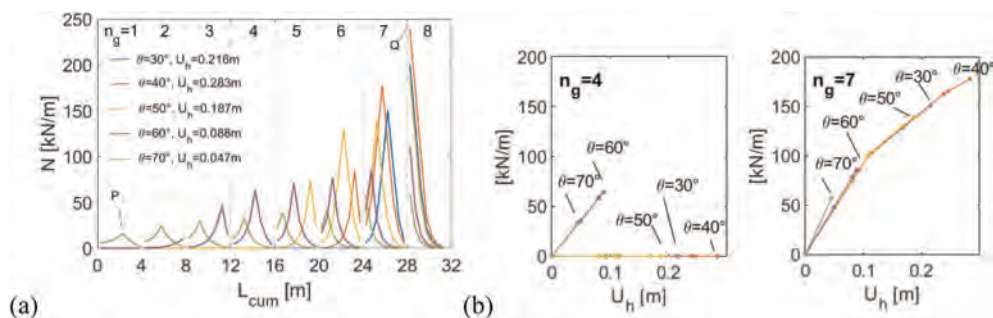
displacement associated to a specific value of F_S is derived for each failure mechanism. By imposing these displacement values in the numerical analyses, the resulting distributions of internal tensile force N can be straightforwardly derived.


Figure 4. Disposal 1: (a) Distribution of the tensile force N for the five considered failure planes (for $F_S = 1.5$); (b) evolution of the peak tensile force in geosynthetic layers $n_g = 4$ and 7.

With reference to disposal 1, and by assuming again the value $F_S = 1.5$, for example, the resulting distributions are plotted in Figure 4a as a function of the cumulative length L_{cum} of the geosynthetics (for the sake of clarity, the values of the horizontal displacement U_h for the five mechanisms read from Figure 3c are reported within the legend of the figure). For each layer the value and the location of the peak tensile force can be estimated, for each one of the considered failure mechanisms. For layer $n_g = 1$, for example, a maximum tensile force of 15.75 kN/m at a distance of about 2.25m from wall façade is observed for mechanism $\theta = 70°$ (point P of Figure 4a); for layer $n_g = 8$, a peak value of about 240 kN/m at the connection with wall façade is instead computed for mechanism $\theta = 40°$ (point Q). Being these tensile force distributions associated to the same value of the factor of safety, they represent equiprobable distributions, and their envelope can be used to perform the tensile safety checks on the geosynthetics.

For the sake of completeness, finally, for the same case represented in Figure 4a, the evolution of the peak tensile action into two representative geosynthetic layers ($n_g = 4$ and 7; the others are omitted for the sake of brevity) is plotted in Figure 4b against the horizontal façade displacement U_h. It is evident how layer 4 is activated only for failure planes $\theta = 60°$ and 70°, and how its mechanical response is still within the elastic regime; layer 7 is instead activated for all the failure planes, with a marked non-linear response. In both cases, however, assuming ultimate pull-out conditions would have led to a large overestimation of the mobilized tensile action.

4 CONCLUSIONS

A simplified displacement-based hybrid method has been presented with reference to the design of geosynthetic reinforced earth walls. The method is based on the evaluation of the mobilized soil-geosynthetic interaction forces as a function of the relative soil-geosynthetic displacements. It allows then to couple the value of the global safety factor of the wall (with respect to internal failure mechanisms) to a consistent evaluation of the wall performance (e.g. the façade displacement). The method is suitable to be extended to complex failure mechanisms for the wall and advanced interface constitutive rules, and it can then be considered a useful design tool for engineers, even for real cases studies. It will in particular highlight the performance of the system, by properly taking into account not only the

pull-out resistance, but also the interface and tensile stiffness of the reinforcements. As a consequence, the method allows for a more accurate evaluation of the geosynthetic internal state of stress, consistently with the wall displacement, that cannot obviously be achieved with traditional ULS design approaches. This method can also be of large importance for promoting the use of more accurate experimental characterization of the long term and pull-out behavior of geosynthetics, since it provides a simple way for practitioners to directly employ these parameters in the design process.

ABSTRACT: Soil nailing technique is extensively used for the stabilization of natural slopes and walls due to its unnumbered benefits viz. ease of installation in congested areas, flexibility, and a remarkable performance under seismic conditions. Various literature have highlighted the effective use of soil nailing technique in the stabilization of slopes, cuts, landslides, and excavations. Recently, researchers have improved the efficiency of the conventional soil nails by adding a set of helices along the length of the nail. The novel soil nail is termed as the helical soil nail. In the present study, the reliability-based analysis of a wall stabilized using the novel helical soil nails, is performed using the pseudo–static framework. The critical mode of failure for a helical soil nailed wall viz. the pullout mode, is considered in the formulation of the limit state function. The probability of failure (P_f) of the wall is approximated using the conventional sampling-based Monte–Carlo Simulation (MCS). The random variables include the internal friction angle of soil (ϕ) and the unit weight (γ). The P_f for a conventional soil nailed wall is compared with that of the helical soil nailed wall, to evaluate the efficacy of the helical soil nailed wall. The results depict a decrease in P_f when helical soil nails are used as a stabilization measure in place of the conventional soil nails. The influence of the randomness of input parameters is showcased by plotting a graph of P_f against the coefficient of variation (COV) of ϕ. The plot indicates a decrement in the stability of the wall with the increasing randomness which demonstrates the need for reliability analysis of the helical soil nailed walls. The paper also discusses the effect of nail inclination angle on the stability of the helical soil nailed wall. To the best of the authors' knowledge, the proposed method is original.

1 INTRODUCTION

Slope stability is a crucial subject of Geotechnical Engineering. The failure of soil slopes may lead to landslides which further lead to serious issues like infrastructure damage, and/or injury or loss of life of inhabitants of that area. It is, therefore, necessary to build stable and safe slopes, renovate and maintain the already built soil slopes, and stabilize the slopes prone to failure. Since slope stabilization's inception, numerous stabilization methods have been

*Corresponding Authors: ekansh1294@gmail.com, mahesh3.ce@gmail.com and pain_anindya@cbri.res.in

proposed which include building retaining walls, and slopes, limiting the driving forces, increasing the stabilizing forces, etc. However, in the 21st century, due to the limitation of space, conventional methods are less feasible. A practical alternative to these conventional methods is the use of reinforcements to provide tensile support to the soil. The soil structures designed and constructed using reinforcements as strengthening materials are referred to as reinforced soil structures. The reinforcements can be of different types such as high-density polyethylene (HDPE) geosynthetics, steel (or metal) strips, soil nails, sheet piles, etc. The present study is based on analyzing the slopes considering the soil nails as reinforcements. However, a specific kind called helical soil nails is considered due to their superiority over their conventional counterparts. Several researchers have used soil-nailing techniques to stabilize the geotechnical structures (Sharma *et al.* 2018, 2019a, b). Helical soil nails and their uses have also been explored by some researchers (FSI 2014; Sharma *et al.* 2020; Tokhi *et al.* 2017). But the methodology is deterministic which ignores the variability associated with the soil parameters. There is a limited study on the applications and usage of helical soil nails as a reinforcement material for soil slopes in the probabilistic domain. The present study is an attempt to analyze the reinforced soil walls (RW) in the probabilistic domain using the pseudo-static framework. The results are presented in the form of comparisons between the conventional and helical soil nails in the probabilistic framework.

2 METHODOLOGY

The methodology adopted for the probabilistic analysis is the conventional Monte Carlo simulation (MCS). It is a benchmark methodology that is highly accurate due to fewer assumptions and has been used recently to probabilistically analyze the reinforced soil retaining structures (Agarwal *et al.* 2022a, b, c). It follows the basic principles of probability theory and calculates the probability of failure (P_f) by using the following simple mathematical rule.

$$P_f = \frac{\text{Number of instances when FoS} < 1}{\text{Total instances}} \tag{1}$$

The FoS is typically not used in reliability analysis. Generally, a performance function is calculated to define the margin of safety. The performance function is calculated as FoS–1. The present study only considers the pullout of helical soil nails as the critical case of failure (Agarwal *et al.* 2022d; Sharma *et al.* 2020). The FoS (pullout) is given by:

$$FoS = \frac{F_{resisting}}{F_{driving}} = \frac{[(k_v + W)\cos\,\psi + P_e \sin\,(\alpha + \psi) - k_h \sin\,\psi]\tan\,\phi + P_e \cos\,(\alpha + \psi)}{(k_v + W)\sin\,\psi + k_h \cos\,\psi} \tag{2}$$

where

$$P_e = \sum_{i=1}^{N} P_i \tag{3}$$

$$P_i = \pi\sigma_i dL_{ei} \tan\delta + \sum_{k=1}^{n} \left(A_k \sigma_i \kappa_o N_q\right) \tag{4}$$

For more details, readers may refer to Sharma *et al.* 2020 and Agarwal *et al.* 2022d.

The analysis is performed using the pseudo-static analysis. It has been previously used by different researchers (Agarwal *et al.* 2022a; Basha & Babu 2012) to analyse the reinforced soil retaining structures. The prime reason to consider the pseudo-static (PS) framework is its

simplicity and efficiency. Though the results might not be as precise as complex frameworks, the main idea of this research work is to explore the usefulness of helical soil nails as reinforcements in soil retaining structures and therefore, the PS framework would suffice. The assumptions stated by Agarwal *et al.* (2022d) are adopted for the analysis. A free-body diagram of RW is shown in Figure 1 for reference to the readers.

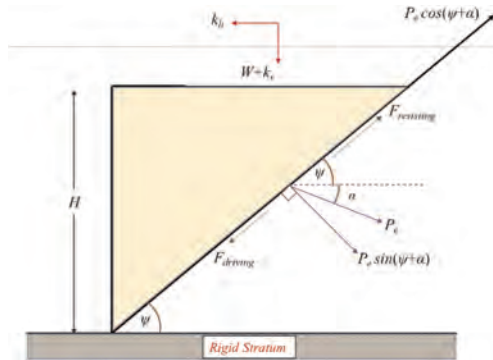
Other basic details have not been included in the manuscript to adhere to the word limit and laid guidelines. The readers may explore some of the works of the authors and other researchers on pseudo-static frameworks, helical soil nails (Agarwal *et al.* 2022a, d), and reliability-based analysis of reinforced soil retaining structures.


Figure 1.   Free-body diagram of a RW.

3   RESULTS AND DISCUSSION

The results section includes the comparison of the competency of conventional and helical soil nails in the probabilistic domain, the influence of randomness on the RW, and the effect of nail inclination angle on the stability of RW. As already stated, the prime motive is to explore the potential of helical soil nails as a reinforcement material in the probabilistic domain, and therefore, only two input parameters (ϕ and γ) are taken as random variables (statistics provided in Tables 1 and 2).

Table 1.   Input parameters.

Parameters	Value
H	10 m
L/H	0.8
k_h	0.1
k_v/k_h	0.5
δ/ϕ	0.75
α	0°
D_{hx}/d	6
β	90°
S_{hx}/D_{hx}	5
d	0.040 m
S_v/D_{hx}	5

3.1 Effect of the variability of random parameters on RW

This effect is demonstrated by plotting P_f against the coefficient of variation (COV), a parameter that depicts the extent of variability of input parameters. The input variables adopted are stated in Tables 1 and 2 and not stated separately in each section and with figure captions. The plot in Figure 2 portrays the influence of COV on the stability of RW. This effect cannot be quantified in a deterministic approach which is the reason why authors have emphasized the use of probabilistic analysis for exploring the applications of helical soil nails in RWs. The P_f of RW is gradually elevating as the COV (or simply the variability) increases. Readers may explore different combinations of COV and consider other parameters as random for more clarity. However, the authors advise checking for efficiency as the parameters increase.

Table 2. Properties of the random variables.

Random parameter	Properties		
	Mean value (μ)	Std. Deviation (σ)	Distribution*
ϕ	32°	1.6–4.8°	Log-normal
γ	20 kN/m³	1 kN/m³	Normal

*According to Basha & Babu (2010).
Figure 2. Plot of P_f against CoV (ϕ).

3.2 Effect of nail inclination angle (α)

As stated in the previous sub-section, the input parameters remain the same except α which is taken as 0° and 15° to see its effect on the P_f of RW. Figure 3 depicts the effect of α on the RW. As α increases, the stability decreases as the P_f increases. This can also be easily justified by the geometry and calculating the horizontal and vertical forces along with the moments. This also justifies the correctness of the used algorithm. The results also illustrate the importance of experience and judgment in deciding the nail inclination angle while designing a live helical soil nail RW.
Figure 3. Plot of P_f against CoV (ϕ) for different α.

3.3 *Comparison of conventional and helical soil nails*

This sub-section is included to appreciate the benefits of using helical soil nails as reinforcement instead of conventional ones. The input parameters are taken from Tables 1 and 2. The value of D_h is taken as $6d$ and $1d$ for helical and conventional soil nails, respectively. Figure 4 provides a clear comparison of the P_f obtained using the above-stated soil nails. P_f for a conventionally reinforced wall is more in comparison to the helical reinforced soil wall. The reason behind this is the greater pullout capacity mobilized by the helices in the helical soil nails apart from the soil-nail shaft resistance. The results encourage the use of helical soils to reinforce the soil retaining structures.
Figure 4. Plot showing the comparison of helical soil nails with conventional soil nails.

4 CONCLUSIONS

This study is basically performed to explore the usefulness of helical soil nails as reinforcement for soil walls in the probabilistic domain. The cost-based analysis and other field parameters have not been included and the study primarily highlights the technical advantages of helical soil nails. Based on the results, the following inferences are drawn.

- Probabilistic analysis quantifies the variability associated with input parameters and therefore, every design of RW should be double-checked using this technique in addition to the deterministic analysis.
- The helical soils provide greater pullout capacity in comparison to the other conventional soil nails.
- The inclination angle of the helical soil nail should be carefully chosen as it affects the stability of RW. An increase in its value may lead to unsafe results.

NOTATION

P_e	equivalent tensile force per unit horizontal spacing acting along the nail axis
σ_i	overburden pressure acting on the interface of helical soil nail
P^i	pullout capacity of the helical soil nail
δ	peak interface friction angle
W	weight of the failure wedge
n	number of helices
L_{ei}	the effective length of the soil nail; δ is the interface friction angle
d	diameter of the soil nail shaft
κ_o	coefficient of earth pressure at rest
N_q	bearing capacity factor
A_k	bearing surface area of the helix
D_{hx}	diameter of helix
H	height of wall
k_h, k_v	horizontal and vertical coefficient of acceleration
α	inclination angle of the soil nail
L	length of the soil nail
β	Angle of inclination of wall from the horizontal
ψ	Angle at which slip surface cuts the horizontal plane
S_{hx}	spacing of the helices
Sv_x	vertical spacing of the nails

ABSTRACT: Reinforced soil walls (RSW) are a proven alternative to conventional earth retaining structures due to their rapid construction, smaller environmental impact, lower cost, as well as more sustainable social/functional features. Design methods for RSW appear in international codes and guidelines. However, they often do not provide detailed calculations for global stability assessment. Global stability can significantly affect RSW design for specific geometric cases and/or site-specific boundary conditions. Traditional limit equilibrium (LE) methods have the disadvantage of not considering reinforcements and/or require iterations to achieve a safety factor (SF) value. Alternatively, numerical methods can be time consuming for both model generation, particularly for complex geometries, and during calculations. The present study discusses different analytical strategies using limit equilibrium formulations and a numerical finite element method, and proposes a simplified analytical method for global stability analysis based on a three-part wedge failure mechanism, and simple wall conditions.

1 INTRODUCTION

Reinforced soil walls (RSW) offer a more sustainable solution to perform the earth retaining wall function compared to conventional gravity structures (Damians *et al*. 2016).

Design practice for RSWs often focus on internal stability modes of failure, which include failure due to connection rupture, reinforcement rupture, and pullout of the reinforcement layers. However, similar to conventional earth retaining structures, RSWs must be externally stable against sliding, overturning, and bearing capacity failure.

Global stability failures of RSWs are characterized by a failure surface beginning in the vicinity of the toe of the wall, extending beyond the reinforced soil and into the retained soil zone. The propagation of the failure surface can be assumed as a circular surface (e.g., FHWA-NHI-10-024 2009) or as a non-circular surface with various segments (e.g., AFNOR 2020). A commonly used methodology to design earth retaining structures is the limit equilibrium (LE) approach together with the method of slices. Variations of the slice method are available, which make different assumptions to satisfy equilibrium between the interacting slices (e.g., Fellenius method, Simplified Bishop method, Janbu method, among others). More recently, the use of numerical tools has allowed the deformational behaviour of RSWs to be included in stability assessment. Numerical techniques such as the finite element (FE) method allow for simulation of construction stages, interfaces between materials, and include the in-soil behaviour of reinforcement layers in the analysis.

The present study focuses on comparing the calculated safety factor for a 6-meter high RSW with polymeric reinforcement layers obtained using LE formulations, numerical tools, and a novel simplified analytical methodology. Different surcharge conditions and geometries are included in the analysis, as well as a parametric analysis using different soil properties.

2 GLOBAL STABILITY ASSESSMENT

2.1 Problem definition

An idealized H = 6 m high RSW with segmental facing panels was studied. Wall dimensions include a front toe embedment of 0.50 m, segmental panels of 1.5 m height and 0.15 m thickness, and polymeric reinforcement lengths of 4.2 m (0.7H) placed at a spacing of 0.75 m (Figure 1a). Foundation, retained, and reinforced soil properties are given in Table 1. Stiffness and weight parameters for the facing panels and polymeric reinforcement are shown in Table 2.
Figure 1.   (a) RSW geometry, and (b) failure mechanism for the proposed simplified method.

Table 1.   RSW model properties.

Parameter	Foundation and retained soil	Reinforced soil
Unit weight, γ	20 [kN/m^3]	20 [kN/m^3]
Cohesion, c	5 [kPa]	0.1 [kPa]
Friction angle, ϕ	28 [º]	34 [º]
Elastic modulus, E	100 [MPa]	80 [MPa]
Poisson's ratio, ν	0.3 [-]	0.3 [-]

Table 2.   Parameters for structures components used in the numerical model.

Parameter	Precast facing panels	Polymeric reinforcement
Axial stiffness, EA	4.5×10^6 [kN/m]	1500 [kN/m]
Flexural stiffness, EI	8440 [kNm^2/m]	–
Self-weight, w	3.75 [kN/m/m]	–

2.2 Limit equilibrium method

LE methods are commonly used to compute the global stability of earth retaining structures, particularly in combination with the method of slices. The slope or structure is divided into discrete slices, each is considered as a rigid body that must satisfy equilibrium conditions. The slice methods result in a statically indeterminate problem. Hence, results may vary

depending on the assumptions adopted to satisfy equilibrium (Fredlund & Krahn 1977). The present study uses the ordinary or Fellenius method, which assumes no forces between slices.

Shear resistance for each slice is determined using the Mohr-Coulomb failure criterion (MC). Using the Fellenius method, the global stability of the structure is quantified using safety factor (SF) and considering the driving and resisting forces in Equation 1:

$$SF = \left(\sum c_i l_i + [W_i \cos \alpha_i] \tan\phi \right) / \left(\sum W_i \sin \alpha \right) \tag{1}$$

Here c_i is the cohesion of slice i acting over a failure surface of length Δl_i, W_i is the weight of slice i, ϕ is the internal friction angle of the soil, and α is the inclination of the bottom of the slice i with respect to the horizontal. LE analyses were conducted using the software package SLIDE (Rocscience 2017) with the Fellenius method option.

2.3   Numerical method

The numerical method to assess global stability was the strength reduction method (Marek-Cala 2003) available in the FE software package PLAXIS (Plaxis 2004). In the strength reduction approach, c-ϕ properties of the soil are continuously reduced until failure is achieved. The SF value is then calculated as the ratio original strength parameters (ϕ_{input}, c_{input}) divided by the reduced strength parameter ($\phi_{failure}$, $c_{failure}$), as shown in Equation 2.

$$SF = \tan(\phi_{input}) / \tan(\phi_{failure}) = c_{input} / c_{failure} \tag{2}$$

Mesh geometry included all relevant structural components with their respective stiffness values (discrete facing panels, reinforcement layers). The FE constitutive model was the MC failure criterion. A soil-reinforcement interface reduction factor of $R_i = 1$ was used. Soil-facing interfaces considered an equivalent material with $\phi_{interface} = (\frac{2}{3})\phi_{reinforced\text{-}soil}$. An initial sensitivity analysis was made to determine the optimum combination of mesh refinement, computation time and amount of output. There were no practical advantages with respect to numerical outcomes for mesh refinement with more than 15,000 nodes. The placement and compaction of the soil was carried out using 4 and 8 rows of elements; no practical differences in model results were detectable using each number of rows.

2.4   Simplified method

The objective of the proposed simplified method is to compute global stability SF in a straightforward manner. Figure 1b shows the proposed failure mechanism. The structure is divided into three zones or slices: the front embedment slice (I), the reinforced soil slice (II), and the retained soil slice (III). LE conditions are then applied, using the Fellenius method and slice boundary conditions adopted using this method. The three-slice failure mechanism resembles that proposed in design standards (AFNOR 2020, BSI 2010), and the failure surfaces often observed from numerical analyses. Slice dimensions are based on wall height (H), depth of wedge III (D), and soil frictional strength (ϕ), as shown in Equations 3–5:

$$\beta = (45 - \phi/2) \tag{3}$$
$$L = H/2 \tag{4}$$
$$\alpha = \tan^{-1}(0.7H/(a/\tan(\beta) - D)) \tag{5}$$

in which a is the relative depth (m) of slice II based on slice I geometry.

To determine the inclination of each slice (θ_i), a reference point must be selected. Past studies have shown that the rotation point of a RSW is usually located above and in line with the vertical facing of the wall (Brand & Shen 1984; Petterson 1955). For a base wall height of 6 m, the reference point was located at a height of 2.5 m above the vertical wall facing. The reference point can be adjusted based on computed SF values from numerical or analytical results. For simplification, the weight of slice II acts in the middle of the reinforced soil

(0.45H). SF is obtained by imposing equilibrium conditions between the acting moment (M_A) and resisting moment (M_R) considering each slice (Eq. 6):

$$SF = M_A/M_R = \left(\sum c_i l + [W_i \cos(\theta_i)] \tan\phi \right) / \left(\sum W_i \sin\theta_i \right) \tag{6}$$

in which θ_i is the angle between the vertical projection of each slice self-weight and the reference point.

3 RESULTS AND DISCUSSION

3.1 *Base case and variable surcharges*

Figure 2a shows SF values for the base case and different load scenarios using the analytical` Fellenius method, numerical PLAXIS model and the simplified method proposed here. Surcharge cases consider an equivalent 12 kPa load. For cases 1 and 2, which include surcharge over the toe of the wall, length L is reduced to H/3, angle β is increased to 45-ϕ/10, and the reference point is relocated to 3.5 m above the vertical wall.

The largest SF values were consistently obtained with the Fellenius method. SF values decreased with the application of a surcharge on top of the wall and increased with surcharge loading applied at the toe. Overall, the simplified method yields SF values similar to those obtained from the FE analysis. SF values for the base case were 1.46, 1.47, 1.50 and 1.37 using PLAXIS, simplified method and Fellenius method, respectively.

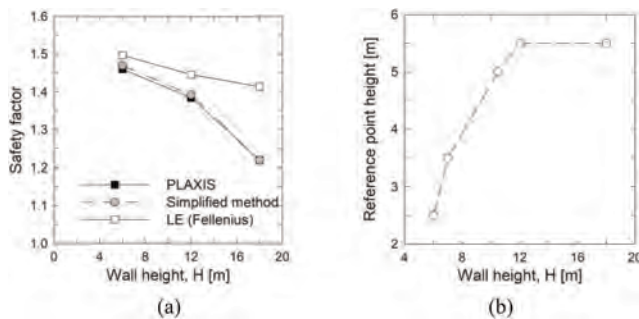
Figure 3a shows the variation of SF values with wall height using the three methods. Wall heights were 6, 12, and 18 m. Reinforcement length was 0.7H for each case. Increasing wall height gave lower SF values, particularly for PLAXIS solutions and the simplified method. SF values using the simplified method match those obtained using PLAXIS.
Figure 2. Safety factor (SF) for (a) the base case (no surcharge) and different surcharge load conditions, and (b) different top and toe wall geometries (H = 6 m).


Figure 3. Variations of (a) safety factor, and (b) reference point location as a function of wall height. Base case comparison (no surcharges nor slope conditions).

Modifications of the reference point and slice I dimensions for the simplified method are required to obtain SF values in general agreement with those obtained using PLAXIS and Fellenius method. As wall height increases, the reference point must be moved higher (see Figure 3b), the length L of slice I decreases, and the angle β increases.

3.2 Variable top and toe wall slope geometry

Figure 2b compares SF values using the three methodologies and considering a top back-slope and/or fore-slope at the toe of the RSW. For cases with a sloped toe embedment, slice I length increases to H/1.5, and the reference point is lowered to 0.5 m above the vertical wall. When considering an inclined toe and top, the reference point was set to 1.0 m above the vertical of the wall facing.

The three approaches yield comparable results. For greater top slope length, SF is reduced progressively. Furthermore, as the resistance at the toe is reduced due to increasing fore-slope angle, SF values are further reduced. As with previous cases, results from the simplified method are in reasonable agreement with those obtained from numerical analyses.

3.3 Soil parameter variations

A sensitivity analysis for the influence of retained and foundation soil parameters was also conducted. Parameter variations include specific weight (γ_s), cohesion (c), and friction angle (ϕ). Parameters were varied individually.

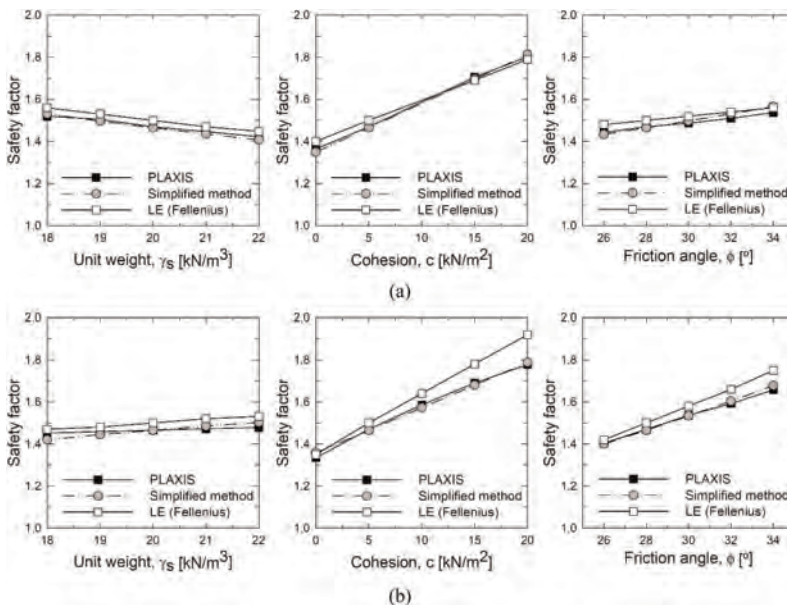
Figure 4 shows computed SF values using the three approaches. Figure 4a shows that increasing γ_s for the retained soil reduced SF, increasing soil cohesion increased SF, as does increasing ϕ. Changing the foundation soil parameters (Figure 4b) resulted in increased SF values for larger values of γ_s, c, and ϕ. SF values obtained using the Fellenius method deviate from those obtained using PLAXIS and the simplified method when and ϕ values for the foundation soil increased. The Fellenius method gave higher SF values when varying soil parameters in all cases, with the exception of the cohesion of the retained soil. The most


Figure 4. Safety factor (SF) parametric analysis results changing material properties for (a) retained soil, and (b) foundation soil.

sensitive parameters were c of the retained and foundation soil, and ϕ of the foundation soil. Changing the foundation soil γ_s, the self-weight of the vertical wall was included in the weight contribution of slice I, which brought the simplified method results closer to those obtained using the PLAXIS program.

Changing the interface resistance values modified the failure surface obtained using the PLAXIS c-ϕ reduction method. For a perfect bonded soil-reinforcement interface (R = 1) the failure surfaces propagate under the reinforced soil, while a sliding interface (R = 0.6) shifts the failure surface, which then intersects the lowest reinforcement layer.

4 CONCLUSIONS

The present study proposes a simplified analytical method to assess the global stability of a reinforced soil wall with simple geometry. The methodology considers a planar three-slice failure mechanism resembling the failure surface obtained in numerical simulations and described in design standards. Horizontal forces between slices are disregarded. Parameters include structure geometry and soil strength properties. The proposed simplified method provides a fast and simple procedure intended as a preliminary estimation of the global stability safety factor for these systems.

Calculated safety factors with numerical techniques using the program PLAXIS, limit equilibrium formulation using the Fellenius method, and the proposed simplified three-slice failure mechanism were compared. Overall, satisfactory agreement was found between the numerical simulation outcomes and the simplified method. The Fellenius method tended to give similar trends but higher safety factor values, mainly due to an overestimation of the resistance at the toe.

Different surcharge scenarios, geometric variations, and sensitivity analyses were performed. The simplified method results consistently showed satisfactory agreement with the results of numerical simulations. Modifications of the toe length (slice I) and the reference point height serve as calibration parameters to obtain closer safety factor values between numerical simulations and other limit equilibrium methods.

The present study analysed simple geometries with generic, static, load conditions. Further work is required to use the simplified method for real, more complex, wall configurations, such as tiered walls and back-to-back walls, among other configurations.

ABSTRACT: Geosynthetic materials and, more specifically, drainage geocomposites are now widely used for water drainage and gas collection in applications as varied as final landfill covers, leachate collection in landfill cells, sub-slab depressurization systems under buildings, groundwater drainage under embankments, etc. The design methods used are based on the in-plane flow capacity of the geocomposites, which is determined by laboratory tests performed on 250-300 mm long product specimens. Fluid is injected into the thickness of the product and the drainage capacity is interpolated for an actual length of several meters. This paper presents the development of hydraulic design software for multi-linear drainage geocomposites, based on laboratory characterizations of the geocomposite and then validated with full-scale tests. The software gives a 3D model of the hydraulic curves in the geocomposite depending on the application for which the geocomposite is used, and the fluid to be drained (water, landfill gas, methane, air, etc.).

1 INTRODUCTION

The design of geosynthetic materials for drainage requires an excellent knowledge of the material's hydraulic properties. The determination of the drainage capacity of drainage geocomposites is based on in-plane flow as determined by laboratory tests according to ASTM D4716, GRI GC15, and ISO 12958. The initial type tests allow the designer to correlate the flow rate with the hydraulic head or hydraulic gradient. In addition to the basic hydraulic characterization, the long-term in-situ drainage capacity of the geocomposite is calculated from these laboratory test results using guidance documents that help the designer address the reduction factors to be applied to the drainage flow capacity as a function of the type of geocomposite, the engineered structure, type of fluid (water, gas), etc. The ASTM D7931 standard guide (based on ASTM D4716 laboratory test), or the ISO/TR 18228-4 standard guide (based on ISO 12958 laboratory test) greatly help the engineers in this regard, but certain points can be misleading for engineers without solid expertise in geosynthetics.

1.1 *Laboratory tests*

The in-plane flow capacity (or Transmissivity) of geocomposites is developed to be compatible with the whole range of products on the market through ASTM and ISO standards.

Because of the different physical characteristics of drainage geocomposites, the laboratory tests performed as per the standards may not be as accurate as expected.

For example, the size of the testing device typically used has a length of 250 mm to 300 mm, underestimating by at least 30% the drainage capacity of Draintube multi-linear drainage geocomposites (Blond *et al.* 2013). This is because the entrance and exit transition flow to the tested length causes additional head losses.

Moreover, taking a single test measurement (even after a seating time of several hours), may not account for the continuous compression of the tested product due to creep throughout its service life and lead to an overestimation of its in-situ drainage capacity. This is particularly noticeable for geocomposites with a monofilament core where the in-situ drainage capacity can be more than 10 times lower than the value measured in the laboratory test (Zanzinger 2000).

1.2 *Boundary conditions*

The drainage capacity of the geocomposite is determined by using laboratory tests with specific test conditions, such as hydraulic gradient, vertical compression load, seating time, and material(s) in contact with the geocomposite. It can be complicated for the designer to correlate these test conditions with the field conditions, or even more concerning, to be aware that the test conditions have a significant impact on the given results.

For example, using steel plates as boundary conditions when testing a drainage geocomposite does not address the geotextile intrusion into the drainage core. This phenomenon will occur in the field when the product is in contact with a soil layer. This typically leads to a significant reduction in flow rate for most drainage geocomposites, up to 90% reduction for geocomposites under high compressive loads like 720 kPa (Zhao *et al.* 1999).

As for creep in compression, the sensitivity to the boundary conditions depends on the type and structure of the drainage geocomposite.

1.3 *Terminology*

The technical terms involved in hydraulic design can be a source of confusion for the designer. Indeed, depending on their field of expertise, geotechnical or geosynthetic, some identical terms do not represent the same quantities and are not directly comparable. One example is "Hydraulic Transmissivity". It is not directly comparable between a granular layer and a geocomposite. The first one is an intrinsic value of a given granular layer, while the second one depends on many factors specific to the geocomposite environment such as the hydraulic gradient, the applied normal load, the material in contact, etc.

2 SOFTWARE DEVELOPMENT

In the trend of Computer Assisted Design (CAD) for engineers, Afitex Group has developed a software for the design of geosynthetics used in drainage applications. The new software, named Lymphea, assists designers in the hydraulic selection of drainage geocomposites (including multi-linear drainage geocomposites) as well as granular drainage layers using site-specific conditions.

The software is based on a previous model developed with LIRIGM university research laboratory at the University of Grenoble (France) and CEREMA (formerly Laboratoire Regional des Ponts et Chaussées de Nancy). It has been updated and improved with the contribution of the SAGEOS (CTT Group, Quebec), the CEGEP of Saint-Hyacinthe (Quebec), and the University of Saskatchewan (USASK) in Alberta.

2.1 Project presentation

The development of the software has been divided into the following three main steps:

– Calculation core for multi-linear drainage geocomposites that has been implemented from the previous model and updated with a 3-year test program performed at SAGEOS and USASK laboratories,
– Calculation modules development for drainage geocomposites and granular drainage layers, based on standard design guidance documents from the geosynthetic industry and publications from specialists in these fields,
– User interface design to have a software that is easy to use and intuitive.

The software also offers design firms a company-restricted database allowing multiple users in the same company to share and update their projects.

2.2 User interface

The user interface has been developed to represent the engineer's needs and the design steps as closely as possible. The software is available in several languages (English, French, and Spanish), in SI and US units, and based on ISO and ASTM standards. When creating a new project, the user can choose between several available drainage applications (Figure 1) such as Sub-slab depressurization systems, Drainage behind MSE walls, Cover drainage systems, or Leachate collection systems. It should be noted that the software allows for the design of drainage geocomposites for both liquid water and gas.

Figure 1.   Home page of the software.

3   CALCULATION MODULE FOR MULTI-LINEAR DRAINAGE GEOCOMPOSITES

The calculation modules for multi-linear drainage geocomposites are based on the previous model initially developed and validated on a large-scale cell experiment (4 m long and 1 m wide) at the LIRIGM university research laboratory (Faure *et al.* 1993) and confirmed many times since. The theoretical model in the software is based on the following flow conditions:

– Fluid supply with a homogeneous flow distribution perpendicularly to the geocomposite,
– Horizontal or non-horizontal position of the drainage layer with the flow condition down or reverse to the slope α,
– Perforated mini-pipes unsaturated, partially saturated, or fully saturated.

The fluid inside the drainage layer is assumed to flow perpendicular to the perforated mini-pipes. This hypothesis is conservative and reasonably good as the distance between the mini-pipes is 2 m maximum, provided the length of the mini-pipes is generally more than 10 m. The head losses to enter into the perforated mini-pipes have been found insignificant compared to the head losses into the drainage layer. The governing equation of the hydraulic head in the multi-linear drainage geocomposite is then given by Equation 1 from Faure *et al.* (1993):

$$h_{\max} = \frac{F \times D^2}{8\theta_{GT}} + \left(\frac{b}{b+1}\right) \times \left(\frac{F \times D}{a}\right)^{1/b} \times L^{(b+1)/b} - L \times \sin\alpha \qquad (1)$$

where F = Flow per unit area; θ_{GT} = Transmissivity of the drainage layer; D = Distance between mini-pipes; L = Length of drainage; a and b = constants experimentally determined from the flow capacity of the mini-pipes.

3.1 Flow capacity of the drainage layer

The drainage layer is composed of a non-woven needle-punched staple fiber geotextile. The drainage layer is protected from the surrounding soil by an additional filter layer, also included as part of the multi-linear drainage geocomposite that prevents soil particle migration. The flow carried out by the drainage layer is given by Darcy's law and is dependent on its Transmissivity.

A series of hydraulic tests have been performed at SAGEOS and USASK laboratories on several drainage layers under multiple loads to characterize their hydraulic Transmissivity. The transmissivity values considered in the software are in-situ Transmissivity, meaning that reduction factors have already been applied to reflect the long-term drainage capacity under load. Recommended reduction factors for geotextile drainage layers are given in the GRI White paper 4. Figure 2 shows an example of the long-term Transmissivity of a 200 g/m^2 drainage layer function of the vertical load applied.
Figure 2. In-situ transmissivity of a 200 g/m^2 non-woven needle-punched geotextile drainage layer.

3.2 Flow capacity of the mini-pipes

Tests have been carried out at SAGEOS laboratory to characterize the flow capacity of the mini-pipes themselves and to confirm the experimental values previously obtained during the development and validation of the software. The flow capacity of the mini-pipes is a function

of the hydraulic gradient and has been measured for the 3 mini-pipe diameters: 16 mm, 20 mm, and 25 mm (Figure 3). Mini-pipe lengths of 0.5 to 1 m were tested, and the resulting flow capacity was calculated, excluding entrance and exit head pressure losses.
Figure 3. Flow capacity of the 3 mini-pipe diameters.

For each mini-pipe diameter, the flow capacity implemented in the software is conservative compared to the test results. A factor of safety of 1.55 has been applied to the measured flow capacity values.

4 CALCULATION MODULE FOR GRANULAR DRAINAGE LAYERS

The calculation module for the granular drainage layer is based on two technical papers published by Giroud *et al.* in 2000. The approach used is to verify that the maximum water flow height is less than the thickness of the granular drainage layer, which becomes the maximum allowable water height. According to Giroud *et al.* (2000), the thickness of the liquid layer is influenced by the hydraulic conductivity of the granular layer, the angle of the slope, the drainage length, and the flow rate per unit area entering through the surface perpendicular to the flow direction. The modeling of the hydraulic behavior of the granular drainage layer is performed using Giroud's formula, where an incoming upstream flow has also been considered, as shown in Equation 2:

$$F \times L + q_0 = K \times \left(h_{\max} \times \sin \alpha + \frac{h_{\max}^2 \times \cos \alpha}{L} \right) \tag{2}$$

where F = Flow rate per unit area; L = Length of drainage; q_o = Incoming upstream flow; K = Hydraulic conductivity of the granular layer; h_{max} = Maximum height of water; and α = Slope.

The user can solve for each parameter mentioned above as the value to be implemented (as the unknown of the equation) in the software. It allows the user to design a drainage solution with a granular layer function of the input data specific to the project. Reduction

factors for chemical clogging (RF_{CC}) and biological clogging (RF_{BC}) can be addressed and applied to the hydraulic conductivity of the granular layer. The factor of safety (FS) is applied to either h_{max} or K, whichever gives the most conservative result.

5 CALCULATION MODULE FOR DRAINAGE GEOCOMPOSITES

The calculation module for drainage geocomposite is based on Darcy's law and the in-plane drainage capacity from ASTM or ISO standard tests.

The hydraulic behavior of the drainage geocomposite is modeled using Equation 3 in an ISO environment and Equation 4 in an ASTM environment. A potential incoming upstream flow has also been taken into account:

$$q_p(\sigma, i, 100h) = FS \times \prod RF \times (F \times L + q_0) \tag{3}$$

$$\theta_{100}(\sigma, i, 100h) = FS \times \prod RF \times \frac{(F \times L + q_0)}{\sin \alpha + \frac{\cos \alpha \times h_{max}}{L}} \tag{4}$$

where $q_p(\sigma, i, 100h)$ = In-plane flow capacity as per ISO 12958-2 (performance test) performed under a vertical load σ, a hydraulic gradient i, and a seating time of 100 hours with boundary conditions representative from the applications; $\theta_{100}(\sigma, i, 100h)$ = Transmissivity as per ASTM D4716 (or GRI GC15) performed under a vertical load σ, a hydraulic gradient i, and a seating time of 100 hours with boundary conditions representative from the applications; FS = Factor of safety; $\prod RF$ = Reduction Factors.

$\prod RF$ is the product of the following reductions factors (Eq. 5):

$$\prod RF = RF_{IN} \times RF_{CR} \times RF_{CC} \times RF_{BC} \tag{5}$$

where RF_{IN} = Reduction factor for geotextile intrusion into the drainage core; RF_{CR} = Reduction factor for creep in compression; RF_{CC} = Reduction factor for chemical clogging; RF_{BC} = Reduction factor for Bacteriological clogging.

The reduction factors are dependent on the type of application and are also product/technology specific. Recommended values for the reduction factors are given in the software and are generally taken from the ISO/TR 18228-4 standard guide. It is important to note that the reduction factors are to be applied on $q_p(\sigma, i, 100h)$ or $\theta_{100}(\sigma, i, 100h)$ i.e. on the 100 hours seating time test results.

As per the calculation module for a granular drainage layer, each parameter mentioned in Equations 2 & 3 can be chosen in the software as the value to be determined (as the unknown of the equation).

6 CONCLUSIONS

The development of a software for the hydraulic design of drainage geocomposite and granular drainage layers is intended to help designers. It is based on formulas and calculation methods well recognized by the geosynthetics drainage industry and it also includes the ability to design multi-linear drainage geocomposites. The Lymphea software allows for a wide range of parameters to be determined to better adapt to the site-specific requirements of each project. Considering its usage throughout the world, it also works in both ISO and ASTM environments, using either SI or US units.

Finally, the software is based on a previous model, initially developed and validated on a large-scale cell experiment and confirmed many times since. The user interface has been

designed to be as intuitive as possible, and it guides the user by explaining the important steps and input data to be considered.

ABSTRACT: The three-dimensional geometry of geocell provides lateral and vertical confinement that is extensively used for stabilizing cover soil on steep slopes. On the steep slopes of the North Saskatchewan River in Edmonton (Canada), around a light rail traffic tunnel portal that was previously stabilized with soil anchors, a 200mm thick facial fill was required for a green cover. The slope varied from 250 to 730 stretching from 40m to 60m along the slope. An attempt was made utilizing a novel polymeric alloy (NPA) geocell to retain the facia fill. A conventional design approach with tendons was not possible due to the lack of anchoring opportunities at the crest. Presence of utility lines limited locations for anchoring on the slope. A novel design technique of load transfer utilizing wire net covers on top of the geocell was developed. This paper discusses the challenges through the design and the remediations.

1 INTRODUCTION

Stabilizing slopes poses many geotechnical challenges depending upon, but not limited to, the slope geometry, surcharge load and the type of soil to be retained. There are already established engineering methods such as soil nails, retaining walls and facia support to stabilize the slopes. Geocell walls and geosynthetic-reinforced geocell facia have also been widely used in reinforced slope stabilization work. Even after stabilizing unstable slopes, erosion control of the topsoil for vegetation growth needs a due attention to avoid gully formation and destabilize the slope and more so when a green slope is desired with select vegetation. The design of green slopes has emerged as a core concept in the leadership in environmental design, with this recognition in engineering design green slopes will get due attention in the foreseeable future.

Geocell owing to its three-dimensional pocket geometry and structural properties has been widely used for load support applications and soil retention designs such as gravity retaining walls, road and pad embankments on soft subgrades and facial cover of slopes. There are several studies performed over the last couple of decades to understand the mechanism of soil retention and the confinement effect of geocell. Pokharel (2010) showed the horizontal and vertical confinement effect of high tensile strength geocell. Studies on the vegetation growth within geocell by Guo *et al.* (2015), highlighted an ideal solution for the current challenge. Hegde (2020) summarized some of the popular reinforcement mechanisms and design methods for various geocell applications. The importance of the proper installation technique, particularly with connecting geocell panels, for uniform distribution of member stresses was highlighted by Liu *et al.* (2018). Though there are several studies with slope stability using a geocell retaining wall system, there is hardly any study available on green facia cover with geocell.

The steep slope on the left side of the North Saskatchewan River in Edmonton (Canada) was designed with soil nails and geonet (by others). However, the problem of surface erosion and retention of topsoil for a well-vegetated green cover on top and around the newly constructed light rail tunnel portal was later identified demanding separate attention. The length along the slope stretched from 40m to 60m. A major portion of the slope was well over 550 with some local areas as steep as 830. For a minimum 10m length along the slope, the inclination varied between 250 to 730. The design required a minimum of 200mm thick soil for regular vegetation growth which would not be naturally stable beyond 300 inclinations. However, once the root of vegetation grows deep enough, stability at a much higher inclination is possible. With accumulating snow and seasonal freeze-thaw, there was an additional risk of the entire soil cover slipping down. Thus, until the roots takeover, it was necessary to provide artificial support to the topsoil. A potential solution was the use of geocell, for its proven past applications, utilizing the lateral and vertical geometric confinements (Hedge (2020)).

For retaining soil along a slope, most designs include tendons anchored at the crest or soil anchors distributed over the entire sloped area or a combination of both. The primary purpose is to support the plant and allow the roots to grow, it should also be able to transfer the plantation soil load through geocell to a stable support system. However, for the slope under consideration, there was no opportunity for anchoring tendons or digging a trench at the crest to support the geocell system due to the presence of other infrastructures. Anchoring hooks were not allowed in some areas due to the presence of buried trenches and utility lines. Rimoldi and Ricciuti (1990) developed a series of equations to calculate the stability of geocell on slopes. For the current application, their method needed modification as their stability calculations heavily depended on the crest resistance and J-hooks.

This paper discusses the design of the green facia cover for that steep slope. The dead weight of plantation soil was confirmed by the designers to have no detrimental impact on the overall global stability of the slope. However, attachments and modifications to the existing system of soil nails and geonet were not permitted. The paper also discusses the performance of the erosion control design over a full year and recommendations for similar designs with polymeric geocell in the future.

2 METHODOLOGY

For the design of geocell on steep slopes with snow loads, freeze-thaw effects, and limited soil anchoring, a failure-based design methodology was developed. The philosophy behind this approach is to identify all possible failure modes (Figure 1a) and then walk back to potential solutions.

The first identified mode of failure was the sliding of soil above the geocell. Geocell provides 100% confinement within some volume of the pocket (Figures 1a and 1b). The amount of confinement provided above that zone of full confinement depends on several parameters such as geocell pocket size, infill particle size distribution, and particle-to-geocell wall interaction. The higher the fill above the geocell higher the risk of a sliding plane formation. Figure 1b shows that there is a balance point that can be approximated where the sliding force equals the geocell confinement effect (equation 1). Through this relation, the acceptable geocell height is determined. If one layer of geocell is not enough, then multiple layers can be effective. Since the topsoil thickness required was 200mm, for the stretched pocket size of 250mm x 210mm the safe geocell height was computed as 150mm for this slope.

$$W_{cover} * sin\beta = F_{conf} / \varphi_{conf} \qquad (1)$$

where W_{cover} is the weight of soil, β is the slope angle under consideration, φ_{conf} is the confinement factor of safety and F_{conf} is the confining force that is a function of geocell pocket size, particle distribution of infill material, and geocell-particle interface friction.

The second identified mode of failure was the formation of a slip plane under the geocell (Figure 1c). To avoid this, it was necessary to break the continuity of the potential failure plane with the geocell pressing into the native surface. J or U hook anchors (Figure 3b) holding the geocell from any upward movement (Figure 1c) is a solution, but the challenge remained where anchoring was not permitted. A stretched wire net on top of the geocell that is anchored independently along all the edges turned out to be an acceptable solution.

The third mode of potential failure was in the continuity of the load transfer. If either a member or a connection transferring the load of vegetated plantation soil along with the seasonal snow cover fails, then the entire system will be at risk of failure. For this, individual members (geocell, wire net, anchors) and their connection (interaction between geocell and anchor, zip ties holding wire net with geocell) were studied separately. Where anchoring was allowed, the sliding force was distributed into the geocell, as per relevant influence areas (Figure 2a). To optimize the number of anchors, a high tensile strength of the geocell was necessary. Given that the slope needed to be green there were additional requirements like perforations in the geocell for water to seep through. Perforated Novel Polymeric Alloy (NPA) Geocell (330-150-C-P) with a tensile strength of >18kN/m, dynamic modulus >750MPa (at 30°C), and stretched pocket size of 245mm x 210mm was selected as the most economical solution.

Figure 1a.   Modes of failure.
Figure 1b.   Geocell confinement.
Figure 1c.   Sliding failure.

The block-out zones where anchoring was not allowed were identified. The largest area identified was around 5m wide and 10m along the slope, right on top of the tunnel portal with an average slope of around 550. The influence area load was computed on the geocell, and the stainless-steel zip ties transferred the load to the wire net. The wire net was independently anchored along the perimeter (Figure 2b). Cross-metal contamination, areas of local failure within the geocell and the local stress zones on the wire net needed special attention.
Figure 2a.   Influence areas based on soil anchor spacing.
Figure 2b.   Wire-net on geocell.

It must be noted that because of passive resistance within the pockets, loads from the local slope variation, and the wavy geometry of the geocell, the tension developed along the length is not necessarily linear. The further away the support pins are located, the higher the risk of this non-linear tension distribution. This can develop local failures ultimately leading to a progressive system failure. Thus, the location of pins had to be optimized to minimize the risk.

The necessary tensile strength of zip-ties was calculated for each of the influence areas, based on the tensile force coming from geocell. The zip-ties needed to be snug tight to the

geocell and wire net through the geocell perforations. This is to avoid any relative movement between the wire net and the geocell that could lead to the development of additional forces not accounted into the design considerations.

A schematic section of the relevant design forces considered is shown in Figure 3a. Anchors were buried 1.2m deep to transfer the end load into the native soil underneath. A passive resistance supporting the pullout force and the resisting moment necessary for the anchor rod itself determined the depth of embedment and the diameter of the anchor rod (Figure 3b). There was no available geotechnical data for the native soil, thus a conservative assumption was made based on the surficial observations. The force applied for driving the anchors into native soil during installation was monitored to avoid the risk of any local areas which do not meet the design assumptions for the native soil.
Figure 3a.   Schematic section for anchored slope.   Figure 3b.   Anchor design detail.
2.1   Design checks can be summarized into the following 5 steps

Step 1: *Total sliding force for the entire slope length per unit width (neglecting local slope changes) < Σ (factored passive resistance for all soil nail anchors within that unit width + factored toe resistance for unit width + factored base frictional resistance)*

Step 2: *Sliding force for influence area < (Factored passive resistance of an anchor + factored base frictional resistance for that influence area)*

Through step-1 and step-2, using a trial-and-error method, the anchor spacing along and across the slope was determined. The potential for the uplift of anchors, either from freeze-thaw or ice lensing or the presence of water was also checked, and the effective resistance forces are adjusted accordingly.

Step 3: *Factored geocell material tensile strength > effective influence area sliding force*

A higher tensile strength geocell shall need a smaller number of anchors and thus, minimize anchor cost, labor costs, and effectively reduce the construction time. Considering the current design, NPA Type C geocell with 19kN/m tensile strength was used. Given the anchor spacing limitations, any lower-strength material would not allow a safe design. Using even higher tensile strength (22kN/m with Type D NPA geocell) would further reduce the number of anchors and thus improve production. However, to optimally use Type D, the zip-ties had to improve in strength as well. The lack of availability of higher-strength zip ties restricted the optimal design to Type C.

Step 4: *Anchors shall pass the effective moment and shear resistance from all applied member forces*

Step 5: *Any stress concentration in local areas is checked independently*

Some limitations of the design were highlighted before the start of construction. No equipment loading on the slope was allowed. However, loads from laborers carrying handheld equipment were acceptable. Since the work was on a steep slope, necessary harnessing equipment as per the safety standards was identified as the contractor's responsibility. The design had considerations for saturated soil conditions. If there was any potential for water streaming down the sloped surface before the vegetation grew, either from heavy rain events or poor drainage, then there was the potential for washouts of the infill leaving the geocells visibly

exposed. Thus, the possibility of refilling the soil was a potential risk. To minimize that risk hydroseeding was recommended. If the contractor or the drainage design team or the client preferred to minimize the risk further, then options for using a sod cover were kept open.

The diminishing material properties of the geocell with time (for UV and creep from sustained load) increase the risk for local failures at stress concentration zones. Thus, checking the long-term properties (creep and stiffness at elevated temperatures) of the geocell is important. For the current design, long-term cumulative plastic deformation at 650C less than 3% was accepted.

3 RESULTS AND DISCUSSION

Installation of the NPA geocell went hassle-free. First, the geocell panels were stapled and then stretched from the crest to the toe (Figures 4 and 6). Geocell was anchored with J-hooks as per the design in the areas where anchoring was permitted, on other areas the wire net was stretched and anchored along the edges (Figure 5). Once all the anchoring was complete, zip ties were used to connect the wire net to the geocell (Figure 5). Finally, plantation soil was filled from the toe with a conveyor (Figure 7) to avoid any local impacts or local damage. In some extremely steep zones exceeding 73^0, it was difficult to retain the soil because of the angle of filling. However, there was still enough material inside the pocket for the vegetation growth and covering the exposed geocell, leaving a green surface (Figure 8).

Figure 4.   Layout of the slope with tunnel portal.

Figure 5.   Installation of wire net with geocell.

Figure 6.   Installation of geocell.

Figure 7.   Filling of geocell.

There were some rain events right after the installation was complete, but nothing major enough to demand a refill. The site was observed periodically (Figures 8, 9, 10, 11) for any washout zones or any other potential failures.

No mentionable failure was noted within the first year of observation. However, in late summer after the vegetation dried, a small area where the geocell pockets could not be filled and the total plantation soil thickness was less than 200mm, the exposed geocell top was visible (within the rectangle in Figure 10).

Overall, the area was so small that through the spring and early summer when the surrounding vegetation was green, it was not visible. Also, with time it is expected that vegetation will take over those patches. This raised no concern about the green solution that the client had expected.

Figure 8.   Early Summer (6 months later).

Figure 9.   Mid Summer (10 months later).

Figure 10.   Exposed soil area with low vegetation.

Figure 11.   End of Summer (12 months later).

An additional rose bed with thicker soil cover was added at the toe (lesser sloped area) 9 months after the completion of construction (Figure 11). Thus, the developed design approach and construction execution were successfully carried out creating positive environmental impacts.

4   CONCLUSION

NPA geocell and design methodology were effectively used to develop a green cover on a steep slope around a tunnel portal, where there was no opportunity for installing tendons and there were patches of areas where anchoring into native soil was not permitted. The innovative use of wire-net and zip-ties helped to bridge the non-anchoring zones without any installation hassle. The stretched pocket size of 250mm x 210mm with a geocell height of 150mm was found optimal for a 200mm thick plantation soil cover. The higher tensile strength of geocell material had a profound effect on overall load transfer integrity and played an essential part in minimizing the number of anchors needed. Periodic observations made over one year showed no signs of damage or any other potential risks. The study can be further extended to find the maximum area that can be installed anchor free. This can have a significant impact on green construction applications where both tendons and anchors play a challenging role.

BGM testing program for use in heap leach pads

E. Escobar

B.S. Breul
Axter S.A.S, Paris, France

B. Breul
Independant, Paris, France

ABSTRACT: Normal practice in Latin America for the waterproofing of heap leach pads involve the use of polymeric membranes (either HDPE or LLDPE) normally coupled with a medium-weight geotextile to protect the polymeric membrane liner from puncturing. Use of a bituminous geomembrane (BGM) for this application is conceptually appealing to the mining industry since it provides the waterproofing with a single geosynthetic as well as the elimination of an additional interface (polymeric membrane against geotextile) that may have an effect in the static and dynamic stability of the heap leach pile. A BGM manufacturer teamed with a large copper mine in Chile to test the puncture resistance of the BGM sandwiched between the overliner and the subgrade as well as the interface friction angles between the overliner and the BGM. This paper describes the test program, the results obtained and their significance for the heap leach pad.

1 INTRODUCTION

1.1 Description of the project

The project for which the use of a BGM was considered belongs to a major copper mine in Northern Chile. It consisted of a large heap leach pile with a design height of 100 m for the leaching of crushed ore with a density of 1.8 tons/m^3. The area of the pad to be waterproofed for the new heap leach was around 600,000 m^2 in total.

Based on the above conditions the actual puncture stress imposed by the heap pile on the waterproofing barrier of the pad is around 1,800 kPa and the mine owner defined a desired safety factor of 3.0 against puncturing. Overall, the liner would have to be tested at a maximum vertical puncture load of 5,400 kPa.

1.2 Structure of a BGM

The bituminous geomembrane is a multilayered product as illustrated in Figure 1 below.
The components of this bituminous geomembrane are:

– a nonwoven polyester geotextile, ranging from 200 to 400 g/m^2, that provides mechanical performance, especially the tensile and puncture strength,
– a glass fleece reinforcement that provides thermal stability during manufacturing,
– a blend of SBS modified bitumen and fillers. This blend impregnates the geotextile and the glass fleece, provides the watertightness, and ensures the longevity of the product,
Figure 1.   Cross section of bituminous geomembrane.

– a terphane film bonded to the underside, to prevent penetration of the membrane by plant roots,
– a coating of fine sand on the upper surface to provide a greater traction on slopes, and to provide increased protection against the degrading effects of UV radiation.

2   PROPOSED TEST PROGRAM

The objective of the test program was to evaluate the puncture resistance of two different bituminous geomembranes – a 4.8 mm thick BGM containing a non-woven 300 g/m^2 geotextile (internally denominated "ES3") and a 5.6 mm thick BGM containing a non-woven 400 g/m^2 geotextile (internally denominated "ES4") – under the loads imposed by the heap leach with the desired safety factor and to measure the interface friction angles at the normal load imposed by the heap to use these figures for the subsequent stability analyses of the heap.

The project requirements indicated the need to do large-scale puncturing tests at a normal load as high as 5,400 kPa and interface friction tests with a normal load around 1,800 kPa. After a careful search of existing laboratories in the Americas the factory selected the SAGEOS laboratory in St-Hyacinthe (QC, Canada) for the puncturing tests. However, the maximum load capacity was 5,000 kPa which already represents a high safety factor of 2.8. TRI Environmental laboratory in Austin (TX, USA) was chosen for the interface friction testing.

Although the main interest was to evaluate the behavior of the BGM between the subgrade and the overliner material normally used at the mine, the test program also included a series of tests with the BGM between the subgrade and the mineral to be leached with a view to eventually eliminate the overliner in the typical design and generate cost savings.

2.1   Sampling and USCS classification of granular materials

SGS Chile was retained to collect at the mine site the samples of the subgrade, the overliner and the mineral in the quantities required by the testing program, pack the materials in moisture-proof recipients holding 25 kg each, label and ship the materials via airfreight to each laboratory (about 300 kg for the puncture tests and 140 kg for the direct shear tests).

SGS was also tasked to do the sieve analysis of the granular materials involved. The Table 1 below contains the size consist of the different materials. Table 1 presents the size consist information of the materials in a graphical form.

Table 1. Size consists of materials (% passing).

No. 40	28		29
No. 200	14		18
Figure 2. Size consists of granular materials.

2.2 Large scale puncturing tests

The large-scale puncture tests were done following a modified version of ASTM D5514, procedure B. The pressure applied to the geomembrane is exerted via a hydraulic cylinder and a small hydrostatic piezometer is used as a tool to determine whether there are leaks through the liner. Figure 3 below shows a schematic of the puncture testing device.
Figure 3. Schematic of puncture testing device.

Under this procedure the pressure is applied by steps in 138 kPa increments (20 psi), the normal load is held constant for 10 minutes to observe if there is a drop in the level of the piezometer. The process continues following these steps until a drop in the piezometer is observed or the capacity of the testing device (5,000 kPa) is achieved. If the latter takes place, the load is maintained for one hour.

The operational condition of a geomembrane in a heap leach pad corresponds to a "mechanical stress" condition – as described by Blond and Breul (2014) in which the geomembrane is sandwiched between a drainage layer and the support material. Each of the designated geomembranes was tested between the overliner and the subgrade and between the mineral and the subgrade. Three replications were done for each test to obtain average values.

In most tests the BGM reached the capacity of the test device without puncturing, which indicates that the puncture resistance under the test conditions exceeds 5,000 kPa although the ultimate puncture resistance could not be determined. The only exception was the test of the "ES3" (thinnest product) against the overliner material, in which the membrane showed leaks when the load reached 5,000 kPa. However, in all three replications of this test, the membrane did not show any leaks in the stage immediately before the maximum capacity of the test device. The results of the puncture tests are summarized in the Table 2 below.

Table 2. Puncture test results.

Test #	Description	Puncture Resistance	Punctures Observed
1	Overliner / ES4 / Subgrade	> 5.000 kPa	None
2	Mineral / ES4 / Subgrade	> 5.000 kPa	None
3	Overliner / ES3 / Subgrade	≈ 4.860 kPa	5,12,11
4	Mineral / ES3 / Subgrade	> 5.000 kPa	None

2.3 Direct shear tests

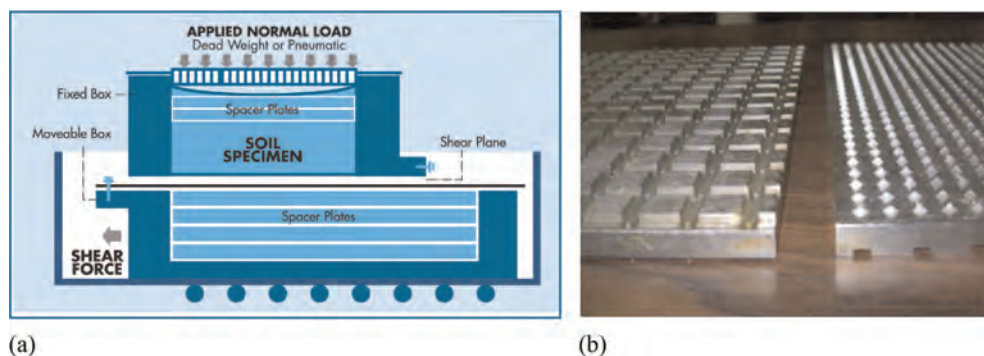
The direct shear tests were done following the ASTM D5321 standard at normal loads of 500, 1,000 and 2,100 kPa. The membrane was placed inside the shear box with a pyramid-toothed grip plate underneath and the material to be tested above. Figure 4 below shows a schematic of the direct shear box and a photo of the grip plate used.


Figure 4   a. Schematic of direct shear box. b. Pyramid-toothed grip plate.

For these tests, the sanded side of the geomembrane was placed against the granular material and the terphane film against the grip plate underneath. The granular materials were tamped in place and the tests were run under wet conditions (deemed to be more unfavorable) at a shear rate of 1.0 mm per minute.

The friction angle between granular materials and the sanded side of the BGM have been measured at the INSA laboratory in Lyon (INSA, 2012) using the sliding table method based on the French standard NF P 84-522. These tests showed the angle friction with gravels to be between 38° and 44°.

Direct shear tests done for the Headworks Reservoir of the Los Angeles Department of Water and Power in the United States (Lew *et al.*, 2013), using ASTM D5321 with a modified speed, showed that the interface friction angle with normal loads up to 250 kPa was around 36° for non-cohesive materials.

Direct shear tests done on railway ballast have shown that the secant friction angles decrease with an increase in the normal stress (Estaire and Santana, 2018). We have not had previous experience with direct shear tests for the BGM at the normal loads for which this test program was designed.

However, based on the above experiences, we were expecting that the friction angle at the higher normal loads would remain around 30°.

At a normal load of 500 kPa the secant friction angle varied between 27° and 30° (depending on the geomembrane and the material on top). However, when the normal load increased to 1,000 kPa, the secant friction angle was reduced to values between 20° and 24° and when the normal load increased to 2.100 kPa, the secant friction angle was further reduced to values between 11° and 14°. It was also noticed that, for the same normal load, the secant friction angles for the thicker, 5.6-mm "ES4" membrane were smaller than those for the thinner 4.8-mm "ES3" membrane. The Table 3 below summarizes the secant friction angles obtained.

Table 3. Secant friction angles.

| Test #. | Description | Normal Load, kPa | | |
		500	1,000	2,100
1	Mineral vs ES3 (Sanded side)	30°	24°	14°
2	Overliner vs ES3 (Sanded side)	29°	21°	14°
3	Mineral vs ES4 (Sanded side)	27°	21°	12°
4	Overliner vs ES4 (Sanded side)	27°	20°	11°

The friction angles derived from the Mohr-Coulomb's linear envelopes obtained from the above tests ranged from 4.3° to 7.5° for the peak stress and from 1.8° to 4.9° for the large displacement measurements. Once again, the friction angles for the thicker, 5.6-mm "ES4" membrane were smaller than those of for the thinner 4.8-mm "ES3" membrane.

The test reports from the laboratory indicate that, in all cases, there was some elongation of the membrane at the grips on the edges. Also, the photo logs of the membrane after the tests show that the granular material got partially embedded into the bitumen and the horizontal movement of the upper box dragged the bitumen along, thus partially exposing the reinforcing geotextile. This could indicate that the shear stresses recorded during the test are somehow affected by the tear resistance of the geotextile and/or by the resistance of the internal interface between the bitumen blend and the geotextile.

After consultation with a geosynthetics consultant, it was decided to run a non-standard "floating" direct shear test (i.e., without clamping the membrane sample at the sides) with

the membrane placed between the overliner and the subgrade (instead of the steel grip plate). The logic behind this test was that, given the usually large dimensions of a real-life pad, the effect of the anchoring of the membrane at the borders of the pad would have little or no impact on the behavior in the middle of the pad. The "floating" direct shear test was done at the same normal loads as the other tests (i.e., 500, 1,000 and 2,100 kPa). Shearing occurred at the geomembrane – subgrade interface (i.e., at the smooth Terphane side of the membrane) at the three normal loads tested. No dragging of the bitumen on the upper side of the geomembrane was observed. The friction angles obtained from this "floating" test were 8.5° for the peak stress and 8.3° for the large displacement. friction angle. These results make us think that the friction angles of the sanded side of the BGM should be actually higher than those derived from the linear envelopes of the initial tests. In our view, the friction angles obtained under this program must be used with caution and further investigation on this matter is required.

3 CONCLUSIONS

Based on the results described above the authors concluded that:

Both the 5.6 mm-thick BGM and the 4.8 mm-thick BGM tested can withstand the puncture loads imposed by the proposed heap leach with a safety factor larger than 2.8 and thus are deemed suitable for the application from this point of view,

The puncture resistance of both BGM's against the mineral to be leached is as good (or maybe better) than the puncture resistance against the overliner. This may lead the design engineers to consider that, provided that the mineral to be leached has enough hydraulic conductivity to appropriately transport the leachate, the overliner could be eliminated altogether, thus resulting in large cost savings for the project,

The actual friction angle of the sanded side of the BGM could be higher than the figures derived from the linear Mohr-Coulomb's envelopes from these tests. In our view this is an aspect that requires further investigation.

Innovative designs for extreme mining applications using bituminous geomembranes

R. McIlwraith*
Director – Axter Australia Pty, Australia

ABSTRACT: The paper describes how bituminous geomembranes (BGMs) are designed in innovative ways to solve engineering challenges on mining sites in extreme environmental conditions and to provide environmental protection. The design of BGMs in mine tailings facilities and environmentally sensitive mine waste capping are focused on, and the technical challenges facing these projects are discussed in detail. The protection of groundwater by using effective and puncture resistant BGM solutions contribute to creating a resilient planet. The innovative use of special high friction angle BGMs on the very steep (1V:1.75H) tailings storage embankments of the new large Ravenswood Gold Mine in Australia are discussed in detail. This mine is under construction from 2021 to 2023. BGMs are multi-layered composite geomembranes with each of the components providing a technical benefit on the mining site. These technical advantages include: Extreme puncture resistance, which allows rapid deployment on rougher subgrades; Excellent resistance to wind uplift due to their high surface mass and this means that installation can continue in winds up to 40km/h. Elastomeric BGMs also retain their flexibility in extremely cold conditions and can be installed and welded down to -25 deg C. This means that elastomeric BGMs are often used in the extreme mining conditions of Siberia, northern Canada and the high altitudes of the Andes mountains in South America. BGMs have a very low coefficient of thermal expansion and do not wrinkle with changes in temperature like other polymeric membranes do and this is particularly useful in high heat projects in Australia. This provides a more secure project in the long run, with less risk of wrinkle-induced cracks and failures. In summary, the paper describes how the technical attributes of the BGM's composite structure provides a wide range of practical on-site solutions for challenging mining applications and environmental protection.

1 INTRODUCTION

Bituminous geomembranes (BGMs) continue to be designed and used in innovative ways to solve engineering challenges on mining sites in extreme environmental conditions and to provide enhanced levels of environmental protection. Environmentally responsible mining will continue to play a vital role in the transition to a more resilient planet, as many of the key materials required for a low carbon future come from mining. For example, a large quantity of copper is required for electric vehicle motors, and lithium and graphite are required for electric vehicle batteries.

Due to their unique characteristics, BGMs are used extensively in four main applications on mine sites. These applications include:

- Tailings storage facilities (TSFs) where the excellent puncture resistance and lack of thermally induced wrinkles are important characteristics in the selection of a BGM. A key

---

*Corresponding Author: RMcIlwraith@axter.com.au

design element for TSFs is also the high mass per square metre of a BGM which gives outstanding wind uplift resistance. A technical design advantage of BGMs is that, due to their internal polyester reinforcement, they can easily be used on slopes up to 2H:1V. For steeper slopes up to 1.3H:1V, the innovated High Friction Angle (HFA) BGMs have been be used. These innovate HFA BGM grades have a releasable siliconized film on the underside of the BGM which is removed at time of deployment to give a self-adhesive underside to the BGM which maximizes interface friction angles on the slope.

Figure 1.   Copper – gold tailings storage facility TSF in South Australia during construction. Note the straight panels on the BGM with no thermally induced wrinkles in extreme 45 deg C heat. This BGM is designed to provide embankment sealing and prevention of tailings migration into sensitive environmental lakes downstream.

- BGMs are also used extensively for capping and closure of mine waste facilities. The key design features of BGMs in these applications are:
  1) extremely low permeability ($< 6 \times 10^{-14}$ m/s) which prevents migration of contaminants into the groundwater and therefore providing a more resilient planet in the long term;
  2) the ability of the BGM to be used on rougher subgrades, typically with aggregate size up to 20mm, and this is a big advantage over other polymeric geomembranes;
  3) the ability to use High Friction Angle (HFA) BGMs on steep slopes on mine waste covers.

Figure 2.   Innovative High Friction Angle (HFA) BGMs being deployed on slopes for mine waste capping and environmental protection. Northern Territory, Australia.

- The third major use of BGMs in mining applications is for containment of stormwater runoff in retention dams, as shown in Figure 3 below. These retention dams prevent runoff entering rivers directly during large rainfall events. Key design features of BGMs in these applications include: puncture resistance on rough subgrades; a specific gravity of 1.22 (which means the BGM is heavier than water and will not float upwards like other polymeric geomembranes which are lighter than water with specific gravities in the region of 0.94); and the excellent wind uplift resistance characteristics of BGMs (Giroud 1995). With little or no ballast required, this results in considerable cost savings and improvements in construction speed for the project.

Figure 3.   BGM being used for environmental protection by containing stormwater run off from a mine before it reaches the river. New South Wales, Australia.

- The fouth main use of BGMs in mining applications is for evaporation and waste ponds. All the key advantages of BGMs play a part in these applications, including puncture resistance, thermal stability, heavy specific gravity and wind uplift resistance.

Figures 4 and 5.   Lithium salt ponds in the extreme Atacama Desert of Chile. Note the thermal stability of the BGM with no wrinkles.

2 TECHNICAL COMPONENTS OF A BGM AND NEW INNOVATIONS

2.1 Multi-component structure of BGM geomembranes

A BGM is a multi-component geomembrane with each of the components providing a technical design or practical benefit on site. Figure 6 below shows a standard BGM structure. The sanded surface provides a non-slip surface for workers which enhances safety in wet conditions. The SBS elastomer modified bitumen provides elastic properties with extremely low water permeability characteristics (<6 x 10^{-14} m/s according to ASTM E 96). The internal non-woven geotextile is fully impregnated with elastomeric bitumen and this provides the mechanical properties of tensile strength and puncture resistance. Various grades of geotextiles can be used to provide different mechanical properties depending on the severity of the application. The puncture resistance of various strength BGMs in direct contact with various size aggregates up to 100mm and with overburden pressures exceeding 1000kPa have been tested (Blond 2014).
Figure 6. Technical components in the BGM geomembrane.

2.2 High Friction Angle (HFA) grade of BGM

For the High Friction Angle HFA grade of BGM, the underside of the BGM has a siliconized self-release film that is removed at time of installation to provide a bitumen surface to be in contact directly with the subgrade. This innovation provides a very high interface friction angle on the underside. This interface friction angle is in the order of 34 deg, but is based on the exact material the HFA BGM is in contact with, so interface friction testing is suggested for critical applications.

2.3 Thermal properties of BGMs in extreme temperatures

BGMs are inherently thermally stable with an extremely low coefficient of thermal expansion of 1 x 10^{-6} C^{-1} when tested to ASTM D 1204-02. This means that BGMs are not effected by heat induced wrinkles that other polymeric membranes suffer from. This
Figure 7. The innovative High Friction Angle BGM being deployed on a steep 1.3H:1V Tailings Storage Facility The white siliconized layer is removed at time of installation to provide a bitumen surface on the underside which maximizes the interface friction angle with the subgrade. This photo also shows another innovation in terms of safety with regard to geosynthetic installations, with the hydraulically operated deployment beam, which uses hydraulics from the excavator. The hydraulic beam enables a safe and control deployment on these steep slopes and it also helps reduce worker fatigue on extremely hot sites.

provides a more secure project in the long run, with less risk of wrinkle-induced cracks and failures.

In extremely cold conditions, elastomeric BGMs have a distinct advantage over polymeric geomembranes. Most geomembranes cannot be welded below 0°C due to brittleness at these temperatures, but BGMs can be installed and welded down to −25°C, which is particularly useful for the many mines in extremely cold environments including the high altitude mines in the Andes of South America, and the mines in Canada. Although there are different types of BGMs, most elastomeric BGMs when tested for Cold Bending according to ASTM D 746 can go down to −25°C.

3 RAVENSWOOD GOLD TAILINGS STORAGE FACILITY USING BGMS

The Ravenswood Gold Mine is Queensland's largest gold mine. It is situated 130km south west of Townsville, Australia.

The photo on the previous page shows the steep 1.75H:1V slopes using High Friction Angle (HFA) BGMs to maximize interface friction angle between the subgrade and the underside of the geomembrane. On the base, a standard BGM is used, as the high interface angles are not required. Both grades of BGM have internal reinforcement providing excellent puncture resistance and they use the same elastomeric bitumen, so they can be bonded directly to each other. The specific gravity characteristic of BGMs being heavier than water, as well as the excellent wind uplift resistance features were also important design considerations when selecting the geomembrane for this application. Due to the large size of the project (more than 1 million m^2 of geomembrane) it was important that the correct type of geomembrane was chosen for the application.

Figure 8.   Ravenswood Gold tailings storage facility.

The sanded non-slip surface of the BGM was an important consideration in membrane selection for construction safety as the tailings storage facility is being raised in a number of incremental stages while there are tailings in the facility.

4   CONCLUSIONS

BGMs have a wide range of technical benefits, due to their multi-component composition, and these benefits are well suited to solving the challenges in mining applications. BGMs have proven themselves on many large mining projects around the world in extreme environmental conditions. The use of BGMs with their excellent puncture strength and thermal stability ensure that they provide excellent environmental protection in an innovative way, which ensures a more resilient planet in the long term.

LDPE geomembrane liner design on soft soil foundation: Case study

B.M.C. Urashima, P.V.S.A. Castro, L. Amaral, M. Castro & P. Martins
WSP, Belo Horizonte, Minas Gerais, Brasil

ABSTRACT: This paper presents a case study of a geomembrane liner design in a mining area for contaminant waste disposal. The presented study involves the need to store steel slag on soft soil foundation that presents a low bearing capacity. The stored material is granular contaminant material with high permeability and high density. Thus, it was necessary to carry out a stress-strain study on a Finite Element Model, followed by an empirical-analytical verification to assess the feasibility of the waste pile construction. The study predicted a maximum strain of 12%, resulting on maximum displacements of 1.4 m. An implementation of plastic geomembranes was proposed considering the need to promote a flow barrier faced to the increasing applications bias of geosynthetics in mining industry. Furthermore, based on the foundation consolidation process under the steel slag waste pile, Linear Low-Density Polyethylene was considered as required by the large expected strains.

1 INTRODUCTION

Geomembranes are geosynthetic materials widely used as hydraulic barriers in waste containment facilities due to its flow reduction characteristic (Chen *et al.* 2009, 2012; Jeon 2016; Mirhaji *et al.* 2019). However, geomembranes are susceptible to damage under dynamic and static loadings during construction phase or during service life cycle. (Hou *et al.* 2021). Extensive research has been conducted to analyze geomembranes behavior under various loading conditions (Yan *et al.* 2021). Area availability is an issue for mining industrial sites. In this context, the construction of embankments on soft foundations with geomembranes application are required. Foundation improvement of the remaining available areas is often needed. This work presents a design study case of geosynthetics application for soft foundations treatment, to make a mine waste pile embankment construction feasible. Its construction was evaluated in two phases.

2 MAIN INPUTS

The stress-strain study was based on a geological-geotechnical investigation which defined a soil profile as presented on Figure 1. A two-dimensional stress-strain modelling was carried out, using RS2 software version 2019 10.002. Table 1 shows the parameters used in the stress-strain study for the soil fill, sand, and silty sand. Table 2 indicates the parameters obtained through the NorSand model for the silty clay and for the fill material.

Figure 1. Generic soil profile for material definition.

Table 1. Mohr-Coulomb foundation parameters.

Parameter	Soil fill	Sand	ilty sand
φ' (°)	32	40	40
c' (kPa)	10	28	0
ν	0.3	0.3	0.3
E (kPa)	15,000	25,000	60,000

Table 2. NorSand foundation and fill material parameters.

Proprieties	Commentary	Fill material	Silty clay
CSL			
Γ	Reference void ratio for CSL	2	1.3
λ	CSL slope for logarithm base 10	0.139	0.113
$_0$	State parameter	−0.5	−0.1
Plasticity			
M_{tc}	Ratio for critical state in triaxial compression	1.55	1.5
N	Volumetric coupling coefficient for inelastic stored energy	0.42	0.3
H_0	Plastic hardening modulus	70	40
H_y	Plastic hardening modulus	500	400
χ_{tc}	Ratio between minimum dilatancy and state parameter	1	4
Elasticity			
$G_{\hat{A}}$ (Mpa)	Shear Modulus	14	10
$N^{máx}$	Poisson coefficient	0.1	0.150

3 GEOMEMBRANE DISPLACEMENTS

The liner system (geomembrane) was analyzed. Figure 2 shows the development of the maximum principal strains in the region close to the silty clay, the most deformable material. It is still observed the concentration of deformations in the central region of the geomembrane of both phases. Figure 2 illustrates the geomembrane total deformations, while Figure 3 shows the
Figure 2. Maximum principal strain at the liner layer.
Figure 3. Evolution of the geomembrane displacements in the phases of initial implantation, phase 1 and phase 2 of construction.

evolution of the geomembrane displacements in the phases of initial implantation, phase 1 and phase 2 of construction. It is observed that the greatest requests are absorbed by the geomembrane corresponding to phase 1. With installation of this liner system, its deformations can reach up to 12% with displacements of the order of 1.5 m. Therefore, plastic geomembranes developed with Linear Low-Density Polyethylene (LDPE) could be used in this case.

4 LINER DESIGN

To the liner system at the base of the deposit, a system composed of linear low density plastic geomembrane (LDPE) was proposed. The strains and stresses expected to act at the liner were firstly generated by the numerical model, however the values were update using analytical methodologies as proposed by (Koerner 1933; Shukla & Yin 2006; Vertematti 2015) during design. This way, the design criteria consider the stress solicitations bellow:

– Stress due to Self-Weight
– Stress caused by settlements
– Stress due to Thermal Contraction
– Stress due to Punching
– Deposit slide over the Geomembrane

4.1 Stress due to self-weight

The geomembrane weight per slope length was obtained through Equation 1 and the stress acting due to this weight was obtained through Equation 2.

$$\mathrm{W} = \Upsilon_{GM} t \frac{H}{sen\beta} \tag{1}$$

where Υ_{GM} = geomembrane specific weight; t = geomembrane thickness; H = slope height; and β = slope angle.

$$\sigma_{tA} = \frac{Wsen\beta - W\cos\beta tg\delta_L}{t} \tag{2}$$

where σ_{tA} = tensile stress acting on geomembrane; W = geomembrane weight; and δ_L = friction angle between geomembrane and foundation material.

The parameters values presented in Table 3 were considered. It is noteworthy that Υ_{GM} was estimated based on average values commonly manufactured, and δ_L was considered based on values presented in literature. The thickness used in all calculations was 1.25 mm, proposing a geomembrane with the needed strength and sufficient deformability.

Table 3. Parameter values considered in stress due to self-weight.

Parameter	Value
Υ_{GM} [kN/m³]	9.20
t [mm]	1.25
H [m]	3.00
B [-]	4.00
δ_L [-]	12.00

4.2 Stress caused by settlements

Equations 3 and 4 were used. Equation 3 related to the tensile force caused by deformation and Equation 4 related to the mobilization length necessary for the resistant friction forces to act.

$$T = \frac{\sigma_n x(tg\delta_U + tg\delta_L)}{\cos\alpha - sen\alpha \quad tg\delta_L} \tag{3}$$

$$x = \frac{(\sigma_r/FS)(\cos\alpha - sen\alpha tg\delta_L)t}{\sigma_n x(tg\delta_U + tg\delta_L)} \tag{4}$$

where α = subsidence angle; σ_n = normal stress due to material weight stored above the geomembrane; and δ_U = friction angle between the geomembrane and the material above. Table 4 presents the values adopted.

Table 4. Parameter values considered in stress caused by settlements.

Parameter	Value
α [°]	14
σ_n [kN/m]	419
δ_U [°]	12
t [mm]	1.25
σ_r [kN/m]	2.5
FS	2

4.3 Stress due to thermal contraction

Geomembranes, when exposed to thermal variation, expands and contracts. The biggest concern in this case is with contraction, which would cause tensile stresses in the material, as it would be anchored. Through Equation 5, the thermal contraction length of the material was calculated.

$$\Delta L = \mu L \Delta T \tag{5}$$

where ΔL = contraction caused by temperature variation; μ = thermal expansion linear coefficient; L = geomembrane length; and ΔT = temperature variation modulus. Table 5 presents the parameters and their values adopted for calculation. μ value was taken from the literature.

To calculate the force caused by this thermal contraction, Equation 6 was used.

$$T = \frac{\Delta L E t}{L} \tag{6}$$

where E = Young's modulus.

Table 5. Parameter values considered in stress due to thermal contraction.

Parameter	Value
μ [°C^{-1}]	11x10^{-5}
L [m]	200
ΔT [°C]	|−30|

4.4 Stress due to punching

Punching in the geomembrane calculation considered that it would be on a terrain that presented, at most, type 2 gravel (~22mm) fragments size. To calculate the stress due to punching in the geomembrane, Equation 7 was used.

$$F_{req} = p' d_a^2 \quad S_1 \quad S_2 S_3 \tag{7}$$

where F_{req} = vertical punch force required to be resisted; p' = pressure exerted on geomembrane; d_a = aggregate average diameter; S_1 = aggregate protrusion factor; S_2 = scale factor that adjusts the average diameter to that used in the punching test described in ASTM D4833; and S_3 = form factor that fits the considered values to ASTM D4833. The pressure exerted on geomembrane was considered equal to stored material weight. Table 6 shows the parameter values considered in calculations.

Table 6. Parameter values considered in stress due to punching.

Parameter	Value
σ_n [kN/m]	419
d_a [m]	0.022
S_1	0.4
S_2	0.4
S_3	0.5

4.5 Deposit slide over the geomembrane

The weight force that could generate slipping and the resistant friction force were calculated trough Equation 8 and 9.

$$W_{slide} = \Upsilon_{slag} A sen\beta' \tag{8}$$

$$F_{at} = \Upsilon_{slag} A \cos\beta' tg\delta_U \tag{9}$$

where Υ_{slag} = slag specific weight; A = slag pile cross-sectional area; and β' = slag pile inclination angle. Table 7 presents the parameters values considered in the calculation.

Were obtained the values: W_{slide} = 2440 kN/m and F_{at} = 7414 kN/m, that is, the slag pile would not slip on the geomembrane. However, there is a difference between the index and required property. The index properties are characteristics of a geosynthetic, determined in tests that do not consider the field requests. The required ones consider the damages that the material can suffer and that can cause its aging, through Reduction Factors. Table 8 shows reduction factors considered in the calculation. Table 9 presents the results summary obtained compared to the material required values.

5 CONCLUSIONS

This paper deals with case study of a geomembrane liner design need for storing a steel slag, a granular contaminant material with high permeability and high density, on a soft soil foundation with a low bearing capacity. The results obtained lead to the conclusion that a 1.25 mm LDPE geomembrane would be ideal for make a mine waste pile embankment construction feasible In a critical scenario in which the traction requests would be occurring all at once, the requesting stresses would be added, resulting in a value of 0.0037 kN/m, which is lower than the required resistance (2.51 kN /m), that is, the specified geomembrane would still meet the required performance.

Working platforms for cranes – review of design approaches and recommendations for a safe design

A.A. Lavasan, V. Poberezhnyi & O. Detert
HUESKER Synthetic GmbH, Gescher, Germany

ABSTRACT: This paper provides a technical insight into the essential aspects to be considered in the proper design of a safe working platform for heavy construction machinery. Considering the complexity of the operational boundary conditions, the uncertainties of the ground characteristics and the variability of the loads applied by the construction machinery, a clear understanding of the possible failure modes and the definition of a criterion for the design of countermeasures seems to be essential in this application. This can be better achieved by considering the significant increase in cost and time delays associated with the failure of the working platforms. This paper discusses various possible failure mechanisms in the working platforms and examines the advantages of using geosynthetic reinforcing elements to avoid the risk of failure.

1 INTRODUCTION

In recent years, a number of heavy construction machines such as drilling rigs, trenchers, pile drivers, mobile cranes and crawler cranes have been involved in serious accidents due to incompetent working platforms. Considering the size and weight of such machines, the overturning of such equipment is often associated with fatal injuries, damage to third parties or work teams, high costs due to recovery of the collapsed equipment, replacement of a new machine as well as production loss or installation delay. Figure 1 shows examples of the working platform failure and the resulting installation machine accident. In addition, these major accidents always have a significant psychological impact on the site personnel. The main cause of most of these accidents is the mismatch between the shear strength provided by the platform and the actual operational loads. This mismatch between available and required shear strength can be the result of improper design of the platform, inadequate knowledge of the geotechnical and geological site conditions and/or insufficient information on the load combinations induced by the equipment in different working conditions. In this context, an adequate design of a competent working platform should properly consider the coupled interactions in the ground and consider all possible failure modes in accordance with an appropriate design method.

Figure 1. Examples of construction machinery overturning.

Considering the significant need to obtain a deep insight into the system behaviour, this paper has investigated and discussed different aspects around the problem, including the coupled interactions such as excess pore pressure evolution and dissipation, relevant failure mechanisms for different loading conditions, and the necessary design criterion. Furthermore, the need to develop advanced and comprehensive numerical tools to predict all these engineering phenomena and not only some of them has been discussed.

2 MEHTODOLOGY AND NUMERICAL MODELLING

In the present study, in order to demonstrate the capability of the finite element modelling approach to evaluate the likely failure mechanism and critical design aspects, a numerical model of a 1 m thick working platform with two layers of geogrid with a short-term nominal tensile strength of 400 kN/m has been developed. In this model, the lower layer of geogrid is placed at the contact between the weak subsoil and the fill material, while the upper layer is placed 0.3 m above the other. The non-cohesive working platform material is assumed to have a friction angle of 38°, dilatation of 8° and modulus of elasticity of 180 MPa, while the undrained soft subgrade with a thickness of 2 m has an undrained shear strength of 20 kPa. This soft subsoil is underlain by a low plasticity silt with an undrained shear strength of 50 kPa. Given the rapid nature of crane loading, an undrained analysis was carried out. The machine track is assumed to be 1.5 m wide with a center-to-center distance of 8 m, carrying a maximum pressure of 200 kPa. The water table is assumed to be 1 m below the ground surface, while the soft subsoil above the water table is assumed to be saturated.

3 TECHINAL ASPECTS IN THE DESIGN OF WORKING PLATFORMS

3.1 *Bearing capacity of the working platform*

One of the essential aspects to be considered in the proper design of a working platform is the correct determination of the available load-bearing capacity according to a realistic failure mode. In this context, it is important to consider all possible failure modes, such as punch, local and global shear failure, and their potential combination in the fill materials of the platform as well as the subsoil as a system.

For example, in the case of a thin platform, there is a high probability that a punch failure will occur within the platform body, which may be associated with a local or global failure of the subsoil. In this context, it should be noted that, depending on the nature of the subsoil material and the water table, the bearing capacity must be determined on the basis of the total or effective shear parameters in the case of a frictional soil or the undrained shear strength parameters for a cohesive soil.

It should be noted that the difference between local and global shear failure in the soil is mainly due to the settlement of the foundation. In other words, local shear failure often corresponds to lower levels of settlement where less shear strength of the soil is mobilised, while the global shear failure mechanism often corresponds to extremely large settlements. In this context, special attention must be paid to the sensitivity of the machine to settlement before considering global shear failure to determine the bearing capacity.

As can be seen in Figure 2, since the mobilisation of the soil shear strength requires the development of strain in the soil, the bearing capacity of the system must essentially be defined in terms of the acceptable settlement in the system.

One of the most commonly observed phenomena with relatively thin (but competent) working platforms is the so-called "trampoline effect". In this situation, the soft, fully saturated subsoil reacts almost undrained to the application of dynamic loads. However, during the operation of the construction machine, the excess pore pressure generated in the

a) punching failure in working platform and local failure mechanism in subsoil (σ=150 kPa, δ=4.9cm)

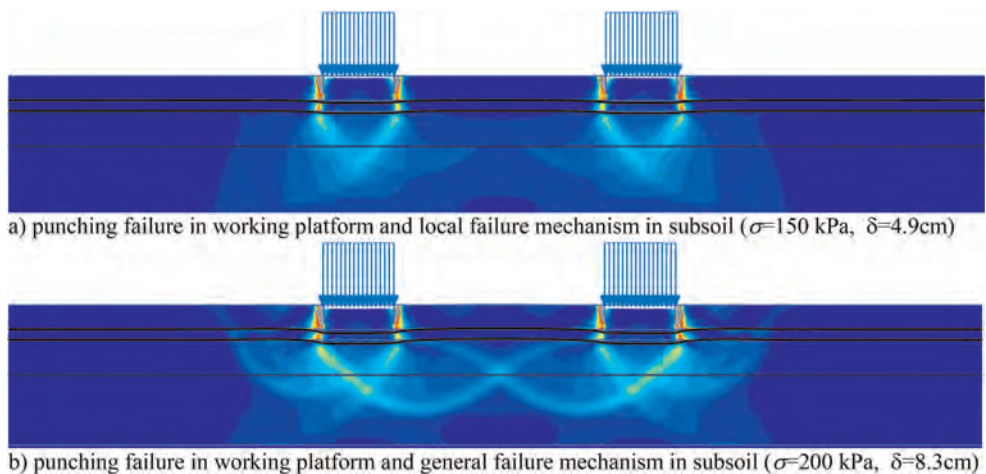
b) punching failure in working platform and general failure mechanism in subsoil (σ=200 kPa, δ=8.3cm)


Figure 2.   Evolution of the failure mechanism and bearing capacity through progressive loading (deviatoric shear strain obtained from FE modelling).

subsoil begins to dissipate (see Figure 3). As a result of this consolidation process, further settlement would develop, particularly below the machine. Accordingly, settlement or, more generally, displacement in the working platform and in the ground occurs as an inevitable part of the system and it is often not appropriate to assume that the only role of the working platform is to distribute the load as a purely elastic rigid body over a wider area in depth. Such an idealised conceptualisation of the design method, without consideration of platform failure, requires a justification for no displacement in the ground. Otherwise, the membrane effect and, consequently, the evolution of the tensile force in the geosynthetic layers is an essential event in the kinematics of the system that must be considered in the design phase.
Figure 3.   Excess pore pressure in subsoil obtained from FEM ($\Delta u_{max.}$=120 kPa, σ=200 kPa).

As shown in Figure 3, excess pore pressure is generated in the subsoil with high water table. Depending on the type of soil, either undrained shear strength (s_u) or effective shear parameters (i.e., φ' and c') must be used to determine bearing capacity.

In the working platforms reinforced with the geosynthetic layers, the proper interlocking between the geosynthetic layer and the fill materials allows the development of a load transfer arch within the working platform. Figure 4 shows the load transfer mechanism in the working platform with two layers of geogrid. As can be seen, the kinematics of the membrane developed by settlement in the geosynthetic leads to the formation of an arch to

transfer the machine load to a wider area. This arching effect is a natural consequence of the deformation in the system and has nothing to do with the oversimplification of assuming a linear load transfer in the working platform.

(a) strain of reinforcement   (b) direction of principal stress   (c) arching mechanism
Figure 4.   Load transfer mechanism in the working platform.

Instead of using fill material with adequate shear strength to construct the working platform, the use of material with low shear strength combined with increased thickness of the working platform is often considered as an alternative solution. In such conditions, a special attention should be paid to properly assess the possibility of shear failure within the platform body (see Figure 5). In this context, the bearing capacity of the working platform alone must be determined and compared with the load applied by the machine operation. If it is necessary to use fill material with a lower bearing capacity, more layers of geogrid must be installed at the design vertical spacing to ensure no shear failure in the working platform.

Figure 5.   Failure within a thicker working platform with insufficient shear strength ($h_{platform}$=2 m, φ_p=27°).

3.2 Slope stability analysis

Given the limitations in the availability of high-quality fill material and the relatively high cost of properly constructing a competent working platform, there is often debate about minimising not only the thickness but also the area of the working platform and reducing the distance between the machine stand and the side slopes of the working platform. However, this is an essential technical issue that must be addressed in a proper design. To do this, the dimensions of the working platform must be such that (1) it provides sufficient stability against slope failure and (2) it provides sufficient resistance to pullout failure of the geosynthetic reinforcement by allowing sufficient length for the reinforcement to extend beyond the zone of the load application. To assess slope stability, classical approaches such as Bishop's method can be used to determine the safety of the slope against failure, considering the distance between the slope and the machine loads (see Figure 6).

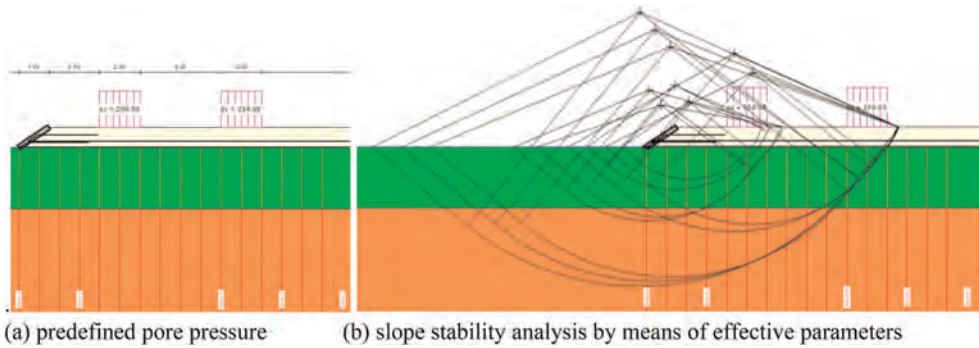
(a) predefined pore pressure   (b) slope stability analysis by means of effective parameters


Figure 6.   Slope stability analysis to determine allowable working area.

If the stability analysis is carried out in conjunction with the effective shear strength parameters (e.g., φ' and c'), the possibility of the development of excess pore pressure in the subsoil and its effect on the stability analysis in conjunction with the analytical solutions should be investigated and properly introduced into the model. The results of the slope stability analysis would be used to determine the permissible working area for the construction machine. In the case of stability analysis based on undrained shear strength, it is recommended to consider the increase in undrained shear strength with effective vertical stress as mentioned in the literature (Mesri 1975). Figure 6 shows a standard stability analysis combined with an analytical approach to design the minimum distance between the permissible working area and the edge of the working platform.

3.3   Lateral extrusion failure in soft subsoil

Another mode of the failure that should be investigated in a proper design of working platforms is the extrusion of the weak subsoil at the under heavily loaded working platforms. For this purpose, it is essential to verify whether the weak subsoil has sufficient strength to resist the unbalanced horizontal load that induced by the active earth pressure. In this frame, Scotland *et al.* (2019) discussed different possibilities to increase the shear strength against lateral extrusion or squeezing of the subsoil. The use of a geosynthetics with adequate interlocking properties would help to reduce the horizontal load transfer to the weak soil. Figure 7 shows how the contribution of the geosynthetic layers can reduce the deficit between the resistance to extrusion and the active earth pressure due to high vertical loads.
Figure 7.   Reducing the susceptibility of the platform to lateral extrusion through geosynthetic reinforcement.

Giffen 2015 proposed the construction of a shear key trench to disrupt the potential for lateral extrusion where the use of geosynthetic reinforcement at the base of the working platform does not fully mitigate the risk of weak lateral soil spreading. This shear key can be constructed as (a) full depth unreinforced, (b) full depth reinforced or (c) partial depth reinforced. In the case of a full depth shear key, the trench involves replacing the full height of the weak soil to achieve the required lateral resistance and improve the drainage capacity of the weak soil. Considering the challenges of excavating in saturated soft ground, the construction of a reinforced partial depth trench is of great preference. The load transfer of extrusion mechanisms with reinforced shear trenches according to BS 8006 (2016) is shown in Figure 8.

(a) reinforced partial trench   (b) reinforced full trench
Figure 8.   Load transfer of a working platform with reinforced shear trenches (BS 8006, 2016).

In addition to analytical solutions, such a lateral spreading failure mechanism can also be evaluated using numerical FE modelling, as shown in Figure 9.

(a) deviatoric shear strain   (b) contours of horizontal displacement
Figure 9.   Application of FE modelling to assess the lateral spreading failure mechanism in the weak soil underneath working platforms.

3.4   Working platform with multiple geosynthetic layers

The monitoring of the tensile forces in the geosynthetic reinforcements as basal reinforcements has shown a non-identical evolution of the tensile force in the reinforcement layers. In this frame, the lower reinforcement layer is overloaded, while the upper reinforcement would be underloaded compared to the lower one. As the mobilisation of the tensile force in the geosynthetics is a direct function of the tensile strength, the different mobilisation of the tensile force between the layers is mainly due to the unequal loading of the layers at different depths. In this context, the required total tensile strength of multiple geosynthetics should not be defined on the assumption of simultaneous mobilisation of tensile force in different layers.

Figure 10 shows an example of non-identical distribution of tensile force between different reinforcement layers in the case of a working platform with two layers of geosynthetics obtained from FE analysis.
Figure 10.   Variation in tensile force in working platform with double layer of geosynthetic reinforcement.

4   CASE STUDY

A project for the construction of a working platform for the storage and transport of offshore wind turbines and their components in northern Germany, Nordenham. The site was located in an area with poor soil conditions and a high water table typical of the region. Both ultimate and serviceability criteria were applied to the storage facility, as the MEWP had to accommodate not only the transient loads from the cranes transporting the heavy equipment, but also the relatively long term loads from the stored wind turbine towers. To overcome the lack of bearing capacity of the existing soil, the use of geosynthetic reinforcement was considered. Woven geotextiles, which provide reinforcement as well as separation and filtration functions, and geogrids were used as reinforcing elements to strengthen the working platform material. Figure 11 shows some construction details and operation of the geosynthetic reinforced working platfrom.

(a) construction of working platform   (b) operation of working platform
Figure 11.   Geosynthetic reinforced worling platfrom (Nordenham, Germany).

5   CONCLUSION

This study discusses possible modes of failure mechanisms that should be considered in the proper design of a working platform. In addition, the essential technical aspects that should be considered regarding the relevant soil parameters, the type of analysis and the excess pore pressures are reviewed. In addition, it has been shown that finite element modelling can be successfully applied to consider most of these phenomena in the design of working platforms.

Towards the use of sustainable protection structures against flow-like movements

S. Cuomo & A. Di Perna
Geotechnical Engineering Group (GEG), University of Salerno, Italy

M. Martinelli
Deltares, Delft, The Netherlands

L. Frigo
Comune di Chiampo, Vicenza, Italy

ABSTRACT: The sustainability of protection structures has been attracting attention in recent times, especially after the introduction of the 2030 Agenda for Sustainable Development. However, such an issue has been hardly discussed in the case of flow-like landslides. Here the concept of de-formable protection systems made up of granular soil reinforced by geogrids is explored and compared to more traditional concrete rigid walls. The numerical analyses concern the impact of fast-moving landslides on these two types of protection structures to understand their performance in stopping the propagation of the flow. To this aim, an advanced numerical model-ling capable to consider the non-zero initial velocity of the landslide and the large deformation occurring inside both the landslide and the structure is used. Both the landslide soil and the barrier material are simulated as frictional elasto-plastic non-associative media. The role and the time-space evolution of the pore-water pressure inside the landslide material under different impact scenarios are computed. Furthermore, the amount, type, and features of the needed construction materials are compared towards a sound assessment of the sustainability of both solutions.

1 BACKGROUND

Reinforced Concrete (RC) walls are commonly used as protection measures in hilly areas to contain falling boulders and landslide debris, and the sliding displacement of these barriers is a key design issue when space is limited. RC walls are usually made as slab concrete dams, that can be reinforced with counterfort. For such slender constructions, the flow impact dynamics must be carefully evaluated, as the wall must retain the flowing material without failure, tilting or excessive displacements. Hence, their foundations are usually very large. In bedrock, the foundations are usually made by steel tension anchors (ribbed bars), while in loose deposits, the ground must sustain the weight of the concrete construction together with the loads generating from the impact (Barbolini *et al.* 2009). An example is provided in Figure 1, for a diverting dam against snow avalanches at Odda, Norway.

MSE (Mechanically Stabilized Earth) wall is an alternative option. In the context of landslide protection, they are also called Deformable Geosynthetics-Reinforced Barrier (DGRB), as they are composed of granular soil and geosynthetics reinforcement elements, such as high tenacity polyester (PET) geogrids (Cuomo *et al.* 2020). These geostructures have been formerly investigated (Cuomo *et al.* 2019, 2020b; Gioffrè *et al.* 2017; Moretti 2019) to reduce the runout (and the potential damage) of flow-like landslides, while they are typically

used as deformable barriers against snow avalanches or rockfalls (Figure 1). The stability of a DGRB is derived by the interaction of coarse material with the reinforcements, involving friction and tension resistances. The facing is relatively thin, with the primary function of preventing erosion of the structural backfill. The result is a massive structure that is flexible and can withstand various loads combinations. DGRB is an appropriate protection structure when a medium to very high kinetic energy event is expected (Descoeudres 1997). The other advantages are the low maintenance costs and the reduced visual impact since DGBR are greened (Brunet *et al.* 2009).

Figure 1. Examples of reinforced concrete (RC) wall (left) and MSE walls (right) used as protection structures (Barbolini *et al.* 2009).

2 MATERIAL POINT METHOD APPROACH

The Material Point Method (MPM) can be considered a modification of the well-known Finite Element Method (FEM), and it is particularly suited for large deformations (Sulsky *et al.* 1994). The continuum body is schematized by a set of Lagrangian points, called material points (MPs). Large deformations are modelled by a set of MPs moving through a background mesh, which also covers the domain where the material is expected to move. The MPs carry all the physical properties of the continuum such as stress, strain, density, momentum, material parameters, and other state parameters, whereas the background mesh is used to solve the governing equations without storing any permanent information (Figure 2).
Figure 2. Concept of MPM computation.

The interaction between phases (solid and liquid in a saturated soil) can be tracked through the "two-phase single-point" formulation (Ceccato *et al.* 2018; Jassim *et al.* 2013), where the liquid and the solid acceleration fields are the primary unknowns (Fern *et al.* 2019). On the other hand, the so-called "one-phase single-point" formulation can be

opportunely adopted for dry soils or for saturated soil in the simplified hypothesis that the ratio of pore water pressure divided by total stress is constant inside the deforming body and throughout the whole deformation process.

The contact between different bodies (flow-base, flow-barrier) is handle with a frictional contact algorithm. An improved contact algorithm was used, proposed by Martinelli & Galavi (2022), where the velocity of the liquid phase is corrected to prevent both inflow and outflow. Moreover, the computational scheme proposed by Martinelli & Galavi (2022) is adopted to compute accurate reaction forces along contact surfaces, especially between non-porous structures and soils with high liquid pressures. All the MPM simulations were performed using a version of Anura3D code developed by Deltares.

A saturated porous medium is schematized as a solid phase which represents the solid skeleton, whereas the liquid phase fills the voids among the grains. Each MP represents a volume of the mixture, given by the sum of the solid and liquid phases volumes. The velocity field of solid and liquid phases are both used, but the material points move throughout the mesh with the kinematics of the solid skeleton. The equations solved are the balance of dynamic momentum of solid and liquid phases, the mass balances, and the constitutive relationships of solid and liquid phases. The accelerations of the two phases are the primary unknowns: the solid acceleration, which is calculated from the dynamic momentum balance of the solid phase, and the liquid acceleration, which is obtained by solving the dynamic momentum balance of the liquid phase. The interaction force between solid and liquid phases is governed by Darcy's law and solved at grid nodes considering the Galerkin method (Luo *et al.* 2008). In the two-phase single-point formulation used here, the liquid mass and consequently the mass of the mixture, is not constant in each material point but can vary depending on porosity changes. For this reason, this formulation is generally used in problems with small gradients of porosity, and laminar and stationary flow in slow velocity regime. However, this formulation proves to be suitable for studying flow-structured-interaction (Cuomo *et al.* 2021). The water is assumed linearly compressible via the bulk modulus of the fluid and shear stresses in the liquid phase are neglected.

3 EXAMPLES AND DISCUSSION

3.1 *The case of a RC wall impacted at 5 m/s*

This section investigates the performance of a RC protection wall under the impact of a flow-like landslide, with the geometric configuration reported in Figure 3.
Figure 3. Geometric schematization for the LSI numerical simulations with RC walls.

The landslide material is assumed as a saturated mixture with hydrostatic distribution of initial pore-water pressure and an elasto-plastic behaviour at failure. The contact along the base is assumed to be smooth to avoid reduction in velocity due to friction. Based on

literature values and other related researches (Cuomo *et al.* 2020a), the mechanical properties are selected as follows: density of the mixture (ρ_m) equal to18 kN/m^3, Poisson ratio (ν) of 0.25, Young's modulus (E) equal to 2,000 kPa, nil cohesion (c'), internal friction angle (φ') is 20°, nil dilatancy angle, hydraulic conductivity (k) equal to 10^{-3} m/s, liquid viscosity (μ_L) of 10^{-3} Pa·s, liquid bulk modulus (K_L) of 30 MPa. Moreover, the initial velocity of the landslide (v_0) is set equal to 5 m/s.

The RC wall is schematized as a homogeneous material, with frictional contact at base and elasto-plastic behaviour. The wall is 6 m high with a foundation platform of 11 m. The material properties used in the study were determined by Ardiaca (2009) from design regulations, considering the type of concrete with a characteristic compressive strength of 25 MPa. The base-concrete interface is handled with a frictional contact, imposing a coefficient equal to 0.67 (Ilori *et al.* 2017). The mechanical properties of the RC wall are: barrier density (ρ_b) equal to 25 kN/m^3; effective friction angle (φ') of 35°; cohesion (c') as 510 kPa; Young's modulus (E) = 30,000 MPa; Poisson's ratio (ν) equal to 0.25; tensile strength (f_t) of 750 kPa and frictional coefficient ($\tan\delta_b$) equal to 0.24.

The computational unstructured mesh is made of 17,267 triangular elements with dimensions ranging from 0.10 (in the proximity of the wall and the impact area) to 0.50 m (elsewhere). The flow and the RC wall are modelled through the two-phase and one-phase single-point MPM formulation, respectively. Also here, the build-up of excess pore-pressure during the impact is considered as well as the hydromechanical coupling and the elasto-plastic failure criterion of the flow.

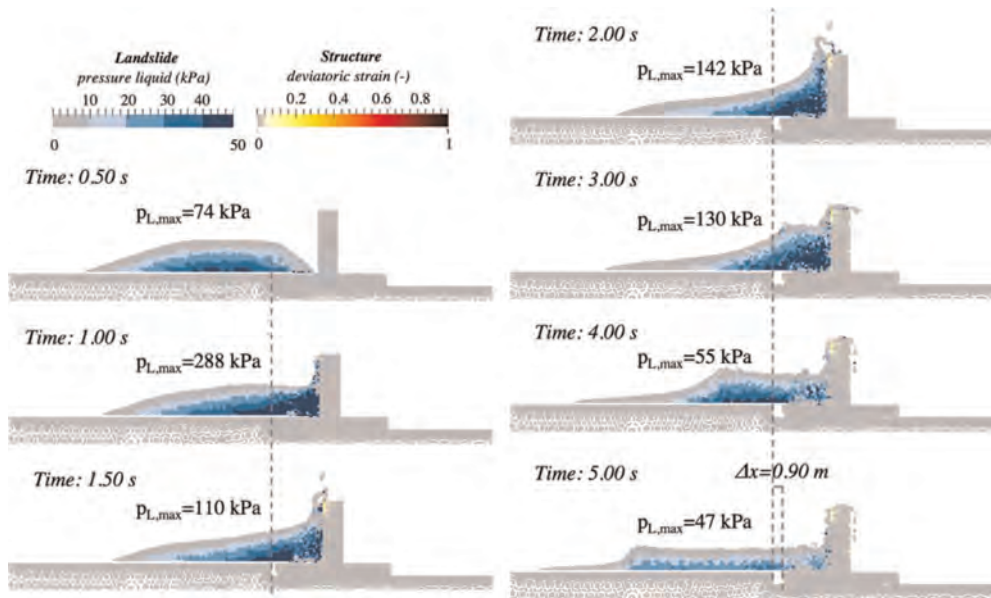
Selected results are shown as the spatial distribution of pore-water pressure within the flow mass and the appearance of deviatoric deformations inside the structure (Figure 4).


Figure 4.   Pore-water pressure (landslide) and deviatoric strain (RC wall) distribution during impact.

At impact (t = 1.00 s) the pore-water pressure increases up to 288 kPa, then diminishes (t = 1.50 s) due to the beginning of wall mobilization and increases again (t = 2.00 s) due to the rising of the flow along the vertical column. After that, the liquid pressure is mostly decreasing, indicating that the landslide is losing kinetic energy. The internal shear

deformations of the wall are practically nil; thus, the wall is subjected to a rigid translation with a final displacement equal to 0.90 m.

3.2 MSE wall impacted at 5 m/s

The interaction between the landslide and the DGRB is analyzed through the same mechanical and geometric features of the flow used before (Figure 5). A full numerical analysis of the geosynthetics-reinforced soil structure is challenging. Thus, an equivalent approach is here employed to analyse the DGRB. A composite reinforced soil properties is considered and with less input parameters needed. However, localized failures cannot be reproduced, and the soil-reinforcement interaction cannot be studied independently.
Figure 5. Geometric schematization for the LSI numerical simulations with deformable barrier.

The assessment of the elasto-plastic parameters to set for the equivalent approach is carried out considering the internal friction angle (φ'), Young's modulus (E) and Poisson's ratio (ν) of the equivalent material equal to those typically employed for the backfill soil for practical applications. In addition, a tensile strength equal to the ultimate shear resistance of the geosynthetics reinforcement is imposed for this equivalent material (Maji *et al.* 2016; Nquyen *et al.* 2011). In this study, the value of cohesion was found by making sure that the Factor of Safety (FS) under gravity load obtained for the composite structure is the same than in the equivalent model.

The mechanical properties chosen for the barrier are: the barrier density (ρ_b) equal to 20 kN/m³; effective friction angle (φ') of 38°; cohesion (c') as 58 kPa; Young's modulus (E) equal to 15 MPa; Poisson's ratio (ν) equal to 0.25; tensile strength (f_t) of 100 kPa and frictional coefficient (tanδ_b) equal to 0.29. The failure behaviour is non-associative (zero dilatancy) elasto-plastic criterion. The frictional resistance along the base is set equal to the 80% of the strength properties of the base material (Cuomo *et al.* 2019). The homogeneous barrier with the achieved cohesion equal to 58 kPa represents a composite structure with FS = 3.73 under gravity load. The factor of safety is calculated through LEM analysis, with Morgenstern-Price method.

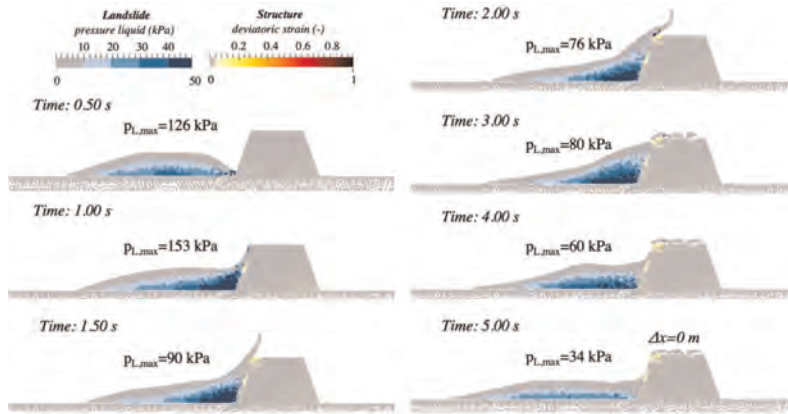
The flow and barrier are modelled through the single-point MPM formulation, respectively with two-phase and one-phase. The computational unstructured mesh is made of 16,356 triangular elements with dimensions ranging from 0.10 (to refine the impact zone) to 0.50 m. The results of pore-water pressure (landslide) and deviatoric strain (barrier) are reported first for the flow with low initial velocity (Figure 6). In particular, the liquid pressure reaches the maximum value of 153 kPa after some instants from impact (t = 1.00 s). This is probably related to the increase of the impacted area. Simultaneously, the shear deformations along the impacted side are growing. For t > 1.50 s, the kinetic energy of the flow decreases and this is well understandable from the lower values of $p_{L,max}$ and from the unchanging deformations inside the barrier. Moreover, the barrier does not show any horizontal displacement and all the flow is completely block by the barrier.


Figure 6.   Pore-water pressure (landslide) and deviatoric strain (barrier) distribution during impact.

3.3   *Comparison*

Based on the numerical results, different options are outlined as capable to perform well against two impressively fast-moving landslides, with 5 to 10 m/s speed and 3 m thick. (Tables 1–2).

Table 1.   Barriers (H = 6 m) designed to well perform against a landslide 3 m thick and 5 m/s fast.

RC wall	B/H	b'/H	θ (°)	V_2 (m³/m)	V_{exc} (m³/m)	V_1/V_0>0.8	$\Delta x < 1.0$ m	Deflection
1	1.83	0.3	6.2	30.6	19.8	Yes (100%)	Yes (0 m)	No
2	1	0.3	11.3	21.6	10.8	Yes (100%)	Yes (0.03 m)	No
3	1.83	0.2	6.2	27	19.8	Yes (100%)	Yes (0 m)	Yes (19.5°)
4	1	0.2	11.3	18	10.8	Yes (100%)	Yes (0.06 m)	Yes (5.7°)
5	1.83	0.3	0	24	19.8	Yes (100%)	Yes (0.90 m)	No
6	1.83	0.2	0	20.4	19.8	Yes (100%)	No (1.90 m)	No

MSE wall	B/H	β (°)	c_{eq} (kPa)	V_2 (m³/m)	V_{exc} (m³/m)	V_1/V_0> 80%	$\Delta x < 1.0$ m	Damage
1	1.83	80	35	59.6	0	Yes (97%)	Yes (0 m)	No
2	1.83	80	58	59.6	0	Yes (97%)	Yes (0 m)	No
3	1.83	70	35	52.9	0	Yes (97%)	Yes (0 m)	No
4	1.83	70	58	52.9	0	Yes (97%)	Yes (0 m)	No
5	1	80	35	29.6	0	Yes (87%)	No (1.43 m)	No

7	1	70	35	22.9	0	Yes (83%)	No (2.75 m)	No
8	1	70	58	22.9	0	Yes (82%)	No (2.80 m)	No

B: base, H: barrier height, b': thickness of RC wall, θ: foundation plane inclination, β: front inclination V_2: barrier volume, V_{exc}: excavation volume V_1: landslide retained volume; V_0: initial landslide volume, Δx: horizontal displacement of the barrier

Performance is assessed based on a multicriteria rationale: retained volume percentage (V_1/V_0), horizontal displacement of the barrier (Δx), and its deflection/damage. For the first landslide case (Table 1), the best solutions are 2 RC walls (ID: 1-2), and 4 MSE walls (ID: 1-4); whereas, for a faster landslide (Table 2) only 1 RC wall (ID: 2) is usable but the same 4 MSE walls (ID: 1-4) options seen before are all still well performing. The construction

Table 2. Barriers (H = 6 m) designed to well perform against a landslide 3 m thick and 10 m/s fast.

RC wall	B/H	b'/H	θ (°)	V_2 (m³/m)	V_{exc} (m³/m)	$V_1/V_0 > 0.8$	$\Delta x < 1.0$ m	Deflection
2	1	0.3	11.3	21.6	10.8	Yes (100%)	No (3.19 m)	Yes (25°)
MSE wall	B/H	β (°)	c_{eq} (kPa)	V_2 (m³/m)	V_{exc} (m³/m)	$V_1/V_0 > 80\%$	$\Delta x < 1.0$ m	Damage
1	1.83	80	35	59.6	0	Yes (99%)	No (2.27 m)	No
2	1.83	80	58	59.6	0	Yes (99%)	No (2.10 m)	No
3	1.83	70	35	52.9	0	Yes (99%)	No (2.15 m)	No
4	1.83	70	58	52.9	0	Yes (99%)	No (2.20 m)	No

B: base, H: barrier height, b': thickness of RC wall, θ: foundation plane inclination, β: front inclination V_2: barrier volume, V_{exc}: excavation volume V_1: landslide retained volume; V_0: initial landslide volume, Δx: horizontal displacement of the barrier

material volume added to the excavation amount are comparable of all the solutions highlighted. This paves the way for further considerations about environmental impacts and sustainability, applied to equally/similarly performant technical solutions in a so complex and fundamental landslide problem.

Requirement guide for a Geosynthetic Clay Liner (GCL) design specification

K.P. von Maubeuge
Naue GmbH & Co. KG, Espelkamp, Germany

ABSTRACT: Geosynthetic clay liners have gained widespread popularity as a substitute for compacted clay liners in many applications. A geosynthetic clay liner (GCL), also known as geosynthetic clay barrier (GBR-C), is a factory-produced clay barrier which consists of two geotextile layers with a layer of sodium bentonite. GCLs are used in multiple barrier applications. The GCL requirements must fit to the anticipated field, mechanical and hydraulic conditions, chemical effects and shear strength parameters. A main consideration is also the lifetime of the project, so that the durability aspect is also of major importance. This paper will present key design criteria that are necessary for a proper design and also cover the calculation of leakage rates and shear stability. Other factors will also be addressed in this paper. Finally, the paper will evaluate current well known specification recommendations, such as GRI-GCL3, and make recommendations for improvements.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) – also known as geosynthetic clay barriers (GBR-C) – are typically needle-punched, reinforced composites that combine two durable geotextile outer layers and a uniform core of high-swelling powder sodium bentonite clay (Figure 1). This construction forms a shear-resistant hydraulic barrier with self-sealing and re-plastification characteristics. When hydrated with fresh water, the bentonite swells and forms a low-permeability gel layer.
Figure 1. Cross-section of a needle-punched GCL with thermal treatment of the needle-punched fibres.

In general, the GCL hydraulic performance is equal to or better than traditional, thick compacted clay liners. GCLs revolutionised the field in 1987 with the invention of the needle-punched manufacturing technology that greatly increased the internal shear strength of bentonite, which has unreinforced an internal shear angle in hydrated state of approx. 8°. In addition to needle-punching, some GCLs have an additional heat-treating process (Figure 1). This manufacturing technique permanently locks the needle-punched fibres of the nonwoven geotextile layer with the carrier layer of GCL types and improves the hydraulic conductivity performance at low confining stresses. Typical GCL applications include canals, dams, dykes and levees; landfill caps, base liners, and slopes; environmental protection beneath roads and railways; noise barriers; secondary containment; mining applications; waterproofing; tunnels.

2 GENERAL GCL PROPERTIES

To ensure that a GCL works best, it is necessary to understand single specific as well as composite product properties.

2.1 Bentonite type

The bentonite can be either sodium (natural sodium or activated sodium bentonite) or calcium bentonite. Decades ago, manufacturers promoted GCLs with calcium bentonite in an effort to avoid possible issues of ion exchange. Long-term field trials (Henken-Mellies 2010) under 1m of cover soil have demonstrated that the calcium bentonite filled GCL (9,500g/m^2) showed high permeation rates through the GCL after 4 years (52mm per year) and up to 81.3mm after 9 years, whereas GCLs with sodium bentonite powder have only allowed a permeation of far less than 10mm/year under similar conditions (Figure 2).
Figure 2. Permeation for sodium bentonite GCLs in three lysimeters #1 (left column, powder bentonite), #2 (middle column, powder bentonite) and #3 (right column, granular bentonite) (von Maubeuge *et al.* 2017).

2.2 Bentonite mass per unit area

The mass per unit area (MPUA) of the sodium bentonite in a geosynthetic clay liner is important to its hydraulic permittivity. Hydraulic permittivity decreases as the MPUA of a GCL's bentonite increases, and that means a better barrier. Standards commonly cite a minimum bentonite MPUA (at 0% moisture content) of 3,700g/m^2 (GRI-GCL3). In Germany (FLL 2022), 4,500g/m^2 is a common minimum MPUA (at 12% moisture content; resp. 4,000g/m^2 at 0% moisture content). GCLs can be produced with a bentonite MPUA up to 13,000g/m^2 if necessary; however, it is recommended to follow worldwide standards starting at minimum 3,700g/m^2 bentonite MPUA.

2.3 Bentonite grade/granularity

Manufacturers choose between two grades of bentonite for use in a GCL's core: powdered or granular.

Hydraulic performance of powder vs granular bentonite has demonstrated that bentonite particle size has a significant effect on the performance (Figure 2) of GCLs. Smaller powder particle sizes have a greater reactive surface area and therefore better swelling and sealing performance compared to larger particles. During hydration water wets powdered bentonite quickly, completely and uniformly due to the larger exposed surface area, and forms an immediate seal. For granular bentonites the water wets the external surface of the particles quickly and leaves the inside dry. Granular bentonites also have bigger voids between the particles (Figure 3) allowing liquids to penetrate the GCL before a seal is formed, leading to high early leakage rates.

Figure 3. Free swell of solely 1g of granular (❶) and powder (❷) bentonite – granular bentonite (❸), granular bentonite GCL (❻)powder bentonite (❹) and powder bentonite GCL (❺) hydrated from the bottom for 24h (powder bentonite closes pores immediately, while granular bentonite still shows several open pores).

2.4 Free swell and fluid loss

Sodium bentonite is commonly distinguished by its ability to swell in water several times its natural volume. The index test method used for quantifying the swelling property of 2g of powdered bentonite used in a GCL is ASTM D5890 – Standard Test Method for Swell Index of Clay Mineral Component of Geosynthetic Clay Liners. The current industry standard is >24 ml.

Another test to determine the water retention capability of bentonite is ASTM D5891 – Standard Test Method for Fluid Loss of Clay Component of Geosynthetic Clay Liners.

Many consider this index test to be a quick qualitative test, suggesting the bentonite's ability to work effectively in a GCL. The current industry standard is <18 ml.

However, it should be noted that both test methods are performed on powder bentonite and are not applicable for bentonite clays amended or treated with polymers. Therefore, if the suitability of the bentonite clay is tested against other liquids than water, these tests might be misleading if GCL contains granular bentonite (see Figure 3 granular (❶) and powder (❷) bentonite).

2.5 *Geotextile components*

The survivability of all GCLs depends upon its protective geotextiles. The higher the mass per unit area, the better the geotextile will perform against possible damage during installation. Nonwoven geotextiles have major advantages compared to slit-film wovens. They typically increase the interface friction value and are more resistant to damage during installation and during the cover soil placement, mainly due to their complex, strong fibre matrix arrangement. The current nonwoven minimum standard is 200g/m^2 (100g/m^2 for slit-film wovens). For critical applications where robustness and interface shear are of importance, GCLs with higher mass per unit area nonwovens than the current industry standard are recommended.

2.6 *Peel strength*

Because geosynthetic clay liners are composite materials, and the layers are designed to work together, the bond strength between GCL components is of particular interest. Correlation between the standard peel test (ASTM D6496-20) – which measures the strength between the carrier and cover geotextile – and the internal shear strength of the GCL are helpful. As peel strength increases, so does shear stress. It should be noted that the benefit of higher peel strength is limited. Findings by Rowe *et al.* (2017) show that a higher peel strength (industry standard is 360 N/m) can increase the water permeability, especially in low-confining stress applications. Even though the strong shear strength transferring fibre reinforcement can hold the GCL composite under hydration together, it is recommended to add a confining stress of minimum 0.3m soil cover over GCLs prior to any hydration.

2.7 *Permeability (hydraulic conductivity) vs index flux*

Permeability is a mathematical constant (k) determined by measuring water flow through a soil or other layer under a prescribed set of conditions. For GCLs, flux test (ASTM D5887 and EN 16416) is used, which contains procedures for calculating permeability as well. Flux is the rate of flow per unit area per unit time through the GCL under 1.5m water head and average confining stress of 27.5 kPa expressed in m^3/m^2/s. Additionally, the manufacturing process and the use of additives such as polymers and glues can affect the index flux and hydraulic permeability.

Permeability is a calculated value, not a directly measured value. Knowing the flux and bentonite thickness, the hydraulic conductivity (routinely called permeability) of the bentonite portion of the GCL can be evaluated by using the calculation methods.

Figure 4 shows index flux test results on a GCL with different bentonite mass per unit area. Index flux is a better indicator of the performance in respect to bentonite mass. As a result, specifying index flux along with bentonite mass per unit area is the better option than specifying the GCL permeability, as this value depends on the true thickness of the bentonite layer, which is a bit more difficult to measure.

The ASTM test method D5887 "Standard Test Method for Measuring of Index Flux Through Saturated GCL Specimens Using a Flexible Wall Permeameter" is a bentonite-related test method but is mainly used on the finished GCL and not the bentonite property.
Figure 4. Range of index flux as a function of GCL mass per unit area tested over a four-year production period for needle-punched GCLs (peel 360 N/m and geotextile components 330g/m^2).

2.8 Upper component of GCL facing towards the cover soil placement

GCLs are covered almost immediately (typically with soil or a geomembrane) after their installation to protect against free swelling of the bentonite. But the placement of the cover soil itself can threaten the GCL. Here, the upward facing layer of the GCL is critical to protection. The GCL cover layer's geotextile type, strength and thickness are key concerns for proper selection. A nonwoven upper geotextile, as recommended by GRI-GCL3, with its minimum mass per unit area of at least 200g/m^2, protects against installation damage and additionally against bentonite migration. Higher mass per unit area geotextiles are available for projects that require even more robust protection against cover soil thickness, site use, and available cover soil quality. In cases where interface shear strength is of concern, GCLs with a nonwoven on both sides (one layer of which is always scrim-reinforced) are the way to go. However, the interface friction values need to be evaluated on a project-to-project basis.

2.9 Safe overlaps for GCLs

When water encounters a GCL, also overlaps between GCL panels must provide security to prevent a breach. Some GCLs standardly impregnate during manufacturing both longitudinal overlaps with 50cm of swelling powdered sodium bentonite to ensure a firm, liquid-deterring area. Some GCLs are even impregnated with an additional, uniform layer of sodium bentonite powder across the entire nonwoven surface. This advance is ideally suited for pond and water-proofing applications, since the outer layer of the nonwoven geotextile creates an intimate contact zone in overlap areas. In general, the wider the bentonite-impregnated overlap section is,

the better it performs. Figure 5 reveals a strong contrast between thinner and wider bentonite impregnation at the overlaps. As can be seen, thinner overlaps, such as 1–2cm, present significantly higher rates of permeability – not what one wants in a barrier application. More bentonite in the overlaps means a safer design and a GCL that will continue to meet performance expectations over the long term.

2.10   Why not to use a double nonwoven without scrim reinforcement

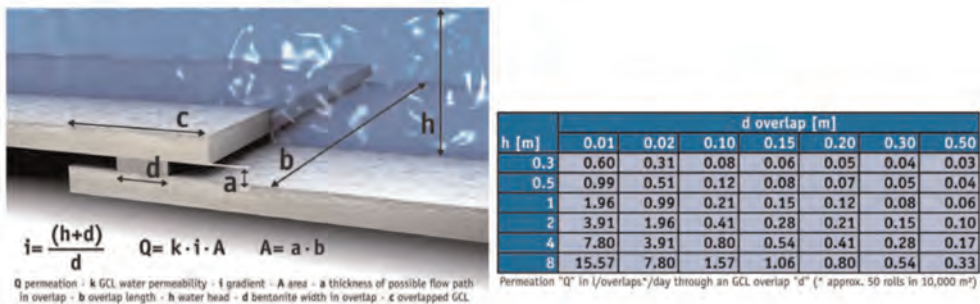
GCLs can be supplied in many different production forms concerning the geotextile com-


Figure 5.   Calculated permeation only through the overlap areas of a project with 10,000m^2 installed GCL.

ponents. During manufacturing, shrinkage occurred with GCL that only used nonwovens, even in field under nearly no confining stress (GRI White Paper #5), which lead to the note in the GRI-GCL3 specification: "For both cap and carrier fabrics for nonwoven reinforced GCLs; one, or the other, must contain a scrim component of mass $\geq$ 100 g/m^2 for dimensional stability. This only applies to GM/GCL composites which are exposed to the atmosphere for several months or longer so as to mitigate panel separation." It is the authors opinion that all GCLs should have a scrim-nonwoven geotextile as a bottom fabric as such GCL types show little to no shrinkage and do not elongate during installation, should the GCL have to be pulled over the surface, which likely could also influence the bentonite distribution.

2.11   Recommended GCL properties

It is recommended to set minimum requirements for a GCL in order to ensure long-term performance. The following listed specification values are therefore recommended as they follow various international requirements, such as the GRI-GCL3 (2016) recommendations.

- GCL consisting of two bentonite-encapsulating geosynthetics: a polypropylene (PP) carrier woven ($\geq$ 100g/m^2) and cover nonwoven ($\geq$ 200g/m^2);
- Layer of sodium bentonite powder encapsulated between two geosynthetic layers; bentonite mass per unit area $\geq$ 3,700g/m^2 at max. 15% water and a free swell value $\geq$ 24 ml following ASTM D5890 and fluid loss (ASTM D5891) $\leq$ 18 ml;
- Uniform shear stress transferring needle-punching through the two bentonite-encapsulating geosynthetics creating a shear strength transmitting GCL with a peel strength (ASTM D6496) of $\geq$ 360 N/m;
- GCL tensile strength (ISO 10319 or ASTM D6768) longitudinal/transverse $\geq$ 10 kN/m;
- Self-sealing, 30cm wide length overlaps with pre-manufactured bentonite impregnation;
- Index flux (GCL) $\leq 5 \times 10^{-9}$ m^3/m^2/s (ASTM D5887 or EN 16416).

3 SUMMARY

Engineered barrier systems protect sensitive environmental, industrial and civil applications. Safety is of the utmost importance. The decisions that a designer makes about the GCL itself during material selection heavily influences the ultimate performance and durability of the GCL system. These include decisions (but are not limited to) on the type of bentonite, its mass per unit area, the overlap design, geotextile protection, peel strength and confining stress prior to hydration. GCLs should be manufactured in accordance with these but should not be limited to these and may be, design depending, exceeded to maximise safety and long-term barrier performance.

ABSTRACT: Over the past 40 years, the advantages of utilising geosynthetic barriers versus traditional earthen barrier materials have been well documented: greater project economy, extended service lives, enhanced environmental protection, greater site safety, etc. Achievements such as conserving water resources and enabling beneficial site reuse have even given geosynthetic engineering a level of social importance. As such, the use of geosynthetic barriers has increasingly been required by government regulators around the world. This is true in modern waste management landfill design. However, there are still regions and applications in which the use of these barrier technologies should be more widely adopted. This paper highlights an overview of applications where geosynthetic barriers are used, and where regulation or recommendations are available, and it describes other emerging applications where geosynthetic barriers are starting to be used.

1 INTRODUCTION

Geosynthetic barriers are an established product group in the geoenvironmental industry. They include factory-made polymeric geomembranes that can be made of polyethylene (PE), bituminous membranes (bitumen attached to geotextile) and geosynthetic clay liners (with clay/bentonite core as the barrier element between two geotextiles). These geosynthetic materials are accepted as barrier solutions in many applications, but due to the material properties not all geosynthetic barriers are suitable for all applications. Applications for geosynthetic barriers include:

- Containment application, non-landfill
- Chemical containment, non-landfill
- Construction waterproofing
- Landfill base lining
- Landfill capping and rehabilitation
- Secondary containment
- Transport infrastructure applications
- Tunnel waterproofing
- Water retaining structure, e. g. balancing ponds, stormwater retention ponds, dams, dykes and canals (usually empty)
- Water retaining structure, e. g. reservoirs, canals (usually full)

The advantages of geosynthetics, especially if compared to traditional earthen construction methods, e.g. compacted clay liners, include:

- Reliability: high-quality control standards, lifetime verification and multiple proven project applications
- Ecology: significantly lower CO_2 emissions, supporting worldwide climate goals, lower energy consumption, reduction of transport amount or kilometres travelled
- Sustainability: limits the use of all resources, e. g. natural clay resources, energy demand, noise impact
- Cost-effectiveness: reduced building cost compared to traditional methods, even greater when natural materials have to be quarried off site and brought in, longer service life, less maintenance
- Ease of installation: easy to handle and install on project sites, saving time in the construction process and reduced excavation required, e. g. less fill required, less land disturbed, no need to compact and test
- Resilience: improved structural behaviour with the ability to respond, absorb, adapt or recover from extreme load cases caused by natural disasters or extreme weather caused by climate change
- Safety: increased serviceability and protection when used in levees, groundwater, infrastructure, and environmental protection for waste management and chemical containment
- Quality: more homogeneous than soil and clear, established quality controls from production through installation

The design of barrier systems in these various applications is a challenge for any group of professionals, as the document produced must add supportive text and areas for consideration to a process which is in its very nature one of professional judgement. Geosynthetic barriers are a complex area for design, and given the large variety of barrier types as well as material differences within each type means that sooner or later a decision is made comparing a great number of variables. Good design utilises the best possible combination of materials, site preparation, installation and checking in line with the intended end use, expected longevity and "local" constraints which may be functions of geography and climate as well as political, labour availability and access constraints. As such, no design guide or standard can hope to solve the complex combinations of each individual site circumstances and as such it is aimed at professionals making such decisions and helping to ensure that each of the many variable factors have been considered both individually and collectively. Often national regulations and recommendations give guidance on a good start point that should then be adjusted to suite the specific site being designed for.

2 BRIEF INTRODUCTION OF POLYMERIC BARRIER SYSTEMS

Geosynthetic barrier materials is the main product group for barrier products and they are divided into polymeric, bituminous and clay geosynthetic barriers. Geomembranes (GM) smooth or textured, also known as polymeric geosynthetic barriers, are essentially impermeable and are used as fluid barriers in geotechnical engineering. Textured surfaces provide an enhancement of frictional characteristics which allows designs on steeper slopes or where shear stress occurs (e.g. with geosynthetic/soil or geosynthetic/geosynthetic interface). In some countries the definition of GM starts at a thickness of 0.5 mm, but not all countries are in agreement on that classification. In France and Germany, for example, the polymeric barrier is considered a GM if the thickness is equal or greater than 1 mm.

Barriers with a clay sealing component are called geosynthetic clay liners (GCLs), bentonite mats or clay geosynthetic barriers. GCLs, a very successful barrier group, are made of a thin layer of typically sodium bentonite between two layers of geosynthetics; generally, these layers are nonwoven and woven geotextiles and all components are needle-punched together. GCLs can be used as a stand-alone barrier or in conjunction with a geomembrane to form a composite barrier.

3 LANDFILL REGULATIONS AND RECOMMENDATIONS

Synthetic barrier designs began in the 1950s, often with canal systems and water conveyance, and have expanded steadily since with new manufacturing and welding technology, better polymeric formulations and additive packages, and stronger engineering education. Geosynthetic barriers have been used in lieu of traditional concrete, asphalt, and compacted clay-only barriers which have not been as effective at preventing contaminated fluid migration into subsurface soils and groundwater.

A major spur to the utilisation of geosynthetics occurred in the early 1980s when the United States and Germany, on a federal level, began to regulate and require the use of geosynthetic barriers to meet minimum containment criteria for landfills (Maubeuge *et al.* 2021). The legacy of this regulatory move is that today waste management seems to have the highest environmental protection standards in many countries where modern landfill designs and geosynthetic technologies are used. However, too many countries are still missing guidelines for the use of geosynthetic barriers in landfills and other applications.

When reviewing a selection of the worldwide regulations, including the European directive, Germany, Great Britain, Australia, New Zealand, China, Japan, Indonesia, South Africa and the United States of America, they mostly reflect a very similar collection of natural and geosynthetic elements to construct a composite liner system. This consists of, working from the top down:

- Leachate collection layer, usually stone aggregate, with perforated leachate collection pipework, with a separation/filtration nonwoven geotextile to protect the stone from clogging with fines from the waste
- Protection layer, usually a nonwoven geotextile
- GM, typically ranging from 1.5 mm to up to 2.5 mm thickness in Germany
- Compacted clay liner (CCL), typically 500 mm to 1,000 mm thick, or GCL, or both
- Prepared, low permeability, in-situ soil

Due to a limit on page length the selected excerpts of the various regulations could not be repeated in this paper, but a follow-up journal paper will be produced that includes these.

Some regions include a double composite base liner in their regulations that allows for the performance of the primary composite barrier to be monitored.

4 COAL ASH APPLICATIONS

Coal is an important source of power throughout the world. Approximately 7 million metric tons of coal are mined and burned each year around the globe. The result of the combustion of these huge volumes of coal is the generation of heat, electricity and the creation of coal ash – roughly 20 % of the weight of the coal consumed. This ash is often quite useful and is perhaps the largest (in volume) recycling success story in the world. Useful applications for coal ash include concrete, fibreboard and a host of other construction and infrastructure applications. However, approximately half of the coal ash generated in the world is not recycled and must therefore be disposed of. In some parts of the world, the coal ash is simply "dumped", more developed nations may dispose of coal ash in large de-watering ponds, store the coal ash using very large levees and use the materials as structural fill to modify the shape of the earth; creating flat areas for airports for example. The proper disposal of coal ash is important to the health of the planet and to human health. Leachate (water that has passed through coal ash) can have high pH, high concentrations of heavy metals, such as lead, arsenic and others, and serves as a global contaminant to groundwater and potable water resources.

Unfortunately, over 50 documented cases of groundwater contamination at or nearby coal ash storage facilities contributed to the US EPA issuance of new regulations for the storage of coal ash which require the use of geosynthetic materials and proper geotechnical

engineering of coal ash disposal sites. The US EPA regulations for coal ash storage propose the most efficient and effective barrier system as a composite liner system using a primary GM, typically 1.5 mm thick, in combination with a CCL, approx. 500 mm thick, or a GCL, although other variations exist. This is a direct result of these systems being compliant with the United States Environmental Protection Agency (US EPA) Resource Conservation and Recovery Act (RCRA) Subtitle "D" regulations which have demonstrated excellent historical performance as groundwater contamination barriers.

5 ENVIRONMENTAL PROTECTION IN INFRASTRUCTURE APPLICATIONS

Solid, liquid and gaseous emissions from motor vehicles contribute to risks to soils, stretches of water (rivers, lakes, ponds, etc.) and groundwater. The protection of these waters is anchored in the German Water Resources Act.

If it is not possible to avoid a road route through a water protection area, despite all the considerations in the line identification process, a number of measures are necessary in order to exclude a risk to the water resources as far as possible. They are described in the German Guidelines for Structural Measures on Roads in Water Protection Areas, RiStWag (FGSV 2016). The guideline describes, among other things, geosynthetic sealing systems for environmental and groundwater protection.

If a road layout through a water protection zone cannot be avoided, all necessary design and constructional measures must be considered in the planning phase. In general, passive protective devices (crash barriers, concrete walls, car run-off barriers) are necessary to prevent vehicles from running off the roadway. Rainwater must be collected via side drains, gutters or pipes and moved out of the protection zone. The artificial barrier, typically a GCL, should be lined at least 1 m under the paved road.

6 ENCAPSULATION OF CONTAMINATED SOILS

In June 2021, the German Substitute Construction Materials Regulation (Ersatzbaustoffverordnung, also called "Mantelverordnung") (Bundesgesetzblatt 2021) was passed and will come into force in August 2023. With this law, politicians want to promote the re-use of mineral construction waste, among other things. Since this waste is often used in road construction and earthworks, the protection of soil and groundwater will be strengthened on a national level.

The reuse of excavated soil, construction waste products, and recycled construction materials in earthworks, contributes to the conservation of resources and the reduction of the depletion of landfill airspace. The use of geosynthetics in this application can be highly efficient, not least due to the comparatively simple installation conditions of the industrially manufactured and quality-assured roll material.

Road noise and view-blocking barriers along roads, motorways and railway lines can be built with substitute construction materials. These waste materials must meet certain environmental-chemical requirements and must be covered with a surface sealing for groundwater protection.

In Germany, as in other European countries (e.g. in the Netherlands – this construction is directed by the "Bouwstoffen Besluit", CUR 1999), protecting the environment by using substitute construction materials is carried out using three barriers, similar to modern landfill practices:

- Hydraulic permeability of the subsoil, depth to groundwater table, groundwater-protecting cover layers
- Limitation of pollutant load through assigned threshold values
- Technical protection measures using water impermeable cover and sealing layers
- Suitable sealing materials for these purposes include GCL and GM

7 WATER CONVEYANCE IN CANALS

Government agencies such as the United States Bureau of Reclamation (BuRec) indicate that seepage from unlined irrigation canals and waterways may be substantial and costly; and that geosynthetic barriers offer economically flexible and highly effective performance enhancement for canals (Swihart & Haynes 2002). They are effective alternatives to concrete, asphalt or compacted clay soils.

No matter the construction, the consistent revelation is that geosynthetic liners and lining systems have outperformed traditional lining methods in longevity and project economics in canal systems.

In Germany, all important technical information on waterway lining systems has been collated in the new guideline "Recommendations for the use of lining systems on beds and banks of waterways". The guideline describes geosynthetic lining systems which additionally need to be covered with rock armor as specified in the MAR code of practice.

GCLs in levee construction must meet special safety requirements as their functionality may depend on the flood protection of entire regions, and in the event of failure the flood defenses can have a significant impact of human lives and civil infrastructure. In levee construction, the use of GCLs as an alternative to a mineral sealing layer, constructed from compacted, cohesive soils, has produced positive experiences.

The Dutch Limburg Water Board, in cooperation with the Flood Protection Program, has prepared a Design, Assessment and Maintenance Guideline (OBOR) for the application in Dutch practice of bentonite mats, also called GCLs, and used the existing experience with the BRAD16 guideline from Germany.

8 STORMWATER RETENTION PONDS

The purpose of the German code of practice DWA-M 176 (DWA 2013) is to provide the designer of stormwater basins with rules that will allow stormwater treatment and retention structures to be designed, or existing structures to be upgraded, according to structural, equipment, operational and economic considerations. It also makes clear statements on the use of geosynthetic barriers (GCL and GM).

9 CONCLUSION

There is every reason to believe that geosynthetic barriers will continue to be adopted into regulations around the world. This has much to do with the innovation and quality control measures in manufacturing and installation in the field. It also has much to do with geosynthetics being used in situations to perform better and/or more economically than traditional geotechnical designs. With a large record of data in support of cost and performance measures, and with secondary benefits such as decreased project carbon footprints, the field's growth is assured.

These geosynthetics offer a wide range of physical, mechanical and chemical resistance properties. Geomembranes can be compounded for greater resistance to ultraviolet light exposure, ozone and micro-organisms in the soil while GCLs can be produced with various geotextiles for enhanced frictional properties. Different combinations of these properties exist in various GM as well as GCL materials to address a wide spectrum of geotechnical applications and designs. Several methods are used to join or seam large panels of GMs and GCLs, in both factory-controlled and field environments. Each material has highly developed quality control techniques and unique characteristics that govern their manufacture and installation.

As advanced products and manufacturing and installation techniques evolve, project economy and performance will continue to improve, both with and in advance of regulatory recognition.

Migrating to probabilistic internal stability analysis and design of reinforced soil walls

R.J. Bathurst

GeoEngineering Centre at Queen's-RMC, Kingston, Canada

ABSTRACT: Reliability-based design for internal stability limit states for geosynthetic mechanically stabilized earth (MSE) walls provides a more nuanced appreciation of the margin of safety for these systems compared to conventional factor of safety, partial factor, and load and resistance factor design (LRFD) approaches. The paper introduces the basics of probabilistic analysis and design for internal stability limit states for MSE walls using the example of geogrid reinforced soil walls. The general approach uses a closed-form solution for reliability index which is easily implemented in a spreadsheet. The paper demonstrates how bias statistics for tensile load and pullout model accuracy can be gathered from load measurements recorded from instrumented walls and found in laboratory pullout box test databases. The paper concludes with example calculations of the probabilistic margin of safety for tensile strength and pullout limit states using the AASHTO Simplified Method and the recent AASHTO Stiffness Method in the USA.

1 INTRODUCTION

In North America there are two reinforcement tensile load calculation methods used for internal stability limit states analysis and design of geosynthetic mechanically stabilized earth (MSE) walls. The first approach is the Simplified Method (AASHTO 2017) which uses an empirically adjusted classical active wedge approach to predict tensile loads in the reinforcement layers under operational conditions. The second approach is the recent Stiffness Method (AASHTO 2020) which retains elements of the Simplified Method but includes the creep-adjusted tensile stiffness of the reinforcement as a key parameter that influences the magnitude of the maximum tensile load in each reinforcement layer. Both methods can be used within a deterministic design framework (i.e., factor of safety approach), and within a reliability theory-based load and resistance factor design (LRFD) approach. Both methods lead to safe designs, but the margins of safety against failure of a limit state equation in probabilistic terms is unknown. The movement towards performance-based design in geotechnical engineering measured by probabilistic margins of safety is now underway (e.g., ISO 2015). However, acceptance of such an approach for the internal stability limits states for geosynthetic MSE walls remains in its infancy. The paper introduces the basics of probabilistic analysis and design for tensile strength and pullout internal stability limit states for MSE walls using the example of a geogrid reinforced soil wall.

2 PRELIMINARIES

Figure 1 illustrates the internal stability limits for a geosynthetic MSE wall and introduces important nomenclature. Each limit state identified in the figure can be expressed by a

DOI: 10.1201/9781003386889-248

performance function of the general form:

$$g = \frac{R_m}{Q_m} - 1 = \frac{\lambda_R R_n}{\lambda_Q Q_n} - 1 \qquad (1)$$
Figure 1. Geometry and limit states for a geosynthetic MSE wall. Q_n = nominal reinforcement tensile load (e.g., kN/m), R_n = nominal resistance (e.g., kN/m), T_{max} = maximum tensile load, S_v = reinforcement spacing, σ_v = vertical stress, γ = soil unit weight, z = depth of layer below crest of wall, q = surcharge pressure, P_c = pullout capacity (e.g., kN/m), f* = dimensionless interface shear coefficient, L_e = reinforcement layer length in passive zone, R_c = coverage ratio due to discontinuous reinforcement roll placement within a layer, ϕ = soil peak friction angle, T_{al} = allowable or long-term tensile load, T_{con} = connection capacity between reinforcement and wall facing, and T_j = tensile load corresponding to soil failure.

Here, R_m and Q_m are measured (observed) resistance and load terms, respectively, and R_n and Q_n are corresponding nominal resistance and load terms. The latter are the computed values using analytical models (equations) such as the equation for ultimate pullout capacity (P_c) shown in Figure 1. In the example here, all nominal values have units of force/length (e.g., kN/m).

If the objective is to quantify the "true" margin of safety for a limit state function, then nominal values must be transformed to expected measured (observed) values using model bias values (λ_R and λ_Q). Bias values can be understood to be quantities that are influenced by: a) intrinsic accuracy of the prediction of nominal values using the underlying analytical models for the resistance and load terms; b) random variation in input parameter values, spatial variation in input values, and quality of data, and; c) consistency in interpretation of data gathered from multiple sources (the typical case) for the purpose of quantification of model accuracy (Allen *et al.* 2005; Bathurst & Javankhoshdel 2017). For perfect models, λ_R and λ_Q are equal to 1. Excluding cases where a nominal value is prescribed, this is an unusual situation for geotechnical soil-structure interaction problems.

It should be noted that model bias is independent of project-specific conditions. The influence of project-specific uncertainty is captured by uncertainty in the choice of nominal values that appear in analytical load and resistance models.

The ratio $F_n = R_n/Q_n$ is called the nominal factor of safety and is used in deterministic analyses and as the starting point (best estimate) in probabilistic analyses.

In the developments to follow, the nominal and bias values are treated as random variables following lognormal distributions. The margin of safety for each limit state is expressed as the probability that the limit state will not be satisfied (probability of failure = P_f):

$$P_f = P(g < 0) \tag{2}$$

3 MODEL BIAS

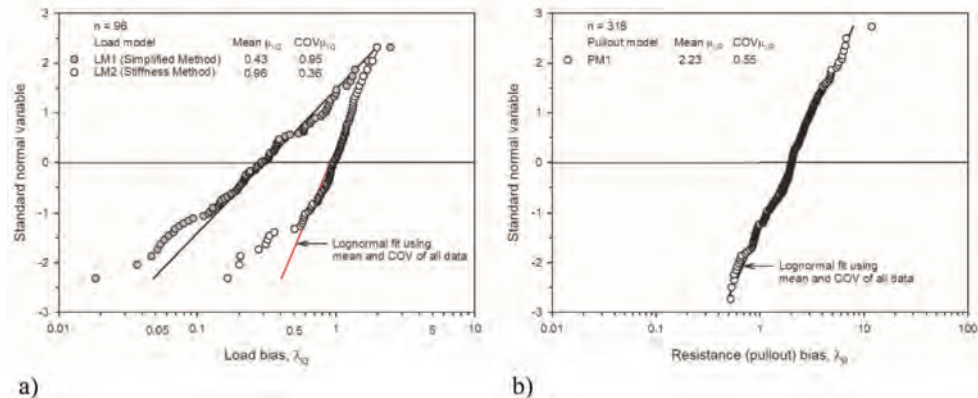
Load model bias data have been collected for geosynthetic reinforced walls with granular backfills using the Simplified and Stiffness Methods to compute the nominal load value $Q_n = T_{max}$. The procedure involved collecting measured tensile loads in instrumented field walls and dividing each value using the equation for T_{max} for each method and the same measured layer conditions; hence, $\lambda_Q = T_{max}(measured)/T_{max}(model) = Q_m/Q_n$. From the population of all λ_Q values the mean ($\mu_{\lambda Q}$) and coefficient of variation ($COV_{\lambda Q}$) can be computed. Examples of these data presented as cumulative distribution function (CDF) plots are provided in Figure 2a. The data trend as a straight line over most of the data range when the bias values are plotted using a logarithmic axis. This demonstrates that the data are reasonably represented by a lognormal distribution as mentioned previously. Figure 2b shows a CDF plot of pullout bias data $\lambda_R = P_c(measured)/P_c(model) = R_m/R_n$. The nominal (model) values were computed using the pullout equation shown in Figure 1 with the input properties for each pullout box test from which a matching measured pullout capacity (P_c) was recorded. These data also present as a linear line on a semi-logarithmic plot for practical purposes.


Figure 2. Example model bias CDF plots for a) T_{max} load models, and b) pullout model for P_c.

Bias statistics for both load models, tensile strength and pullout capacity are summarized in Table 1. Bias dependency captures the correlation between bias values and predicted nominal values. A model is judged to improve as the mean bias approaches 1, the COV of

bias values becomes small, and bias dependencies can be ignored at a level of significance of 5%. The Simplified Method is judged to be a relatively poor model based on these criteria compared to the Stiffness Method. Pullout model (PM1) is also a poor model but it remains current in North American MSE wall design specifications. The mean bias value for the tensile strength limit state is slightly greater than 1 because the unfactored nominal value for design is typically taken as the minimum average roll value (MARV) which is less than the average of rupture strength values from multiple specimen tensile tests carried out on the same material (Allen & Bathurst 2019). The spread in bias values (COV) is very small as may be expected from an engineered material. Similar data for PET geostrip MSE walls can be found in the paper by Bathurst *et al.* (2020).

Table 1. Summary of bias statistics and bias dependency values for load and resistance models for geogrid reinforced soil walls constructed with granular soil.

Model	Number of data points, n	Mean of bias	COV of bias	Bias depen-dency ρ	Original data source
Simplified Method (LM1)	96	0.43	0.95	−0.41	Allen & Bathurst (2015)
Stiffness Method (LM2)	96	1.00	0.28	0	Allen & Bathurst (2015)
Pullout (PM1)	318	2.23	0.55	−0.46	Huang & Bathurst (2009)
Tensile strength (TM)	N/A	1.10	0.10	0	Bathurst & Miyata (2015) Miyata & Bathurst (2015) Miyata *et al.* (2014) Bathurst *et al.* (2011, 2012)

4 CALCULATION OF RELIABILITY INDEX

Using the bias statistics in Table 1, the magnitude of the actual reliability index (β) can be computed for tensile strength and pullout limit states using the following equation:

$$\beta = A + B \times Ln(F_n) \tag{3}$$

where, A and B are collections of bias statistics described above and uncertainty in choice of nominal values Q_n and R_n at time of design (COV_{Q_n} and COV_{R_n}) (e.g., see Bathurst & Allen 2021 for the full expression). The equation shows that β varies log-linearly with the magnitude of the nominal factor of safety $F_n = R_n/Q_n$. This equation provides a quantitative link between deterministic allowable stress design (ASD) (factor of safety approach) and modern concepts of reliability-based design. The relationship between P_f and β is $\beta = \Phi^{-1}(1-P_f)$, where Φ^{-1} is the inverse of the standard normal cumulative distribution function (CDF) (NORMSINV in Excel).

5 RESULTS

Results of calculations using Equation 3 are shown in Figures 3a and 3b for the tensile strength limit state using the Simplified Method (LM1) and Stiffness Method (LM2), respectively, for the load side (Q_n), and the long-term tensile strength (TM) for the resistance

side (R_n). Figures 3c and 3d show calculation outcomes with the same load side equations but with the AASHTO pullout equation for the resistance side. The calculations assume uncertainty in the estimate of nominal load values and nominal pullout values taken as $COV_{Qn} = COV_{Rn} = 0$, 0.1, 0.2 and 0.3. The non-zero values correspond to the concept of high, typical and low levels of understanding at time of design that are used in Canadian foundation engineering practice (Fenton *et al.* 2016). A value of $COV_{Rn} = 0$ for the tensile strength nominal value since all uncertainty in its value is captured by the COV of the bias. Curves with values of $COV_{Qn} = COV_{Rn} = 0$ can be understood to correspond to current practice in the US where the concept of level of understanding is not used in any formal way. Calculation outcomes using the Stiffness Method (load model LM2) show that for the same F_n value, β values decrease in the order of COV = 0, 0.1, 0.2 and 0.3. This may be expected since margins of safety in probabilistic terms can be expected to decrease as uncertainty in the magnitude of nominal load value increases. The opposite trend is observed when the poorer Simplified Method (load model LM1) is used. This counter-intuitive outcome is a result of the large negative bias dependency for this model (Table 1). This is an unfortunate outcome of using a poor load model for reliability-based design.

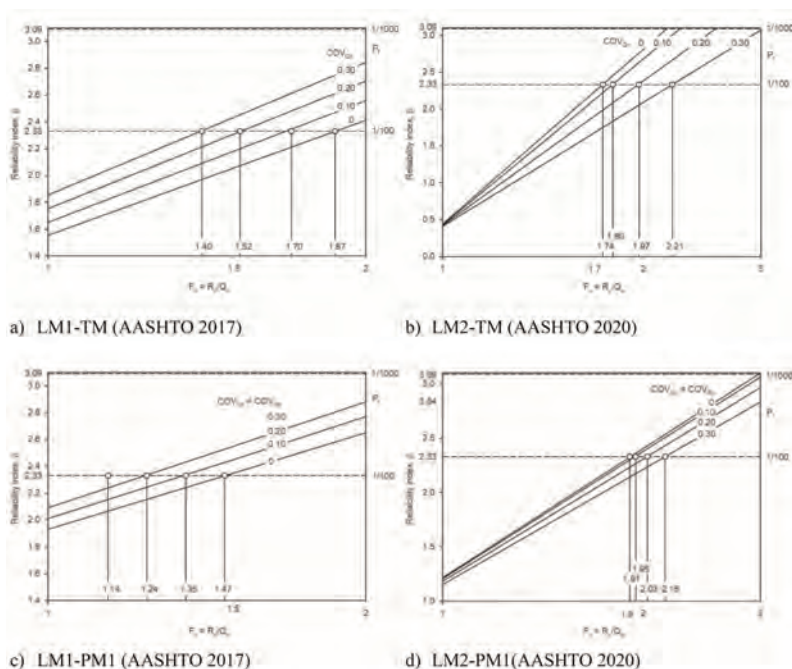
c) LM1-PM1 (AASHTO 2017) d) LM2-PM1(AASHTO 2020)


Figure 3. Reliability index versus ratio of nominal resistance to nominal load. a) LM1-TM (AASHTO 2017) b) LM2-TM (AASHTO 2020) c) LM1-PM1 (AASHTO 2017) d) LM2-PM1 (AASHTO 2020).

Also shown in Figure 3 are β values of 2.33 and 3.09 corresponding to probabilities of failure of the limit state of 1/100 and 1/1000. For internal stability limit states for MSE walls, the recommended target probability of failure is 1/100 (Allen *et al.* 2005). This may appear to be very high but the multiple reinforcement layers in MSE walls make these systems highly strength redundant; i.e., if one layer fails, the other layers can compensate. For reliability-based design the curves in Figure 3 can be used directly. The internal design of the MSE wall can be adjusted by changing nominal load (Q_n) and nominal resistance (R_n) values so that $F_n = R_n/Q_n$ gives a value $\beta \geq 2.33$.

6 CONCLUSIONS

This paper demonstrates (albeit briefly) reliability-based analysis and design concepts applied to internal stability limit states for geosynthetic MSE walls constructed with geogrid layers. The concepts are general for simple linear limit state functions and have been used to carry out similar analyses for polymeric geostrips, steel strips and steel grid MSE walls. A necessary precursor to the general approach are bias data for load and resistance terms in the performance function described by Equation 1. Fortunately, these data are available as described in the cited work by the writer and collaborators. The general approach has the advantage that it provides a quantitative link between nominal factor of safety used in conventional ASD practice (i.e., factor of safety approach) and margins of safety expressed probabilistically using reliability index which is used in structural civil engineering LRFD calibration practice. Furthermore, the general approach includes provision for judgement by including the concept of project-specific "level of understanding" when selecting the magnitude of nominal input values for load and resistance models at the time of design.

ABSTRACT: The Oosterweel Link project is a new 15 km-long motorway connection developed by Lantis for completing the Antwerp ring road R1 (Belgium). The total estimated cost of the project is approximately €4.5bn. The Antwerp ring road is a key part of the Trans-European Transport (TEN-T) Core Network. Maccaferri collaborated with the design and building of the Mechanically Stabilized Earth (MSE) walls with its main product family „Terramesh". This is a well-known system used in Europe and in the rest of the world to support or enable the construction of infrastructures in tight urban corridors, forming retaining walls, road embankments, wing walls and bridge abutments known as Geosynthetic Reinforced Soil-Integrated Bridge Systems (GRS-IBS). „Terramesh" double twist steel wire mesh reinforcements have been used in combination with ParaLink[®] and Paragrid[®] geogrids representing an evolution and a significant advantage for both cost-effectiveness and performance.

1 INTRODUCTION

1.1 *Overview of Oosterweel Link project*

The Oosterweel Link project is a new 15km-long motorway connection developed by Lantis for completing the Antwerp ring road R1 (Belgium). It is a major project in Belgium and its design started in the 1990's to find a solution to the congestion problems in and around Antwerp.

This new project will link the E17 (Ghent) and the E34 / N49 (Bruges) on the left bank of the Scheldt river with the E19 / A12 motorways towards the Netherlands and the E34 / E313 motorways towards Germany and Luxembourg. Five sub-projects are included, like „Linkeroever", „Scheldt tunnel", „Oosterweel junction", „Canal tunnels" and „R1-Noord".

In February 2018 the first construction works finally started. The new highway infrastructure on the left bank and Zwijndrecht will be completed in 2024, while the Scheldt tunnel will open to traffic in 2027. The entire Oosterweel connection is scheduled to become operational in 2030.

1.2 *Framework of the project*

The Antwerp ring road is a key part of the Trans-European Transport (TEN-T) Core Network. The Oosterweel link will be used for heavy truck traffic and will shift important southern side traffic to the northern side while reducing congestion, resolving bottlenecks

and mobility problems on the ring road (Figure 1). Oosterweel Link was launched by the Flemish Government as part of its Masterplan 2020. It also forms part of the government's broader Route Plan 2030 mobility plan.

Figure 1.   Oosterweel Link project overview.

2   THE CONTEXT

2.1   Project background

The environmental impact assessment report for the project was approved by the Flemish Government in 2016. Lantis invested approximately €180m for site preparation for the construction of the Oosterweel connection. A major part of it will be built underground.

The left bank interchanges will be redesigned and reconstructed, and a new road will be constructed next to E17 and E34 in Zwijndrecht, which will bring the local traffic to the motorway.

The new junctions will provide a connection to Burcht, Zwijndrecht, and Linkeroever. A 9 km-long bike lane will also be developed to link Zwijndrecht and Linkeroever to the new Scheldt tunnel (a 1.8 km-long twin tube immersed tunnel with three lanes on each side, as well as a separate lane for cyclists).

The total estimated cost of the project is approximate €4.5bn, of which €3.6bn will be borrowed from the Flemish Government and the European Investment Bank.

Lantis awarded a €570m contract to the Temporary Trade Association COTU consortium consisting of Besix, Bam Contractors, Deme, and Jan de Nul for the construction of the Scheldt tunnel in June 2020. The consortium will also be responsible for the design and implementation of the traffic and tunnel installations.

2.2   Linkeroever subproject

The Linkeroever subproject was contracted to the Rinkoniên consortium comprising of Artes Roegiers, Artes Depret, CIT Blaton, MOBILIS, and Stadsbader.

Arcadis was subcontracted by the Rinkoniên consortium to perform engineering studies for the subproject.

Together with local partner Texion, Maccaferri was selected as the main supplier for the construction of the reinforced soil structures (BGS, Belgian Geosynthetics Society 2022).

2.3   Other subprojects

ENGIE Fabricom team is responsible for traffic and tunnel installations in order to offer a safe and smooth driving experience during construction.

ZJA Zwarts & Jansma Architects is responsible for designing the link over the right bank of the Schelde river, while Tunnel Engineering Consultants, a joint venture of Royal Haskoning, DHV and Witteveen & Bos, performed engineering works for the left bank works.

Asite's Common Data Environment (CDE) solution was chosen by Lantis to efficiently manage, maintain and share information on the development of the project.

3 DESIGN AND INSTALLATION

3.1 *Maccaferri's collaboration*

Maccaferri collaborated with the design and building of the Mechanically Stabilized Earth (MSE) walls with its main product family „Terramesh". This is a well-known system used in Europe and in the rest of the world to support or enable the construction of infrastructures in tight urban corridors, forming retaining walls, road embankments, wing walls and bridge abutments known as Geosynthetic Reinforced Soil-Integrated Bridge Systems (GRS-IBS). The peculiarity of the case study is to present the design and building of GRS-IBS, which are innovative solutions for the construction of bridge abutments, made environmentally friendly thanks to the combined use of polymeric geosynthetics and „Terramesh" double twist steel wire mesh reinforcements.

„Terramesh"double-twist steel wire mesh reinforcements have been used in combination with polymeric geosynthetics representing an evolution and a significant advantage for both cost-effectiveness and performance. Geogrid-reinforced MSE walls are recommended in case of non-conventional retained soils such as poor subsoil conditions, warm climates, or chemically aggressive environments since they are resistant to deterioration. In fact, the design life of the walls is 120 years.

The design of the Mechanically Stabilized Earth (MSE) wall structures and their general behavior depend on the interaction between the soil reinforcing elements and the surrounding soil and this interaction is based on the properties of the materials used and the construction methods (Masola *et al.* 2018). Soil-reinforcement interaction is extremely important because it is the mechanism by which forces are transferred between the reinforcements and the surrounding soil (Lugli at al. 2019).

3.2 *Provided installation*

The project includes 23.000 facing sqm of „Terramesh Green®", 16.000 facing sqm of „Terramesh Mineral® and System®, 275.000 sqm of ParaGrid® and ParaLink® geogrids, and 5.000 facing sqm of gabion cladding. During 2020–2021 and 2022, 37.000 sqm of MSE walls have been already installed by the partner company „Carlucci Costruzioni s.r.l." with a maximum height of 13m for the structures erected so far (Figure 2). The Terramesh products can be either with a stone mineral facing or a green facing, according to the architectural plan: in Oosterweel for architectural reasons most of the structures present a stone facia. The

Figure 2.   Installation phase of ParaLink geogrids® in combination with Terramesh Systems®.

main products used are Maccaferri Terramesh System®, Mineral Terramesh®, Cladding Gabions, ParaLink®, and Paragrid® geogrids.

3.3 Benefits of the solution

Maccaferri Terramesh proved to be a flexible and more suitable system for the construction details and a reliable system thanks to the continuity and integrity of the double-twist steel wire mesh with the facing (Figure 3).

Figure 3. Reinforced soil structure made with Terramesh Green® and Terramesh Mineral® units underneath a cycle bridge overpass.

The polymer-coated double-twist wire mesh can provide greater durability in highly aggressive environments. The durability of the polymer-coated double-twist steel wire mesh embedded in soil ensures a design life of 120 years.

For some civil structures, the main designer opted to build some walls with Maccaferri environmentally friendly solutions if compared to the usual reinforced concrete retaining walls selected in the original design. Reinforced soils guarantee fewer CO_2 emissions thanks to the use of in situ soil with respect to concrete. Indeed, concrete has a finer material selection of aggregates and cement which has a more harmful effect on the environment with respect to reinforced soils. Moreover, the velocity of execution of reinforced soils is higher than concrete structures since there is no concrete curing time. These features result also in a cheaper solution thanks to time and labor savings (installation ratio: between 100 and 150 sqm/team/day without earthworks).

3.4 Design support

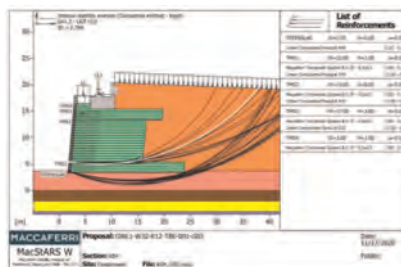
Maccaferri's Corporate Technical Department has supported and is still supporting the main designers step by step from the first preliminary Global and Internal stability checks (Figure 4) with Limit Equilibrium Method (LEM) analyses carried out with MacStars


Figure 4. Stability design checks carried out with MacStars® for G03 direct bridge abutment.

Software to Finite Element Method (FEM) deformation analyses due to the strict restrictions on displacements. Maccaferri provided the designers with all material properties for the correct modeling of double-twist steel wire mesh products and geogrid reinforcements (Tubertini *et al.* 2021). MacStars is an internal Software and it stands for Maccaferri Stability Analysis of Reinforced Soils and Walls. The MSE walls have been designed according to Eurocodes and NBN EN 1997-1 ANB (National Annex for Belgium).

3.5 BIM collaboration

Furthermore, due to the big number of interfering elements, such as bridge supports, concrete walls, and sheet-pile walls in each direction, Building Information Modelling (BIM) was required to define the layout and the number of facing units and soil reinforcement needed in each orthogonal direction. Maccaferri BIM Objects (www.maccaferri.com/bim/) have been also used to help the contractor in the design of particular challenging geometries (Figure 5) and for the executive drawings used for the placing of the materials used for the construction of the civil structures.

Figure 5.   Object G02B, Maccaferri's BIM design.

Figure 6.   Direct bridge abutment G03 after the launch of the bridge.

3.6 Challenges

In the year 2022 the main direct bridge abutment, called G03, was built (Figure 6). The maximum retaining height is 13m with a front inclination of 85°. For the front Maccaferri Terramesh System® units were used, while for the main reinforcement, ParaLink® and Paragrid® geogrids were laid with a nominal tensile strength from 150 kN/m up to 700 kN/m.

Main challenges have been encountered in the optimization and computation of the materials during the design processes, which have been made with the combined use of LEM, FEM, and BIM technologies, and mainly during installation due to the strict restrictions given by demanding geometry of the facing of the structures provided in the design (maximum retaining height of 13 m and facing inclination up to 85°). The geometry of the constructed structures has been checked with in situ testing, resulting in consistency within the design tolerances. The correct application of the suggested installation procedures has guaranteed the achievement of these important works by the constructors. The use of BIM has allowed anticipating some construction issues and interferences, by providing comprehensive construction details, benefitting the installation of the materials and the completion of the works. Moreover, the control of the settlements was carried out during the whole construction and post-construction phase. These checks were particularly important for the launch of the bridge. The monitoring showed that the final vertical measures were below 160 mm (Figure 7).
Figure 7.   Direct bridge abutment G03 settlement monitoring from October 2021 to March 2023.

4   CONCLUSIONS

The aim of the paper has been to present the Oosterweel Verbinding, Linkeroever project, and the role of Maccaferri in this framework. Maccaferri has collaborated in the design, supply, and installation of steel wire mesh solutions and Geosynthetic Reinforced Soil-Integrated Bridge Systems (GRS-IBS).

The peculiarity of the case study has been to present the design and building of GRS-IBS, which are innovative solutions for the construction of bridge abutments, made environmentally friendly thanks to the combined use of polymeric geosynthetics and „Terramesh" double-twist steel wire mesh reinforcements.

Regarding some benefits with respect to other standard solutions, Maccaferri Terramesh proved to be a flexible and more suitable system for construction details and a reliable system thanks to the continuity and integrity of the double-twist steel wire mesh with the facing.

Challenges have been encountered and the installation due to the strict restrictions given by demanding geometry of the facing of the structures provided by design has been the main one. The main adopted technologies and recommendations to solve the main challenges have been presented. From the lessons learned point of view, LEM, FEM, and BIM proved to be decisive in material optimization and computation and in anticipating some construction issues and interferences, despite the initial encounter with technical difficulties in the use of these technologies. Finally, the appropriate construction procedures suggested by the suppliers and the installers of the systems have been fundamental to preventing construction difficulties.

Alpine protective structures with geosynthetic reinforcement

G. Mannsbart & M. Uebigau
TenCate Geosynthetics, Linz, Austria

D. Illmer
Ingenieurbüro Illmer Daniel, Fulpmes, Austria

ABSTRACT: Defence against natural hazards is important for the preservation of the Alpine region as a valuable living space and economic area, as well as recreational area for present and future generations. Protective structures against natural hazards like rockfall and avalanche events are of specific importance.

Construction in Alpine regions requires special measures concerning design, execution and the selection of construction methods and materials. Especially for rockfall and avalanche protection, aspects of safety, construction cost and material availability, as well as the limited construction time are of crucial importance. All these factors play an important role in design and execution. Examples are given to show how the use of suitable geosynthetics can lead to an economically and technically optimum solution for protective dams.

In the paper, design, dimensioning, and execution are presented based on selected projects, realised with geosynthetics.

1 GENERAL

In the Alps, it is state of the art today to consider geosynthetic reinforced earth dams as defence structures against natural hazards like snow avalanches, mudflows and rock falls. These protection systems must be considered as complex engineered structures by their high-altitude location and the difficult terrain in which they must be built, but also due to the considerable consequences a failure might have for goods and human life. The danger of these kinds of natural hazards was once restricted to mountainous regions but expanding urban areas close to rocky slopes are increasingly at risk. Conventional protective structures are often unable to withstand those impacts.

Primary protection measures, such as foresting or artificial retaining systems, are designed to prevent initial avalanche or rock movement. Secondary protection measures, such as fences, nets, dikes and retaining walls constructed across the path and/or along the peripheries of avalanche or rock movements, are designed to withstand the dynamic forces with the aim of restricting, splitting and/or deviating the already moving mass.

Earth dams as secondary protection barriers using geosynthetic reinforcement can be constructed quickly, provided the proposed site is accessible to construction equipment. A further advantage of geosynthetic reinforced structures can be seen in the use of locally available soil which can be used as main construction material. In combination with adequate geosynthetics, fill of locally available quality may be used, even if the (usually higher) requirements for standard fill material are not met. Drainage of fine-grained soils can be provided by geosynthetic reinforcements with additional drainage function. Finally, geosynthetics provide a strengthening of the soil mass and improvement of resistance against dynamic impacts. Due to all these reasons, more and more of these structures are being built in the alps, taking advantage of construction technologies using geosynthetics.

2 AVALANCHE PROTECTION

2.1 *Types of dams*

The design of avalanche protection dams in the fall zone is complex. If an avalanche cannot be prevented in the area of origin, structures are erected in its fall-path or in its runout area to deflect the avalanche in another direction (deflection dam), to limit the lateral extent of the avalanche (guide dam) or to stop the avalanche completely (avalanche arrest dam).

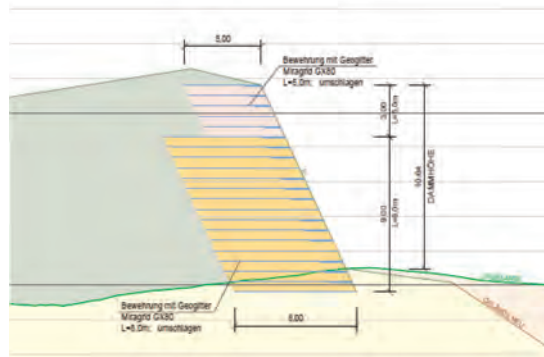
Earth Dams are often used in the run-out areas of snow avalanches as protection measure against both wet- and dry-snow avalanches. According to the desired function, catching and deflecting dams may be distinguished. Various models are used to design avalanche protection dams, most of them are based on simple point-mass considerations, widely used in Alpine countries; Alternatively, the description of the dynamics of the front of the avalanche, but also numerical computations of the trajectory of a point-mass on the upstream side of the protective dam can be used.


Figure 1.   Typical cross section of an avalanche deflecting dam.

Once the location for a dam has been decided, the forgoing analyses are important to help determine the design avalanche which helps to estimate the appropriate size and shape of a dam or mound.

Usual design methods use the avalanche analysis calculations for an estimated, initial dam height and will help to develop ideas of geometry. In that sense, a careful selection of only a few design parameters will often be useful. In a second stage, more complex design models might be used, taking in to account more variables to improve the numerical simulations that are based on depth-average equations and shock-capturing algorithms. This design approach will help to establish the dam height, length, width, and geometry of a dam. For catching dams, the storage capacity available on the upstream slope, on top of the existing snow cover must be evaluated.

Design work will also establish a critical dam height, defined as the maximum height of the obstacle (above snow cover) that changes the avalanche from supercritical to subcritical flow state as parts of the snow mass passes over the crest. By adding the upstream flow depth, the minimum physical height of the dam to arrest the flow can be estimated.

The design assumes no loss of momentum in the avalanche during its impact with the dam. Tests with glass beads have shown that where the upstream faces of dams have angles of at least 60 degrees to the terrain they have similar efficiency in dissipating energy to those built perpendicular to the slope. In any case the design and geometry of the catching dam have the most influence on retardation and retention of moving snow masses. [Issler et al. 2009]

2.2 Project example Tauernmoos

The so-called Tauernmoossee is an artificial lake in the central Alps of Salzburg, located more than 2000 m above sea level containing a volume of more than 20 mio. m^3 of water used for a hydroelectric powerplant. With the expansion of the Stubachtal power plant around the Tauernmoos pumped storage plant, the Austrian Federal Railways (ÖBB) focuses on sustainable and environmentally friendly mobility, using renewable energy for public transport.

Between the two existing reservoirs of Weißsee (2250 m above sea level) and Tauernmoossee (2023 m above sea level) in the rear Stubachtal valley near the municipality of Uttendorf (Oberpinzgau), the unused net head of 220 m will be used to generate 460 gigawatt hours of traction current.

Figure 2.   Tauernmoos avalanche deflecting dam during construction. (Nov. 2021).
Figure 3.   Cross section of the Tauernmoos avalanche deflecting dam.

A 6 m high and 100 m long combined deflection and catchment dam had to be built to protect the intake structure of the by-pass against avalanches. Due to the quick and easy construction procedure the decision was made to build a geogrid reinforced structure using an approved reinforced soil system. The design was done using a quasi-static loading assumption and 70° slope inclination.

2.3 Case history Axamer Lizum

In the Austrian Alps alone, approximately 8,000 avalanche catchment areas are existing in which countless avalanches occur every year. With the continuous climate change, an on-going increase of these natural events is also expected for the coming years. Avalanches can occur from a gradient of 15 percent and may destroy settlement areas and infrastructure.

In the high alpine ski region of Axamer Lizum in the Tyrol (Austria), two avalanche protection dams had to be built in 2018 to secure a water storage pond used for artificial snow production in the middle of a rock massif. A technically tailor-made geosynthetic solution, In the Tyrolean ski resort of Axamer Lizum, two dams are protecting against tidal waves caused by avalanches since 2018.

The dimensioning of the dams refers to the required dam height and avalanche forces acting on the dam structures and affecting their stability. It should be noted that due to the limited space on the uphill side of the storage pond, no catchment structure can be erected that has a sufficient effective height to completely stop 150-year avalanches. The solution chosen for this site was a reinforced slope system with special steel mesh angles as a lost scaffolding, which can ideally be used in hard-to-reach steep mountain regions. The installed

geogrids are used to reinforce the earth and, due to their high tensile strength, provide effective load distribution against avalanches.

For the protective dams with a height of well over 20 meters and individual length, the soil available directly on site is used as fill material. As a result, this form of avalanche protection is resource-saving, can be used almost everywhere and causes considerably less CO_2 emissions than conventional structures, for which material is delivered, for example, by helicopter. The visible facing of the dams can be flexibly designed so that they optically harmonize with the natural environment. The durability of the constructions is designed up to 120 years. [Gruber 2022]

Figure 4.   Avalanche protection dam Axamer Lizum after completion.

Table 1.   Dimensions of The Axamer Lizum Dam.

Property	Dimension
Flow velocity v_f (150-year avalanche)	22 m/s
Flow height h_f (150-year avalanche)	1.5 m
Energy level h_e	16,4 m
Snow height h_{snow}: (considering regular dam clearance)	1 m
Pre-deposit $h_{deposit}$ (considering regular dam clearance)	0 m
Dam height HD he + h_{snow} + $h_{deposit}$ + h_f	16.4 + 1 + 1.5 = 18.9 m
Safety board	2,0 m

3   ROCKFALL PROTECTION

3.1   *Rockfall as natural hazard*

Changing climate conditions, anthropogenic influences and seismic processes can have dangerous consequences in the form of rockfalls and landslides. Rockfall can be defined as the collapse of large stone blocks, fragments of rocks and just a free fall of stones on mountain slopes under the influence of gravity. The reason for these processes is the separation of soil masses from the parent rock. Several types of protective structures are available to prevent damages on goods and human life.

Among the main investigated parameters in the analysis of rockfall processes and design of engineered protection constructions are the stone trajectory and the impact energy of the stone. The trajectory of the rockfall is influenced mainly by the following parameters:

- the average diameter d of the blocks.
- volume and weight of an unstable array.
- slope angle (inclination) and slope configuration (cross-section).
- physical and mechanical characteristics of the soil.

The impact energy of the stone is experimentally determined and depends on volume and weight of blocks and the speed of falling stones. In the past, fence capacities were once considered large at only 100 or 500 kJ, whereas nowadays systems are commonly installed up to 5000 kJ, and some of them even higher. The fundamental possibilities of different protective structures are described in Figure 5.
Figure 5. Schematic overview on rockfall protection structures.

3.2 Case history Eisgratbahn Stubaital

Boulders of the size of a single-family house had fallen from a steep slope above the parking area of the Eisgratbahn cableway during a rockfall in May 2021. To eliminate the potential danger of further rockfalls and to secure the slope in time for the start of the next winter season, a fast and durable solution was needed.

Figure 6. Rockfall protection dam Eisgratbahn-Stubaital.

A vegetated geosynthetic reinforced slope system was able to provide a solution absorbing the dynamic forces of falling rocks while requiring a minimum of surface area. The protective dam was designed according to the ONR 24810 standard and offers an optimal combination of a maximum performance and cost efficiency coupled with a minimal time investment.

The implementation was carried out in record time: after the start of the project, the geosynthetics were delivered within only 4 weeks. After only 6 weeks of construction, the project was completed and Stubaier Gletscherbahnen could use the parking lot for the start of the winter season.

The use of the special system made it possible to install the fill material available on site, with a total volume of 18,100 m^3 and therefore considerably reduce the transport effort and environmental impacts. With a total of only four truckloads to transport construction materials to the site, the project has a minimal ecological footprint. It also reduced the impact on residents from construction noise and dust. A conventional concrete structure would have required much more energy and transportation than the modern construction method using geosynthetics.

On the mountainside, the dam surface in the rockfall zone was constructed with a mortared tile set as surface protection against falling rocks. Greenery was planted on the remaining embankment surfaces, the front sides, and the top of the dam to ensure everything will blend perfectly into the landscape.

Figure 7.   Rockfall protection dam Tenneck.
Figure 8.   Cross section of the protection dam.

3.3   Quarry site "Ehrensberger" near Salzburg

Since decades a limestone quarry site is in use close to the Village of Tenneck near the city of Salzburg. To widen the area of mining, a rockfall protection dam had to be built as a back-to-back structure. The dam was up to 6 m high and mor than 100 m long. The structure was built using a geogrid with a short-term strength of 160 kN/m installed at a vertical spacing of 0,6m. The requirement was to use coarse-grained granular fill without any organic content. Compaction of 98% proctor-density and a bearing capacity Ev_1 value of 15 MN/m^2 by plate-loading test had to be achieved.

4   DESIGN OF PROTECTIVE DAMS USING ONR 24810

The first use of geosynthetics in protective structures dates to 1990ies. [Mannsbart 2002] At that time, design methods for usual reinforced soil structures were available, but consideration of impact loading was not common practice. [Adam et al. 2002] First design approaches were mostly empirical, whereas today a number of design methods do exist.

For rockfall protection structures, the Austrian guideline ONR 24810 provides a design basis. Rockfall protection dams are used particularly in cases, where slope geometry and available space permit such a structure. Dams show advantages over nets, especially in terms of service life, construction cost and - depending on the design - energy absorption capacity. Before starting the design, the structure is assigned to a certain defined type. As an important part of the document, it is shown that reinforced dams can absorb a considerably higher energy of falling blocks. For geosynthetics reinforced structures both the impact time as well as the dissipated energy are increased (Figure 9).
Figure 9.   Impact time and energy absorbed.

Specifically, for rockfall catchment dams, it has sections dedicated to the verification of the superstructure itself, reinforcement design, non-standard actions, construction rules and lifespan.

Two tables set requirements for geosynthetic reinforcement, especially on strength and stiffness of geosynthetics at 5% elongation.

This relatively high stiffness requirement seems to be far on the safe side which might restrict the range of allowable products to high-strength, brittle geogrids. If this approach seemed justified for the first edition of the guideline, it might probably require some adaptation to more common geosynthetic reinforcement elements with its next edition.

The construction of protection embankments has increased markedly in areas with a high risk of rockfalls and avalanches. Suitable design models for soil embankments are used among which the Austrian guideline is a useful tool for the design of rockfall protection dams, but might need some adaptation concerning the geosynthetics requirements.

Novel landscaping applications of geosynthetics in 'Museum of the Future' project in Dubai

P.V. Jayakrishnan, L. Mottadelli & M.H. González
Maccaferri Middle East LLC, Dubai, UAE

ABSTRACT: The 'Museum of the Future' in Dubai is one of the most innovative buildings in the world, which is designed in three main parts, namely the lower green hill, the middle building, and the top elliptical void structure. As per the architectural design, the green hill is designed as a smooth transition from ground, in the form of an earthen vegetated mound which eventually should cover the embedded three-story podium structure. As a result, the green hill had to be constructed as claddings around the base structure rather than as a solid earth hill. Three different types of geosynthetic green systems were used to recreate the different slopes, which included reinforced soil for steep slopes, heavy revetment with geocells for moderate slopes, and rolled erosion control mats for gentle slopes. In most cases, the available thickness of soil layer was only 30 cm, complicating the design and construction of the geosynthetic systems. To ensure the stability of the geosynthetic green cover systems for moderate and gentle slope cases, continuous veneer reinforcement was installed below the thin soil fills, using double-twisted wire mesh netting that was anchored to the concrete structure at the top of the cover system. Due to existing space constraints, the soil reinforcement had to be anchored to the concrete structure in most of the cases for reinforced soil slopes. Additionally, a layer of geosynthetic drainage composite was installed below the entire surface area of the green cover system to enable easy drainage of the continuous irrigation water expected from the gardening activities. Through the successful case reference of the 'Museum of the Future' project in Dubai, this paper sheds light on the possibilities, opportunities and challenges associated with the use of sustainable geosynthetic systems in iconic projects for landscaping and architectural applications.

1   INTRODUCTION

The 'Museum of the Future' project in Dubai is created with sustainability as the key requirement. Project stakeholders wanted the facility to be designed, built, and operated sustainably using the most updated technologies. A large portion of the building is situated underneath the green roof of the podium, which further contributes to the project's sustainability credentials by reducing solar gain and the heat island effect. Accordingly, the structure is divided into three main parts: the embedded building, the green hill, and the top void. The green hill is designed as a smooth transition from the ground in the form of an earthen vegetated mount covering an embedded podium structure. An iconic feature of the project is the garden on the green hill comprising around one hundred species of trees and plants. The lower hill's unique setting made traditional landscaping techniques difficult. This slope with drastically varying inclinations needed a novel way of retaining soil and growing greenery. Due to the high summer temperatures in Dubai and with limited rainfall, irrigation was one of the main considerations. This project utilized a wide range of geosynthetic products to address soil retention, revegetation, and smart irrigation needs. It is the purpose of this paper to present the possibilities, opportunities and challenges associated with the use of sustainable geosynthetic systems in landscaping and architectural applications for iconic

projects, through the reference of the successful implementation in the 'Museum of the Future' project in Dubai.
Figure 1.   Architectural rendering of sectional view of the project (image courtesy: Buro Happold Engg.).

2   GEOSYNTHTIC APPLICATIONS IN THE PROJECT

To reduce the vertical load on the slabs and walls of the embedded podium structure, a lightweight geofoam block was required to be used as the main body of the green mount. This resulted in only 30 cm of cover soil thickness available in most cases, complicating the design and construction of geosynthetic systems. To recreate slopes at different angles, three different geosynthetic green cover systems were used. As a final solution, biodegradable erosion control blankets, geocell revetments and reinforced soil structures were implemented. In moderate and gentle slope cases, continuous veneer reinforcement was installed below the thin cover soil to ensure stability of the geosynthetic green cover systems.

2.1   Solutions for gentle slope (up to 35° inclination)

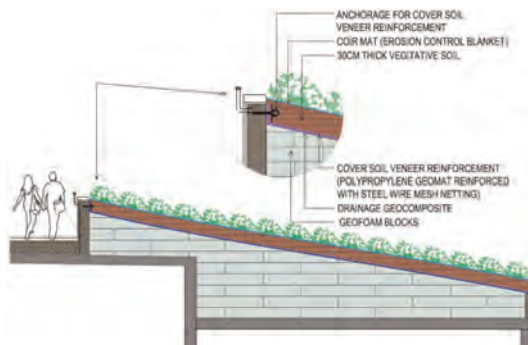
For gentle slopes up to 35°, biodegradable rolled erosion control blanket type Biomac® was used as the green cover system (Figure 2). The purpose of the erosion control blanket made with coir geotextile is to avoid erosion of the slope and to facilitate quick vegetation of the slope. The beige colour of Biomac blanket helped create the impression of a soil filled slope during the installation before development of full vegetation. Biomac being a soft erosion control material, irrigation pipes could be seamlessly installed using its fixtures. To improve the sliding stability of the thin cover soil, Macmat HS® veneer reinforcement was installed continuously below the thin soil layer. Macmat HS is made by extruding a high frictional


Figure 2.   Typical cross-sectional details of geosynthetic application for gentle slope (up to 35°).

polypropylene mat onto a double twisted steel wire mesh netting. In the absence of any underlying soil that can support and frictionally interact with the veneer reinforcement, the Macmat HS had to be anchored to the concrete slab of the embedded building structure. As part of the smart irrigation system, Macdrain® geosynthetic drainage composites were used below the cover soil to reduce water wastage as well as to deliver water directly to the root system of the plants and trees.

2.2 Solutions for moderate slope (for 36° to 45° inclination)

For moderate slopes ranging from 36° to 45°, heavy revetement with geocells were adopted. Geocell provides the required confining effect without local movement of the cover soil (Figure 3).

For this slope case also, veneer reinforcement and drainage composure were continuously provided below the green cover soil, as well were anchored to the top concrete slab.

Figure 3. Typical cross-sectional details of geosynthetic application for moderate slope (up to 45°).

2.3 Solutions for steep slope (for 46° to 80° inclination)

For steep slopes ranging from 46° to 80° inclination, reinforced soil structure type Green Terramesh® was used (Figure 4). When space was limited, the soil reinforcement tail of the Green Terramesh system was anchored to the concrete walls of the embedded building using concrete anchors, thereby dissipating the residual stresses from the soil reinforcement. For this slope case also, veneer reinforcement and drainage composure were continuously provided below the green cover soil, as well were anchored to the top concrete slab.
Figure 4. Typical cross-sectional details of geosynthetic application for steep slope (up to 80°).

3 DESIGN

MACSTARS W software (Maccaferri Stability Analysis of Reinforced Soils) was used for the design of Green Terramesh reinforced soil slopes (external & internal stability check) as per AASHTO Allowable Stress Design method. MACSTARS W is a limit equilibrium-based design software. The interaction factors between the soil reinforcement & backfill soil were reduced by 50% to account for the lower friction due to the presence of geofoam instead of soil.

Zinc coated concrete anchors made of carbon steel were used in the project (Figure 5). Anchors were designed conservatively for the pull-out strength equivalent to the long-term design strength (LTDS) of the soil / veneer reinforcement. In the actual field condition, the anchor load would be less than the LTDS of the soil reinforcement in many layers, considering the typical stress distribution within the soil reinforcement layers. Chemical adhesive was used to grout the anchor within the drilled hole in concrete wall.
Figure 5. Details of concrete anchor used in the project.

The stability of thin cover soil in gentle and moderate slope cases were evaluated following the principles of analysis of veneer soil reinforcement, ensuring a minimum factor of safety of 1.5.

4 CONSTRUCTION ASPECTS

Pertaining to the various geosynthetic solutions, the following sequence of construction was adopted at site.

- Anchoring and installation of Green Terramesh units and laying of geofoam block core.
- Laying of drainage geocomposite.
- Anchoring and laying veneer reinforcement.
- Laying of cover soil, unconfined for 35° slope or confined in geocell for 45° slope case.
- Laying of the coir-based erosion control blanket above cover soil.
- Fixing irrigation pipes.
- Plantation works.

5   GEOSYNTHETIC'S CONTRIBUTION TO PROJECT'S SUSTAINABILITY

The 'Museum of the Future' project in Dubai is created with sustainability as the key requirement. As a result of use of geosyntics in the project, the following sustainability benefits are achieved.

- Replacement of a 30cm thick gravel drainage layer sandwiched between two geotextile layers (Case A) below the cover soil by a thin drainage geocomposite (Case B).
- Reduction of cover soil thickness from 50cm (Case A) to 30cm (Case B) by using geomat veneer reinforcement.
- Around 25% of irrigation water conserved by recycling the excess water collected from drainage geocomposite.
- Carbon sequestration from trees & plants growing within the different geosynthetic layers.
- Reducing solar gain and the heat island effect of the embedded building due to **the green roof.**

To ensure sustainability in engineering, quantitative design tools are needed to perform the metrics that can be applied in the design process. Life cycle assessment (LCA) is one such tool for evaluation of sustainability in engineering designs. Basically, LCA involves a complicated methodology for identifying the energy and other resource requirements as well as the environmental impacts associated with every stage in the life cycle of a product, process, or system.

Typically, the LCA study are done by adhering to the requirements of ISO 14040 and 14044 standards. In the present work, the environmental performance of Cases A and case B are assessed with the following impact category indicators.

The conventional drainage layer and thicker vegetative soil (Case A) causes comparatively higher impacts in all categories than using the drainage composite & geomat veneer reinforcement (Case B). The higher impacts of Case A are caused by the emissions and the

resource consumption related to the production and transportation of the amount of gravel required, as well as increased land excavation for sourcing of vegetative soil. Compared to Case A, no gravel is used in Case B for drainage purpose. The environmental impacts of gravel are mainly caused by mining machines, the use of electricity during mining and the energy requirements for transportation from stone quarries to jobsite.

6 CONCLUSIONS

Due to the limited extent of industry awareness, the potential of using geosynthetics in landscaping applications is often underutilized or overlooked, especially those involving soil retention and irrigation along complex slopes. It is the purpose of this case study paper to present the possibilities, opportunities and challenges associated with the use of sustainable geosynthetic systems in landscaping and architectural applications for iconic projects, through the reference of successful implementation in the 'Museum of the Future' project in Dubai.

ABSTRACT: Geomembranes (GMs), especially high-density polyethylene (HDPE) ones, are used to provide a barrier to water and oxygen in mine site reclamation cover systems. The physical stability of these GM remains a major concern as it affects their performance to control fluid flows. Considering that HDPE GMs can crack even while being in the elastic domain, a maximum allowable strain (MAStrain) was fixed at 4% to avoid stress cracking. The MAStrain corresponds to a maximum allowable stress that must not be exceeded. This paper assessed the chemical and mechanical properties of exhumed GMs from two cover systems installed 13 and 20 years, and the impact of the tensile properties on the MAStrain. The results show that the GM remains in the first degradation stage and no negative impact was found on the mechanical properties. The tensile behavior of the exhumed GM indicates a gain of stiffness that reduces the MAStrain.

1 INTRODUCTION

Geomembranes (GMs) are widely used in the mining industry. They are used in the mining operations as a liner in heap leach pads or for water ponds, as in the mine waste management as a liner for tailings storage facilities or in the reclamation process as a fluid-tight component in cover systems (Lupo & Morrison 2007; Touze-Foltz & Lupo 2009). For this last example of use, the role of the GM is to prevent water and oxygen ingress into the sulphide tailings to limit the generation of acid mine drainage that could be harmful to the environment (Maqsoud et al. 2021; Rarison et al. 2022). Almost all of the GMs used in covers are high-density polyethylene (HDPE) (Maqsoud et al. 2021). Nevertheless, HDPE GMs are prone to stress cracking because of their high crystallinity (Müller 2007; Scheirs 2009). Stress cracking is defined as "an external or internal crack in a plastic caused by tensile stresses less than its short-time mechanical strength" (ASTM D883 2005). Those cracks would then compromise the performance of the cover to control fluid flows. The physical stability of GMs then remains a major concern, especially in covers as the tailings can settle over time. Settlement can generate tensile stresses inside the GM during the service life of the cover. The maximum allowable strain was then introduced as a design criteria in order to ensure the long-term durability of the cover system (Dixon & von Maubeuge 1992; Eldesouky & Brachman 2018; Jones et al. 2000; Peggs et al., 2005; Rowe & Yu 2018; Rowe & Yu 2019; Rowe et al. 2020).

Nevertheless, little is known about the in situ long-term behaviour of GMs in service. One way to learn more about this behaviour is to exhume GMs installed in cover systems. GM exhumation is commonly used for in-service performance assessment (e.g., McWatters et al. 2020; Rowe et al. 2010). The main objective of this study is to assess the actual properties of GMs after years of service. To this purpose, GMs were exhumed from two sites. The exhumed

geomembranes were characterized in the laboratory to assess their antioxidant and stabilizer levels to know the degradation stage of the GMs, and their tensile properties. The aim is not to compare the properties of the two GMs. As the initial properties of these GMs are unknown, the obtained results would be compared to typical virgin HDPE GM properties. The results will be then used to assess the impact on the design criteria of maximum allowable strain.

2 GEOMEMBRANE EXHUMATION

To reach the study objective, two sites were selected, S1 and S2, where cover systems with smooth HDPE GMs were installed 13 and 20 years ago to reclaim these sites. S1 is located in the western part of Québec, Canada. S1 was reclaimed in 2005-2006 with a cover system composed by a 1.5 mm-thick smooth black HDPE GM installed directly above oxidized tailings and a 0.6 m-thick silt protection layer. S2 is located in the mid-north of Québec, Canada. This site was reclaimed in 1999-2000 with a cover system made up of 1.5 mm-thick smooth black HDPE GM installed directly above oxidized tailings and covered by a 1.4 m-thick till protection layer. The cross sections of the two cover systems are presented in Figure 1. On both sites, the surface of the protection layer was vegetated.
Figure 1.   Cross sections of the cover at the sites 1 and 2.

To access the GMs, S1 was exhumed in August 2019 and S2 in August 2022. The first step was to form tiles of surface vegetation of the cover systems. The second step was to excavate the protection layer through to the GM level with a mechanical shovel, with particular care to the proximity of the GM so as not to damage it during excavation efforts. The third step was to sample the GM with dimensions of 2 m by 2 m and 1 m by 1 m for S1 and S2, respectively. The fourth step was to substitute the exhumed GM with new HDPE GM patch that was seamed by extrusion to the GM on the site to ensure the sealing of the cover. Finally, the excavated soil was returned and recovered with the surface vegetation tiles.

3 GEOMEMBRANE CHARACTERIZATION

Details on the performed physical, chemical and mechanical characterizations of the two HDPE exhumed GMs are presented below. The initial properties of these GMs are unknown as the different characterizations were not performed when the membranes were put in place. The results obtained with the exhumed GMs will be compared to those obtained from a typical virgin HDPE GM that was characterized in the laboratory and is assumed to be representative of the initial GM installed in the two sites. To assess the significance of the differences of the GM mechanical properties (typical virgin GM compared to S1 GM, and typical virgin GM compared to S2 GM), two-sample t-tests (Student 1908) were performed. Prior to two-sample t-tests, the normality of the distributions was verified with Kolmogorov-Smirnov tests (Lilliefors 1967). The significance was set at 0.05 (95% of confidence) for these two tests; which means that when the p-value obtained with the two-sample t-test is higher than the 0.05, the difference between the compared data is not significantly different; and when the p-value obtained with the normality test is higher than 0.05, the data are significantly drawn from a normal distribution.

3.1 *Physical characterization*

The physical characterization of the GMs (virgin, S1 and S2) consisted of measuring the GM thickness. The thickness measurement was performed according to ASTM D5199 (2019b) using MTG-DX2 thickness gauge which has the accuracy of ± 4 μm (Checkline, USA). The GM thickness T_{GM} is defined as the mean of 10 thickness measurements on 10 disks of 80 mm diameter.

3.2 *Chemical characterization*

To assess the antioxidant and stabilizer level, which would give information on the GM degradation state, low-pressure and high-pressure differential scanning calorimetry (DSC) were performed. The low-pressure DSC (140 kPa) was operated at high temperature (200°C) to measure the standard oxidative-induction time (Std-OIT) according to ASTM D3895 (2019). The high-pressure DSC (3.4 MPa) was conducted at lower temperature (150 °C) to measure the high-pressure oxidative-induction time (HP-OIT) according to ASTM D5885 (2017). The two tests give complementary information as antioxidant and stabilizer effective temperature ranges are different. For example, hindered phenols and phosphites whose effective temperature range is above 150°C can be detected with std-OIT while hindered amines and thiosynergists whose effective temperature range is up to 150°C can be detected with HP-OIT (Hsuan & Koerner 1998). The Std-OIT was performed in duplicate (for the virgin, S1 and S2 GMs). Only single measurements of the HP-OIT were performed for the S1 and S2 GMs. The HP-OIT of the virgin GM was given by the manufacturer.

3.3 *Mechanical characterization*

The mechanical properties of the GM from S1 and S2 were assessed with tensile tests performed on dog-bone shaped specimens (Figure 2.a) according to ASTM D6693 (2015). Raw data are presented in terms of force-displacement curves as illustrated in Figure 2.b. The force-displacement curve gives four parameters: the yield force (*YF*), the yield displacement (*YD*), the break force (*BF*), and the break displacement (*BD*). These parameters are used to define four tensile properties following equations (1) to (4): the tensile yield strength (*TYS*, N/mm) and the percent yield elongation (*PYE*; %); the tensile break strength (*TBS*; N/mm) and the percent break elongation (*PBE*; %).

$$TYS = \frac{YF}{W} \tag{1}$$

$$PYE = \frac{YD}{GL_Y} \cdot 100 \tag{2}$$

$$TBS = \frac{BF}{W} \tag{3}$$

$$PBE = \frac{BD}{GL_B} \cdot 100 \tag{4}$$
Figure 2.   Dog-bone shaped specimen for tensile test (a) and typical raw result from a tensile test (b).

where W (specimen width), GL_Y (gauge length for yield) and GL_B (gauge length for break) are defined on Figure 2.a.

The dog-bone shaped specimens were prepared in the machine/roll direction (MD) and in transverse or crossmachine direction (CD) to assess the anisotropy. Five tensile tests were performed in each direction for each GM (virgin, S1 and S2).

4 RESULTS

4.1 *Geomembrane thickness*

The thicknesses of the three GMs assessed in this study are presented in the Figure 3. The T_{GM} of the virgin, S1, and S2 GMs are 1.51 mm, 1.55 mm, and 1.57 mm, respectively. The three values are above the nominal thickness of 1.50 mm and show the variability of the GM thickness.
Figure 3. Box plots of the thicknesses of virgin and exhumed geomembranes.

4.2 *Antioxidant and stabilizer level*

The results of the antioxidants and stabilizers level are presented in terms of Std-OIT and HP-OITs in Table 1 below for the virgin, and the S1 and S2 GMs who are 13 and 20 years old, respectively. The Std and the HP-OITs of the GM from the site S1 (211 min and 496 min, respectively) are close to those of the typical virgin GM (195 and >400 min, respectively), which means that the S1 GM degradation is in its earlier part. The Std and the HP-OITs of the GM from the site S2 (111 min and 314 min, respectively) are lower than those of the typical virgin GM. The lower OITs (Std and HP) of S2 GM would then indicate that this GM has an advanced degradation state.

The Std and HP-OITs of the S1 and S2 GMs are higher than the residual values (when the antioxidants and stabilizers are completely depleted) that can be as low as 1.5 min and

Table 1. Standard and High-Pressure OITs of a typical HDPE geomembrane and of the exhumed geomembranes.

Properties	Units	Virgin	S1	S2
Std-OIT	min	195	211	111
HP-OIT	min	>400[*]	496	314

[*]Provided by the geomembrane manufacturer.

80 min, respectively (Ewais et al. 2014). These results then show that there are still anti-oxidants and stabilizers inside the GMs from S1 and S2, which means that the GM remains in the antioxidant depletion stage according to Hsuan and Koerner (1998). During this stage, the GM's properties (e.g., tensile strength) are expected to remain unaffected.

4.3 Mechanical properties

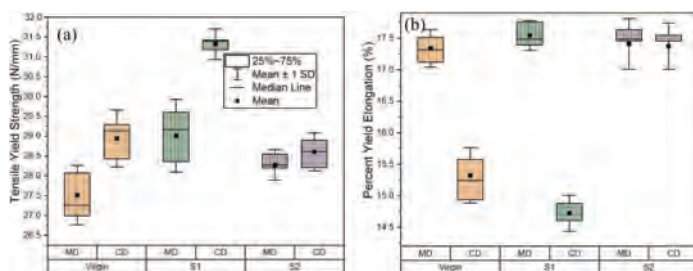
The box plots of the yield and break properties of the virgin, and the exhumed HDPE GMs (S1 and S2) are presented in Figures 4 and 5, respectively. The results from the two principal directions (MD and CD) are also included. All the data are significantly drawn from a normal distribution as all the p-values obtained with the Kolmogorov-Smirnov tests are above the significance level of 0.05 (presented in Table 2). Two-sample t-tests could be then performed to assess the significance of the differences (e.g., MD vs. CD, virgin GM vs. S1 GM, virgin GM vs. S2 GM).


Figure 4. Box plots of tensile yield strength (a) and percent yield elongation (b) obtained with the virgin and the exhumed HDPE GMs.
Figure 5. Box plots of tensile break strength (a) and percent break elongation (b) obtained with the virgin and the exhumed HDPE GMs.

Table 2. P-values obtained with the Kolmogorov-Smirnov normality tests.

GM	Direction	TYS	PYE	TBS	PBE
Virgin	MD	0.89	1.00	1.00	1.00
	CD	1.00	0.51	0.63	0.84
S1	MD	1.00	1.00	1.00	1.00
	CD	1.00	0.64	0.90	0.82
S2	MD	1.00	0.50	1.00	0.53
	CD	1.00	0.35	1.00	1.00

Regarding the anisotropy of the tensile properties, it can be seen in Figures 4 and 5 that the results obtained in MD can be different from those obtained in CD. The two-sample t-

tests show that the anisotropy is verified for the yield properties of the virgin and S1, for the TBS of the S2 GM and for the PBE of the S1 GM as it can be seen in Table 3. The anisotropy would then be more observable for recent GMs.

Table 3. P-values obtained with the two-sample t-tests for the anisotropy assessment.

GM	Compared direction	TYS	PYE	TBS	PBE
Virgin	MD and CD	0.00[*]	0.00[*]	0.93	0.13
S1	MD and CD	0.00[*]	0.00[*]	0.11	0.02[*]
S2	MD and CD	0.27	0.88	0.04[*]	0.35

[*]Anisotropy is verified.

Table 4. P-values obtained with the two-sample t-tests for the assessment of the difference significance.

Direction	Compared GM	TYS	PYE	TBS	PBE
MD	Virgin and S1	0.02[*]	0.17	0.55	0.68
	Virgin and S2	0.02[*]	0.73	0.00[*]	0.00[*]
CD	Virgin and S1	0.00[*]	0.01[*]	0.08	0.01[*]
	Virgin and S2	0.30	0.00[*]	0.00[*]	0.00[*]

[*]Difference is significative.

Regarding the yield properties, TYS of both exhumed GM are significantly higher than TYS of virgin GM (except for S2 in CD) while there is no statistically significant difference for the PYE (except in CD). That means the exhumed GMs are stiffer than the typical virgin HDPE GM. These observations can be observed in Figure 4 that presents box plots of TYS and PYE, verified with the statistical analyses in Table 4.

Regarding the break properties, there is no significant statistical difference between the TBS and PBE results for the GM exhumed from the site S1 and the virgin GM (except the PBE in CD); while TBS and PBE are significantly higher for the GM exhumed from the site S2 than the virgin GM. The GM exhumed after 20 years (site S2) is more resistant than the typical virgin one. The GM used at that time could be more resistant than those manufactured more recently.

All the tensile properties of the exhumed GMs are at least similar to those of the typical virgin GM.

5 DISCUSSIONS

The above data indicate that the exhumed GMs are stiffer than the typical virgin HDPE GM. It would be then interesting to know how this gain of stiffness could impact the design criteria concerning the maximum allowable strain (MAStrain). Indeed, the GM could also break under a constant load, even in the elastic zone, due to stress cracking, particularly for HDPE GMs owing to their high crystallinity (Hsuan et al. 1993; Müller 2007; Scheirs 2009). Hence, some authors use the MAStrain as the strain that should not be exceeded to ensure the durability of the GM (Dixon & von Maubeuge 1992; Eldesouky and Brachman 2018; Jones et al. 2000; Peggs et al. 2005; Rowe & Yu 2018; Rowe & Yu 2019; Rowe et al. 2020). Initially, a MAStrain of 6% was proposed for HDPE GMs (Dixon & von Maubeuge 1992; Jones et al. 2000). Different MAStrain values were subsequently proposed, depending on the GM use, for example, from 4 to 5% for GMs used as a cover which consider a safety factor of 1.5 to 1.2, respectively, compared to the initially proposed 6% (Rowe & Yu 2019), and 3% for GMs used as a liner which means a safety factor of 2 (Jones et al. 2000; Rowe & Yu 2019; Rowe et al. 2020).

In this study, the GMs were exhumed from cover so the MAStrain considered is set at 4% with a safety factor of 1.5. To assess the impact of the gain of stiffness on the MAStrain, consider first the maximum allowable stress ($MAStress_0$) that corresponds to the initial MAStrain of 4% of the virgin GM. $MAStress_0$ is determined graphically with the linear stress-strain curve obtained with the tensile test of a virgin GM (Figure 6.a) as 17.7 N/mm and 18.1 N/mm in MD and CD respectively. These values are then used to plot the corresponding strain on the stress-strain curve of the GM exhumed from the sites S1 and S2 (Figure 6.b). These values will be the strains that would be needed to mobilize the $MAStress_0$ and would be then the MAStrain that should not be exceeded.
Figure 6.   Determination of the $MAStress_0$ (a) and the $MAStrain_{S1}$ and $MAStrain_{S2}$ (b).

Figure 7 presents the obtained MAStrain of 3.55 % and 3.04 % for S1, in MD and CD, respectively; and 3.71 % and 3.73 % for S2, in MD and CD, respectively. All the data are significantly drawn from a normal distribution as all the p-values are higher than the significance level of 0.05. The two-sample t-tests can then be performed to compare the results of the virgin GM to the exhumed ones (see Table 5). The obtained MAStrains are significantly lower than the initial MAStrain of 4% as the p-values are lower than the significance level of 0.05, except for S2 in CD where the p-value of 0.06 is above the significance level (see Table 5). The strain corresponding to the MAStress0 would be lower than it was initially, which means that the maximum allowable stress is mobilized earlier. The critical stress could be reached before the critical strain considered in the design. It is important to note that the GM behaviour could change over time. In this case study, there is a gain of stiffness that could negatively impact the design criteria.
Figure 7.   Box plots of the maximum allowable strains determined for the typical HDPE GM and the exhumed GMs.

Table 5. P-values of the normality tests and the two-sample t-tests on the obtained MAStrains.

Direction	GM	p-value of the normality test	p-value of the two-sample t-test
MD	Virgin	1.00	0.01
	S1	1.00	
	Virgin	1.00	0.03
	S2	0.52	
CD	Virgin	1.00	0.00
	S1	0.94	
	Virgin	1.00	0.06
	S2	0.92	

6 CONCLUSIONS

This paper presents actual physical, chemical, and mechanical properties of 1.5 mm-thick HDPE geomembranes exhumed from cover systems used for the reclamation of two mine sites (S1 and S2) that have 13 and 20 years of service, respectively. Results are compared to those of a typical virgin HDPE geomembrane with the same thickness. It can be concluded that:

- The antioxidant and stabilizer level of the S1 geomembrane is close to that of the virgin one, and the S2 geomembrane degradation is in an advanced state;
- The exhumed HDPE geomembranes still contain antioxidants and stabilizers, and remain in the antioxidant depletion stage during which no negative impact is expected on the mechanical properties;
- The exhumed HDPE geomembranes are stiffer than the virgin one and may have better resistance.

The effect of the tensile behaviour on the design criteria of the maximum allowable strain is that the gain of stiffness reduces the MAStrain, which could impact negatively the design criteria.

However, it should be noted that the comparisons were made with a typical virgin HDPE geomembrane whose properties could be different of the initial properties of the exhumed geomembranes. This was done for comparison purpose only. A large and complete characterization of the geomembranes should be done before its installation to complete the data provided by the manufacturer. These data should be then available for a better understanding of the in-service durability of geomembranes. In the absence of the initial properties of the GM as installed, the results presented in this study constitute reference values for future in-service performance assessments.

Introduction of geogrid reinforced MSE retaining structures in major Ghanaian Interchange project

M. Nods
Admir Africa, Enschede, The Netherlands

K. Bempong
Associated Consultants Ltd, Accra, Ghana

ABSTRACT: This project case study describes the design and construction of 23 MSE walls at the Pokuase Interchange Project in the Accra region (Ghana). The wall heights varied up to approximately 10m. The walls are supporting the approach embankments of various fly-over bridge structures at the Interchange. It concerned a first application of this technology in Ghana, and it was executed successfully within 2 years time. The vertical MSE structures were finished with prefabricated concrete panels as a protective facing, which were placed after construction of the wrap-around geogrid reinforced walls. Local granular fill could be used in the structures. The design and construction were performed in accordance with international standards (BS 8006, EBGEO, EN14475). The design included a stability analysis, consolidation and settlement analysis, and a detailed Method Statement.

1   INTRODUCTION

Geosynthetics have been used effectively to overcome many geotechnical, roadway, hydraulic and environmental challenges during the last decades. The geotechnical applications mainly include geosynthetics performing reinforcing, separating and stabilizing functions (BSI 2016). They can enable the improvement of structures on soft and even organic soils as basal reinforcement elements, and they can provide soil reinforcement over concrete piled embankments. This paper focuses on the large-scale introduction and description of geosynthetic reinforced retaining structures or mechanically stabilized earth (MSE) in Ghana. In general, these types of structures are frequently used to construct steep slopes or vertical to sub-vertical retaining walls. Due to the high load carrying capacity of geosynthetic reinforced retaining structures they have also been utilized for bridge abutments all over the world and in the process have become an established construction method

2   POKUASE INTERCHANGE

The Pokuase Interchange and Local Roads Project was planned and executed under the Accra Urban Transport Project (AUTP) by the Department of Urban Roads (DUR) under the Ministry of Roads and Highways (MRH). The project was financed with a facility from the African Development Bank (AfDB) and matching funds from the Government of Ghana (GoG). Associated Consultants Limited, a local engineering consulting firm, undertook the design assignment. Supervision was performed by same firm with support of their partners, Bigen Africa from South Africa. Originally the interchange was designed as a Three-Tier Single Point Urban Interchange (SPUI) and later after a value engineering process initiated by the contractor, Zhongmei Engineering Group Ltd, an additional tier was included to form the Four-Tier Stacked Interchange (Figure 1).

Figure 1.   Pokuase Interchange.

The project is located at the northwestern corridor of the Greater Accra Metropolitan Area. The Awoshie, Pokuase, Amasaman and Kwabenya areas all feed directly into the project area. These areas are rapidly developing as a consequence of Greater Accra Metropolitan Area's urban sprawl. This expansion has made it difficult to meet the project zone residents' service demands in terms of transport, water, health, education, sanitation etc. The urban sprawl has resulted in traffic congestion, overcrowding, substandard housing, inadequate education and health facilities, poor sanitation and a generally degraded environment. This project therefore aimed to promote sustainable economic growth and reduce poverty through greater employment and income generation opportunities; an increase in economic activities; improved accessibility to and within the project area; and enhanced access to socioeconomic infrastructure (health facilities, schools, local markets, water supply, sanitation facilities and drainage). In this way, the project through its components creates significant linkages and synergies that will contribute towards attaining economic growth, poverty reduction, and expanding social benefits to greater numbers within the respective communities.

The 4-Tier stacked Interchange was constructed as part of the project and involved the construction of Mechanically Stabilized Earth (MSE) Retaining walls for the approach roads to the bridge ramps and top tier bridge. The construction of these walls made use of geosynthetic-reinforced soil (GRS) systems, which have the ability to accommodate tensile forces and improve the mechanical properties of the composite material. The geogrids applied excel not only by their good tensile stiffness and tensile strength, but also by their exceedingly high interaction flexibility. Innovative precast concrete wall panels with a concrete column and beam grid arrangement, which had local artistic 3-D signs, were used for the first time ever (Figure 2).

Figure 2.   Precast concrete wall panels with artistic 3-D signs.

3   PRINCIPLES OF DESIGN

The design principles in the British (BSI 2016) and German (DGGT 2011) codes are similar and each code follows the 'limit state' concept. In the design codes these limits are considered

as two groups, ultimate limit states (ULSs) and serviceability limit states (SLSs). ULSs are associated with collapse either by structural and/or geotechnical failure, or by excessive deformation. SLSs correspond to unacceptable deformations or minor structural damage, leading to increased maintenance requirements and reduced service life. For each failure mode partial load factors are applied to the actions (disturbing forces) to increase their value and partial material factors are applied to resistance (restoring forces) to reduce their values broadly in line with the principles in Eurocode EC7. However, the codes differ in the application of the load and material partial factors.

3.1   *British code BS 8006: 2010*

BS 8006 (BSI 2016) was first published in the UK in 1995. It was one of the first European codes to adopt the limit state concept. It detailed the design of retaining walls, steepened slopes and embankments overlying weak foundation soils. In additional general sections dealt with fundamental principles of design, materials, testing and construction considerations. This code was subsequently reviewed and updated to be in line with the European guidance on execution (construction): EN 14475, and geotechnical design: EN 1997-1. Both external and internal ULS modes of failure are considered in the detailed design. BS 8006 defines a boundary between steep slopes and walls and applied different design criteria for each designation. Reinforced soil 'structures' within 20° of the vertical are defined as a wall, reinforced soil 'structures' with inclination below 70° are defined as a steepened slope. Three load cases are defined to ensure the worst-case load combinations are considered for the design. Load case A (1.5) partial load factor applied on all loadings. This is usually the critical condition for reinforcement rupture, wedge stability and bearing capacity. Load Case B considers maximum load factors applied to the earth pressure and loads behind the reinforced soil block (1.5) and minimum partial factors (1.0) applied to self-weight. This combination is normally critical for pull-out or adherence failure and forward sliding. Load Case C considers self-weight in the working condition and is used for the SLS limit states only. BS 8006 prescribes a SLS limit on the internal Post Construction strain occurring between the end of construction and the end of the design life. This is limited to 1% in walls (non-abutments) and 0.5% for abutments. The restricted tensile capacity of the geogrid, T_{cs} is obtained using isochronous load-strain curves (BS 8006, Figure 43).

3.2   *German standard EBGEO*

In Germany design follows the guidelines EBGEO (DGGT 2011), which are based on the German National Standard for Earthworks: DIN 1054. In contrast to the approach taken in the UK, EBGEO does not distinguish between wall and slope. For both the magnitude of partial factors as well as the definition of potential failure modes to be analyzed and the design approach are identical.

The geotechnical category varies depending on the structure's height, difficulty or risk (e.g. bridge abutments). Furthermore design must not contradict DIN 4084:2009-01 (Calculation of embankment failure and overall stability of retaining structures) where geosynthetic reinforcement is considered a "non pre-stressed tension member". Important is to consider a correction factor ψ, which is depending on the type of fill-material. Beside conventional checks of sliding, bearing and tilting failure, design calculations shall include the check of all potential slip surfaces regardless of whether they are surrounding or intersecting the reinforced structure entirely, partly or without cutting a reinforcement layer.

Special attention also needs to be given to prove the stability at the front facing where the classification of the facing types has been adopted as per EN 14475 (CEN 2006). With regard to the serviceability limit state EBGEO recommends that the following post construction deformation components are considered: foundation settlement; internal settlement of reinforced fill; horizontal movement, of the front of the structure and face deformation.

Table 1. Partial factors for actions (effects).

	BS 8006 Combination A	BS 8006 Combination B	BS 8006 Combination C (ULS)	EBGEO Limit State 1B	EBGEO Limit State 1C	EBGEO Limit State 2 (SLS)
Permanent effect-mass of RS block	$f_{fs} = 1.5$	$f_{fs} = 1.0$	$f_{fs} = 1.0$	$\gamma_G = 1.35$	$\gamma_G = 1.0$	$\gamma_G = 1.2$
Permanent effect-Earth pressure behind the RS block	$f_{fs} = 1.5$	$f_{fs} = 1.5$	$f_{fs} = 1.0$			
Unfavourable variable effect	$f_q = 1.5$	$f_q = 1.5$	$f_q = 1.0$	$\gamma_Q = 1.5$	$\gamma_Q = 1.3$	$\gamma_Q = 1.0$

3.3 *Geosynthetic design strength*

The geosynthetic design strength can be considered as the restoring force by the geosynthetic (resistance), which is used as input parameter in the stability analysis.

BS 8006 prescribes a limit on the internal Post Construction strain occurring between the end of construction and the end of the design life. This is limited to 1% in walls (non-abutments) and 5% in slopes. The restricted tensile capacity of the geogrid, Tcs is obtained using isochronous load-strain curves (Figure 3), before reducing this value to the SLS design strength TD using equation (1).

$$T_D = \frac{T_{CR}}{f_m} = \frac{T_{char}/RF_{CR}}{RF_{ID} \cdot RF_W \cdot RF_{CH} \cdot f_s} \tag{1}$$

where RF_{ID} = reduction factor (RF) for installation damage; RF_W = RF for weathering; RF_{CH} = RF for chemical and environmental effects; and f_s = factor of safety for the extrapolation of data.

Figure 3. Layout and input parameters for stability analysis in GGU Stability software.

These factors are determined in accordance with PD ISO/TR 20432 (British Standards Institute, 2007). Considering EBGEO the long-term strength of the geosynthetic reinforcement $F_{B,d}$ is determined from equation (2):

$$F_{B,d} = \frac{T_{CR}}{f_m} = \frac{F_{B,k0}}{A_1 \cdot A_2 \cdot A_3 \cdot A_4 \cdot A_5 \cdot \gamma_m} \tag{2}$$

where $F_{B,d}$: Design strength; $F_{B,k0}$: Characteristic tensile strength (EN ISO 10319); A_1: Reduction factor for creep strain or creep rupture; A_2: Reduction factor considering any damage during transportation, installation and compaction; A_3: Reduction factor for joints and connections; A_4: Reduction factor for environmental effects (weathering and resistance

to UV light, effects of temperature, chemical resistance, microbiological resistance); A_5: Reduction factor for dynamic action; and γ_m: Partial safety factor for the structural resistance flexible reinforcement elements (Table 2).

Table 2. Partial safety factors for flexible reinforcement DIN 1054.

	Load Case		
	LC1	LC2	LC3
γm	1.4	1.3	1.2

It is to be noted that above reduction factors are meant to be mean values. $F_{B,k0}$ however is denoted as based on 95% confidence level EBGEO defines the serviceability limit state as structural deformation being a consequence of characteristic dead loads and soil parameters.

4 STABILITY ANALYSIS

The MSE design was carried out for the maximum height of H = 12m (including embedment depth). The walls support the approach embankments of various fly-over bridge structures of the interchange. A vertical spacing of 0.60m between geogrids was used in the design.

The assumed geotechnical data for foundation and fill material can be found in the output of the calculations performed (Figure 3). They were based on geotechnical investigation reports submitted by the contractor Zhongmei Engineering Ltd. Groundwater level is assumed at the base layer level (first geosynthetic layer), which can be considered as worst-case scenario.

A horizontal seismic coefficient of $a_h/g = 0.15$ has been included in the stability analysis. This coefficient was based on available seismic data in the area, and a discussion with the supervising consultant.

The external traffic load is set at 22.5 kN/m^2, which is considered a minimal traffic loading condition for motorways. In addition a dead load of 10 kN/m^2 (simulating the pavement structure) and 15 kN/m^2 (simulating the parapet) have been applied. For the interaction between soil and geogrid a reduction factor was used of 0.90.

According to EC7 and BS 8006 both Ultimate Limit States (ULS) and Serviceability Limit States (SLS) have been analysed. The software GGU Stability (GGU 2020) was used for the analysis.

All parameters that form the basis of this design have been verified before construction. In case of changes in the parameters, the design calculations had to be revised or adapted to the new parameters. The software program analyses the internal, external and compound stability of an assumed reinforcement scheme for steep slopes and walls using different methods and theories such as Bishop (cycles slices), Janbu (polygonal slices), Krey (cycles slices), general wedge method and block sliding method. The software allows the use of geogrids via the input of relevant design properties.

In the Ultimate Limit State (ULS) all possible failure mechanisms and slip planes intersecting the reinforcement layers, not intersecting the reinforcement, partially intersecting the reinforcement layers and when the sliding body moves directly over the reinforcement layer, were investigated in accordance with BS 8006, Figures 54, 55 and 56. The most unfavourable failure mechanism had to be identified. The software also allows the analysis of sliding, overturning and bearing failure of the MSE (GRS).

The stability analysis in the ULS has been performed for different wall heights up to 12 m with an embedment depth of 1 m. All possible slip circles have been considered and the most unfavourable failure mechanism has been identified. With the use of BBA certified geogrid reinforcements, independently certified design strengths in different fill types had been defined and used as input parameter in the software. This allowed working with guaranteed

and certified design strengths for different soil types and eliminated the time and cost consuming laboratory testing of different geogrids and soil types.

Eventually 3 different types of geogrids were used in the stability analysis: F80T, F110T and F150T. The geogrids are made from high-modulus, low-creep polyester (PET) yarns enclosed in a protective polymer coating. The number of different geogrid types was kept to a minimum.

A geotextile filter was applied between the geogrid and the reinforced fill at the wall facing to prevent the flush out (erosion) of fines from fill material.

The concrete panel design was made based on the design requirements of the Client, the production location, and required handling on site (transport and erection on site). The actual design of the panel was the responsibility of the contractor. The actual placement of the panels was done after constructing the MSE structure, which minimized possible post-construction settlements.

Serviceability analysis comprised the analysis of the settlement of foundations, post-construction strain in reinforcements and post-construction creep strain in saturated fine-grained fills (BS 8006, Figure 57).

Empirical data indicate that intrinsic settlements of 0.2% to 1% of the height of the MSE wall are normal when installation guidelines and best practices are followed. It is important to adequately compact the fill material of the MSE. The compaction of the fill material should be done following the EN 14475 execution standard for reinforced earth structures. From experience the expected intrinsic settlement of fill material in the MSE in an adequately compacted soil mass is very low.

An empirical value for the horizontal displacement for the front of the MSE wall is given as a maximum of approx. 1% to 2% of the MSE wall height, see EBGEO 7.5.1 (DGGT 2011).

5 CONCLUSION AND DISCUSSION

The 23 MSE structures were constructed without significant delays, and with the help of locally trained labour. Experts from the Netherlands provided the local training. No specific special skills were required. With the help of quality assurance documents supervision of the works was easy.

An important advantage of the wall system was the possibility to plan construction of the reinforced soil wall without the need to install the panels at the same time. This gives the following advantages:

– Settlements are allowed in the construction stage, the panels can be placed after consolidation
– Wall construction is not depending on the concrete panel production timing
– Panel repairs are possible after finishing the wall.

Other advantages of geosynthetic reinforced retaining structures compared to concrete rigid structures and gravity walls are the cost advantages, and much better resistance against seismic influences because of the flexibility of the structure.

Head – Special Projects, Terre Armée, India

ABSTRACT: This paper presents a case study for a landslide rehabilitation project comprising in-situ grouted soil nailing and pre-stressed ground anchors for slope stabilization, hybrid Reinforced Earth® structure for widening of existing road, and drainage measures to prevent development of hydrostatic pressure. The project site is located on National Highway 55, Siliguri-Darjeeling Road in the state of West Bengal, India. This paper profiles the completed composite/shored Reinforced Soil structure S2 (102.8m high).

Keywords: Landslide Rehabilitation, slope stabilization, geosynthetic strap, hybrid reinforced earth structure, innovative technology

1 INTRODUCTION

A massive landslide occurred in Tindharia, West Bengal, India in September 2011 following a significant earthquake and heavy rainfall in the area. The landslide affected three locations, resulting in collapse of a portion of road and railroad on the valley side. The Darjeeling Himalayan Rail service, a UNESCO heritage structure and significant tourist attraction in the area was also severely affected.

The location of the S2 landslide was from chainage Km. 52 + 650 to Km. 52 + 750 on NH 55, thus a 100m length on the valley side of the road. This entire stretch of NH-55 and DHR track was totally cut off (Figure 2). The tender drawing specified composite/shored reinforced soil solution for stabilizing the slope by Soil Nailing and widening the constricted portion of NH-55 (Figure 1).

Figure 1. Major Landslide location: S2, Km. CH: 52 + 650 to Km. CH: 52 + 750.

Figure 2. Area where DHR track was totally cut off.

2 THE PROBLEM

The zone is earthquake-prone and experiences long durations of heavy rainfall, combined with poor surface/sub-surface drainage. Steep slopes comprising of loose unconsolidated material, and weathered rocks result in percolation of rainwater through joints and increase pore water pressure. The road width was very narrow due to collapse of valley side, i.e., an extremely steep an unstable one. Hence, the solution proposed for the project was to be designed for three requirements: widening of existing road from 5m to 10m width while ensuring overall slope stability during construction, building permanent asset structure requiring minimum maintenance, and providing a permanent solution for surface/sub-surface drainage.
Figure 3.   Typical soil nail view.
Figure 4.   Typical ground anchor detail.

3 THE SOLUTION

Terre Armée India provided a permanent and sustainable solution to the restoration project using the reinforced earth composite/shored system [8]. This system comprised of soil nails that are hot dip fully threaded galvanized bars with yield strength of 670 MPa and ultimate strength of 800 MPa. The bars are joined together using couplers for higher length as in-situ passive soil reinforcing elements and pre-stressed ground anchors as active soil reinforcing elements for cut slope stabilization and construction of Mechanically Stabilised Earth structure using high adherence GeoStrap® (geosynthetic straps) soil reinforcement for widening with limited space (2.5m) at base (Figure 5). This technology maintains a perfect balance between cut and fill solution. The composite/shored reinforced earth composite/shored system guarantees not only the slope stability but also ensures safety during construction, effective release of hydrostatic pressure through a well-designed subsurface drainage system and enabled construction of a very tall, reinforced soil structure despite limited space availability for base width. Due to the massive height and complex geometry of the structure, two layers active soil reinforcements in the form of Pre-stressed Ground Anchors (Design Load 42 MT) were also installed at the bottom of each tier. The structure has been designed [7] in two stages, the first stage of design check has been done by providing Soil nailing and deep ground anchors to achieve overall global stability of the structure. The second stage of design has been checked for stability of shored retaining structure and the tensile force in GeoStrap soil reinforcement which is connected directly with the soil nailed structure. The design stages are described below in section 4 and 5.

4 DESIGN OF TERRANAIL® STRUCTURE

Design check was done for the soil nailed slope with the aim of arriving at a soil nailing layout to overcome postulated failure mechanism. Additionally, each nail should be capable to resist local stresses acting on it. The relevant mode of failure for stability analysis are rotational failure either partially or totally through the soil nail block involving breakage and/or pull out of soil nails. The method adopted for the purpose of assessing failure mechanism is Bishop's slip circle method. Typical failure modes are as shown below in Figure 6 [6]. Soil Nails provide complete resistance against anticipated sliding from

1905
Figure 5. Detail showing the reinforced soil facing arrangement and mechnical connection system.

Figure 6. Typical rotation stability checks of a soil nailed slope.

backslope, offers global stability and hence, transfers no retained pressure to the composite/shored reinforced earth hybrid structure.

5 DESIGN OF TERRALINK® STRUCTURE

The composite/shored reinforced earth hybrid structure has been designed [1,3] *for both* internal checks *by* calculating the required *tensile forces in the* soil reinforcement including checks for the soil nails against tension and pullout and external *stability* checks by slip circle method. The tension in the soil reinforcement has been calculated by "Silo" method by considering the effect of inclination and the skin friction as expressed in the figure below (Figure 7). The effect of deformation, due to compaction and progressive filling of the structure has been addressed by providing intermediate berms in the cutting profile (Figure 14). This "Silo" effect and deformation has been validated by numerical modelling.

The overall stability is then checked by slip circle method for both static and seismic load conditions (Figures 8 and 9). The minimum factor of safety of 1.3 and 1.1 has been considered for static and seismic analysis [4]. Additional checks are also carried out considering the effect of internal water profile, thanks to the Piezometer installed at the site which provided the variation of water profile. The design of internal drainage system is most critical for the overall stability of structure. Hence, special provisions for the drainage system have been provided and discussed in subsequent sections.
Figure 7. The tension in soil reinforcement by "Silo" calculation considering single friction surface.
Figure 8. Typical output of slip circle analysis along with water profile for static case for soil nailed slope.

6 DESIGN OF GROUND ANCHORS

The basic components of a grouted ground anchor include: (1) anchorage; (2) free stressing (unbonded) length; and (3) bond length. The design of anchorage [2] is the combined system of
Figure 9.   Output of slip circle analysis for seismic case of shored reinforced soil structure.

anchor head, bearing plate, and trumpet that can transmit the prestressing force from the pre-stressing steel (strand) to the ground surface or the supported structure. The unbounded length is the initial portion of the prestressing steel that is free to elongate elastically and transfer the resisting force from the bond length to the structure. A bond breaker is a smooth plastic sleeve that is placed over the tendon in the unbonded length to prevent the prestressing steel from bonding to the surrounding grout. It enables the prestressing steel in the unbonded length to elongate without obstruction during testing and stressing and leaves the prestressing steel unbonded after lock-off. The tendon bond length is the length of the prestressing steel that is bonded to the grout and is capable of transmitting the applied tensile load into the ground.

7   DRAINAGE SYSTEM

The drainage system (both surface and sub-surface arrangements) is the most important function for any slope construction, design, and performance.

7.1   Surface drainage system

The surface drainage arrangement consists of (i) drops and guides on both side of the structure to collect all surface water from various interconnected drainage channels and discharge it away from the main structure and (ii) Network and series of surface drainage channels to collect the surface water at all tier levels. The network of surface drainage arrangements has been provided for the entire height of the structure. It follows along the tier of the composite/shored reinforced earth structure to the final discharge point away from the toe of structure (Figure 10).

Figure 10.   Berm provided to collect & drain surface water.
Figure 11.   Internal drainage system shown during construction.

7.2   Sub-surface drainage system

The function of sub-surface drainage system is to collect seepage water inside soil mass and discharge it to the nearest outlet point, which is the surface drain. Though the Mechanically

Stabilised Earth fill is considered a self-draining media, having sufficient permeability to eliminate any destabilizing lateral forces caused due to hydrostatic pressure and ground water seepage. It was very important to have proper drainage system to improve the overall stability of the structure, considering its criticality.

Inside the composite/shored reinforced earth structure, the sub-surface drainage system consists of 600mm thick well graded granular drainage gallery (Chimney Drain) placed at the rear end of the geosynthetic strap. It is then connected inside the reinforced fill with 110 mm diameter of semi perforated PVC pipe wrapped with non-woven geotextile to collect and dissipate water to the nearest outlet point (outside the structure) as shown in Figure 12.

The most important provision incorporated in the design is semi-perforated drainage pipes deep inside the ground (Figure 13) to prevent development of additional hydrostatic pressure and to maintain equilibrium in ground water table. It was important to place these drainage pipes very deep to intercept the water table to ensure a constant seepage of water flow and to prevent development of hydrostatic pressure (Figure 13). These pipes are wrapped with non-woven geotextile and then inserted inside by drilling larger size hole.

Figure 12.   Sub-surface drainage outlets.

Figure 13.   Sub-surface water discharge through. weepholes.

8   CHALLENGES ENCOUNTERED

The project team faced several challenges from the design stage to the completion stage. This included convincing the client to adopt solutions as per actual site conditions, change in structural geometry, inclusion of drops and guide surface drain, additional toe stabilization and installation of deep perforated pipes as sub-drainage system. These provisions were vital for the long-term stability of the structure. The team faced other challenges during construction stage, including safety aspects, traffic management, space constraint, absence of any access road, drilling difficulties through challenging soil strata, high water table, unstable base, and toe slope. Appropriate construction methods were adopted to overcome all these challenges and are described in the subsequent section.

9   CONSTRUCTION SEQUENCE

i) Slope cutting and stabilization by top-down construction method: This activity commenced at the site after implementing all safety measures based on site risk assessment including provision of safety barricades, traffic management scheme and adopting a safe construction method. Firstly, the drilling activity for Soil Nails and Ground Anchors started from RL 36m up to founding level.

ii) Hillside slope was protected by fixing galvanized welded wire mesh underlaying with a layer of non-woven polypropylene geotextile filter simultaneously with soil nailing activity (Figure 14). This construction method ensured the structure's overall and local stability.

Figure 14. Slope stabilization through installation of soil nails and fixing one layer each of non-woven geotextile and GI back mesh.

iii) Composite/shored reinforced earth hybrid system was developed from the founding level up to RL 36m by keeping all projected anchors cables outside the composite/shored reinforced earth hybrid structure's facia.

iv) Drilling and development of the composite/shored reinforced earth system and pre-stressing of ground anchors were carried out by using the composite/shored reinforced earth structure as a working platform for the remainder of the project.

v) RCC Anchor Blocks were cast, keeping the anchor cables projected for future pre-stressing. Ground anchors were prestressed after developing the composite/shored reinforced earth hybrid system up to 10m above the anchor level.

vi) Surface drainage system (PCC Drops and Guides) were constructed simultaneously along with the composite/shored reinforced earth system's development.

vii) Toe protection works and arrangements for final discharge of surface and sub-surface water were carried out to prevent weakening of the toe from rain-cuts and scouring.

10 BENEFITS AND INNOVATIVE FEATURES OF COMPOSITE / SHORED REINFORCED EARTH HYBRID TECHNOLOGY

The composite/shored reinforced earth system is an ideal solution for both slope stabilization, restoration and widening of any collapsed road or slope due to any landslide. The following key features and conclusions can be made based on the learnings experience from this project.

(i) It has been conclusively proven that it is possible to construct very tall retaining structures without cutting the toe of the hill and with an available small base width at toe which is as less as 5m for 100 m height of wall/slope.

(ii) The technology not only addresses local and compound stability issues but also global stability issues.

(iii) This technique can address very complex and challenging landslide issues by adopting suitable and innovative measures as per site conditions.

(iv) Slope stabilization using grouted soil nail by top-down installation method is a safe construction method. However, it is important to conduct a detailed risk assessment prior to the start of any site activity and needs to address all risks by adopting all safety measures.

(v) Use of galvanized welded wire mesh facing system for slope stabilization of soil is a suitable solution. The exposed hillside slopes were quite loose and steep at some

locations steep ($>$ 85 degree), but the welded wire mesh performed very well (without any local collapse-related incidents) despite heavy rainfall.

(vi) High strength fully threaded galvanized bars guarantee the long-term durability of nails and act as a secondary corrosion protection layer as the grout may crack due to any internal deformation/settlement.

(vii) Drilling is challenging with presence of water table or through high hydraulic pressure but can be well controlled by releasing pressure through the provision of deep perforated drainage pipes.

(viii) Sub-surface drainage system played an active role in releasing hydrostatic pressure and maintaining a state of equilibrium of the natural water table. Functionality of weepholes needs to be ensured throughout the structure's design life to reduce hydrostatic pressure. Drainage system performance is key to ensuring the structure's long-term stability.

(ix) The direct linking connection system adopted is unique and has rotational movement flexibility (in horizontal and vertical planes) that helps in reducing any additional stress at connection points caused due to any fill compression or foundation settlement.

(x) The foundation base for such a composite/shored reinforced soil structure needs to be competent and settlement below the composite/shored reinforced earth structure needs to be limited within 100mm. Any settlement of foundation base is likely to trigger high stresses (both in shear and tension) at connection points. The stress due to any settlement can be further reduced by providing intermediate berms at back cutting face as in Figure 15.

(xi) Recent inspection of the structure indicates successful performance.

Figure 15. The completed structure.

11 SAFETY AND ENVIRONMENT

Composite / shored reinforced earth hybrid technology used in this project restored mountain slopes with minimal impact. The adoption of shored reinforced soil structure has enabled in reduction of backfill by 90%, resulting in overall carbon emission reduction. The sub-surface drainage system adopted in the design helped in saving 4 million litres of water during project execution. The project also continues to provide uninterrupted potable water supply to 31 households in the area.

ABSTRACT: The village of Ludrigno, located in the lower part of the Seriana Valley (Bergamo, Italy), is known to be exposed to a significant avalanche risk. The first historical information about avalanches affecting the village dates back to the 17th century and throughout the years the avalanche events have repeatedly caused loss of goods and lives. The article intends to present the design process followed to identify the optimal defense strategy within a cost-benefit analysis framework. The design choice fell on a geogrid reinforced avalanche protection embankment 140 m long and 10 m high, as it was found to be the best solution both in terms of cost-effectiveness ratio and environmental integration. The stability analyses carried out on the embankment due to the avalanche impact are presented and the choice of the reinforcing geogrids, based on their long-term design strength, is discussed. The article aims to highlight the relevance of this topic, which involves the safety of population living in mountain areas and several issues related either to design or quality control of materials and construction.

1 TERRITORIAL FRAMEWORK

Ludrigno is a small village within the Seriana Valley in the province of Bergamo (Italy), located at 560 m a.s.l. on the right-hand side of the Serio River at the bottom of the Orobie Alps. The Vendulo stream is a right-hand side tributary of the Serio River. The basin has an extension of 275 hectares and the stream has two major branches, the longest of which is 3.5 km long and has a 38% mean slope. The ridges surrounding the Vendulo Valley are 2.4 km long and the highest peak is Mount Secco (2207 m a.s.l.). The slopes developing from the ridge have a main aspect of 90° East, even if exposure ranges for NE to SE moving from south to north along the crest.

2 THE LUDRIGNO AVALANCHE (ALSO KNOWN AS VENDULO AVALANCHE)

2.1 *Historical background*

The Ludrigno avalanche, is the snow avalanche that flows along the Vendulo valley and has often affected goods and lives inhabiting the valley bottom. In 1916 an extreme avalanche

detached from the slopes underneath Mount Secco. Once it had reached the valley bottom, the main flow took a right-hand turn moving towards Ludrigno, destroying some of the buildings and causing multiple fatalities. In 1984 a massive avalanche flew to the valley bottom; it remained mainly within the riverbanks and reached the National Road n.49. Luckily only one person was injured but the road remained closed for several days isolating many villages. During the years other avalanche events occurred without reaching the valley bottom, mainly stopping in the lower part of the channel or along the fan. Seldom, as a precautionary measure, the inhabitants of Ludrigno are evacuated because of avalanche risk; latest evacuations are dated 2008, 2009 and 2014.

2.2 Avalanche features

The avalanche release area deploys along a ridge 2400 m long: there are 3 main release basins (A, B and C in Figure 1), including 7, 6 and 5 single starting areas respectively, which cover a total surface of 33.5 ha. Outline of single potential release areas was supported by the AFRA code (Barbolini *et al.* 2011). The possible combination of the 18 single starting zones gives us in principle 262,124 different potential avalanche release scenarios, even if a simultaneous release of avalanches originating from the three basin is highly unlikely and was not considered. In the upper part the avalanche track is divided in two main channels that come together at about 900 m a.s.l.. The final part follows the riverbed, with avalanche deposits that could reach the National Road 49 and extend until the Serio River; when the riverbed is filled by previous avalanche debris the avalanche could overtop the right riverbank and spread along the fan in the direction of Ludrigno.

Figure 1.   Main avalanche features (left) and PRA outline (right).

3   MODELLING ANALYSIS AND ASSESSMENT OF ALTERNATIVE SOLUTIONS

3.1   Avalanche simulation analysis

The analysis of the design avalanche scenario has been undertaken through the 2D avalanche simulation software RAMMS (Christen *et al.* 2010).

At first, input data and simulation parameters have been calibrated by a back-analysis on known past events (1916 and 1984 avalanches) and available avalanche maps (Avalanche Cadastre, see Figure 2). Once we gained enough confidence and stability within the 2D avalanche simulations, 21 avalanche scenarios have been selected in order to get the design parameters (run-out distance, flow height, velocity and pressure) and evaluate the worst-case scenario. Avalanche simulation showed that for each main basin (A, B and C in Figure 2), a simultaneous release of the potential starting zone generates avalanches able to severely affect exposed elements in the valley bottom.
Figure 2.   Example of RAMMS's simulation output (left) compared to the Avalanche Cadastre (right).

3.2   *Assessment of alternative protection measures and choice of optimal solution*

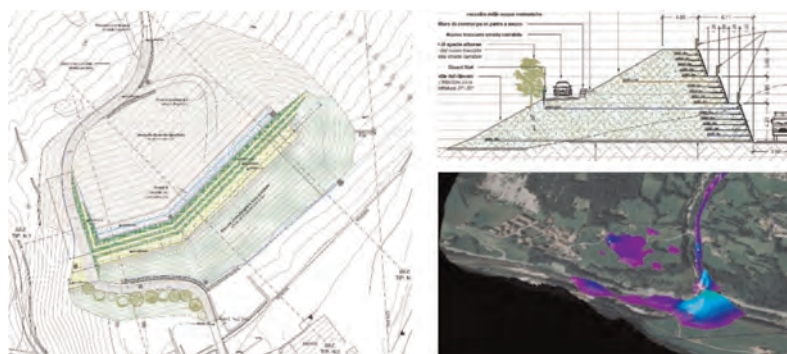
The modelling analysis gave us an insight of possible solutions to reduce the avalanche risk. Three different alternative solutions have been investigated: a) active defense structures in avalanche release areas (snow bridges or snow net); b) passive defense structures in the downhill area (catching or deflecting dams); c) mixed solution (combination of active and passive defense structure). In order to get a significant risk reduction by means of active works in the release zones numerical simulation showed that reduction of potential release areas was necessary in all three basins, with a need for an overall reduction of about 50% of potential starting zones and an estimated cost of about 9 million €. Conversely, by means of passive work in the lower part of deposition zone, where the avalanche is slower, a significant reduction of risk for the road and the village was evaluated achievable with a significantly reduced cost (about 3 million €). The mixed solution was found to be not effective, because the increase of cost for installation of active works in the most critical areas does not yield a relevant reduction of the sizes (and costs) of the passive works. Cost-benefits analysis showed the construction of an avalanche catching to be the optimal solution. Due to budgetary constraint, in a first batch of works the dam was limited to the protection of the village, postponing the protection of the National Road to a subsequent batch of works.


Figure 3.   Plan and section view of the catching dam with an example (bottom-right) of post-operam simulation performed to evaluate its effectiveness (DTM integrated with catching dam).

4 ESTIMATION OF MINIMUM DAM HEIGHT

The main design parameter of an avalanche catching dam is its minimum height needed to avoid avalanche overtopping. According to widely used approaches (Mears 1981), the estimation of the minimum dam height (H_D) can be done with the following formula (Figure 4):

$$H_D = h_0 + h_s + h_r \qquad (1)$$

$$h_r = \frac{V^2}{2 \cdot g \cdot \lambda} \qquad (2)$$

where h_0 is the snow cover depth, h_s and V the flowing height and velocity of the avalanche at dam location, h_r the run-up height of the avalanche on the uphill side of the dam and λ an empirical parameter that accounts for energy loss at impact. For Ludrigno case, the estimate was based on the avalanche dynamic simulation output for the worst-case scenario (V = 12 m/s and h_s = 2 m) and setting h_0 = 1 m and λ = 1.5, thus obtaining a value of H_D of ∼7 m. The calculation of the minimum dam height was verified using the more recent physically based criteria (Johannesson *et al.* 2009), resulting in a higher value of H_D (9.7 m) that was finally fixed to 10 m to stay on the safe side.
Figure 4. Scheme for dam height estimation.

5 STRUCTURAL AND GEOTECHNICAL DAM DESIGN

The structural design of the dam must comply with the Ultimate Limit State regulation and the scenarios that need to be verified are: (a) sliding and overturning of the upper part due to the avalanche flow impact pressure; (b) internal stability of the earth embankment and structural design of geogrids; (c) global stability of the whole slope.

5.1 *Sliding and overturning*

In this scenario the acting load is the pressure of the avalanche which hits on the uphill side of the dam (calculated as product of snow density and velocity squared, according to Eq. 3.18 of Rudolf-Miklau *et al.* 2015). The pressure has a uniform value through the flow-height and drops to zero along the run-up height. The impact may happen at different heights from the ground depending on the ground snow cover thickness when the avalanche event occurs. In this scenario the dam is modeled as a solid element which can slide or overturn at any height and its resistance depends on geometry, weight and geotechnical properties of the structural terrain. The assumption that the earth embankment behaves as a solid element is granted by reinforcing geogrids whose resistance will be described later.
Figure 5. Sliding and overturning analysis schemes.

5.2 *Internal stability and structural design of geogrids*

The integrity and structural resistance of the earth embankment is achieved through 60 cm thick layers of fill material, carefully compacted above geogrid reinforcements which are shaped at a 70° slope by means of steel mesh formworks. Reinforced slopes are analyzed using modified versions of the classic limit equilibrium slope stability methods. A circular potential failure surface is assumed (Figure 6) and the relationship between driving and resisting forces determines the slope's factor of safety. Reinforcement layers intersecting the potential failure surface are assumed to increase the resisting force. The structural design must address all possible failure modes that a reinforced slope will potentially experience, uphill and downhill. In this scenario, the most demanding loads are the variable live loads acting on the earth embankment, which usually are snow deposition and construction or maintenance vehicles. The resisting force of the geogrids to be used in the evaluation of the safety factor is the long-term design resistance T_D evaluated according to the following equation (HAPAS Certificate 2014):

$$T_D = \frac{T_{char}}{RF_{CR} \cdot RF_{ID} \cdot RF_W \cdot RF_{CH} \cdot f_s} \tag{3}$$

T_D is calculated by reducing the characteristic short-term resistance of the geogrids (T_{char}) with the following partial safety factors: reduction factor due to creep (RF_{CR}), reduction factor due to installation damages (RF_{ID}), reduction factor due to weathering (RF_W), reduction factor due to chemical and environmental effects (RF_{CH}) and reduction factor due to extrapolation of data (f_s). The characteristic short-term resistance is evaluated according to EN ISO 10319.
Figure 6. Internal (red) and global (blue) potential failing surfaces.

1916

5.3 *Global stability of the whole slope*

The global stability examines the as-built scenario and evaluates the minimum safety factor for each potential sliding surface which starts uphill of the embankments and ends downhill of it. In order to evaluate the worst-case scenario, in the calculation, the weight of the avalanche snow deposit in the case of complete filling of dam is taken into account (Figure 6). The embankment acts as a rigid body, and it affects the analysis with its weight and geometry.

5.4 *Main structural components and technical details*

The earth embankment is made of the following components: fill material, geogrid, erosion control net and steel mesh formwork. Filling material has no specific requirement, even though it is suggested to use non-cohesive materials such as gravel, crushed stone, sand-macadam mixture, sandy soil and rock filling, which may not be affected by water and have small settlements once compacted. Geogrid reinforcements are provided with different short-term resistance: due to the lack of specific Italian regulations for geosynthetic reinforcements, it was required that geogrid products were to be certified by the British Board of Agrément (BBA). In this construction site, 65 kN/m and 110 kN/m short term resistance HUESKER Fortrac T polyester geogrids have been used in 60 cm thick layers. Higher grade resisting geogrid have been used in the lower part where major stresses occur. A 3.5 mm x 3.5 mm polyester mesh erosion control net was placed between the fill material and the geogrids to prevent soil erosion before the greening of the slope. Steel mesh formwork are made of electro-welded mesh, usually 8 mm rebars on a 15 cm mesh size. The steel formwork does not provide any structural resistance; it only allows a better and easier shaping of the embankment. The formwork is provided with stiffening rods which guarantee a better resistance in the initial compacting stages.

6 LANDSCAPE AND ENVIRONMENTAL REQUIREMENTS

In order to optimize the dam, it has been built in the lower part of the fan, where the avalanche velocities are lower. As a consequence, the visual impact on the Ludrigno village landscape could be relevant, therefore. For that reason, in order to minimize the impact on the landscape but at the same time to maximize the storage capacity, the protection dam has been designed as an earth embankment with reinforced soil in the up-slope side and as a natural slope of about 30 degrees in its down-slope side (Figure 3), with special attention paid to the greening of slopes. In terms of environmental impact of the works, a great attention was paid to earthwork balance, in order to avoid supply of earth materials from outside the construction site as well as landfilling.

7 CONSTRUCTION

The construction of the avalanche protection dam was carried out in 2016. The quality of the embankment has been assessed during construction by surveys at various stages. The geogrid quality inspection was undertaken by checking bills of materials and certified documentation assessing the resistance of the product according to BBA; the quality of the filling material and its compaction procedures were assessed through several different on field validation in different points and stages of the construction (Figure 7).

Figure 7. The avalanche dam at the end of construction.

8 CONCLUDING REMARKS

Earth dams are effective avalanche protection measures especially in those sites with several potential release areas, where active protection is usually not viable for very high construction and maintenance costs. The use of geogrids allows to increase the slopes of dam walls, with advantage in term of footprint, storage capacity and energy dissipation at impact. In the design of geogrids particular attention must be paid to the reliability of the reduction factors used to estimate design resistance and to the quality of certifications that guarantee the long-term behavior of the material.

The application of modularized MSE wall in the project of Montenegro BB expressway

H. Yaming
CCCC Expressway Consultants Co., Ltd. Beijing, China

C. Lili & X. Wang
BOSTD Geosynthetics Qingdao Ltd., Shandong, China

ABSTRACT: Modularized MSE wall is a supporting structure with the characteristics such as simple and clear structure system, high industrialization process in the production and construction. Comparing with the traditional supporting structure, modularized MSE wall has lower requirement on the construction spacing and geology environment, except beauty contour and green initiative, which makes it well used in urban structure, building and road project, especially in the design and construction of mountain area expressway. With the advantage of overcoming the limitation of geomorphology and geology, it becomes a worth well alternative solution. In this article, based on the project in the Montenegro BB expressway, the authors introduce the challenges of designing modularized MSE wall in high embankment with complicate geology condition, meanwhile, analyzing the problems and solutions during the design and construction, to provide the experience and reference for the future use.

1 PROJECT BACKGROUND

Montenegro Bar-Boljare expressway is about 180 km, which connects the famous port Bar and Boljare in north, it is the first expressway in Montenegro and one of the most important corridors to the heart of the Europe. This project is the priority section of Bar-Boljare expressway, from Smokovac to Matesevo, with the length of about 41 km, including 18.3 km tunnel, 6.3 km bridge.

Within this project, modularized MSE wall solution is widely adopted for different structures (bridge abutment, toll station, retaining structure), in various terrain (flat plan, hill area, mountain area), as well as with complicate geology (limestone, flysh). Totally, there are 17 MSE walls in length of 3.5 km, the highest wall is about 30.9 meters, and the total quantity of geogrid is 1.4 million square meters.

2 INTRODUCTION OF DESIGN

2.1 *Design scheme comparison*

There are many limitations for the design of this project, such as defined expropriation, environment protection, use ability of land and complicate geology. For the construction of high embankment, if it goes with slopes, then extra expropriation and huge quantities of embankment material are required; if bridge solution is adopted, the limitation spacing, and complicated terrain will make trouble for construction and cost. So, retaining structure is a relatively proper solution.

The designer compared different types of retaining structures-masonry wall, reinforced concrete wall (RC wall) and mechanical stabilized earth (MSE) wall from the following aspects:

(1) Structure analysis

Masonry wall and RC wall have higher requirement of bearing capacity; also, for the structure safety reason, these kinds of wall cannot be too high, which will not be able to work as supporting structure for high embankment. While MSE wall has relatively low requirement on the bearing capacity and could be high enough for the use.

(2) Resistance to Seismic

This project locates on the extensive seismic zone, which is not favorable for rigid structure such as masonry wall and RC wall because of deformation displacement. MSE wall is a flexible structure with good adaptability to the deformation of foundation and displacement of wall body, especially in the seismic zone.

(3) Economic and Environmental Benefits

Masonry wall and RC wall demand huge quantity of concrete and reinforcement, which will not only increase the cost, but also go against the environment because of the carbon emission.

(4) Construction feasibility

In some part of the project zone, complicate terrain environment like deep valley and sharp hillside makes it not possible for large scale machinery works, which is necessary to the masonry wall and RC wall. While MSE wall has lower dependency of huge machine, but more relies on human power and simple equipment.

Based on the above comparison, MSE wall could be a proper solution for some special case because of the complicate site situation.

2.2 Design principle

According to the EC7, the design of MSE wall includes Serviceability limit states and ultimate limit states verification.

2.2.1 Serviceability limit states

The serviceability limit states mainly contain calculation or qualitative analysis of settlement, durability, and displacement of structure.

2.2.2 Ultimate limit states

Two design conditions are carried out for the ultimate limit states, the permanent and seismic condition. The verification of these two conditions is achieved by the overall stability analysis, local stability analysis, internal stability, and detail structure analysis, to guarantee the safety of structure. EC7, EC8 as well as Germany and Italy guidelines are applied.

2.3 Calculation program and content

The stability verification of MSE wall is carried out by the program MSEW3.0 and ReSSA3.0, which are the copyright of US Company ADAMA Engineering, Inc., and are authorized by the FHWA. For a compatibility of using EC7 and EC8, input parameters are adjusted.

The stability verification includes an internal, external, and overall stability analysis. During the analysis of external stability, the MSE wall is treated as a reinforced composite, while the soil within the geogrid zone is assumed to be rigid, together with geogrid working as gravity retaining structure. In this concept, the anti-sliding calculation, overturning calculation, foundation stress and eccentricity are calculated.

The internal stability analysis is mainly focusing on the geogrid and its interaction with soil, including the strength and anchor length definition. To ensure the geogrid and soil works efficiently, the maximum tensile strength, the potential sliding surface, the pullout strength, as well as spacing of geogrid need to be designed.

Except the above mentioned two aspects, the overall stability should also be checked, mainly about deep sliding which may happens in the foundation soil. Traditional slip circle

method or other well accepted method could be adopted to define the potential critical sliding surface, and then to check the safety factor for the given solution.

Settlement and deformation calculation are more related to the performance of structure, especially for the structure which is close to other existing or planed structures, or those structure with high serviceability.

2.4 Detail design elements

The MSE wall in Montenegro project is a retaining system made of prefabricated modularized concrete block and high-quality geogrids, as well as other auxiliary elements.

2.4.1 Facing block foundation
For a better control of flatness and alignment of wall, after the excavation of wall foundation, a cast on site reinforced concrete foundation is performed. The dimension of the foundation is decided by that of block. In this project, it is 0.45 m in width and 0.25 m in thickness, with minimum C30, V8 and M100 in quality control. A tooth is given to make sure all the blocks are in the same line.

2.4.2 Modularized concrete block
According to the EN14475, this type of block belongs to the hard units, conform to the En771-3, part 3. The dimension is 400 mm*220 mm*220 mm. On the top of the block, a groove is set, and at the bottom a tooth is set correspondingly. With these structures, the fixing of geogrid and the installing of block will be easily done in according to the design principle.

The concrete block used in this project is prefabricated in local factory, with high efficiency and quality. The size of gravel for the block is less than 10 mm, and the concrete should be with minimum C40, V8 and M150 for water and frozen resistance.

2.4.3 Uniaxial geogrid
The geogrid shall be an integral, rigid geogrid manufactured from high density polyethylene polymer containing only virgin polymer, appropriate Carbon Black master batch and in-process regrind, with well anti-creeping, anti-aging performance, as well as other necessary characteristics.

The geogrid used in this project is E'GRID, provided by BOSTD Geosynthetics Qingdao Ltd, which is approved by the Employer and Engineer. The product has the BBA certification on the reinforced soil system (Figure 1).
Figure 1. Certification of E'GRID geogrid.

2.4.4 Polymer connector
The connection of facing block and geogrid is achieved by special unit-Polymer connector. It is designed by the characteristic of geogrid and block, with required strength. The function and effectiveness of connector is verified as a component in the retaining system.

2.4.5 Drainage system
The drainage system is designed to facilitate the discharging of water out of the wall body, to reduce the unfavorable influence of water to the structure, including internal and external drainage system.

The internal drainage system includes a drainage layer at the rear of wall facing block and longitudinal drainage pipe covered by geotextile. The thickness of drainage layer is 50 cm. The purpose of the system is to discharge the potential water in the soil mass to reduce the water pressure and mechanical properties of soil.

The external drainage system includes a drainage ditch in front of the wall foundation, which is collecting water from the internal system, and open channels to discharge water out of the ditch.

The connection of internal and external drainage system is achieved by T Junction and outlet pipe.

3 SPECIAL DESIGN AND CONSTRUCTION DETAILS

3.1 *Design*

3.1.1 *Unfavorable geology*
The project locates on middle and north part of Montenegro, where the geology is dominated with limestone and flysh composite. In the zone of limestone, nature slope is covered by thick and loose layer of highly weathered limestone debris and clay mixtures. While at the zone of flysh, the bearing capacity is not enough for the high structure, even the bearing capacity for MSE wall is relatively low. To increase the bearing capacity where is not enough, replacing nature soil with better material is necessary. For example, at K31, the after removing the nature, 2 m thick crushed river gravel is placed and compacted to achieve the required bearing capacity.

3.1.2 *Steep terrain*
There is part of the expressway going along the steep hill slope, and the overall stability is not verified because of the steep terrain and thick layer sandy clay with gravel debris. At the section of retaining wall K6, ballast together with permanent landfill is designed at the foot of the retaining wall to guarantee the overall stability, at the same time reuse the extra material from tunnel excavation.

3.1.3 *Underground water*
Underground water is rich in some location of the retaining wall in the zone of flysh, because of the heavy vegetation and cracking of base rock. To guide the water from the nature soil and foundation soil, various of drainage solution are adopted case by case. At K35, the after excavation of wall foundation, seepage water from excavate slope and foundation cause problem. A close drainage system is designed with drainage layer between the embankment material and nature soil, at the bottom of the wall, as well as at the back of the facing wall, to make sure the water to be collected and discharge through the drainage layer.

3.1.4 *Special purpose and function*
MSE wall is usually working together with other structures, such as bridge abutment, culvert, underpass. In this case, special attention should be paid to the connection of two types of structures. At the design of Moraca bridge abutment in Smokovac interchange, since the abutment is about 20 m high, with the limitation of expropriation, and to reduce the soil pressure behind the abutment, MSE wall solution is proposed. Meanwhile, toll station and an underpass are right after the bridge, a widen platform is required for the office of toll station (Figure 2). MSE wall plays an excellent role because of its shape and structural adaptation and resolve the complicate case properly.

3.2 *Construction*

3.2.1 *Preparation of filling material*
The filling material is one critical factor to the quality of the construction. In this project, it is strictly required with high quality. It should be friction material, inert, stiff, and durable,

Figure 2.   The application of MSE wall in complicate structure group.

without organic, plastic, metal, rubber or any other harmful or combustible material. Silty stone and marl stone are also not allowed to be original material because of their poor physical and mechanical characteristics.

In the design, the specific requirement of filling material is $\gamma = 20.5$ kN / m^2, friction angle is $38°$, cohesion is $0\sim5$ kPa. Besides, to have a better compaction to reduce the future deformation, it is required to have a well-graded filling material (Figure 3).
Figure 3.   Particle size distribution of fill for reinforced soil walls.

To satisfy the requirement form design, two types of filling materials are chosen as options, one is crushed limestone, and another one is crushed and mixed gravel from Tara River. All the mixture are prepared according to the required size distribution, and then sent to the authorized laboratory in North Macedonia.

3.2.2   Quality control of filling construction

The quality of filling material construction has significant influence on the long term stability of MSE wall. To have a high quality, the following requirements are given and achieved:

1. The maximum size of filling material is less than 100 mm, the quality control is performed every 44 cm in thickness.
2. The compaction is performed every 22 cm, with minimum compaction 95%, Ms $\geq$ 40 MPa.

The compaction technology is well organized and performed on site, with strictly monitoring of each step, spreading, and rolling of material, vibration compact, static compact as well as the direction of roller. At the part close to the wall face, huge machine is not allowed but with human power and hand compactor to work.

3.2.3   Precise control of facing block

One of the advantages of MSE wall is aesthetics, and this depends on the precise control of wall facing block.

The control of block installation starts from the first layer, after the finishing of foundation pad, the position of each block is marked on the foundation. The blocks at the first layer are with flat bottom without the tooth. The second layer of block is installed on the first layer

in zigzag role, to make sure the joint of upper layer blocks is in the middle of the lower block. The tooth of the upper layer block should be tightly attached to the groove of the lower block to keep the wall facing in the 86° vertically. Any block with uneven surface, especially the bottom and top surface should be polished carefully.

3.2.4 *Finishing of facing block*
When the wall is higher than 6.6 m, it is designed as steps from top to bottom, each step is 6.6 m. At each step, to a have an aesthetic view and avoid water going inside the block (block is with openings), a cast in-situ concrete cover is placed, which can also be a effective solution to make the top layer block stable.

3.3 *Quality control*

Except the quality control of all the materials, the control of construction is also necessary. With the agreement of the Employer and Engineer, to have better control of construction quality, the following quality control items are given, with testing method and criteria (Table 1).

The control item is only based on this specific project, but it is always better to have a unified control requirement for MSE wall structure, or at least some guidance for the future construction and application.

Table 1. MSE wall construction quality control.

No.	Item	Test method/Equipment	Criteria
1	Static Compressive modulus	Plate Test	$\geq$ 30 MPa
2	Compaction	Sand Cone Method	$\geq$ 95%
3	Flatness	4 m Rule	$\leq$3 cm
4	Facing Inclination	Total Station	$\pm 1°$
5	Height	Leveling Gauge	± 10 cm
6	Foundation Position	Total Station	± 5 cm

4 CONCLUSION

As a well-developed retaining system, MSE wall has many technology and economic advantages compared with traditional structures. In the Montenegro project, based on the site conditions and project requirements, the design and construction team overcame lot of difficulties, fully taking the advantage of the MSE wall, resolve the project problems properly.

The successful application of MSE wall accumulates plenty of design and construction experience, which can provide reliable guidance and help to the similar project in this field, also proves that the quality of products from all the suppliers.

Meanwhile, during the project design and construction, there are also some open questions found, such as gradation of filling material, deformation calculation, which may need more efforts in study and application.

Combination of geosynthetics used as riverbank slope normalization in Cimanggis residential area, West Java, Indonesia

D.A. Nurjannah, N.A. Anindita, F. Widhiastuti & D.S. Harninto
P.T. Geoforce Indonesia, Central Jakarta, Indonesia

ABSTRACT: This paper presents the study case related to combination of geosyntethics used as riverbank slope normalization located in Cimanggis residential area, West Java, Indonesia. The combination of gabion, geogrid reinforcement combined with wiremesh facing and geo-composite of geotextile non woven-geogrid slope protection were applied along the section of the riverbank slope. The riverbank slope section spans 390 meters along Cikeas river where it will later become access road and near the crest will be constructed housing area. Slope stability analysis was conducted to determine the value of the slope safety factor with the aim of concluding what preventive and security measures could be. From the results of the analysis, it showed that the 13 meters high slope of the Cikeas river's safety factor was below the criteria stated in Indonesian National Standard for Geotechnic Design Requirements with a safety factor 1.20 (the slope safety factor must be above 1.50). The combination of geosythetics were applied in the program and yield the safety factor up to 1.613 which indicated safe slope. This design also considered the earthquake pseudostatic load, where the result of the safety factor was 1.103 and fulfilled the criteria stated in Indonesian National Standard for Geotechnic Design Requirements (the slope safety factor must be above 1.10). The combination of those geosynthetics application worked effectively for normalizing the river bank slope.

1 INTRODUCTION

The exclusive residence of Podomoro Golf View Cimanggis, is located on the Cikeas river which has contours and slopes of land. To support the construction of the dwelling, careful planning is needed, especially regarding slope stability. The Cikeas River has a fairly steep river slope and there are several points of a fairly swift current. Based on the geological map, the area along the Cikeas river, the geological condition is a layer of silt, sand, gravel, gravel and boulders. This is in accordance with the conditions in the field and the results of soil investigations which has been done.

Figure 1. Riverbank location.

2 LITERATURE

2.1 *Geosynthetic material*

The geosynthetic material that is used for earth retaining structure is geogrid, woven and non-woven. Geogrid and woven are used as reinforced elements, and the non-woven is used as separator element.

Figure 2.   (a) Non-Woven and (b) Geogrid.

The strength parameter of geosynthetic material is influenced by the field condition, applied load (construction, operational and earthquake loading). The Geosynthetic materials have the specification of their tensile strength. But, during the analysis the ultimate tensile strength must be divided with several reduction factors of geosynthetic as the euation [1] below.

$$T_{design} = \frac{T_{ult}}{RF \times RF \times RF} \tag{1}$$

The factors like installation damage (RF_{id}), durability (RF_d), and creep (RF_{cr}) must be consider during analysis. The value of the reduction factors of geosynthetic could be taken from the table reduction factors of geosynthetic. Based on the use of geosynthetic materials in the field. material for area slope the value of installation demage (1.10 – 1.50), creep (2.0 – 3.0), durability (1.0 – 1.50). (Koerner 2007)

The value of tensile strength that is used for analysis is the allowable tensile. Hence, the analysis of stability could be conducted.

2.2 *Design criteria*

Slope stability analysis should consider live load, dead load and earthquake according to the designation of excavated slopes and heaps. Traffic load is added as live load to the entire width of the road surface and the magnitude is determined based on the class of roads given referring to SNI 8460:2017 for road class 1 the value of traffic load is 15 kPa.

The minimum safety factor required for analysis using pseudostatic models is greater than 1.1 (SF>1.1) using seismic coefficients obtained from peak acceleration on the surface (PGA) with the determination of the site class and amplification factor. The size of the FPGA depends on the site classification. Seismic calculation is done in pseudo-static, with the acceleration coefficient as follow

$$
\begin{aligned}
\mathrm{Kh} &= 0,5 \times \mathrm{PGA} \times \mathrm{FPGA} \\
\mathrm{Kh} &= 0,5 \times 0,42\mathrm{g} \times 1,08 = 0,226\mathrm{g}
\end{aligned}
\tag{2}
$$

2.3 Soil backfill

The soil backfill material must be compacted minimum 95% of dry weight laboratory. The recommended materials for backfill is Gravel-Sand. If the fine grained material is used as fill material, the drainage system behind and inside the retaining wall must be well managed. The spaces inside the system that may water to infiltrate, must be collected and delivered outside the system (Koerner 2005)

3 METHODOLOGY DESIGN

3.1 Soil investigation

The soil investigation area closest to the river contains drill points BH-02 and BH-03 while sondir data is at sondir points S-03, S-07, and S-07. The description of the type of soil is as follows.
Figure 4.   Soil profile at BH-03, S-03, S-07, and BH-02.

From the results of soil investigations, it was found that the field conditions in BH-02 were dominated by clay soil with soft consistency at a depth of up to 1.5 meters from the surface. At a depth of 1.5 meters to 4 meters, a layer of clay with medium consistency was found. Hard soil layers are found at depths above 8 meters. At point BH-03 it is dominated by clay soil with soft consistency at a depth of up to 3 meters from the surface. At a depth of 3 meters to 8 meters, a layer of clay with medium consistency was found. Hard soil layers are found at depths below 10 meters.

3.2 Parameter analysisi on PLAXIS

Slope stability analysis is carried out to determine the safety factor of the slope to be made. To carry out this analysis, the following parameters are used based on the interpretation and assumptions of the soil data because the available data are incomplete.

The analysis was carried out using the finite element method with the Plaxis 3D program with soil modeling as follows. The soil parameters are based on assumptions and the closest available soil data, namely BH 02 and BH 03. This analysis was carried out at STA 2 + 975, which was taken at the most critical slope location.

Table 1. Soil data parameter with hardening soil model.

Soil Type	γ_{uns}/γ_s (kN/m³)	E_{50}^{ref} (kPa)	E_{oed}^{ref} (kPa)	E_{ur}^{ref} (kPa)	c' (kPa)	ϕ' (°)
Silty with Sand	14/17	55000	165000	38500	35	11
Silty Sand with Gravel	14/17	105000	315000	73500	30	50

Material	EA (kN/m)	N_p (kPa)
Geogrid 40 kN/m	253	12.63

4 RESULT AND DISCUSSION

4.1 *Global safety factor result*

Targeted FOS against Global Stability of the structure are

– Under static condition, FOS $\geq$ 1.5. (Based on Indonesian Standard SNI 8460:2017)
– Under seismic condition, FOS $\geq$ 1.1. (Based on Indonesian Standard SNI 8460:2017)

Achieved Global Safety Factor are

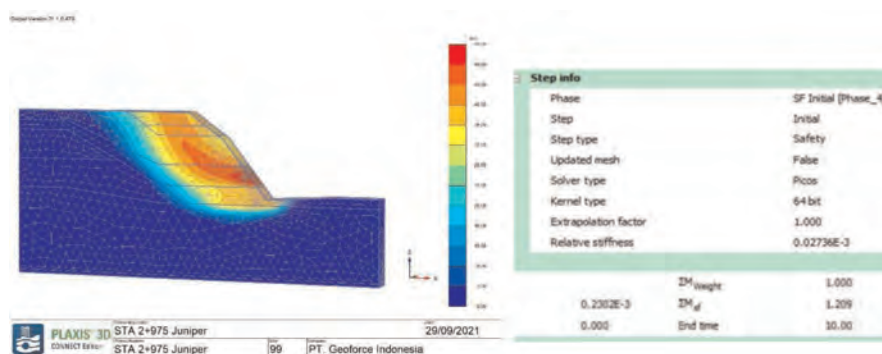
– Static condition at Initial Condition: 1.209 $\leq$ 1.50 NOT OK!
– Static condition at Slope Protection: 1.613 $\geq$ 1.50 OK!


Figure 5. Estimation of static failure mode and safety factor of initial condition slope.
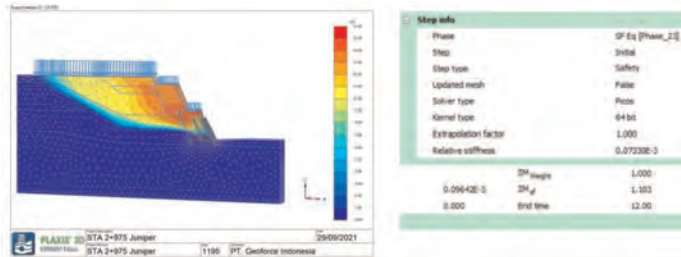
Figure 6. Estimation of static failure mode and safety factor of slope protection.


Figure 7. Estimation of pseudo-static failure mode and safety factor of slope protection.

4.2 *Tensile working of geogrid under static and seismic loading condition*

The comparison of axial tensile force working on GI-Strip under static and seismic loading con- dition based on PLAXIS are as follow:

Table 4. Tensile strength comparison of geogrid – Static and seismic.
The value of the allowable tensile strength after the reduction factor is 12.63 kN/m for a design period of 50 years. The value of the axial tensile force acting on the Geogrid under static and seismic loading conditions is less than the 50-years design requirement.

5 CONCLUSION

The results of the slope stability analysis obtained the value of the safety factor in accordance to Indonesian National Standard for Geotechnic Design Requirements (8460:2017). This analytical modeling design criteria that have been targeted. The design life time of reinforcement under static and seismic loading conditions is less than the 50 year design requirement. Combination of geosyntethics can be used as an alternative riverbank slope normalization.

MSE wall with geosynthetic reinforcement and polymeric connections case studies in Maryland and California

M.L. Ferrara & G. Lugli
Officine Maccaferri S.p.a., Zola Predosa, BO, Italy

ABSTRACT: MSE retaining wall with concrete facing panels is a pretty popular system used globally to support or enable the construction of infrastructure, forming retaining walls, abutments and wing walls. Polymeric reinforcement strips have been introduced in the MSE wall market as an alternative from traditional reinforcements with performance and cost-effectiveness significant advantages. They are also recommended for non-conventional situations such as marginal fills, chemically aggressive environment or in warm climates, where other reinforcements might be strongly affected by corrosion. Polymeric reinforcing strips, encased in LLDPE coating, have proved to perform like other non-extensible linear reinforcements, reaching higher values of pullout resistance. MSE walls with geostrips can be designed following International Standards, however, some considerations on the design methods applicability and nature of the reinforcements are provided here. MSE walls with polymeric strip were first introduced to the European market in the mid-1970s and their market has been growing ever since all over the world but only recently has been developed in North America. This paper presents two case studies of MSE wall projects reinforced with geostrips recently realized in Maryland and California.

1 INTRODUCTION

MSE walls described in this paper feature segmental precast concrete facing panels and layers of polymeric strip reinforcements connected to the panels by a polymeric connection system.

Soil reinforcing strips are manufactured from high-tenacity, multi-filament polyester yarns aligned and co-extruded with liner low density polyethylene (LLDPE). These strips have been used for many years all over the world in MSE walls as a geosynthetic alternative to steel reinforcements, due to their chemical stability and low creep characteristics. Polymeric strips are available in a wide range of tensile strengths and dimensions (thickness and width) to fit the specific project needs and design requirements; additionally, the polyethylene coating allows the use of geosynthetic strips in highly alkaline soils (pH up to 11) such as recycled concrete or lime-treated backfill materials.

The connection system is composed of a high-density polyethylene (HDPE) cavity insert box to create a void space secured by a steel anchor bar in the precast concrete facing panel. A non-degrading, polymeric sleeve covers the steel anchor bar to protect it from corrosion. Each polymeric strip reinforcement is continuously threaded though the sleeve and looped back to form a pair of geosynthetic strips that extend in a "V-shape" from each connector as shown in Figure 1.

Figure 1. Polymeric strips extending from the rear side if the concrete panel.

2 DESIGN PARAMETERS AND SOFTWARE INPUT

The design of this type of structures is governed by AASHTO LRFD Bridge Design Specifications and FHWA design guidelines in US territories.

AASHTO broadly categorize geosynthetics reinforcement as 'extensible' and metallic reinforcements as 'inextensible'. Although these categories have a major impact on the maximum load in each reinforcement layer (T_{max}) and its location, AASHTO does not provide a tangible measure to categorize an MSE system when it comes to design. That is, categorization is purely empirical and therefore, new MSE systems have to establish their category based on field data to facilitate their acceptance in the public sec-tor.

The internal design of MSE walls determines the magnitude and location of Tmax in each reinforcement layer. The maximum load in each layer is function of the frictional shear strength, φ, the self-weight expressed through unit weight of the backfill soil, γ, and the surcharge loading anticipated during the life of the structure. Furthermore, T_{max} enables the designer to select a reinforcement that has adequate long-term strength and it is used to calculate the pullout resistive length and the required strength of the connection between the reinforcement and the concrete panel facing.

Figure 2(a), reproduced from AASHTO, shows the locus of T_{max} as a function of depth below the crest, considering a wall having extensible or inextensible reinforcement. It can be seen that the loci are significantly different thus affecting the pullout resistive length which enables the reinforcement to mobilize its T_{max}. Figure 2(b) shows the distribution of the lateral earth pressure coefficient, K_r, with depth, normalized relative to Rankine's active pressure coefficient, K_a.

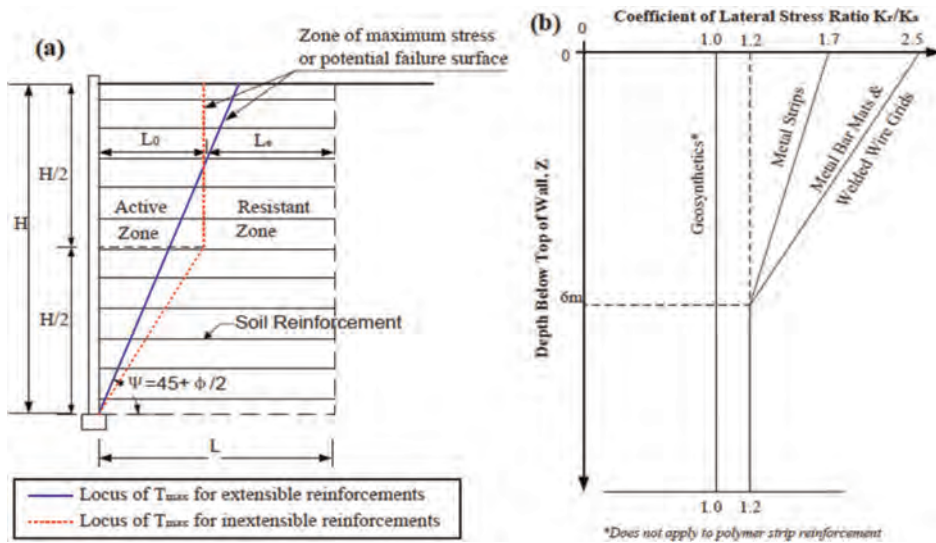
Although polymeric strips are not excluded by AASHTO LRFD Bridge Design Specifications, the lateral stress coefficient, K_r, for calculating the stresses at each level of polymer strip reinforcement is explicitly not included in Article 11.10.6.2.1 (AASH-TO 2018a) with regards to the internal design of the stresses in the reinforcement. AASHTO (2018a) commentary C11.10.6.2.1 states that Kr values for other reinforcement types can be developed as needed through analysis of measurements of reinforcement load and strain in full-scale structures and FHWA (2009) recommends supporting the instrumentation data


Figure 2. Implications of extensibility: (a) Locus of T_{max}, and (b) Variation of K_r/K_a.

with numerical models. Based on results of the studies reported by Lou, *et al.* (2015), and Rimoldi, *et al.* (2013) it appears that Kr value rec-ommended by AASHTO (2018a) for extensible reinforcement of 1.0 Ka at the top of the wall (depth z = 0) and Ka = 1.0 at depths z below the top of the wall of greater than or equal to 6.1 m (20 ft) is valid for discrete geosynthetic strip type reinforcing. These values are based on instrumented field perfor-mance testing presented by Luo *et al.* (2015) at the SR1/I95 interchange in Christiana, DE. The study showed that based on the field measurements of the experimental wall, using a linear failure plane extensible reinforcement model) was more conservative and more appropriate than a bilinear failure surface. AASHTO (2018a) had a default value of pullout resistance factor, F*, for geosynthetics, however this value did not explicitly apply to geo-synthetic strip reinforcements. The interpretation of F* is based on specific tests on rein-forcing elements used for this system as recommended by AASHTO (2018a) and FHWA (2009a). The pullout scale correction factor, α, for these soil reinforcing strips is at least 0.90 (as verified by the pullout data), therefore the recommended data for designing was considered 0.90.

The projects presented in this paper were designed using the MSEW 3.0 computer program, commercialized by ADAMA Engineering, Inc. Although the program gen-erally follows the guidelines of established design procedures, the user can explore design options and concepts beyond the formal guidelines. This option is important to integrate the polymer strips specific values and characteristic behavior into the design input values for these structures. The geostrips are first modelled as geogrids then the geometry is properly modified by acting on the reinforcement coverage ratio, Rc, lesser than 1, to be assigned to each reinforcement layer to input the real coverage, depending on the number of connections per column and geo-strip width. As explained above, the pullout inter-action coefficients (Ci, F* and α) are not considered as the default values used for the geogrids, but are determined by conducting extensive laboratory or full-scale pullout testing on various geostrip grades and types using concrete sand, and graded aggregate base (GAB) backfill materials, as shown in Figure 3. Testing was conducted in general accordance with ASTM D 6706.
Figure 3. Coefficient of Interaction variation with depth tests results.

3 CASE STUDY IN PRINCE GEORGE'S COUNTY, MARYLAND

The MSE wall presented in this case study is located in Prince George's County, Maryland and it is part of a bigger project called Andrews Federal Center Bus Operations and Maintenance Facility. The project included the design and construction facilities, garages and buildings in support of the Washington Metropolitan Area Transit Authority's (WMATA) mixed fleet of transit vehicles. Four different types of retaining wall systems were considered for this complex: unreinforced segmental block system with average height ranging from 1m to 1.5m, massive gravity concrete blocks when heights ranged from 1.5m to 3m, gabion walls for the slope stabilization from 3m to 4m high and MSE walls with concrete facing panels and soil reinforcing system for supporting heavier load and heights in the range of 6m.

Significant challenges were associated to this project: the quality of the structural soil to be used, the presence of obstacles like drainage pipes and ornamental fences, and the layout of the wall itself with several bends and curves. An MSE wall with concrete facing panels and polymeric strip reinforcement was selected to face these challenges due to the flexibility of the geosynthetic reinforcement to accommodate obstructions and bends, and the suitability of the polymeric strip for non-conventional backfill material.

In situ soil used as structural soil, as per requirement of the project, was classified as orange brown poorly graded sand with silt and gravel with the following characteristics:

	Value
pH	9.3
Resistivity	2900 ohm-cm
Sulfate	89.3 ppm
Chloride	44 ppm

pH values were closer to the upper bound of the standard range (5-10 according to FHWA) while resistivity was not appropriate for standard steel reinforcements. Particle size distribution report showed a percentage of fines passing #200 sieve slightly below 10% and maximum particles equal to 1". Moisture content was 6.4% and the soil classified as SP-SM, AASHTO A-1-a. The MSE retaining walls were designed in accordance to AASHTO LRFD Bridge Design Specifications, 7th Edition, considering a standard traffic live load (12 kPa), a guardrail impact of 0.41 kN/m and a seismic acceleration coefficient As = 0.05. These walls were designed considering a service life of 120 years. The structures were designed to support a 3-m wide concrete sidewalk directly behind the wall, and a live load traffic surcharge starting within about 3 meters behind their front face.

4 CASE STUDY IN SAN DIEGO, CALIFORNIA

This case study is about two MSE concrete facing walls located on the southern side of the Snapdragon Stadium in San Diego, as shown in Figure 5.

Figure 5.   SDSU Stadium under construction.

The new venue, completed in 2022, was designed as a hub for sports and entertainment and, with its 35,000 seats, provides a location for SDSU's NCAA Division 1 football team to play.

These permanent retaining walls create the Service Level that is located within the western and southern portions of the Snapdragon Stadium. The maximum height of the walls range from about 7.5 m (25 ft) to 9 m (30 ft).

Some of the challenges associated to these walls were: the quality of the structural soil to be used, the presence of drainage pipes and the layout of one of the walls. Geosynthetics strips were selected because of two main aspects:

- the resistivity of the backfill material, imported from a project on a beach nearby, was not suitable for metallic reinforcement;
- the flexibility of the polymer strips was considered critical during the installation of the walls because they needed to accommodate different types of obstacles horizontally and vertically.

Both walls were designed in accordance to AASHTO LRFD Bridge Design Specifications, 7th Edition, considering a service life of 75 years.

5 CONSIDERATIONS ON BOTH CASE STUDIES

All the walls involved in the projects presented so far have the same characteristics:

Concrete panels with rectangular shape (1.52 x 3.04 m and 14 cm thick), except as necessary to maintain grade and length.

The polymeric reinforcement elements consist of planar strips manufactured from high tenacity, multifilament polyester yarns aligned and co-extruded with LLDPE (Linear Low-Density Polyethylene) to form polymeric strips. The ParaWeb^{TM} mechanical and physical properties have been qualified by NTPEP (National Transportation Product Evaluation Program). Furthermore, the polyethylene coating allows the use of these polymeric strips in highly alkaline environments (pH>11) as recycled concrete or lime-stabilized backfill materials.

The connection is a bar encased in a HDPE plastic box and precasted with the concrete panel to guarantee the mechanical link and the geostrips are placed and pre-tensioned on the jobsite.

The HDPE cavity insert box is connected to the panel by a steel embedded rebar encased in a polymeric sleeve for corrosion protection. The sleeve avoids water and cement from entering during the casting phase and prevents damage to the polymeric soil reinforcing strips in contact with the deformed rebar.

During installation the panels were positioned with a slight back inward inclination to compensate for outward movement that can occur during placement and compaction of the "non-conventional" backfill. The inclination was obtained by pulling the top of the panel towards the rear face of the structure and was maintained inserting timber wedges and using clamps to fix two adjacent panels.

The timber wedges were then removed when the next row was placed to avoid panel damage.

Overall there were no issues with the vertical and horizontal alignment of the panels and the inclination was checked with a level regularly.

Gallivaggio rock cliff: Risk management and reinforced earth embankment for rockfall protection

G. Bragonzi & P. Cancelli
Studio Cancelli Associato, Milan, Italy

A. Simini & S. Mazzarolli
HUESKER Srl, Trieste, Italy

ABSTRACT: The Gallivaggio landslide falls within the San Giacomo Filippo municipality (Sondrio) and affects a portion of slope situated in the lower Spluga Valley. The rock cliff overlooks the "Madonna di Gallivaggio" Sanctuary (17th century), a restaurant, a few houses and a section of the National Road no. 36 "del Lago di Como e dello Spluga" which leads to the tourist resort of Madesimo and to the Spluga Pass on the Swiss border. Hence the need for careful planning of control and design tools aimed at both risk management and risk mitigation. The first monitoring activities of the rock cliff date back to 2006, while in 2011 a survey activity with GBInSAR technology was started by the Geological Monitoring Centre of ARPA Lombardia (CMG). On 29th May 2018, a rock mass of about 5500–6000 m^3 detached from the top of the rock cliff, completely filling up the existing catchment ditch behind the protection wall, demolishing part of the defence works and affecting the Sanctuary, the National Road and part of the other accommodation facilities situated at the foot of the rock face. This rockfall, as well as other minor recent falls, allowed to recognize the urgent need for a more adequate protection works. As a first step of a complex of works for the mitigation of the rockfall hazard, a new earth reinforced embankment was conceived. Both phases, designing and building, are described in the paper.

1 INTRODUCTION

The area of the present study lies in the Val San Giacomo, in the municipality of San Giacomo Filippo (Sondrio, Italy) on the left bank of the Liro River and is bordered by the Val d'Avero and the Valle Zerta to the north and south, respectively. The rock face, oriented NNW – SSE, overlooks the Sanctuary of the Madonna di Gallivaggio (17th century), a restaurant, a few houses and a section of State Road no. 36 "del Lago di Como e dello Spluga", which leads to the tourist resort of Madesimo and the Spluga Pass on the Swiss border.

This is a road with a very high volume of traffic in both summer and winter. Moreover, the Sanctuary itself is a site of great religious and cultural interest.

In 2006–2009, following numerous collapses that had affected the area in the previous years, an earth embankment for rockfall protection approximately 100 m long was built on top of which 5 m high rockfall nets were installed with absorption energies ranging from 250 to 2000 KJ.

Since December 2010, the ARPA Lombardy Geological Monitoring Centre (CMG), at the request of the Region's Civil Protection, has been designing and installing a monitoring system consisting of a continuous survey using terrestrial radar interferometry.

Figure 1. View of the Sanctuary area from national road 36.

2 GEOTECHNICAL-GEOMECHANICAL MODEL

The slope is approx. 500 m high with a slope angle of 65 to 70° at the sub-vertical wall and 15 to 20° at the detrital slopes and fluvioglacial deposits and the rock face above the Sanctuary is interrupted by 4 families of discontinuities with the following preferential positions: 280/75 (K1); 225/60 (K2); 120/75 (K3) and 015/35 (KS): K1 and K2 are the potential sliding planes of the rock masses and condition the orientation of the wall: K1 in the north-western part of the slope, K2 in the remaining sector; K3, less frequent and more irregular than the previous ones, forms the lateral junctions of the unstable rock masses; KS, parallel to the plunging schistosity planes at a low angle to the north, forms the "roofs" visible in the wall and is the summit junction of the unstable rock masses.

The most critical situation from the point of view of the stability of the mass (i.e. volumes above 1000 m^3), is precisely the summit part of the wall, from which the generalised collapse occurred in May 2018. The extent of the phenomenon, with an estimated volume of around $4000 \div 5000$ m^3, was such that it involved other portions of the slope, so the total volume of landslide material is of the order of 7000 m^3. Moreover, on 7th June 2017, an isolated block (more than 1 m^3) had already collapsed from the top of the rock face, in correspondence with the zone of emergence of the fracture that delimits the unstable rock mass upstream, which then subsequently collapsed. Some fragments, centimetric to decimetric in size, bypassed the existing passive defence works and hit the Sanctuary and the surrounding structures, causing some damage.

3 STUDY OF COLLAPSE PHENOMENA

The rock face is affected by isolated boulder collapses or mass collapses up to several thousand cubic metres. As resulting from interferometric monitoring, as well from the presence of an interruption in the verticality of the rock face at an altitude of approximately 1050 m a.s.l., two main possible collapse scenarios were considered: A1 between an altitude of 1050 m a.s.l. and the top of the rock face; A2 between an altitude of 900 and 1050 m a.s.l.

The study of collapse phenomena was conducted both in terms of single trajectory analysis (following isolated block collapse) and in terms of rockfall runout range (following mass collapse) in order to define the propagation scenarios for the worst possible collapse condition.

4 DESIGN OF HAZARD MITIGATION WORKS

During the various meetings held at the Prefecture of Sondrio in the presence of the competent institutional bodies, it emerged that there was a substantial insufficiency of economic

resources for the realisation of the entire complex of works for the mitigation of the risk of rockfall in the Gallivaggio area.

Having established that the risk mitigation should be pursued only through the realisation of all the works initially planned, during the final design phase the definition of functional sections was carried out according to a decreasing priority scale.

Section 1 – passive defence works: construction of a new earth reinforced rockfall protection embankment of greater height and in a more recessed position (downstream).

Section 2 – active defence works: reprofiling of the ledge at an elevation of approx. 940 m a.s.l. by controlled demolition with explosives in order to eliminate the main source of bouncing of the trajectories that bypass the embankment. The preliminary analysis imposed the necessity to precede the demolition of the ledge with the realisation of a higher containment capacity embankment.

Section 3 – active defence works: covering the top of the rock face with mesh and nails and punctual consolidation works. In this way, the residual risk is mitigated by preventing the collapse of particularly fractured portions of the mass and partially detached rock blocks, the detachment of which could lead to detensioning and subsequent mass collapse.

Figure 2.   Effect of embankment relocation.

The final project consists in the construction of a reinforced earth embankment for rockfall protection replacing the existing one. The new structure, in addition to its greater length, which allows the protected areas to be extended, will also have a greater height, so that it will be able to intercept the trajectories not retained before.

In order to further increase the interception capacity, the axis of the new embankment was planned downstream.

Relocating the embankment in a direction with a smaller inclination of the fall trajectory allows for a greater interception capacity. Furthermore, other positive results are expected to be achieved: the trajectories heights are lower, which makes it therefore possible to reduce the height of the new embankment; the lower embankment height reduces the loads on the foundation soil and therefore better overall stability conditions are obtained; the reduced size of the embankment leads to a significant reduction in construction costs.

The design impact considered provided the highest kinetic energy (30,040 KJ) in the trajectory analyses; this impact occurs at a height from the upstream side of 13.37 m, at a distance from the crest of 5.23 m and with an inclination of 67.93°.

The new rockfall protection embankment is made of a two-sided reinforced earth embankments (with 70° slopes guaranteed by means of steel mesh formworks) on top of a single-sided sided reinforced earth embankment. The maximum design height of the embankment is 23.43 m, which includes a 5 m high concrete anchored wall at the bottom, designed in some areas. On top of the embankment a steel rockfall barrier was installed, with

the purpose of containing any minor blocks resulting from the fragmentation of larger blocks after impacts on the rock face. The project is completed by a drainage system at the base of the embankment and the planting of new shrubs between the embankment and the Sanctuary.
Figure 3.   Plan view and typical cross-section.

5   STABILITY ANALYSIS

The stability of the reinforced earth wall was checked according to the current Italian Regulations (NTC 2018) and stability calculations under different combinations of actions have been performed: Internal, compound and overall stability of the reinforced earth wall, using both circular (Bishop) and polygonal (Janbu) sliding surfaces; Stability against overturning; Bearing capacity of foundation soil at the base of the embankment; Impact of an individual rocky body with diameter 1.44 m, weight 8270 kg, travelling at 98.11 m/s with a kinetic energy of 39,800 kJ; Shear resistance against sliding at the base of the embankment and at every level of reinforcing geogrids. With this regard a reduced angle of friction along the interface geogrid /soil has been adopted (reduction factor 0.8).

All the stability calculations were performed in both static and seismic conditions, and they have been done on two typical cross sections. The geosynthetics which were used as reinforcements are flexible, high modulus PET geogrids, having the technical data indicated in Table 1 and laid with a vertical spacing of 60 cm:

Table 1.   Geogrid characteristics.

Geogrid type	Fortrac 55 T	Fortrac 80 T
Tensile strength – UTS [kN/m]	$\geq$ 55	$\geq$ 80
Max strain [%]	$\leq$ 10	$\leq$ 10
Max. strain at design strength [%]	$\leq$ 5.5	$\leq$ 5.5
Creep (from 1 hour to 120 years at 50% UTS) [%]	$\leq$ 1.0	$\leq$ 1.0
RF_{creep}	1.52	1.52
RF_{ID}	1.20	1.15
RF_W	1.00	1.00
RF_{CH}	1.03	1.03
f_s	1.02	1.02
LTDS @120 years [kN/m]	$\geq$ 28.70	$\geq$ 43.56

where RF_{creep}: reduction factor for creep (120 years, T = 20°C), RF_{ID}: reduction factor for installation damage (coarse gravel), RF_W: reduction factor for weathering, including exposure to ultraviolet light, RF_{CH}: reduction factor for chemical/environmental effects (pH between 4 and 9, T = 20°C), f_s: factor of safety for the extrapolation of data (120 years)

The LTDS (Long Term Design Strength) was calculated according to BS8006:2010 and the partial safety factors were derived from the BBA certificate of Fortrac T geogrids (HAPAS Certificate 13/H197):

$$LTDS = \frac{T_{char}}{RF_{CR} \cdot RF_{ID} \cdot RF_W \cdot RF_{CH} \cdot f_s} \tag{1}$$

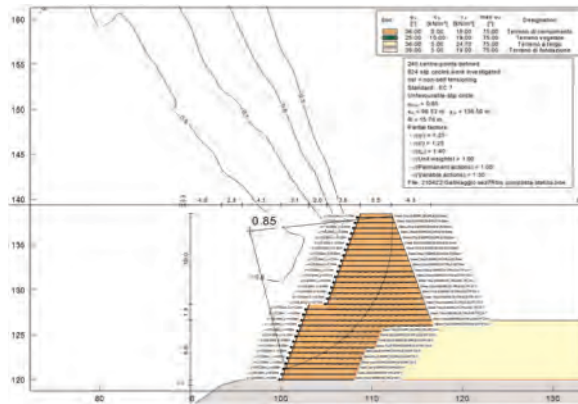
In Figure 4 the structural configuration of a typical cross section is shown, with indication of the reinforcement distribution, the type of geogrid, its anchoring length, thicknesses, etc. while in Table 2 all the safety factors obtained in the calculations performed calculations are shown.


Figure 4.   Typical cross-section with the one the internal stability analyses (utilization factor obtained: 0.85).

Table 2.   Safety factors obtained in the performed calculations.

Type of analysis	Section 5R		Section 7R-bis	
	Static analysis	Seismic analysis	Static analysis	Seismic analysis
1 Sliding along the base	1.34	1.27	1.35	1.27
2 Global stability	1.14	1.35	1.22	1.44
3 Bearing capacity	5.45	7.41	5.66	7.73
4 Overturning	7.31	8.08	7.60	8.41

The soil which was used as fill of the wall was coming both from the demolition of the existing embankment and the material which fell from the cliff and accumulated behind the old embankment. These materials were appropriately crushed and screened to fall into groups A1, A3, A2-4, A2-5 according to UNI 10006, UNI EN 13242, 13285 and UNI EN ISO14688-1. Soil parts larger than 20 cm were excluded, except for a maximum percentage of 10%–15%.

The geotechnical properties required for the fill were the following: friction angle $\geq 35°$; unit weight greater than 15.90 kN/m^3 – a dry mass by volume, measured at the base of each layer, not less than 95% of the maximum dry mass by volume identified by the AASHO Mod test (CNR 69 – 1978), (CNR 22 – 1972); modulus of deformation at the first load cycle on the plate (diameter 30 cm) (CNR 146 – 1992) ≥ 15 MPa, in the load range between 0.05 and 0.15 N/mm^2 on the sub-layer; ≥ 50 MPa, in the load range between 0.15 and 0.25 N/mm^2 on the top of the sub-layer and on the top of the wall.

A biodegradable erosion control jute net was placed between the fill material and the geogrids to prevent soil erosion before the greening of the slope. The steel mesh formwork is made of electro-welded mesh, 7–8 mm rebars having a mesh size of ~15 cm. The steel formwork does not provide any structural resistance; it only allows a better and easier shaping of the embankment. The formwork is provided with stiffening rods to guarantee a better resistance in the initial compacting stages.

6 CONSTRUCTION

Prior to the commencement of the work, it was necessary to secure the tunnel by laying netting on the upper part of the wall above, also in the event of new detachments after the project delivery. A total of 50,000 m^2 of netting was laid on the upper part of the 450 m high wall. With the help of a Kamov helicopter, 300 m long and over four tonnes heavy nets were laid, making it Europe's first and largest netting project on a rocky slope. At the end of the construction activities, a total of approx. 45,000 m^3 of material was moved.

Thanks to the screening and crushing activities, which were foreseen by the project and coordinated during the construction management phase, the new embankment was entirely built using all the material that collapsed in May 2018, all the material that made up the old embankment and part of the slope debris within the site area.

The reinforced earth fill embankment is 243 m long and has an interception height varying from 4 to 14 m while the height of the face on the downstream side varies from 7 to 23 m.

Figure 5.   Construction phases.

The construction of the access roads to Pelješac bridge with the use of geogrid reinforced soil structures

L.S. Calvarano & P. Recalcati
Tenax SPA, Viganò, Italy

ABSTRACT: The construction of Pelješac Bridge and of the roads connected to the bridge is currently the largest and most ambitious infrastructure project in Croatia. The project was completed largely on time thanks to the use of reinforced soil technique. Preliminary project foresaw conventional and expensive viaducts to bypass the deep valleys intercepted by the road layout. To reduce the cost and to increase the construction rate, replacement of traditional viaducts in Doli and Brijesta with geogrid reinforced embankments was proposed. This solution turned out to be cheaper and faster respect the traditional ones; on the base of the time and cost effectiveness of the reinforced soil solution, it has been decided to modify the design of wing walls and abutments of the Dumanja Jaruga viaduct, crossing a valley over 25 m deep. Design and construction of the above strategic infrastructures were a great challenge and certainly a great success, thanks to the great work done by the general contractor, who was able to finish the job very precisely and accurately, despite the logistical difficulties given by the position and by the time scheduled imposed by the construction of the bridge support structure.

1 INTRODUCTION

The construction of the Pelješac bridge (2,404 km long and inaugurated on 26th July 2022, Figure 1) and of the roads connected with it is currently the largest and most ambitious infrastructure project in Croatia.

Figure 1. Pelješac bridge (source: www.dw.com).

This infrastructure will be part of the Adriatic-Ionian highway, starting from Trieste and reaching Greece after crossing the eastern Adriatic coast.

This impressive project has a key, geostrategic and symbolic importance for the Croatian population as, in addition to constituting an important and fast communication artery between the Southern Dalmatia and the Pelješac peninsula, it will contribute to its future development and growth.

Construction of the Pelješac bridge and of connecting roads has unified the country, guaranteeing the territorial continuity (after three centuries) of the southern extreme of the country (exclave of Dubrovnik) with the national highway network, by-passing the territory of Neum, 24 km of Adriatic coast belonging to Bosnia and Herzegovina. This has allowed delays associated with border formalities.

In the last twenty years various solutions have been proposed and evaluated, but all the attempts to start the works have always been opposed due to the very high construction costs.

The project of the road infrastructure crossing the Pelješac peninsula and accessing to the Pelješac bridge receiving the highest consents was designed by the Croatian firm Institute IGH dd.. Preliminary project foresaw to bypass the deep valleys crossed by the road layout with expensive and conventional viaducts.

Thanks to the collaboration of Tenax SpA, the Croatian partner Kotonteks of Varaždin and the contracting company Strabag, replacement of some of the viaducts with geosynthetics reinforced soil technique was proposed. All the proposed modifications to the original project have been accepted by the investor (Croatian Road) and by the European Commission, which was financing the project (Figure 2).

Figure 2.   Location of the different geogrid reinforced slopes along the access roads of the Pelješac bridge (source: www.dw.com and Google Maps).

In recent years, the use of geosynthetics has deeply changed the design methods of geotechnical and environmental engineering interventions. In fact, the correct use of these materials makes it possible to improve the safety conditions and the operating behavior of the engineering structures, reducing, at the same time, construction costs, construction times and environmental impact.

2   GEOGRID REINFORCED SOIL STRUCTURES

The term "reinforced soils" refers to a composite material that combines, synergistically, the strength of two different materials, soil and reinforcing geosynthetic.

The geogrid reinforced earth structure is a construction system based on the principle of improving the geotechnical properties of the fill soil (which, by its nature, is able to resist

very well to compression actions but do not have a significant tensile resistance) by providing it with tensile strength. Therefore, insertion of reinforcement geogrids (polymer structures with a very high tensile strength) capable to interact effectively with the soil in which they are embedded, results in a composite system (the reinforced soil) with higher performance compared to those of the soil alone. The function of the reinforcement is, therefore, to exert an effective confinement on the surrounding soil increasing its mechanical characteristics, developing tensile resistant forces that improve the stability conditions of the reinforced soil structures and, at the same time, limiting their deformations.

Thanks to this construction technique, it is possible to build and stabilize soil slopes with very steep angles and reduced cross-sections, with important savings on excavation material and fill material with consequent of lower costs of expropriation and construction, and therefore a reduce environmental impact.

In addition, reinforced soil structures with very steep faces are a valid alternative to conventional design solutions in reinforced concrete, especially when the huge dimensions of the structures require an accurate environmental impact assessment.

In this context, a wrap-around reinforced soil with polymeric reinforcing element consisting in a mono-oriented geogrid 100% in HDPE (high density polyethylene) and integral joints, manufactured from a unique process of extrusion and certified for the construction of steep reinforced slopes with inclines of up to 85°, was proposed.

The reinforcements' layers, suitably designed in terms of tensile strength and anchoring length, are embedded inside the fill soil at a vertical spacing of 0.60 m, with a wrap around at the front face of the slope.

This soil reinforcement system, foresees the use of a welded wire steel mesh formwork (Φ = 6-8 mm / mesh 15 cm x 15 cm) at the face, acting as a support system, equipped with specific stiffening rods (1 rod at 0.45 m spacing). The face formworks are sacrificial and do not have a structural function but act as a guide and support allowing a rapid installation and an accurate profiling of the reinforced soil structures. Finally, at the face a biomat was used to protect the structure against erosion and to ease vegetation of the face, allowing the growth of lawn or other suitable plants and providing an aesthetically pleasing solution (Figure 3).

Figure 3. Construction phase of reinforced earth structure with mono-oriented extruded geogrids in HDPE.

It should be noted that the use of high density polyethylene (HDPE) guarantees high resistance to chemical-physical degradation processes such as hydrolysis, oxidation and exposure to atmospheric agents, thus giving the reinforced soil structure a large durability over time.

3 PROJECT AND OPERATIONAL ASPECTS

Among the different structures along the road accessing to Pelješac bridge, the expensive Doli viaduct (about 180 m long with a maximum height of 17 m, Figure 4) and two external

portions of Brijesta viaduct (total length of about 200 m and with a maximum height of 15 m, Figure 5) were replaced with wrap-around geogrid reinforced embankments.

Figure 4.   Replacement of the Doli viaduct with a wrap-around geogrid reinforced embankment (span 180 m, maximum height over 17 m).

Figure 5.   Replacement of external portions of the Brijesta viaduct with reinforced earth embankments (total length about 200 m, maximum height about 15 m).

The proposed solution turned out to be cheaper and faster respect to traditional construction. Besides the above-mentioned works, and on the base of the time and cost effectiveness of the reinforced soil solution, the biggest challenge was to modify the design of wing walls and abutments (U0 and U4, respectively 102.0 m and 155.60 long, Figures 6 and 7) of the Dumanja Jaruga viaduct crossing an over 25 m deep valley.

Figure 6.   Aerial drone view of the U0 wing wall and abutment of the Dumanja Jaruga viaduct made with the reinforced soil technique with extruded HDPE mono-oriented geogrids.

The greatest challenges of the projects were connected both to height of these structures and to high loads during their construction phases and operation life (Figure 8).

Figure 7. Aerial drone view of the U4 wing wall and abutment of the Dumanja Jaruga viaduct made with the reinforced soil technique with mono-oriented extruded geogrids in HDPE.

Figure 8. Front drone view of the U4 wing wall and abutment of the Dumanja Jaruga viaduct constructed using a wrap-around reinforced soil technique with a sacrificial steel mesh formwork at the face and mono-oriented extruded geogrids in HDPE.

As it is necessary in the project of any geotechnical structure, the design phase of the reinforced soil structures was not separated from an adequate assessment of the morphological, geological, hydrogeological and geotechnical characteristics of the sites. Geognostic investigations and subsequent mechanical characterization of the site soils were essential both to geotechnical stability checks and to define the mechanical design parameters of the reinforced soil. The latest aspect was particularly important as excavation material was used as fill material for the construction of the reinforced structures.

A careful analysis of the logistical and construction site aspects was done too. The limited dimension of the operating areas, the access roads and the construction site, as well as the size of the machineries that could be safely used were crucial factors both for the good execution of these structures and for the cost-effectiveness of the work.

It should be noted that the required fill material volume was very high, therefore, it has been of paramount importance evaluate and validate the possibility of recovering the material available on site, thus avoiding the need to dispose excavation material and to source fill material from quarries. The storage of the fill material within the construction site areas, especially in a

mountain or hilly area with steep geometries, was carefully evaluated in order to mitigate the risks associated with slopes stability problems that could occur due to the soil piles storage.

Eurocodes 7 and 8, both in static and seismic conditions, were used to check the stability, taking into due account the seismicity of the site, the geotechnical model and the construction phases of both the reinforced earth embankments that replaced the viaducts of Doli and Brijesta, as well as, the wing walls and abutments of the Dumanja Jaruga bridge.

Design and construction have been particularly complex due to the high seismicity of the area (Peak Ground Acceleration equal to 0.34 g); the height of the geogrid reinforced structures (average height 17.0 m, maximum height up to 25.0 m) and to the inclination of the reinforced slope face (up to 80 °). The presence of rock at the back of the reinforced slope in some cases has required a fine optimization of design in order to reduce as much as possible excavations.

The geogrid reinforced soil with steep slopes brought many advantages respect to the original traditional solution:

- the speed (20% higher) and easiness of execution compared to the original design solutions (construction rate was 40 m^2/day of face of wrap-around geogrid reinforced soil with a team of three men; furthermore, compared to the construction of a viaduct the solution does not require deep foundations, the use of heavy machineries, skilled personnel and does not require the typical curing time required by reinforced concrete). Finally, the use of reinforced soil technique allowed to follow the time schedule;
- the aesthetics and the lower environmental impact at the end of the work ensure some facilitations in getting all the required approvals, especially in protected areas and in areas subject to particular urban or landscape-environmental constraints;
- cost-effectiveness was ensured by the possibility to recover material coming from excavations, thus eliminating the costs of dumping and getting fill material from quarries (including transport costs for both the operations). The proposed design solution for the reinforced embankments allowed a reduction in construction costs of almost 30% as the location of the construction sites were close to the Kamenice tunnel, therefore, much of the excavated soil was used. Excavated rock was crushed and selected until reaching a size suggested by the designers based on the calculation of the internal and external stability of the reinforced earth structures;
- better behavior in seismic conditions. The reinforced soil constructions allow deformations capable to absorb seismic stresses, even of considerable entity, without compromising the functionality of the structure; on the other hand, the traditional reinforced concrete rigid structures, in the same seismic conditions, would risk collapsing;
- less environmental impact and pollution. The trucks used for the construction of reinforced earth works produce lower emissions of CO_2 into the atmosphere than those associated with the construction of traditional works;
- The project and the construction of the geogrid reinforced structures have been a big challenge and definitely a great success, thanks also to the great work done by the general contractor who has been capable to finish the job in a very precise and accurate way despite all the logistic difficulties given by the location and by the time scheduled imposed by the construction of the bridge support structure.

A case study on strengthening the backfill of a prefabricated reinforced concrete double wall with geogrids

H. Özçelik
Promer Consultancy Engineering Inc., Ankara, Turkey

Ü. Küçükkayalar, S. Küçükkayalar & D. Küçükkayalar
Ka-Yapi Prefabrication Inc., Bursa, Turkey

ABSTRACT: The construction of geosynthetic-reinforced soil retaining walls with a staged-constructed full-height rigid facing for railways, including high-speed train lines, roads and other retaining walls began to be used in Japan in the late 1980s. After the wrap-around type geosynthetic reinforced soil wall is constructed, the front face is covered by a cast-in-situ reinforced concrete wall. The earthquake performance of these walls is extremely high and is economical compared to classical retaining structures. This system was used in a slightly different way on the reinforced concrete wall of an industrial building in Bursa, a city located in the first degree seismic zone of Turkey. The 10m high reinforced concrete wall was staged-constructed in three parts using the prefabricated modular double-wall system, while the backfill was reinforced with geogrids. In this paper, the effect of using a geogrid-reinforced fill and unreinforced fill on the calculation of the reinforced concrete wall section is compared, and the details of the system and its construction are discussed.

1 INTRODUCTION

Since 1987, geosynthetic reinforced soil walls with a full height rigid (GRS-FHR) facing invented by F. Tatsuoka, were in use on Japanese roads and approved by the Japanese Ministry of Transport in 1992 (Tatsuoka *et al*. 1997). After the 1995 Kobe earthquake, the Japanese railways administration decided to use the GRS-FHR facing walls as retaining and bridge abutments. These walls are formed by building a wrap around GRS wall and casting an in-situ reinforced concrete wall as the FHR facing (Tatsuoka *et al*. 1996). This system is frequently used in the reconstruction of classical type retaining structures (reinforced concrete or gravity structure) that collapsed as a result of earthquakes, heavy rains and similar natural disasters (Tatsuoka *et al*. 2007). In the 1995 Kobe and 2011 Great East Japan earthquakes, transportation on the railways supported by the FHR-GRS walls continued without interruption (Yonezawa *et al*. 2014).

2 CONSTRUCTION PROCEDURE FOR THE FHR-GRS WALL SYSTEM

The FHR-GRS wall system has now become a standard retaining wall construction technique, replacing classical retaining walls in Japanese railways (Figure 1). The construction procedure of the FHR-GRS wall system consists of the following stages:

1. A simple levelling pad is constructed as per the shop drawings.
2. Geogrid wrapped sacks filled with granular fill are arranged in an orderly manner.
3. Granular fill is laid in layers and compacted
4. While the sacks are wrapped with geogrid, steel reinforcement bars are left between them (Figure 2).
Figure 1.   Typical FHR-GRS wall section (Tatsuoka 2008).
Figure 2.   Typical connection detail of FHR-GRS concrete facing and the geosynthetic reinforced fill (Tatsuoka 2008).

Figure 3.   Finished GRS embankment prior to cast-in-situ RC wall construction (Tatsuoka 2018).

5. This process continues until the fill reaches the top of the wall level.
6. The possible settlements in the embankment and ground need to be completed (Figure 3).
7. After the settlements are completed, a cast-in-situ reinforced concrete wall with a thickness not exceeding 30 cm is formed as the facing.
8. In this way, the cast-in-situ reinforced concrete wall is connected to the reinforced soil mass, thanks to the steel reinforcement bars placed between the sacks.

3 CONSTRUCTION METHOD OF DOUBLE-WALL

3.1 *Case study*

The retaining walls of the Ada Sofa factory, located in the 2nd Organized Industrial Zone of the Inegol district of Bursa, were built using prefabricated reinforced concrete hollow panels forming the retaining wall system called Double Wall. While backfilling the retaining wall, the fill was strengthened by placing geogrids between the fill layers. This is similar to the FHR-GRS wall system developed by Prof. Tatsuoka, described above. In Tatsuoka's system, geosynthetic reinforced fill is formed first, and after the possible deformations taking place, a cast-in-situ reinforced concrete retaining wall is formed as the facing. In the other, the front side reinforced concrete wall, i.e. the facing is gradually built in using prefabricated RC modules, and geosynthetic reinforced backfill is done afterwards.

There is a level difference of approximately 11m between the base level factory and the neighboring parcel. In the neighboring parcel, there is a building at a distance of 10 m from the parcel boundary. The natural ground between the two plots is formed by a slope greater than 45degrees. Geogrid reinforced fill was made in this area.

3.2 *Construction of prefabricated double wall*

The first prefabricated double wall module with dimensions of 3.33 x 7.00 m (HxW) is placed on the prepared steel frames and fixed with props from the back (Figure 4a). After the

Figure 4a. Installation and propping of double wall modules.

Figure 4b. Formwork of foundation and installation of steel reinforcement.

Figure 4c. Installation of horizontal continuity reinforcements.

Figure 4d. Pouring of concrete.

formwork of the wall foundation is installed, the necessary reinforcements for the foundation are laid under the steel frames (Figure 4b). After the horizontal continuity reinforcements are placed inside the double wall modules (Figure 4c), concrete pouring takes place (Figure 4d). The molds have been removed, after the concrete has set, and the surrounding of the foundation is filled with backfill and compacted. The perforated drainage pipe is placed, and covered with gravel. This layer of gravel, having a width of 30cm, is applied between the wall and the backfill, up to a height of 3.30m which is the height of the first double wall module.

3.3 *Backfill with geogrid*

Backfilling is made in layers like in any reinforced soil wall backfilling and compacted with a minimum 95% standard proctor. While placing the backfill, geogrids of required strength and length are placed between the fill layers according to the design section (Figure 5). Typical Double Wall cross section is given in Figure 6.

The walls between the prefabricated columns of the factory building were made with double wall as a curtain system wall and the backfill is reinforced with geogrids (Figure 8).

While backfilling the geogrids, it is important that the geogrids are laid flat and there is no slack. If necessary, the geogrid should be pinned to the ground at its rear end using wooden or steel stakes. Backfilling, compaction, geogrid laying, and gravel placing continue in successive layers until the top level of the wall is reached. The backfilling of the Ada Sofa factory wall (H=10m) was made by reinforcing it with geogrid by wrap around method. The design of the geogrids was carried out according to BS8006 (2010).

Figure 5.   Installation of geogrids.

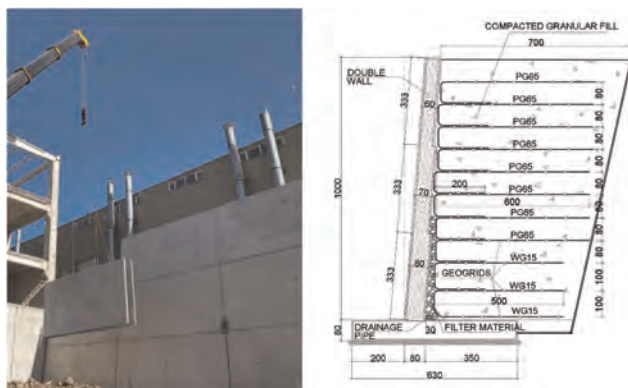
As a result of the design, geogrids with a vertical spacing of 1m and an ultimate breaking strength of 150kN were used in the bottom three rows, and geogrids with a vertical spacing of 80cm having an ultimate breaking strength of 65kN were used in the following eight rows (Figure 6). In the section of the building where the Double Wall panels are used as curtain


Figure 6.   Front view and cross section of the double wall.

walls, geogrids having an ultimate breaking strength of 80kN with a vertical spacing of 60 cm in the bottom 4 rows and a vertical spacing of 80 cm in the following 7 rows were used (Figure 7). While placing the geogrid, first the short length is placed and after, the full length of geogrid is folded over the compacted fill layer. It is strained as much as possible and pinned at the rear end on the ground. There exists a self placed gravel drainage layer at the of the rigid facing which helps for the mobilization of the geogrid strength even with small deformations which takes place during the compaction of the fill.

3.4 *Double wall cross section calculation*

Three of the 3.33 x 7.00 m double wall modules were placed on top of each other to form the retaining wall. The thickness of the lowest module is 80cm, the middle one is 70cm and the top one is 60cm. The geogrid-filled portion is a self-stable mass that theoretically retains the earth pressure thrust behind the wall. However, in the double wall section calculation, 33% of the classically calculated earth pressure was considered. On the other hand, a double wall section was analyzed with full earth pressure acting at the back of the wall, according to the new Turkish Earthquake Regulation (TBDY 2018). At the end of the analysis, double wall modules were calculated to be 20cm thicker than the ones actually used with the geogrid reinforced fill. Reinforced concrete section calculations were made with Prota Structural Details V:22 software. Comparison of materials used for a 1m run of unreinforced and reinforced backfill sections of the 10m high wall of Ada Sofa factory are given in Table 1.

Reinforcing the backfill with geogrids, introduce savings of about 15% in concrete and 30% in steel reinforcement quantities compared to unreinforced backfill. In 1m run of 10m high
Figure 7. Typical view and cross section of the factory walls which are also made with the double wall system and the backfill is reinforced with geogrid.

Table 1. Comparison of materials used for a 1m run of unreinforced and reinforced backfill sections of a 10m high wall.

Backfill	Cross Section (cm)	Concrete (m^3/m)	Steel Reinforcement (kg/m)
Unreinforced	100–80–60	12.9	1,492
Reinforced (geogrid)	80–60–40	10.7	1,026
Difference	20–20–20	2.2	466

double wall's backfill, 25.5m^2 and 73.2m^2 of 150kN and 65kN geogrids were used respectively. So it is 9.9m^2 geogrid in 1m^2 face area of the double wall including 2m wrap around.

    The savings can be calculated as follows for the whole double wall which was 36m long.

Concrete cost (∼66€/m^3) : … … … … … … … … … .. … . 2.2m^3 x 36m x 66€/m^3 = 5,227€

Steel reinforcement cost (∼770€/ton) : … … 0.466ton x 36m x 770€/ton =12,918€

Geogrid cost (average ∼1.50€/m2) : … .9.9m^2 x 36m x 10m x 1.50€/m2 = 5,346€

So the net saving is : 5,227 + 12,918 – 5,346 = 12,799€

    There are also savings from the construction time, labourship, and energy which were not considered in the above calculation.

4 CONCLUSIONS

i) Geosynthetic reinforced soil retaining walls (FHR-GRS) with a full-height rigid facing is a standard retaining wall construction technique, which has been accepted by the Japanese Railways Administration, replacing classical retaining walls. The earthquake performance of all types of geosynthetic reinforced walls are extremely high. In the 1995 Kobe and 2011 Great East Japan earthquakes, the railways supported by such walls continued their functions without interruption.

ii) In FHR-GRS walls, granular material filled sacks are wrapped around with geogrids; after the possible settlements of the embankment and the foundation soil have taken place, the front of the system is covered with a cast-in-situ reinforced concrete wall.

iii) The retaining wall of a factory built in İnegöl-Bursa was constructed in 3 stages using a prefabricated reinforced concrete double wall panel retaining wall system. Similar to the FHR-GRS system, it's backfill was reinforced by placing geogrids between the fill layers.

iv) Contrary to the FHR-GRS system, in the İnegöl retaining wall, wrap around geogrid backfill was done after the double wall panels were installed.

v) While analyzing the cross section of the double wall system, an economical solution was obtained by taking 33% of the earth pressure thrust.

vi) When comparing the double wall sections where backfill is unreinforced and reinforced with geogrids, 2.2m^3 of concrete and 466kg of steel reinforcement were saved per meter run of wall. The savings about 15% of the concrete and %30 of the steel reinforcement quantities.

Earthquake resistant design of shallow foundations using geogrid reinforcements

J. Kupec, D.P. Mahoney & I.D. McPherson
Aurecon New Zealand Ltd, Christchurch, New Zealand

ABSTRACT: New Zealand experienced several large earthquakes which damaged residential and commercial properties. For post disaster recovery, solutions were sought to rebuild on land prone to seismically induced liquefaction and lateral spreading. Engineering guidance in NZ introduced the basal geogrid reinforced gravel crust concept to allow construction of lightweight timber framed buildings on liquefaction prone ground. This paper describes the design and construction aspects for multiple layers of geogrids. It provides the detailed concepts behind the reinforced crust approach, including case studies of structures surviving repeated seismic shaking without major damage. The paper then describes several case studies of completed projects. It focuses on construction details that are considered essential for successful application of a reinforced crust subject to strong seismic shaking. Lastly, the paper provides releveling and repairability considerations to ensure that buildings can be returned to full functionality by relevelling after a major event.

1 INTRODUCTION

This paper reflects on design for multi layered reinforced soil gravel rafts in New Zealand. The authors were actively involved in many residential and commercial rebuild projects in New Zealand. They attempted to condense their design experience and provide the regulatory and design approaches common in NZ, especially those they consider can be applicable to many other parts of the world.

Following the Canterbury Earthquake Sequence in 2010 to 2011 in New Zealand light weight timber or steel framed structures, usually single to double storied, survived the earthquake shaking rather well. However, buildings were generally compromised once the foundation system was affected by seismically induced ground damage, notably differential settlement due to liquefaction related effects. The most common form of damage was noted where shallow liquefaction ejected large soil volumes directly from below foundation elements. Subsequent reconsolidation settlement required shallow footings to span and cantilever more than their, generally meagre, capacity. Seismically induced lateral spreading, extending up to 150m away from stream edges, often compounded the foundation damage. Lateral stretch, a term coined for lateral spreading directly below the spread building footings, caused significant foundation and structural distress. The lightly reinforced footings were not required by the then design standard to be tied together and they readily pulled apart and settled differentially, creating significant structural distress. While many buildings exhibited severe distress, due to their light weight and well braced nature very few initiated collapse. Older unreinforced masonry buildings did collapse from a combination of severe shaking and ground settlement.

Most structures were compliant with the New Zealand Building Code (NZBC). However, liquefaction and its associated effects prior to 2010 were often not appreciated by designers and regulatory authorities, with static bearing capacity and only a simple earthquake overstrength check for seismic conditions.

The need to provide readily available design approaches arose from the rebuild of over 20,000 severely damaged residential dwellings, with over 6,000 damaged well beyond economic repair (Cubrinovski 2012). Further, NZ is forecast to continue to be subjected to strong seismic shaking. The South Island features a major fault line on the West Coast that has a very high probability of rupture, (>75% in the next 50 years) generating a M8+ event. The North Island features on its entire East Cost a subduction line between the Pacific and Australian Plates that has triggered Mega Thrust events in the past, with shaking in excess of M9+.

The engineering challenge was to provide guidance on resilient foundation rebuild and repairs. The Ministry of Business, Innovation and Employment (MBIE), formerly the Department of Building and Housing, published guidance for the assessment and rebuild of timber or steel framed structures, (MBIE 2012). One of the proposed solutions for land susceptible to moderate to severe liquefaction induced land damage was the use of geogrid reinforced gravel rafts, where two biaxial geogrids provide basal reinforcements. This approach creates a strengthened surface crust.

2 PAST PERFORMANCE

The prevalent types of foundations for residential and light commercial buildings in Canterbury, and much of New Zealand, featured either a lightly reinforced concrete slab on grade or timber flooring with concrete perimeter footings. The typical damage observed after the Canterbury Earthquakes 2010-2011 and later Kaikoura Earthquake in 2016 is shown below.

Figure 1.   Typical damage patterns for house foundations, after (Department of Building and Housing 2011).

Christchurch and much of New Zealand is built on low lying alluvial or estuarine or coastal deposits, often loose granular soils with a shallow to near surface groundwater table. Geotechnical practitioners needed to consider both static and seismic bearing capacities and account for potential land subsidence and differential settlement associated with ground liquefaction.

Pre 2010, geogrids were used to improve ground below light commercial, industrial and residential structures, when the need arose to improve the static bearing capacities and/or provide temporary platforms for construction. A review of structures with geogrid reinforced foundations indicated that those structures outperformed similar structures on unimproved ground.

(Tensar 2019) reported that 'several foundations which had been constructed on a Tensar MSL geogrid stabilised granular mattress following the 09/2010 event were investigated after the 02/2011 EQ and showed no sign of failure, while nearby buildings showed up to 700mm settlement and up to 500mm horizontal movement. The buildings resting on the Tensar MSL foundations however, showed only 40-50mm of movement and no failures or cracks in the superstructure. Only minor refurbishment was required for the buildings to be fully usable.'

The authors designed the above two-level residential housing estate in Huxley Street, Christchurch, prior to the Canterbury Earthquakes. Multiple geogrids placed in competent well compacted 900 to 1,200mm thick granular fill were used to create a reinforced crust. The main design objective was to meet static bearing capacities and allow construction plant access. The incidental benefit was an improved seismic bearing capacity below the main structural load bearing elements.

3   NZ GUIDANCE

Observations identified that liquefaction-induced settlement severely damages buildings, however it rarely affects life safety. Further, liquefaction and lateral spreading caused disproportionate damage to the foundation system even at lower shaking levels, Serviceability Limit State (SLS) and above. The Ministry for Business, Employment and Innovation (MBIE) worked with the Engineering Advisory Group (EAG) to develop NZ specific guidance on assessing, repairing and rebuilding foundations on land susceptible to earthquake induced liquefaction and lateral spreading, (MBIE 2015). The guidance was developed to provide context for designers in relation to the New Zealand Building Act, as the standard solutions were not considered appropriate and Alternative Solutions had to be quickly developed.

The importance of the surface crust was identified to be critical for the performance of buildings. Where the water table was deeper than 3m, or the upper 3m of ground were not liquefiable, forming a crust, the foundation damage was generally minor. The NZ guidance therefore provided a basal geogrid reinforcement as one option to support a well braced light weight structure on land with a thin to non-existent non-liquefiable crust to provide the necessary support. The function of the basal geogrids and gravel fill was to reduced bearing stresses by distributing foundation loads over a larger area and prevent liquefaction from ejecting from directly below individual foundation elements.

4   DESIGN APPROACH

Following the earthquakes there was a need to provide economically viable footings for the rebuild of light weight commercial, industrial and residential structures. The authors developed the concept of a multi layered reinforced soil crust, rather than relying on a basal geogrid only. The principal design objectives were to:

- Increase static bearing capacity of well tied together shallow footings [strips and pads];
- Prevent punching failure into liquefied soils during and after earthquakes;
- Enhance spanning across liquefaction settlement induced hollows and weak spots;
- Increase the flow path of ejecta, to reduce volumetric soil loss from directly underneath footing elements;
- Provide tensile resistance against lateral stretch; and
- Provide a competent layer to enable repair via relevelling of the structure following large earthquake event.

Based on design experience gained on large scale transport infrastructure and construction of mechanically stabilized soil systems, i.e. walls and pavements, we identified several key design details:

- Geotextile at the base to separate insitu soils from the granular reinforced raft.
- Double layer of a dampproof membrane (geomembrane) to act as a slip surface at the base in areas where lateral spreading and lateral stretch are of concern.
- At least two, but ideally three to four layers of high stiffness biaxial geogrids embedded in the reinforced gravel raft;
- Competent well compacted (95% to 98% of Maximum Dry Density (MDD)) angular granular fill with at least two broken faces to obtain high dilatancy and high angle of shearing resistance.
- Fill thicknesses were ideally 1,200mm, but could be as low as 900mm, below the lowest point of the foundation elements.
- Construction observations were used to assess the actual ground conditions, and where required a 300mm thick layer of railway ballast wrapped in a robust geotextile and placed below the lowest reinforcement layer to act as a capillary break to protect the weak subgrade material. Often observed was the inability to compact the lowest fill layer beyond 92% of MDD (Modified Proctor), as vibratory compaction caused liquefaction and weaving of the insitu

ground. The authors adopted static compaction of the lowest layer with vibratory compaction of the upper layers which provided satisfactory density. Compaction plant were compaction plates or/and smooth drum rollers with weights ranging from 200kg to 10t, respectively. A compaction plateau testing was commonly adopted to define the compactive effort.

- The structures constructed on the reinforced crust had to have a regular plan layout to provide even loads. Further, they had to have the ability to readily redistribute stresses if individual footing elements settled differentially to their adjacent neighbors.
- The geogrid reinforced gravel raft must continue beyond the building footprint, ideally 2m minimum, to ensure that liquefaction ejecta does not create a volumetric loss of soil directly below a foundation element. Where footing elements were close to a property boundary a geogrid reinforced gravel beam was designed to support a well reinforced concrete foundation edge beam. The beam is deeper than the raft and has more geogrid layers, potentially using higher strengths geogrids as well.
- All footing elements, whether strips, ground beams or individual pads, had to be well tied together to prevent differential lateral movement and provide base shear resistance during seismic shaking.

The provision of a 1,200mm thick triple reinforced (usually biaxial geogrid, but uniaxial geogrids laid crosswise can be also used) gravel raft met all the above conditions. The mandatory design checks were:

- Static bearing capacity of individual footing elements or the raft, using NZBC B1/VM4, (MBIE 2008) meeting NZBC limit state strength reduction factor requirements;
- Seismic bearing capacity (short term loading during an earthquake) and punching, assuming a non-liquefied crust over liquefied soils with residual liquefied soil strengths using a two-layer bearing capacity assessment, (Das 2014) and (Bowles 1996), while still meeting the NZBC limit state strength reduction factor requirements;
- Post-earthquake reconsolidation induced settlements using the 'Simplified Procedure' CPT liquefaction triggering assessment after (Boulanger & Idris 2014) in combination with reconsolidation settlement assessment after (Zhang *et al*. 2002) to assess deformation based demand. This is predicated on the raft extending at least 2m beyond the footing thus limiting any 'ejecta' based volumetric soil loss induced settlements;
- Potential for lateral spreading and lateral stretch below the building footprint by direct site observations of actual earthquake response, or published methods after (Zhang *et al*. 2004), (Youd *et al*. 2002), and the Newmark Sliding Block after (Bray & Travasarou 2007) which would require the provision of a slip surface at the base of the reinforced gravel raft.

5 CASE STUDIES

A 5,500m^2 new grocery store was designed and built in Ilam, western Christchurch on a site with moderate liquefaction susceptibility. The design of this relatively well braced building with a
Figure 2.   Typical layout using triple layer geogrid reinforced crust for moderately susceptible sites. Note: CIV = Clegg Impact Value, testing for insitu subgrade.

regular plan layout required some strengthening of the crust to achieve satisfactory static and seismic bearing. The supermarket was halfway completed when the 22 February 2011 earthquake hit. As expected, liquefaction of the subsoil and numerous ejecta (sand boils) were observed after the earthquake. However, there was no manifestation of the liquefaction ejecta from below the foundations or the partially completed reinforced crust. The partially completed structure exhibited no damage, despite shaking well in excess of SLS levels on site, (Mahoney & Kupec 2013).

A large residential development with 1,500 lots was constructed in Halswell, to southwest of Christchurch. About 10% of the residential area was capped to improve ground performance under ULS earthquake shaking. Geogrid reinforced gravel rafts with a 1.2m thickness were used, instead of the (MBIE 2015) recommend a 2m thick unreinforced crust, thus saving cost and construction time, while aiming for similar structural performance. Additionally, by capping multiple residential lots, as a continuous raft a significantly improved overall performance is expected as ejecta material from below the raft is not anticipated. Therefore, 'group' performance is expected to be better than that of an individually improved house site. A limitation of this approach is to provide sufficient space for residential services and allow for sufficient depth of looser topsoil for landscaping.

A two storey office building on 140 Montreal Street, Christchurch, was constructed with a quadruple layer of high stiffness biaxial geogrids. The site had a very poor ground, with the subgrade readily liquefying during initial compaction efforts. The geogrid reinforcements however confined the soil to such a degree that by second lift (300mm) the reinforced fill density increased to over 97% MDD (Modified Proctor).

A grocery store in Eastern Christchurch was extended and it used a modified multi geogrid layer system to provide support to the heavily loaded areas below precast concrete panels. The geogrid layered system also protected underfloor services as those are critical to post disaster functionality of the grocery store, where disruption following large and rare earthquakes is to be kept to a minimum.

The above examples are all on alluvial ground comprising interbedded lenses and layers of liquefiable soils and non-liquefiable soils. Soil structure interaction is essential and will dictate the overall building form, geometry, and bracing requirements. The structures are all well braced light weight sitting on a 'rigid' capping layer with the ability to employ secondary load paths under extreme earthquake loading.

6 REPAIRABILITY

Geogrid reinforced ground is particularly easy to repair following a large, rare earthquake event as it provides a stiff platform to relevel the foundation against. Mechanical jacking, grout or resin injections against the reinforced gravel raft, or compaction grouting below the reinforced gravel raft, are all considered viable options. Any relevelling voids below the foundations can be readily flooded with non-shrink grout to provide ongoing full support to the foundations. One key provision is that all services must be encased within the concrete foundations and are not to be routed through the reinforced gravel raft. Services need controlled exit points and flexible, or easily repairable connections.

7 CONCLUSIONS AND DISCUSSIONS

Geosynthetics are critical for the satisfactory performance of shallow spread foundations on a reinforced gravel raft. A geotextile separator should be used to separate geogrid reinforced high quality fill from the poor insitu ground. The insitu ground is often saturated due to high ground water table and compaction can be difficult to achieve. Where the ground is very soft and weaves under compaction, a ballast layer (coarse granular material) encased in a geotextile separator can be used as a capillary break and subgrade improvement layer.

Lateral spreading can create lateral stretching across the building footprint. While the geogrids will provide tensile restraint, preventing the reinforced crust to be pulled apart, a geomembrane

double layer below the geogrid reinforced raft will act as a slip surface. A heavier duty geotextile is recommended on either side of the double geomembrane to protect them from installation damage. The reinforced gravel raft needs to comprise well graded well compacted, granular materials with an appropriate particle size distribution to match the geogrid apertures. High stiffness biaxial geogrids are ideal, but uniaxial geogrids laid in two direction can be used. All past projects used products with a high modulus (stiffness) with a characteristic strength of 40kN/m (UTS) in both directions.

A 2m extension (skirt) beyond the building footprint on all sides is considered essential as it limits the potential for ejecta to flow out from under the building.

From a structural perspective footings need to be designed to span 4m and cantilever 2m over a corner to account for post earthquake reconsolidation settlement and cope with relevelling stresses. Waffle slabs, ribrafts, 300 to 350mm thick double reinforced rafts are all common foundations for residential buildings. While ground beams with thickenings where columns and shear walls are present are usually used for commercial and industrial structures. All footings are required to be well tied together and be able to compensate for differential deformations, i.e. do not have a brittle failure mode.

Service provisions need careful consideration, especially where they exit the structure. Flexible connections that are readily accessible are highly recommended. Services encased in the ribraft or ground beams must be installed at a grade that accounts for maximum differential settlement. Repairs and relevelling is possible using mechanical jacking, cementitious grout or resin injections between the concrete foundation element and the reinforced gravel raft; or resin and grout injections below the gravel raft (predrilling or percussive penetration of the injection lance through the reinforced gravel raft would be required).

Cost-effective method of road embankment foundation stabilization using basal reinforcement technique for Duqm roads project in Oman

P.V. Jayakrishnan & M.H. González
Maccaferri Middle East LLC, Dubai, UAE

ABSTRACT: The Duqm area in the Central Eastern Oman is located 600km southwest of Muscat, the capital city of Sultanate of Oman. Extensive developmental projects like seaport, airport, dry dock, oil refinery, crude oil storage terminals, infrastructure like roads, railway, bridges, factories, buildings, and residential villas etc. are under construction or on the anvil. The Duqm area is marked by the significant presence of 'soft sabkha' soil which drastically influences the construction of foundations for civil engineering structures in that area. Generally, soil having low undrained shear strength is often referred to as 'soft soil'. Construction of embankments on soft soil can be critical because they have low strength and high compressibility. Since such soils have low permeability, the failure happens at an undrained condition within a short period after the embankment construction. 'Sabkha' is an Arabic expression to describe a type of soft soil with high salt content and are characterized by low bearing capacity and low SPT values. Sabkha soils are widely distributed in the Arabian Peninsula. Generally, for sabkha soil having SPT value less than 5 in muddy conditions, the first and foremost conventional solution of ground improvement adopted by designers for road projects in the Middle East region is provision of stone columns below the road embankment for total depth of soft soil. High strength geosynthetic layers can be used as basal reinforcement for the construction of embankments over soft soils, satisfying the stability criteria laid by the international standards like BS 8006: 2016. Unidirectional high tensile strength geogrids like Paralink is well suited for basal reinforcement applications in Sabkha soil. Depending on the type and magnitude of expected settlement of foundation sabkha soil, this technique can be adopted replacing the conventional deep ground improvement solutions, for most of the cases. Through the case reference of basal reinforcement technique application for Duqm roads project in Oman, this paper briefly outlines the problems associated with the design and construction of embankments over soft sabkha soil commonly found in the Arabian Peninsula and the application of geosynthetic materials as basal reinforcement for stabilizing such embankments, avoiding time consuming and expensive deep ground improvement techniques generally adopted by the road designers.

1   INTRODUCTION

Duqm is a port town on the Arabian Sea, in central-eastern Oman (Figure 1). The scope of the project presented in this paper is construction of roads located at Duqm port, Al Wusta, Oman. The road starts from an existing intersection with National Road No.32 (Duqm-Mahoot Road) and goes towards Duqm Port and to the proposed liquid berths at the seaside. The project location is marked by the extensive presence of 'soft sabkha' soil which drastically influences the type of foundation for proposed road high embankments (Figure 2).

Figure 1. Physiography map of Arabian Peninsula with location of Duqm area.

Figure 2. View of the Duqm roads project location showing the extend of muddy sabkha soil.

Generally, soil having low undrained shear strength is often referred to as 'soft soil'. Construction of embankments on soft soil can be critical because they have low strength and high compressibility. Since such soils have low permeability (10^{-5} mm/sec - 10^{-8} mm/sec), failure happens at an undrained condition within a short period after the embankment construction. 'Sabkha' is an Arabic expression to describe a type of soft soil with high salt content and are characterized by low bearing capacity and low SPT values. Sabkha soils are widely distributed in the Arabian Peninsula. Generally, for sabkha soil having SPT value less than 5 in muddy conditions, the first and foremost conventional solution adopted by designers for road projects in the Middle East region is provision of stone columns below the road embankment for total depth of soft soil.

Reinforcing the base of the embankment with high strength geogrids is a cost effective and technically feasible solution of ground improvement instead of the traditional deep ground improvement solutions like stone column, vacuum consolidation, dynamic replacement etc. Geosynthetic reinforcement layers can be used for improving the stability of embankments over soft soil, which is governed mostly by the shearing resistance of the foundation and is mainly a problem of bearing capacity. The geosynthetic reinforcement may be placed at foundation level to prevent shear failure both in the embankment fill and in the foundation soil.

2 GEOTECHNICAL PROPERTIES OF SABKHA SOIL

Table 1 highlights the general physical characteristics of both sabkha types; namely muddy and sandy Sabkha (Julie *et al.* 1983). Clearly, muddy sabkha are the worst to construct a road embankment, and so is the case of majority of locations in Duqm roads project.

Table 1. Typical geotechnical properties of sabkha soil (Julie *et al.* 1983).

Properties	Muddy Sabkha	Sandy Sabkha
Percentage fines (%)	25 to 95	5 to 25
Salt content (%)	2 to 18	2 to 15
Water content (%)	25 to 90	4 to 40
In-situ density (KN/m3)	10 to 13.5	13 to 18.5

3 CONTRIBUTION OF BASAL REINFORCEMENT FOR EMBANKMENT STABILITY

The general failure mode of an unreinforced embankment is shown in Figure 3(a). By placing a stiff geosynthetic reinforcement layer at the embankment base as shown in Figure 3(b), improved safety factors can be achieved for the rotation, sliding, overall and foundation extrusion stability criteria. Figure 3(c) reveals the stress condition at the base of a reinforced and unreinforced embankment. Because of the presence of stiff geosynthetic reinforcement at the base of the embankment, the stress condition shall be "vertical and inward" against "vertical and outward" case for an unreinforced embankment. This "vertical and inward" stress condition contributes significantly to the stability of such basal embankments. Generally, the load in the reinforcement increases to a maximum during construction, and as the foundation consolidates, the reinforcement tension decreases. When the foundation soil has consolidated, it carries the entire embankment load and thereafter theoretically reinforcement is no longer required.

4 DESIGN GUIDELINES FROM BS 8006: 2016

BS 8006: 2016 (Code of practice for strengthened/reinforced soils and other fills) is a limit state code of practice which considers the ultimate limit states such as local stability, rotational stability, lateral sliding stability, foundation extrusion stability and overall stability and serviceability limit states.

4.1 *Local stability*

For local stability, the geometry of the embankment side slopes should meet the following.

$$\frac{H}{L_s} \leq \frac{\tan \phi'_{CV}}{f_{ms}} \tag{1}$$

where:

H is the height of the embankment

L_s is the horizontal length of the side slopes of the embankment

Φ'_{CV} is the large strain angle of friction of the embankment fill under effective stress conditions,

f_{ms} is the partial material factor applied to tan Φ'_{cv}
Figure 3. (a). General failure mode for an unreinforced embankment (b). Typical Details of a geosynthetic reinforced embankment (c) stress condition within a geosynthetic reinforced and unreinforced embankment.

4.2 Rotational stability

The rotational stability criteria may be analyzed by methods like slip surface analysis, plasticity solutions and finite difference techniques.

4.3 Lateral sliding stability

The basal reinforcement functions to resist the horizontal outward thrust of the embankment fill.

The load in the reinforcement is a maximum at the edge of the crest of the embankment. The reinforcement load is:

$$T_{ds} = 0.5K_aH(f_{fs}\gamma H + 2f_q w_s)$$ (2)

where:

Ka is the active earth pressure coefficient

f_{fs} is the partial factor for soil unit weight

γ is the unit weight of the embankment fill

f_q is the partial load factor for external applied loads

w_s is the external surcharge loading.

To generate the tensile load T_{ds} in the reinforcement, the embankment fill should not slide outward over the reinforcement. To prevent this horizontal sliding, the maximum reinforcement bond length, L_e should be, Figure 4:

$$L_e \geq \frac{0.5K_aH(f_{fs}\gamma H + 2f_qw_s)f_sf_n}{\gamma h \frac{a' \tan \phi'_{CV}}{f_{ms}}} \tag{3}$$

where:

f_s is the partial factor for reinforcement sliding resistance

h is the average height of the embankment fill above the reinforcement length Le

α' is the interaction coefficient relating the embankment fill/reinforcement bond angle to $\tan \Phi'_{CV}$
Figure 4.   Analysis of foundation extrusion stability.

4.4   Foundation extrusion stability

The geometry of the embankment induces outward shear stresses within the soft foundation soil.

Where the foundation soil is very soft and of limited depth the outward shear stresses may induce extrusion of the foundation. To prevent this extrusion, the minimum the side slope length of the embankment, L_s, has to be great enough to prevent mobilization of these outward shear stresses.

$$L_s \geq \frac{\left(f_{fs}\gamma_1 H + f_qw_s - \frac{4C_U}{f_{ms}}\right)z_C}{\frac{(1+\alpha'_{ab})C_U}{f_{ms}}} \tag{4}$$

where:

γ_1 is the unit weight of the fill

C_U is the undrained shear strength of the soft foundation layer

Z_C is the depth of the soft foundation layer

α'_{ab} is the interaction coefficient relating to the soil/reinforcement adherence to C_U

4.5 *Reinforcement strain*

The maximum allowable strain in the reinforcement max should be limited to ensure differential settlements do not occur at the surface of the embankment. The initial tensile strain in the reinforcement is needed to generate a tensile load. BS 8006: 2016 imposes a practical upper limit of 6 % strain. The long-term strain (due to creep) of the reinforcement should be kept to a minimum to ensure that long-term localized deformations do not occur at the surface of the embankment.

5 APPLICATION OF BASAL REINFORCEMENT TECHNIQUE IN THE PROJECT

Figure 5 shows the plan view of the road network (indicated in black colour thick lines) and drainage channels (indicated in light blue colour thick lines) planned in Duqm roads project. The roads are designed to be constructed on a 3m high embankment with 2H:1V side slopes. Drainage channels are planned alongside the road to prevent submergence of the road embankment in the event of a high tide flood.

Figure 5. Plan view of road network and drainage channels in Duqm roads project.

5.1 *Soil Investigation program and test results*

For the whole stretch of 8km length of Duqm road project, 21 number of trial pits and 5 number of bore holes were done as part of soil investigation. The investigation revealed the presence of 5m to 8m thick top layer of sabkha soil followed by medium dense sand; in most of the bore holes and trial pits. On an average basis, the SPT value were less than 5 and CPT values were less than 2MPa, with water table at existing ground level.

5.2 *Ground improvement options considered in initial design*

Constructing the planned road embankments over the sabkha soil without any improvements has the following technical disadvantages.

– The sabkha soil had a very limited bearing capacity that would result in foundation extrusion failure, especially along the embankment edges.

– The embankment would experience significant normal and differential settlements affecting the serviceability of the road and the traffic above it.
– The embankment would undergo rotational shear failure, especially along the embankment edges.

    Accordingly, the enhancements expected on the road embankment from the final ground improvement solution were the following.

– Improved factor of safety for bearing capacity failure / extrusion failure.
– Improved rotational stability of embankment.
– Improved lateral sliding stability.
– Improved load transfer and reduced differential settlements.

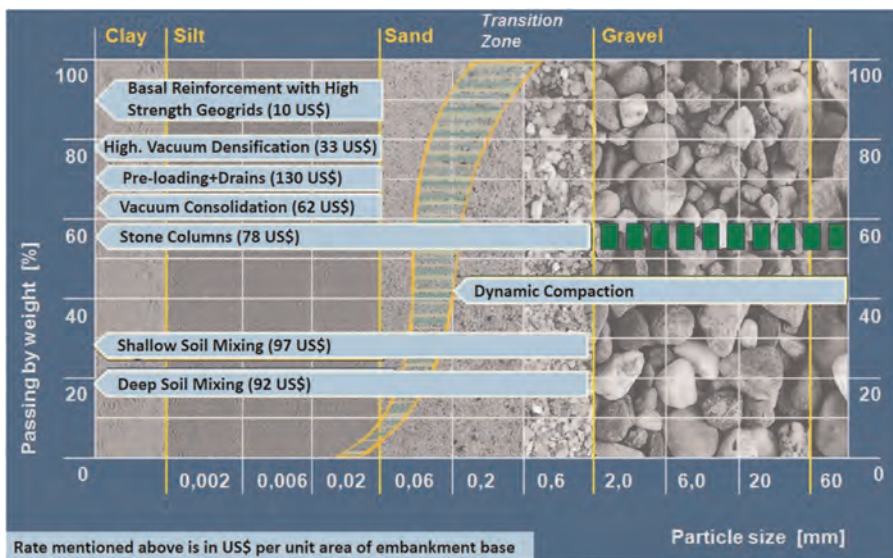
A wide range of ground improvement methods were explored by the designer by consulting the specialized subcontractors in each field, including the initially preferred method of deep ground improvement through stone columns. Accordingly, the final technical & financial recommendations and project specifications were prepared. Figure 6 below gives the summary of the various ground improvement methods considered by the designer versus their corresponding cost in terms of rate per unit area of road embankment base. For obvious reasons, the finally chosen and specified ground improvement solution was basal reinforcement technique which was significantly economical and faster in construction in comparison to the stone columns method.


Figure 6. Summary of various ground improvement methods versus rate per unit area of road embankment base.

5.3 Final design details of basal reinforcement option

One of the most important geotechnical parameters of foundation soft soil needed in basal reinforcement design is the undrained cohesion (C_U) value. Initially, in the absence of direct Cu value of Duqm sabkha soil from lab testing, it had to be conservatively interpreted from available SPT and CPT test results.

    From the available SPT values of bore holes, the corresponding average N_{60} (SPT value corrected for field procedure) was calculated which was eventually used to interpret the Cu value based on the correlation in Figure 7 between Cu and N_{60} with reference to the
Figure 7.   Correlation between N_{60} value and C_u (after Stroud 1974).

measured plasticity index of the Duqm Sabkha soil. To determine the Cu value based on the CPT values from the available 21 trial pits, the below correlation was used.

$$C_u = q_{c.av} - \sigma_v / N_k$$

where,

C_u = Undrained cohesion (KPa)

$q_{c.av}$ = Average CPT value (KPa)

N_k = Empirical cone factor (conservatively considered as 25 for the weak sabkha in Duqm)

Based on the BS 8006:2016 design guidelines explained in section 4 of this paper, the basal reinforcement design was done to find out the strength of geogrid and bond length with reference to various categories of sabkha soil identified at Duqm roads project site. Accordingly, a high strength geogrid type ParaLink 300 with 300KN/m strength was required where C_u value was more than 10KPa while a 400KN/m type Paralink 400 was required wherever the C_u value was less than 10KPa. Refer Figure 8 for the typical details of the final adopted basal reinforcement application in Duqm roads project vs the initial consideration of ground improvement by stone columns.
Figure 8.   Stone columns option in first design Vs finally adopted basal reinforcement technique.

Ninety percent of the total calculated consolidation settlement of 425mm was expected to happen during construction period itself before laying the final pavement layers. To realize

this assumption at site practically, staged construction of embankment (with incremental loading) in 3 layers were recommended such that the excess pore water pressure developed would be fully or partially dissipated and shear strength gain achieved with every increment and the safety factor against shear failure increases (refer Figure 9 for details). The dissipation of excess pore water pressure is accompanied with settlement, so an additional ground improvement is achieved. This is a kind of preloading using the same engineering loads proposed for the construction with controlled rate such that the shear strength and stiffness of the soil is improved and the final settlements after the embankment construction would be tolerated.
Figure 9.   Scheme of staged construction of embankment with incremental loading.
Figure 10.   Stages of basal reinforcement installation.

Figure 11.   Roads completed in Duqm on basal reinforced embankments.

6   CONCLUSIONS

Very low bearing capacity muddy sabkha soils are often found around the coasts of the Middle Eastern Peninsula. New stabilization methodologies are currently available to construct infrastructural works on these sabkha soils. A very cost-effective way of stabilization is the use of geosynthetics. High strength geosynthetic layers can be used as basal reinforcement for the construction of embankments over soft soils, satisfying the stability criteria laid by the international standards like BS 8006: 2016 Unidirectional high tensile strength geogrids like Paralink is well suited for basal reinforcement applications in Sabkha soil. Depending on the type and magnitude of expected settlement of foundation sabkha soil, this technique can be adopted replacing the conventional deep ground improvement solutions for majority of the cases.

The reference of basal reinforcement technique application for Duqm roads project in Oman clearly throws light to understand the problems associated with the design and construction of embankments over soft sabkha soil which is commonly found in the Arabian Peninsula, and how the application of geosynthetic materials as basal reinforcement for stabilizing such embankments can be successfully adopted, avoiding time consuming and expensive deep ground improvement techniques which generally adopted by the road designers.

Settlements of a heterogeneous soil deposit improved with geosynthetic vertical drains

G. Di Filippo, O. Casablanca, E. Cascone & G. Biondi
University of Messina, Messina, Italy

ABSTRACT: The soil improvement through the technique of preloading associated with vertical drains was used to accelerate the consolidation process and reduce the post-construction settlements of the foundation soil of two cylindrical oil tanks founded on alluvial deposit. A summary of the work sequence is provided together with the main aspects of site investigation and geotechnical characterization. An extensive field monitoring of the site was carried out during the embankment construction, the preloading period and, after the embankment removal, during the hydraulic leakage test of the tanks. Differential settlements and angular distortions of the tank foundation evaluated from the measured settlement profiles were compared with expected profile shapes for tanks overlying homogeneous compressible soil layers. Observed absolute and differential settlements and distortions are consistent with the allowable limits provided by the literature and with the design prescriptions, thus confirming the effectiveness of the preloading and drainage technique adopted in the project.

1 INTRODUCTION

The use of geosynthetic vertical drains combined with pre-loading is a cost-effective ground improvement technique widely adopted to improve the bearing capacity and settlement response of fine-grained soft soil deposits. If the design procedure aims to keep settlements within allowable limits in a given time-interval, a proper choice of the in-plane water flow capacity and discharge capacity of the geosynthetic drains as well as their length and spacing is required. To this purpose well known design procedures, generally referred to the case of a homogeneous soil deposit, are widely adopted together with the observational method.

This paper focuses on the latter approach and describes the results of an almost two-year long monitoring period of the settlement performance of the foundation soils of two tanks founded on a heterogeneous fine-grained soil deposit improved using 97-mm-wide and 3-mm-thick wick drains, consisting of a three-dimensional porous polyester filament core protected from clogging by a nonwoven polyester filter.

The whole set of settlement measurements, obtained through topographic survey of settlement platforms, are presented, and discussed in the paper. The application of well-established observational method and a back analysis of the settlement measurements allowed showing the relevant role of the lithological and mechanical heterogeneity of the foundation soils. These led to a scattering in the measured settlements in a portion of the preloaded area, and, for the case at hand, pointed out the minor relevance of the smear effect on the rate of consolidation.

2 SITE GEOTECHNICAL CHARACTERIZATION

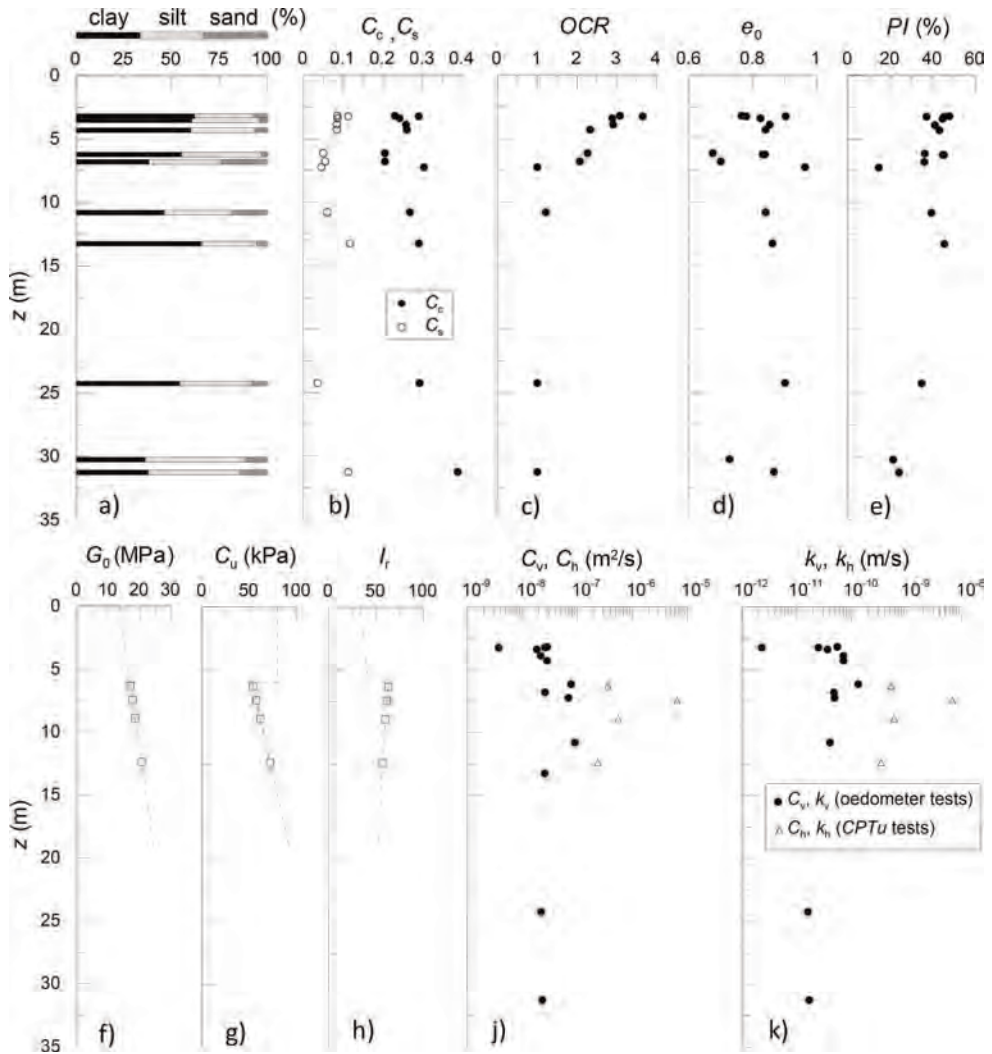
The dataset of measurements consists of the settlement induced by preloading and 20 m long prefabricated vertical drains on a heterogeneous, medium to stiff clayey and silty soil deposit, representing the foundation soils of two large steel tanks and incorporating randomly distributed discontinuous layers of granular soils (Figure 1). Figure 1a shows the longitudinal cross-section of the site with the profile of the pre-loading embankments superimposed to the soil profile and to the profiles of tip resistance q_c and excess pore water pressure u, as obtained from *CPT* and *CPT*u tests. The soil deposit was investigated through boreholes (*BH*), cone penetration tests (*CPT*), piezocone tests (*CPT*u) and laboratory tests on undisturbed samples: it consists of an about 27 m thick layer of high plasticity clay with
Figure 1. a) Longitudinal cross-section of the site; b) plan view of the preloading embankment, location of the geotechnical investigations and of settlement platforms (adapted from Di Filippo *et al.* 2017 and Cascone & Biondi 2013).


Figure 2. a) Grain size profile; b-d) oedometer test results; e) plasticity index profile; f-h) Profiles of G_0, C_u and I_r and values (square dots) adopted for the evaluation of the horizontal consolidation coefficient C_h; j-k) permeability and coefficients of consolidation obtained by oedometer and CPTu test results.

sandy silt ($L1$, $L2$ and $L4$ in Figure 1a), which is lightly over consolidated in the upper portion, embodies discontinuous and randomly distributed (1 m thick) layers of sand ($L3$ in Figure 1a) at a depth of about $z = 20$–22 m, and overlies a silt with sandy clay layer ($L6$ in Figure 1a), extending to the maximum investigated depth of 40 m, with the interposition of a thin (less than 1 m) layer of silty sand ($L5$ in Figure 1a) located at a depth of about $z = 27$–28 m. The water table was detected at a depth of 3 m from the original ground surface.

The development of settlements was monitored measuring, by topographic survey, the vertical displacements of 20 settlement platforms.

These consisted of square steel plates welded to the base of steel riser pipes. The riser pipes were covered with sleeve pipes to prevent the transmission of the down-drag forces induced

by embankment settlements to the plates. The settlement platforms were placed on the natural soil under the drainage blanket. The location of the platforms (SP) is shown in the plan view of Figure 1b.

Figure 2 shows the grain size profile, the oedometer test results and the profile of the plasticity index *PI*. The soil deposit is mainly made of clay and silt, the former prevailing in the upper part of the deposit, the latter at depth $z > 30$ m; the sand fraction varies between 1% and 24%, being generally less than 10% (Figure 2a). The compression index C_c ranges between 0.205 and 0.388 and the ratio of C_s to C_c varies in the interval 0.12–0.40 (Figure 2b); the soil deposit is lightly overconsolidated in the upper 10 m (Figure 2c) with a void ratio e_o approximately ranging between 0.65 and 0.97 (Figure 2d) and *PI* generally greater than 30% (Figure 2e).

Four dissipation tests were performed during the *CPTU*1 (at the depths $z = 8.90$ and 13.38 m) and *CPTU*2 (at $z = 6.32$ and 7.44 m) and values of the horizontal consolidation coefficient C_h were obtained through the procedures suggested by Houlsby & Teh (1988) and by Teh (1987).

For the four depths of interest for the dissipation tests, Cascone & Biondi (2013) computed values of I_r in the range 57–62 (Figure 2h, Table 1) and values of C_h in the narrow interval $(2.39 \div 5.56) \cdot 10^{-7}$ m²/s (Figure 2j, Table 1). An exception is represented by the test at $z = 7.44$ m, probably referred to a sand layer Cascone & Biondi (2013), leading to a larger value ($C_h = 6.70 \cdot 10^{-6}$ m²/s) which was not considered in the analyses described in this paper. In Figure 2j the values of the vertical consolidation coefficient C_v, obtained from oedometer test results and referred to a vertical effective stress $\sigma'_v = 200$ kPa, are also represented, showing values generally larger than $2 \cdot 10^{-8}$ m²/s in the upper 15 m of the soil deposit. Herein, the value $C_v = 6.9 \cdot 10^{-8}$ m²/s, determined on a sample retrieved from BH7 located at the center of the preloaded area, was considered since it is representative for the depth interval investigated through the dissipation tests ($z = 6.32 \div 12.38$ m).

Finally, the theory by Baligh & Levadoux (1980) was applied to compute the values of the horizontal permeability coefficient k_h. The obtained results are plotted in Figure 2k together with the interpretation of oedometer tests in terms of the coefficient of vertical permeability k_v referred to a vertical effective stress $\sigma'_v = 200$ kPa. In the upper 15 m of the soil deposit k_v and k_h vary in the range $(2 \div 11) \cdot 10^{-11}$ and $(3 \div 6) \cdot 10^{-10}$ m/s, respectively.

3 PVDS AND WORK SEQUENCE

In the area where the tanks had to be constructed the ground surface was excavated to a depth of about 0.7 m and 20-m-long prefabricated vertical drains (PVDs) were installed in a triangular pattern, with a spacing of sd = 1.5 m. PVDs were 97-mm-wide and 3-mm-thick

wick drains, consisting of a three-dimensional porous polyester filament core protected from clogging by a nonwoven polyester filter. The equivalent diameter dw and the cross-section Aw of the drain are dw = 63.66 mm and Aw = 3183 mm2. According to the manufacturer the in-plane water flow capacity of the composite drain under a i = 0.1 hydraulic gradient is about 1600 and 2500 m3/year for values of the pressure applied to both filter sides of 200 and 300 kPa respectively; the drain discharge capacity qw for i = 0.1 and r = 300 kPa is greater than 4000 m3/year ($\approx$1.27·10-4 m3/s); the corresponding value of the equivalent drain permeability is kw > 0.4 m/s.

Figure 3 summarizes the work sequence, the duration of the work phases and the corresponding loading history with reference to the beginning of the construction of the preloading embankments, assumed as a datum (t = 0). The main (H = 9.2 m) preloading embankment was built in 98 days with an increase of the rate of loading after the first 66 days.
Figure 3.   Work sequence.

The embankment was kept in place for further 186 days (until t = 284 days); the net average pressure applied on the ground surface of the preloaded area was about 174 kPa. The net average pressure applied by the smaller (H = 5.2 m) embankment was about 98 kPa.

At t = 144 days water was observed flowing out of the drainage system. This delay in the achievement of PVDs full effectiveness may be ascribed to the effect of drain unsaturation (Indraratna *et al.* 2003). During the preloading period settlements under the 9.2 m high embankment developed to a maximum of about 39 cm and, as soon as deformation rate became negligible, both the preloading embankments were removed in 21 days (t = 305 days) leaving in place the tank foundation embankment.

Then the site was prepared for the construction of the RC foundation rings and of the steel structures of the tanks, corresponding to the application of a net average pressure of about 80 kPa (including the selected fill foundation embankment). The tank construction ended at t = 455 days. The hydraulic leakage test at t = 605 days for tank No. 1 and at t = 621 days for tank No. 2. Tank No. 1 was filled of water in 24 days, was kept full for 22 days and was finally emptied in 13 days.

Tank No. 2 was filled of water in 10 days, was kept full for 35 days and was emptied in 12 days. The volume of water stored in each tank during the tests was about 4000 m^3, loading the foundation soil with an additional average pressure of about 143 kPa.

4 MONITORING DURING THE HYDRAULIC LEAKAGE TESTS

The field monitoring of the site was carried out also during the hydraulic leakage tests of the two tanks. The settlements of the tanks were measured using a level probe along a flexible pipe placed in a shallow excavation under each tank before construction, in the direction of the transversal axes of the main pre-loading embankment. Measurements were taken every 2-3 days at five aligned locations under the tanks: at the edges under the foundation ring, at 1/4 and 3/4 of the diameter and at the centre of the tanks.

Figure 4 shows the settlement profiles under the tanks at different times during the tests. All the data show that both tank foundations exhibit the classical dish-shaped settlement profile with larger values near the centre and settlements that decrease smoothly toward the edges. Specifically, maximum settlements under the centre of the tanks are about 6 cm for tank No. 1 (Figure 4a) and about 7.5 cm for tank No. 2 (Figure 4b).

At the edges of the two tanks the observed settlement variation, due to filling and emptying, resulted always less than 3 cm, consistently with the prescribed design limit. This behavior confirmed the effectiveness of the soil improvement technique adopted at the site and allows predicting a satisfactory performance of the tank under future service conditions when oil will be stored instead of water.

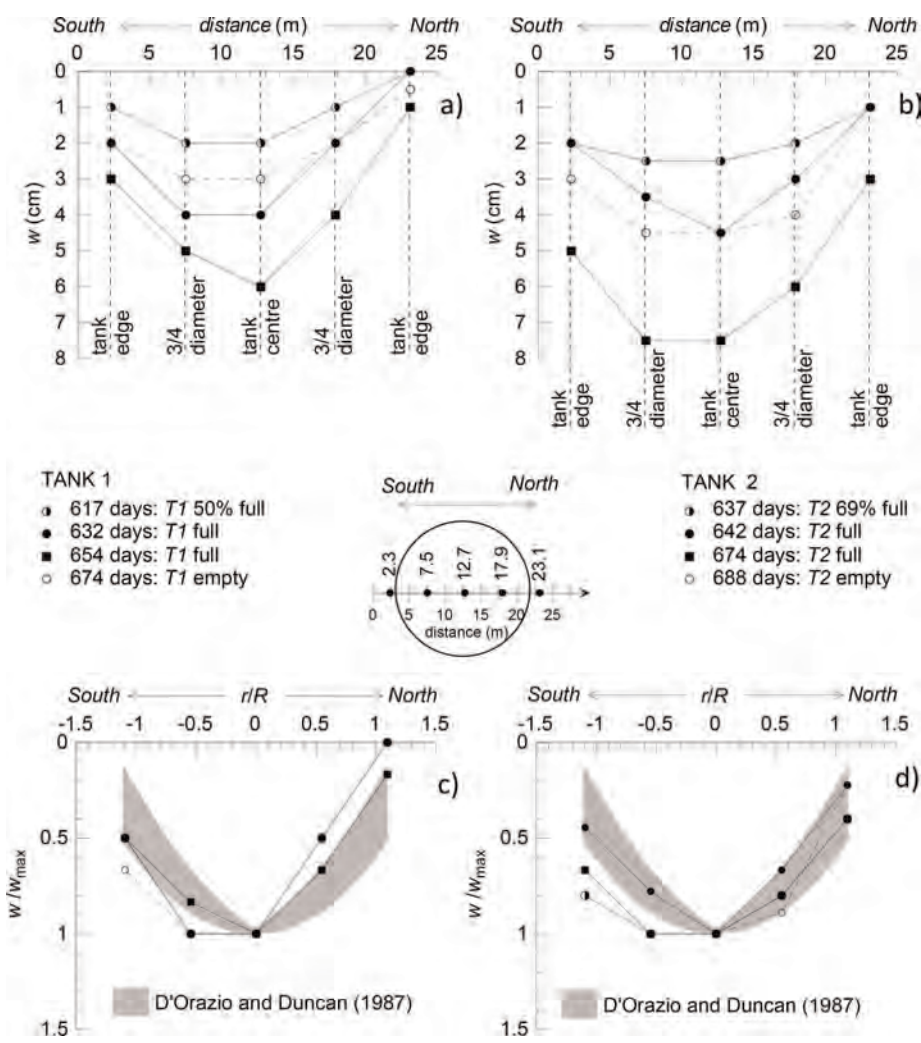
According to D'Orazio & Duncan (1987) the main factors affecting the shape of the settlement profile for the foundations of tanks resting on compressible homogeneous soil deposits are the values of the factor of safety F_s with respect to undrained shear failure of the foundation soils and the geometric ratio D_e/t_c , between the effective diameter of the tank (i.e. the actual tank diameter D plus the thickness t_g of the granular layers between the base of the tank and the top of the underlying compressible soil layers), and the thickness of the compressible soil deposit beneath the tank. Specifically, as observed by D'Orazio & Duncan (1987), through the analysis of a large amount of data available in the literature, a dish-shaped settlement profile of the tank bottom typically occurs when $D_e/t_c < 4$ and $F_s > 1.1$. For the two tanks under consideration both these conditions are verified. In Figure 4 it can also be observed that, despite the symmetry in the tank structures and in the applied load, the measured settlement profiles along the transversal section of the tanks are not symmetric. Again, a stiffer response of the northern area of the tank foundation was observed and can be reasonably attributed to the lithological and mechanical heterogeneity of the alluvial deposit values of the rigid rotation a_o ranging from 0.5 to 1% can be estimated from the settlement profiles of Figure 4.


Figure 4. Settlement and normalized settlement profiles during the hydraulic test of tank No. 1 (a, c) and No. 2 (b, d).

The effect of soil heterogeneity on settlement response becomes apparent by comparing the profiles of measured settlements with the profile shapes suggested by D'Orazio & Duncan (1987) for tanks overlying homogeneous soil deposits.

To this purpose the measured profiles (Figure 4a,b) are plotted in Figures 4c,d in a normalized diagram where the settlement w and the radial distance r are divided by the settlement w_{max}, measured at the centre of the tank, and by the tank radius R, respectively. The shaded area in Figures 4c,d represents the range of variation of the ideal shape profiles defined by D'Orazio & Duncan (1987) for the case $F_s > 1.1$ and $D_e/t_c < 4$. The normalized settlement profiles under tank No. 2 satisfactorily match the range of ideal profiles, especially for the northern side of the foundation that exhibited a stiffer response. A fair agreement is also observed between the normalized profiles obtained under tank No. 1 and the ranges provided by D'Orazio & Duncan (1987).

5 CONCLUSIONS

In this paper the field performance of the foundation soil of two tanks, improved using the technique of preloading associated with vertical drains, was illustrated. Due to soil compressibility and large stresses acting under service condition, settlements of the tank foundations larger than the maximum displacement that could be accommodated by the joints between the tanks and piping could be anticipated. It was then decided to induce soil consolidation by preloading the area and to accelerate the process by installing prefabricated 20 m long vertical drains.

After the embankment removal the tanks were built and tested to verify their hydraulic tightness.

Data of the observed behavior during the preloading period and the hydraulic leakage tests of the tanks were collected during an almost two-year long monitoring period. Maximum settlements measured during the preloading period were of about 39 cm and were approximately uniform under the longitudinal axis of the preloading embankment. Conversely, asymmetric settlement profiles were observed along the three monitored transversal axes of the preloading embankment. This behavior was ascribed to the lithological and mechanical heterogeneity of the alluvial soil deposit. A delay in the achievement of *PVD*s full effectiveness was observed during the monitoring period and was ascribed to the presence of an unsaturated interface between the drain and the soil induced by drain installation.

During the hydraulic tests the maximum absolute settlements were attained under the centre of the tanks and were in the range 6-7.5 cm; differential settlements between tank centre and edges in the range 3-5 cm were measured. Consistently with the prescribed design limit, at the edges of the two tanks settlement variation, due to filling and emptying, was less than 3 cm. Differential settlements and angular distortions evaluated from the measured settlement profiles were compared with expected profile shapes for tanks overlying homogeneous compressible soil layers. A general fair agreement was observed even if the heterogeneity of the soil deposit affects the tank response.

Absolute and differential settlements as well as angular distortions are consistent with the allowable limits suggested in the literature and with the design prescriptions, thus confirming the effectiveness of the pre-loading and drainage technique adopted in the project and envisaging a satisfactory performance of the tank under service conditions.

ABSTRACT: The Paper presents a case study demonstrating the use of geocells to replace concrete approach slabs and reinforce transition at railway bridge approaches. The objective is to study the effect of geocell system to enhance the train speeds up to 160 kmph on the Bombay - Delhi railway route.

Geocell layers of differential lengths were installed over the blanket layer on the existing track to ensure a smooth transition. Field observations confirmed that the geocell layers were successful in ensuring a smooth transition of bridge approaches. Further, the geocell layers proved that by avoiding the conventional concrete slab, there is considerable saving in capital costs and construction time. The proposed cross-section of the bridge transition system also minimizes differential settlements and imposed bearing pressures on the subgrade soil. With this system, the maintenance cycle is extended which not only reduces downtime but also the life cycle costs.

Keywords: Railway transition, HDPE geocells, bridge approaches, nonwoven geotextiles, load spread

1 THE OBJECTIVE

Differential settlements between the railway embankment and the bridge structure, often supported on well or pile foundations, are some of the major issues that limit the intended train speeds. This issue required a solution with ambitious plans on the anvil to increase the speed limits and hike up the axle load to 32.5 Tons from 25 Tons. Differential settlements at the structure-embankment transitions manifest as rough running at bridge approaches. This also causes increased wear and tear of track, stock wheels and bearings.

*Corresponding Authors: shahrokh.bagli@strataindia.com, gopalkr@faculty.iitm.ac.in, mmanjul@hotmail.com, edgerdso2019@gmail.com, yashodeep.patil@strataindia.com, suraj.vedpathak@strataindia.com and gautam.dalmia@strataindia.com

To ensure a smooth ride, an appropriate transition system is needed which provides a gradual change in the "spring stiffness" or deflection characteristics of the track bed from the earth embankment to the more rigid bridge structure. The proposed system should bridge over the differential settlements between the two structures. It would also help in spreading the track load over a wider area below the ballast and reduce the deformation of the embankment fill at entry and exit of the bridge.

While devising a solution, it was assumed that the subgrade of the embankment had achieved 90% consolidation and deflections below the subgrade are negligible. This assumption is quite valid for embankments that have been constructed several decades ago and well maintained according to Railway routine guidelines and true to the Indian Railway protocols and traditions.

2 THE SOLUTION

The Western Railway (WR) proposed using a system essentially comprising layers of geocells to considerably improve the rigidity of the sub-ballast/formation and reduce deformations of the track surface/formation and maintain the track geometry at the bridge approaches. Hence geotechnically at the approaches, there would be three sections progressively increasing in rigidity:

1. the flexible embankment formation,
2. the more rigid section with layers of geocells in the sub-ballast (to safely connect the flexible formation and rigid bridge structure),
3. the rigid bridge structure.

Before adopting the proposed system on a major scale, it was decided to carry out monitored trials on the busy and high-speed Bombay-Baroda route of the Western Railway near Surat. It is significant to note that the proposal does away with the conventional concrete approach slab. The conventional concrete approach slab treatment requires a track downtime of about 24 hours while the treatment with geocell layers can be completed within about 5 hours. As per Ministry of Railways/RDSO Guidelines, approach slabs are to be provided on both bridge entry and exit approaches of unballasted bridge deck with spans of 12.2 m or more. One end of the approach slab is supported on the bridge abutment and the other end rests on the formation. The approach slab should be minimum 4 m long and should be of reinforced concrete.

However, the conventional style for approaches has the following limitations:

1. Non-uniform settlements of the slab with movement of the track that it supports. The track movement is due to several reasons including climatic variations, temperature variations over 24 hours and traction forces due to rolling friction, rocking, acceleration, and braking.
2. Quite often, the approach slab is damaged prematurely and is not replaced in time owing to voluminous work involved, adherence to maintenance schedules, etc.

The WR desired to strengthen the bridge approaches to cater to an increased speed of 160 kmph on the prime Mumbai-Delhi trunk route. The Railway engineers desired to consider the use of geocell layers to overcome the limitations of the conventional concrete approach slab and enhance the performance.

3 LOCATION OF THE TRIALS

To save on downtime, a bridge without the concrete approach slabs was chosen. The bridge designated Major Br No. 417 across Mindhola River near Lajpore Village was selected. The

bridge has thirteen 18.3 m long plate girder spans. The concrete approach slabs of this bridge were not yet placed, pending proposed major maintenance. Hence the approaches of this bridge were deemed ideal for trials with geocell layers in lieu of the concrete approaches.

Figures 1 and 2 shows a satellite imagery and close up of the bridge location with respect to its environs.

Figure 1.   Google satellite imagery of bridge 417.

Figure 2.   Close-up of the location within the rectangle.

4   ORGANIZING THE TRIALS

Two trial stretches were taken up at the bridge, on March 02, 2021 and March 16, 2021, respectively. The first trial stretch was taken up on the Up line (for South bound traffic towards Mumbai) at the North end. The second trial section was taken up on the same track at the South end of the Bridge.

5   PROPOSED TRANSITION SYSTEM AT THE APPROACHES

The trials were carried out with three layers of geocells having depth of 150 mm and weld spacing of 356 mm according to analysis and design recommended by IIT Madras. The proposed system was developed after carefully performing 3-dimensional computer based numerical model studies. The infill material is as per G-14 specifications of the Indian Railways. A nonwoven geotextile separator layer was placed below the three-layer geocell system to prevent penetration and loss of aggregates from geocell pockets and to also act as a drainage layer to some extent. The transition system with geocells is shown in Figure 3.
Figure 3.   Section for trials.

6   TRIAL PRE-REQUISITES AND PRE-BLOCK ACTIVITIES

Traffic on the Southbound Up Line was required to be blocked for adequate time to carry out the work safely and to conform to the strict Indian Railway quality parameters. Block on the

track could only be secured over a limited time, owing to heavy traffic on one of the country's busiest trunk routes. A block period of only 4 hours and 30 minutes was allocated to carry out the entire set of activities for the installation of the system at each trial stretch respectively.

7 PRE-BLOCK ACTIVITIES

Considering the strict and limited time allocated for the work during the block and the limited work-space constraints on the embankment, the execution of activities during the block was required to be well-planned, coordinated and concerted. Hence prior to the commencement of the block, preparations were made to keep in readiness to commence work sequentially on the set of activities for timely and quality installation, under the space and time constraints. Activities prior to the respective blocks are shown in Figures 4–9 with traffic plying with a speed limit of 20 kmph. The work on first stretch commenced on March 02, 2021, as scheduled. To ensure that all activities are completed within the allocated traffic and power block time ($4\frac{1}{2}$ hours), timings were allocated to each activity. This was also a Time Study exercise of sorts as basis for time allocation for similar works on other bridge approaches in the future.

8 CONSTRUCTION SEQUENCE

The construction sequence during the block was as follows:

1. The tracks were dismantled by removing the rails and sleepers (Figures 4 and 5). The formation including ballast was excavated up to 1400 mm below the rail level (Figures 6 and 7) Soil was excavated to reach 700 mm depth of formation over the 20 m length and 5 m width. The excavated area was levelled and compacted prior to laying nonwoven geotextile separator layer (Figure 8). Nonwoven geotextile was placed over the entire excavated stretch (Figure 9). Overlap of geotextiles at edges were a minimum of 300 mm.
2. Blanket material was placed over the nonwoven geotextile, watered and hand-tamped to 100 mm thickness. The procedure is shown in Figures 10 and 11. A timber template was used to ensure that compacted thickness of 100 mm was achieved.

Figure 8. Checking the excavation level.

Figure 9. Laying the nonwoven geotextile.

Figure 10. Infilling 100mm thick blanket layer.

Figure 11. Compaction with manual hand tamper.

3. The bottom-most layer of geocell (weld spacing 356 mm and 150 mm depth) was placed. The dimensions of this layer were 10 m length × 5 m width. The layer was placed on top of the 100 mm thick compacted blanket. The geocell layer was held in expanded position by temporary steel hooked stakes. The stakes maintained the expanded panels before infilling and kept them in position. The stakes also ensured that the cells were not distorted and maintained their dimensional integrity. The blanket material was infilled within the geocell pockets with a backhoe and spread manually with shovels. The infilled material was watered and compacted with a hand tamper to achieve the required compaction. The infilling of the geocell panel was done to 25 mm above the brim of the geocell as a cushioning layer to prevent damage to the brim of the geocells. The final compacted thickness of this layer was maintained as 175 mm. This procedure is shown in Figures 12, 13 and 14.

Figure 12.   Bottom-most geocell layer.

Figure 13.   Infilling the geocells.

Figure 14.   Watering and compaction of infill.

4. The middle layer of geocell (also weld spacing 356 mm and 150 mm depth) was placed, with expanded overall dimensions 15 m length × 5 m width. This layer was placed on top of the bottom-most layer of infilled geocells (overfilled by 25mm). Placing infill, spreading, and compaction were carried out similar to the procedure for the bottom-most geocell layer.
5. The topmost geocell layer (also weld spacing 356 mm and 150 mm depth) was similarly placed. The expanded dimensions of this layer are 20 m length × 5 m width. The infill material was placed, spread, and compacted after watering, similar to the lower two geocell layers.
6. The 100 mm thick compacted blanket layer was provided over the uppermost geocell layer. Ballast was laid over the blanket, Figure 15. Sleepers were placed back into position after laying and spreading the required thickness of ballast as shown in Figure 16. Rails were placed back in position on the sleepers manually by sliding on rollers. Rail rubber pads were placed between the steel rails and the concrete sleepers. After placing rail rubber pads, adjacent rails were joined together by fish plates (rail joint bars or splice bars), as seen in Figure 17.
7. Rail clips were clamped to the sleepers to ensure proper fastening between sleeper and steel rail, and maintain the alignment of the rail which can go out of alignment due to any

Figure 15.   Laying ballast over the blanket layer.

Figure 16.   Placing sleepers over ballast.

Figure 17.   Placing rail fish plates; left picture shows stiffening fishplate.

movement, bending, warping etc. Once the fastening systems were in place, rail alignment was checked using a Track Gauge and superelevation measuring device. After the alignments were checked to satisfaction, the sides of the sleepers were packed with ballast. Compaction of the ballast was further carried out by the "Dynamic Tamping Express" (Figure 18) which compacts the ballast by impacting.

8. After the required compaction by Dynamic Tamping Express machine, the track was opened for movement of passenger express trains and cargo freighters on March 02, 2021, itself. Initially, the speeds were restricted to 20 kmph. Figure 19 shows the first passenger train on the geocell reinforced approach. The completed and operational track surface provided smooth movement of train traffic over the bridge - approach transition (Figure 20). Two weeks after opening to traffic, on March 16, 2021, the track was monitored visually. It was noted that there was no deflection nor change in track geometry/alignment. The second trial stretch was taken up on the South approach of the bridge of the same Up track on March 16, 2021. Both the trial approaches were completed as scheduled within the stipulated shut down periods.

9   POST STRENGTHENING TRACK PARAMETERS - PERFORMANCE MONITORING AND EVALUATION

The Western Railway has monitored the performance of the trial approaches as part of routine inspection and maintenance. The monitoring is generally done as follows:

1. Periodical level/deflection measurement with progressive increase in speed of trains every month, starting with the initial speed limit of 20 kmph and progressively increasing by 20 kmph to the maximum speed of 160 kmph.
2. Periodically monitor and evaluate Track Geometry Index (TGI), using track recording machine (usually done twice/thrice a year).

On an immediate basis, following successful completion of work, the speed limit caution of 20 kmph was relaxed to normal after 3 rounds of tamping on April 3 and 28, 2021. Thereafter, track parameters were recorded periodically in duration of few months.

Considering the magnitude of quality parameter readings, the Western Railway concluded that there was no deterioration in track, even after a period of more than one and half years of traffic. In addition to recording the track parameters, frequent inspections were carried out. The transition system at the Bridge approaches was found to provide smooth transition for high speed trains.

Figures 21–23 shows the observation for the different stations over periodical measurement on South approach. Similar measurements were noticed on North approach also. All the measurements were within the tolerable limits as per the railway guidelines. The geocell

Figure 23.   Periodical measurement of cross levels at different stations.

layers at bridge approaches showed substantial reduction in differential settlements by virtue of spreading the load uniformly over the entire area. Further initial inspection (Table 2) and periodical Track Recording Car (TRC) and Oscillation Monitoring System (OMS) runs were carried out on the stretch and presented in detail in Tables 3 and 4 respectively. With the results of track parameters monitored continuously and with consistently good results of TRC runs and OMS runs, it can be concluded that the proposed transition system is quite effective in overcoming the problem of rough running on bridge approaches.

10 CONCLUSION

Ever since the bridge approaches were reinforced with geocell layers, the Western Railway has carried out at least two OMS runs. No peak has been observed at the approaches. Considering passenger comfort reactions and reports from locomotive motormen, the transitions are found to be smooth without the customary jerks even at high speeds. The system, being practically workable, can be adopted especially in the case of doubling and in cases where sections are likely to run higher axle loads or at higher speeds. The system can be adopted for both ballasted and non-ballasted bridges having problems of rough running on approaches. It is therefore concluded that the trials of strengthening the approaches were successful. Based on this successful trial, the Research, Designs & Standards Organization

(RDSO) of the Ministry of Railways of the Government of India has published *"Transition System on Approaches of Bridges"*, Report No. GE: R-50 (Revision 1) in July 2021.

E. Tamaro
Harpo spa, Italy

ABSTRACT: A smart solution for covering waste storage facilities is described. It allows vegetated covers for full environmental integration while optimizing the storage volume of the landfill for a given footprint by allowing slope angles up to 2/3, depending on the shear strength of the cover soil. The design process is described for the reinforcement and drainage functions that the geocomposite solution ensures. The case study illustrates the importance of the design of the anchorages required by this application.

1   INTRODUCTION

Of the civil infrastructure sectors, the environmental sector is the one which is growing the fastest as we seek to address the multiple issues posed by man-made pollution and population growth. Landfill industry needs to keep increasing both in terms of its capacity and its ability to safely dispose of the remaining waste and ensure that the existing landfill remain safe. The key task facing governments and landfill operators is one of maximizing the space available within landfills and safely containing the waste to ensure it will not contaminate groundwater or watercourses or pose threats in terms of instability or the build-up of potentially explosive gases.

Geosynthetics form a key part nowadays of the toolbox that the landfill designer and operator has available. They also reduce the need for mineral exploitation by reducing the need for thick clay liners, granular collectors, and filter systems.

Within two years of the end of the operation phase of a landfill, a permanent capping has to be implemented to prevent penetration of uncontrolled water in waste and biogas emission into the atmosphere which would increase the carbon footprint of the landfill.

2   LANDFILL CAPPING DESIGN

2.1   *Design target*

Minimizing the footprint of waste storage areas is a paramount concern to everybody involved. At the same time, storage capacity needs to be optimized in parallel with a successful integration into the finished landscape through installation of cover soil on top of the construction. These requirements lead to increased side slope angles of the construction, with

consequences on the design regarding the stability of soil veneer layers and the reinforcement performances of the multi-layers geosynthetic system on top of the geomembrane.

A part of the rainwater goes through the covering layer of soil and creates water pressure in the soil which would reduce the stability of the soil and increase the risk of direct sliding. That's why a drainage layer is always recommended on top of the geomembrane. In some conditions, therefore, the upper part of the multi-layered geosynthetic system located on top of the smooth geomembrane has to include a drainage layer and also a soil-gripping layer. Multifunctional geocomposites are available on the market which incorporates drainage, reinforcement, protection, and soil gripping in one product, and has been in use now for more than 15 years.

2.2 *Hydraulic design*

Usually, original design/tender specifications is requiring either:

- granular drainage layer with given permeability and thickness e.g. usual 50 cm thick granular drainage layer with a permeability of 10^{-4} m/s can be replaced by a drainage geocomposite which is hydraulically equivalent,
- input flow rate, it must be consistent with the permeability of the topsoil and the runoff ratio
- discharge capacity of a specified product

In all cases, hydraulic gradient is, along with dead and live loads, a main parameter to assess the water flow capacity of a drainage composite, it is related to slope angle and allowed water pressure in the topsoil layers. Designers should take care that no water pressure on top of the drainage composite has been taken into account for hydraulic gradient calculation [AFNOR NF G38-061 2017]. This would prevent reduction of the shear resistance of the topsoil layer which can lead to direct sliding failure.

Justification and comparison of drainage geocomposites have to consider, under given load and hydraulic gradient, relevant boundary conditions in the test of discharge capacity in the plane to be carried out according to EN ISO 12958 for product performance assessment, i.e. at least standardized foam layer on one side of the geocomposite in the index test (EN ISO 12958-1) [Touze N *et al*. 2014] or standardized sand layer in the performance test (EN ISO 12958-2).

Reduction coefficients are applied on the short term discharge capacity of the drainage geocomposite to take into account the compressive creep behavior of the drainage composite, including thickness reduction of the drainage core and filter intrusion into the drainage core, both leading to a reduction in the water flow cross-section. Since the values of these reduction coefficients depend on the product and project specific conditions [Stoltz G *et al*. 2016], specification of a product without any information on the needed long term discharge capacity is not relevant and does not allow any comparison with competition products. In capping, for clean water, reduction coefficients for chemical and biological clogging are equal to 1 for any product.

2.3 *Mechanical design*

Multi-level shearing resistances have to be checked or considered in the design of the geocomposite (Figure 1) [AFNOR NF G38-067 2017]. Internal stability of the veneer soil layer is a first condition, its external stability is the next step, it depends on the friction angle between soil and the top layer of the basal multi-layered geosynthetic system. When needed, this friction angle is increased with the help of a three-dimensional open monofilament structure, intimately stitched onto the appropriate reinforcement product. Thus, high density of monofilament structure prevents direct sliding of the veneer soil layer on the drainage geocomposite when the slope angle is too high.

① Internal stability of topsoil layer

② External stability of topsoil layer

③ Internal shear strength of the filled soil-gripping geocomposite

④ Tensile strength of the reinforcing material is related to the smoothest interface

Figure 1. Multi-level shearing resistances.

The third step in the design is linked to the minimum interface friction angle of the multi-layered geosynthetic system, the goal being to calculate the required long term design strength of the reinforcement component, when it is needed. Usually, the multi-layered geosynthetic system includes, above the capping, a smooth geomembrane which ensures the water tightness of the capping slopes. Due to the slope angle and the weight of the cover soil, this smooth interface creates tensile forces in the upper geosynthetic layer, which requires the use of a reinforcement component.

Depending on the project specific data, this can be either a geogrid, preferably installed over a non-woven protection geotextile or a geocomposite such as EnkaGrip & Drain specifically designed for each project, combining from top to bottom:

— an open three-dimensional monofilament structure offering a high density (1810 m/m^2) of filaments for soil-gripping,
— a reinforcement woven fabric and
— a drainage composite.

Before cover soil installation on the side slopes, the geocomposite is anchored on top of the slope, usually in a trench. This is the last phase of the design but is as crucial as the previous ones to avoid any failures. Care has to be particularly taken with anchoring on intermediate berm due to limited available footprint.

Fill material characteristics also have an impact on the anchorage performances through their internal friction angle, their grain size and shape. This can be particularly sensitive in anchorage trenches where severe installation conditions and/or inappropriate fill material can damage the sealing system and lead to a failure.

3 CASE STUDY: VILLEPARISIS LANDFILL (FR)

The Villeparisis waste storage facility, located close to Paris, is one of the five hazardous waste storage facilities of the SITA FD, a subsidiary of the SUEZ group Environment. The site is authorized to receive 250,000 tons of industrial hazardous waste per year requiring many refurbishment work.

3.1 Challenge

The works consisted on a slope refurbishment 20° and 54 meters long above 15 000 sqm of industrial waste storage area. Following the local regulation, a waterproofing system and drainage layer against rainfall have to be installed. Geosynthetics have been chosen as solution to work with as they can provide easy to use solutions and technically reliable and experienced. The main problematic here was to insure stability of the 30 cm covering soil above smooth waterproofing geosynthetic capping system.

3.2 Solution

In such conditions, multiple functions geocomposite EnkaGrip & Drain was a unique solution providing effective drainage with a strong reinforcement and soil stabilization in a significant cost saving. The drainage core is a three-dimensional V-shape monofilament structure made of polypropylene. Polyester woven geotextile (TS = 200 kN/m) ensures the reinforcement function. High density (1810 m/m^2) open three-dimensional filament structure made of polyamide provides the required porosity ($> 90\%$) for efficient topsoil gripping. All components are sewn together forming a unique product installed in a single operation allowing cost and time saving.

The technical proposal insures a safe and secure solution to meet the technical and regulation objectives for drainage and soil stabilization. In addition, the solution allows installer to reduce installation time and minimize circulation impact on the geosynthetic layer. Risk of potential damage during installation are reduced. Sustainability of geosynthetics is better ensured with a reduction in costs.

3.3 Installation benefits

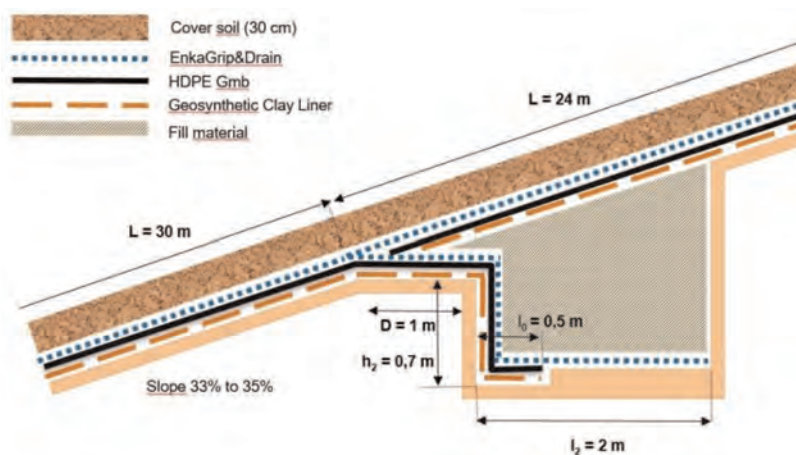
Due to the length of the slope, a specific implementation methodology has been developed to avoid traffic on slope close to the waterproofing geosynthetic capping system, as recommended by the French rules. Intermediate anchorage was designed (Figure 2), the topsoil was installed using a long arm shovel Caterpillar 325 BL able to work at over 20 m from the bottom and the top of the slopes (Figure 3). The shovel has always evolved smoothly over a minimum thickness of 1 m materials to avoid dynamic loading and accidental damage of geosynthetics allowing a coverage rate of approximately 2 000 m^2 per day.


Figure 2.   Details of the intermediate anchorage.

3.4 Result

Design was made according to the French design standard NF G 38-067 including partial factors of the Eurocode 7 on dead loads (soil weight) and live loads (snow . . .) insuring stability on each interface of the capping system. Thus, legal and technical requirements have been reached and in the meantime, the solution allowing time and cost savings during installation. The works objectives were achieved in accordance with budgetary costs and deadlines.

Figure 3. Long arm shovel able to work at over 20 m.

4 CONCLUSION

This paper highlights a smart solution regarding veneer soil reinforcement combined with drainage function, as it is required particularly on landfill capping. We reminded that this application requires a design based on the knowledge of the shearing resistances of the multi-layered geosynthetic system. As manufacturer, we can help designers and other stakeholders to detect wrong design as soon as we are contacted, particularly thanks to our interface friction angle data base.

Interaction between sealing system components being a main parameter as well of the anchorage stability, the designers of the waste landfill have to incorporate this in their design as early as possible for the most critical conditions to prevent any nasty surprises later and adopt the appropriate solution for anchorage. All the stakeholders shall appreciate this topic in addition to the design of the sealing system itself, particularly when slope length can be an issue for design and installation. Inappropriate design is a source of delay, extra cost and dispute.

The effect of Prefabricated Vertical Drain (PVD) with membraneless vacuum preloading method on the North Coast of Central Java

Nastiti Tiasundari & Dandung S. Harninto
PT. Geoforce Indonesia, Jakarta, Indonesia

ABSTRACT: Prefabricated Vertical Drain (PVD) is a composite geosynthetics material which designed to have a high permeability property. It is often used to accelerate consolidation process on a compressible soft soil layer. In order to reach a minimum number of 90% consolidation at the beginning of the building or structure construction project, a certain number of preloading is required. The number of preloading depends on the load that would be acting on the ground in the future. There are several methods of preloading, such as: conventional earth embankment, vacuum with membrane, and membraneless vacuum. In this paper, a test area of 800 m2 located in the north coast of Central Java would be tested using PVD with membraneless vacuum preloading method. An approximately 80-90 kPa of vacuum pressure would be applied during vacuum preloading period. The vacuum pressure successfully reached the edge of the area with almost the same pressure as exerted by the vacuum pump. The difference value of vacuum pressure at the edge with the vacuum chamber are ranging from 2-6 %. At the toe of PVD material, vacuum pressure is about 3% smaller than the vacuum pressure measured on the top of the PVD. After three months of vacuum, the result showed that 70-80% of total predicted settlement was reached. Soil investigation data from before and after vacuum showed that qc value of CPT test was slightly increased whereas SPT value increased by 1.5 times. Laboratory test data showed that the natural water content value decreased by 1-4%, unit weight increased by 4-9%, void ratio value decreased by 10-20%, and shear strength increased by 5-20%. The recorded bouncing potential two months after vacuum was 2-3%.

1 INTRODUCTION

Construction over soft soil is very challenging. There were already several methods to improve the strength of soft soil layer, one of them is soil improvement using Prefabricated Vertical Drain (PVD) and preloading. The main idea of this soil improvement system is to ensure that settlement had already reached a minimum 90% of total settlement before the construction of the main structure. At the end of soil improvement using PVD, the value of shear strength is expected to be higher.

PVD system is often combined with preloading. The main purpose of preloading is to apply enough load equivalent to the main structure that will be built in the beginning of construction to minimize the risk of settlement or differential settlement during service period of the structure. There were several methods of preloading: conventional preloading (using soil embankment) and vacuum preloading.

Vacuum preloading is a common method of preloading used in soil improvement (Bergado *et al.* 2002; Chu *et al.* 2009; Holtan 1965; Indraratna *et al.* 2019; Seah 2006). It was first

introduced by Kjellmann (1952) to reduce the time for consolidation period. The advantage of this method is reducing the pore pressure, whereas maintaining a constant total stress instead of increasing total stress (like the conventional preloading), thus effective stress increased because of the reduction of pore pressure from the vacuum preloading (Lam *et al.* 2015).

There were two types of vacuum preloading: membrane and membraneless vacuum preloading. Membrane vacuum preloading system use a membrane on top of a sand blanket, sealed, then applied a vacuum pressure. The efficiency or the membrane vacuum preloading system depends entirely on the damage caused on the membrane over a long time of vacuum period (Indraratna *et al.* 2019). Membraneless vacuum preloading system connected each PVD into a tubing system which directly connected by vacuum pump without a membrane. This system is very efficient when an area is to be sub-divided into different parts and will be improved individually (Indraratna 2019). Direct tubing vacuum consolidation does not require the sand blanket and sealing membrane since the connections from the top of PVD to the vacuum line are completely sealed (Seah 2006).

This paper will be focusing on the effect of the individual vacuum preloading system on a pilot test area on the North Coast of Java.

2 SITE CONDITION

The site was located on the side of the road heading to Kendal Harbor, on the North Coast of Central Java. The location of the pilot project was originally a large fishpond. The pilot test area was marked with a turquoise area in Figure 1(a). The total area was 800 m^2.

The research area is currently still in a flooded condition with water depth ranging 80 cm to 90 cm from the bottom of the pond, therefore backfilling work needs to be done before to provide a firm platform at elevation +1.5 The long section is shown in Figure 2.
Figure 1.   (a) The location of pilot project area, (b) The initial condition of the area.

3 SOIL CONDITION

The soil condition of the pilot test area can be shown in the table below. The soft soil with N-SPT<5 was located until 20 m deep. Installation of PVD will be done to 20 m deep from the surface.

4 DOUBLE VACUUM SYSTEM

Double Vacuum System (DVS) is a membraneless preloading method using a very efficient vacuum pump and collection tank to divide water from air. A high vacuum pressure exerted from the vacuum pump would take the air and water from each individual PVDs connected
Figure 2. The long section of the test area.

Table 1. Soil condition.

Depth (m)	N-SPT Value	Soil Description
0–2	4	Fill Material
4	0	Soft Silty Clay, Yellowish Grey, High Plasticity
6–8	0	Very Soft Silty Clay, Grey, High Plasticity
10–14	0	Very Soft Silty Clay With Trace of Shell, Grey, High Plasticity
16–22	0	Soft Silty Clay With Trace of Shell, Dark Grey, High Plasticity
24–30	11–14	Stiff Silty Clay, Dark Grey, High Plasticity
Figure 3. Schematic of DVS system (DongAh Geological Engineering Co. Ltd.).

to vacuum pipe towards vacuum collection tank. A high vacuum efficiency collection tank will divide water from air. Water will drop at the bottom of the tank and will be discharged outside the vacuumed area using a submersible water pump. This method prevents water from flowing to the vacuum pump which could impair the vacuum pump.

Arrangement type of drain that will be used is rectangular with 1.0 m spacing. PVD material which is going to be installed has a 100 mm width and 2 mm thickness.

5 RESULT AND DISCUSSION

5.1 *Vacuum pressure during preloading period*

The vacuum pressure throughout the entire trial process was kept at 81-94 kPa. At some point, vacuum pressure was decreasing, but then it was back up to 90 kPa. In case of any pressure change, it is normal to have a variety of vacuum pressure as long as the vacuum pressure did not drop significantly. The difference value of vacuum pressure at the edge with the vacuum chamber are ranging from 2-6 %. A piezometer was installed inside the PVD and at the edge of vacuumed area. As a result of the measurement, the vacuum pressure was stably maintained at 78-90kPa (average 84kPa), which is about 3% smaller than the vacuum pressure measured on the top of the PVD.
Figure 4. Vacuum pressure during vacuum period.

5.2 *Settlement*

The settlement in the vacuumed area reached 1.27 m by the end of 90 days vacuum. At the very beginning of vacuum process, the rate of settlement is quite big and almost reached 1-2 cm of settlement/day. To predict the total settlement, hyperbolic and Asaoka method is used. Hyperbolic method uses the relationship of settlement at time t in a hyperbolic function of initial settlement and time. The final settlement from hyperbolic method is defined as the intersection and slope of the fitting line of data $t/(S_t-S_0)$ versus t. Asaoka method is widely used for its simplicity and good accuracy. The final settlement from Asaoka method is defined as the intersection of the trendline of S_n and S_{n-1} with a 45° line which can also be defined as the condition where S_n and S_{n-1} are equal.

After 90 days of vacuum, through the hyperbolic method, percent settlement achieved was 72.2%, while with Asaoka method was 85.4%.

5.3 *Increasing in CPT and SPT value*

The value of cone resistance (qc) from CPT test is expected to increase after vacuum process, but the result of CPT test conducted on site was slightly increased by a small number. Qc value of CPT 01 after the test shows a small increase, but the total friction value increased by four times than the initial value. It showed that the soil had better adhesion after vacuum.

N-SPT value after vacuum increased by 1.5 times and the classification of the soil went from very soft before ground improvement to soft to medium after ground improvement.

5.4 *Changes in soil laboratory data*

The result from laboratory test showed the deeper the soil, the greater decrease in water content. Decrease in water content after vacuum is within the range of 1-4%, but the highest was at 20 m with a 27% difference from its initial value. The value of unit weight after
Figure 5. Result of predicted settlement using Asaoka method and Hyperbolic method.
Figure 6. Result of CPT test and SPT test before and after vacuum.

vacuum process increased by 4-9 percent than initial value. Result of laboratory data showed that void ratio value decreased by 10-20% after vacuum process.

Triaxial unconsolidated undrained (Triaxial UU) test result showed that cohesion value increased by 5-20 %. The deeper the soil, the increasing rate of the cohesion is higher.

5.5 Bouncing effect after vacuum

Approximately two months after vacuum period, settlement data was obtained to determine whether there was a bouncing effect after vacuum. Based on the data below, there was a bouncing effect after vacuum about 2-3%. This needs to be considered as the after effect of the vacuum preloading system.
Figure 7. Result of (a) Water content; and (b) Unit weight.
Figure 8. Result of (a) Void ratio; and (b) cohesion value from Triaxial UU test.

Table 2. Bouncing effect after vacuum.

Points	Last Settlement after vacuum (m)	Settlement 2 months after vacuum (m)	Changes in settlement (m)	Percent heaving from total settlement (%)
SP 1	-1.271	-1.232	0.039	3.07
SP 2	-1.1065	-1.0815	0.025	2.26

6 CONCLUSION

Double Vacuum System (DVS) is a membrane less preloading method using a very efficient vacuum pump and collection tank to divide water from air. This system is proven to be effective for an alternate preloading method. The result showed that 70-80% of total predicted settlement was reached. Soil investigation data from before and after vacuum showed that qc value of CPT test was slightly increased whereas SPT value increased by 1.5 times. Laboratory test data showed that the natural water content value decreased by 1-4%, unit weight increased by 4-9%, void ratio value decreased by 10-20%, and shear strength increased by 5-20%. However, after shutting down of the vacuum system, bouncing potential should be considered. The recorded bouncing potential two months after vacuum was 2-3% from the total settlement.

ABSTRACT: This paper focuses on the application of Bituminous Geomembrane (BGM) for the waterproofing of new and existing earthen canals. The start of its application is about half-century back when USBR first time applied BGM in canal waterproofing and the first time BGM was used in waterproofing of a large dam by Coletanche in 1978 in France. In India, the first application of BGM has been done in one kilometer stretch of Pench Canal in Nagpur, Maharashtra which was given as a pilot project to Yooil Infra to arrest the seepage and enhance the stability of the canal. The area comprises expansive soil which has been problematic for canal banks stability, concrete lining failures, heavy seepage through banks and breaching of banks at different reaches of canal. The BGM application resulted in a complete stoppage of seepage through that section of the canal and no stability related problem was observed due to the elimination of drawdown conditions while and after the full flow of canal during monsoon. BGM is unique due to its properties of being flexible, high puncture resistance, practically impermeable, resistant to thermal expansion, UV resistant, non-biodegradable, low maintenance cost and overall exceptional durability. This paper gives the technical assessment of slopes of the canal with the existing concrete lining, outlining possible reasons for the failure of concrete lining and remedy with the impervious bituminous geomembrane.

1 INTRODUCTION

The Pench Left bank and Right bank canals were built in 1970s as a part of Totladoh project on Pench river. Their total length is 84 km. It is being operated un-der Vidarbha Irrigation Development Corporation (VIDC), Maharashtra, India.

Under the prevailing situation of reduced rainfall coupled with reduced reservoir capacity followed by canal seepages and breaches, the only option left to meet the drinking and irrigation requirements is water conservation by increasing the stability of canal, minimizing the seepage loss, reducing the canal friction loss and thus ensure the maximum utilization of available water.

2 PROJECT LOCATION AND SALIENT FEATURES

The site is about 3.4 km from National Highway 44 and is on state highway 249 (see Figure 1). The project is 1km from Gundhari Village in Nagpur district, Maharashtra, India.

Figure 1.   Project location map of Pench Canal.

The salient features of canal selected for BGM lining are as follows:

Table 1.   Salient features of Pench LB Canal.

Length	1000	m
Bed width	13	m
Full Supply Depth	3.8	m
Design Discharge	90	Cumecs
Mean Velocity	2	m/s
Bed Slope	1 (V):7000 (H)	
Side slopes	1(V):1.5 (H)	

3 CANAL BEHAVIOR WITH PLAIN CEMENT CONCRETE LINING

During the site inspection of left bank Pench canal, it is observed that concrete lining of canal is severely damaged (see Figure 2). Root causes behind the cracking of concrete lining of canal can be summarized as below:

Figure 2.   Original condition of canal stretch.

Lining has joints at regular interval, through which seepage was taking place into the banks of the canal. General soil type along the canal alignment is expansive soil which is popularly known as "Black Cotton Soil". Expansive soil exert pressure on the concrete lining due to volume expansion. As plain cement concrete is weak in tension, the expansion joint crack become wider, and sometimes new cracks develops in concrete lining.

Flowing water cause internal erosion below the lining of canal when enter in these cracks. During drawdown condition, situation becomes even worse when uplift force due to pore water pressure along with the swell pressure exerted by bank soil causing cracking of lining and sometime sliding of the whole soil mass into the canal.

A distinct disadvantage of Concrete lining is its brittleness. Thus, concrete lining frequently cracks due to contraction taking place from temperature change, drying and shrinkage and settlement of sub-grade.

4 ALTERNATIVE LINING - BITUMINOUS GEOMEMBRANE

Bituminous geomembranes (BGM) have been developed 40 years ago. This durable Geo-composite is an effective waterproofing layer with significant properties, such as UV resistance, workability at temperatures -40°C to 55°C, mechanical / puncture resistance, harsh chemical resistance, dimensional stability, and mechanical workability, easily installed, welded, and repaired by local crews or maintenance people of any client.

5 CANAL BEHAVIOR WITH BGM LINING

The installation of BGM layer forms an impermeable barrier all around the inner surface of canal and along the top width of embankment up to half of embankment top width. This layer prevents the seepage of canal water to enter the embankment fill. Thus, the moisture variation almost ceases to take place in the canal embankment and hence no excess pore pressure develops during drawdown condition. Thus, the critical failure surface is on the slope of embankment opposite to the canal side. But in actual practice, there is no failure anywhere at the site on outside slope of canal. Hence the system is completely safe with BGM layer.
Figure 3. Canal during BGM installation and after 4 years of flowing condition.

6 METHOD OF ANALYSIS & SOFTWARE USED

To access the actual cause of failure based on the in-situ strength and deformation characteristics of embankment, stability analysis of the embankment is performed using Limit Equilibrium method using "Slide" as well as through FEM analysis using "Phase2" from Rocscience Inc.

7 DESIGN INPUT PARAMETERS

Following are the input parameters adopted for the slope stability analysis based on the lab test results of embankment fill material.

Table 2. Salient features of canal embankment (in Filling).

Properties of Slope	
Total Height	5 m
Water Table Location	At ground level, Full Supply level (FSL) and Drawdown condition
Embankment Slope	1.5H:1V

Table 3. Geotechnical design parameters for embankment fill and foundation.

S.n	Description	Unit	Value
1	Bulk Density	g/cc	1.83
2	Liquid Limit	%	41
3	Plastic Limit	%	19
4	Shrinkage Limit	%	12
5	IS Classification	-	C I
6	Free Swell Index	%	25
7	Peak Cohesion	KPa	23
8	Peak Friction Angle	Φ	13
9	Residual Cohesion	KPa	20
10	Residual Friction angle	Φ	5
11	Permeability	m/s	3×10^{-7}
12	Swelling Pressure	KPa	51.2
13	Young's Modulus	MPa	23

The above parameters were obtained by testing the actual soil samples extracted from the canal embankment and canal bed level (foundation) and conservative value is considered in design.

7.1 *Loading condition*

As per Indian road congress, IRC 75-2015 (Guidelines for the design of high embankments), following are the loading conditions to be used for the stability analysis of embankment.

Live Load (External Traffic Load): 24 KPa to be considered across the width of carriageway.

Dead Load: Self weight of embankment and any other structure resting on the embankment.

Static Condition: Deal Load + Live Load

Table 4. Summary of recommended min Factor of Safety (FOS) required for stability.

Loading Condition	Factor of Safety under static load
Static Load	1.4 (at the end of construction), 1.2 (*Initial factor of Safety)
Sudden Drawdown	1.3
Steady Seepage	1.3

During the canal site visit, it was observed that no failure has occurred in the base of the canal, and the concrete at base remained intact all throughout. Accordingly, in the analysis, the parameters of the foundation layer were increased considerably to avoid the failure slip circle passing through the base of embankment. Only slip circles passing through the slope of embankment were considered to evaluate the FOS during analysis.

8 SIMULATION OF VARIOUS CONDITIONS IN SOFTWARE

8.1 With Cohesive Non-Swelling (CNS) layer and concrete lining as conventional technology

8.1.1 Normal operating condition
The normal operating level is 3.8m. Accordingly piezometric head of 3.8m is applied in the embankment. In the canal portion, additional Uniformly distributed load (UDL) corresponding to head of 3.8m is applied on the bed as well as canal slopes to simulate the water head in canal, since piezometric lines action in some material only and not in open space.
Figure 4.   Model of stage-1 under normal condition of conventional canal lining.

8.1.2 Sudden drawdown condition
First FEM analysis with groundwater and stress condition is considered with Normal water levels.

Phreatic line in the embankment body under steady state condition is generated.

To simulate the Sudden drawdown condition, in the analysis, groundwater type is changed to piezometric, and phreatic line obtained from step "b" is imported for water levels in the dam body under drawdown condition, and piezometric water level at canal bed level is modelled for remaining portion.

SRF (strength reduction factor) is computed for sudden drawdown condition.
Figure 5.   Model of stage-2 under drawdown condition (Conventional canal lining).
Figure 6.   Output: Failure surface with displacement contours.
Figure 7. Output: Deformation Vectors showing the potential failure direction.

8.2 With BGM layer

8.2.1 Normal operating condition

The normal operating level is 3.8m. Since permeability of BGM is of order of 10^{-14} m/s, which is practically impermeable, membrane applied on the canal surface.
Figure 8. Model of stage-1: BGM layer installed as liner under normal condition.

Hence no water level is considered in the embankment body and additional UDL corresponding to head of 3.8m is applied on the bed as well as canal slopes to simulate the water head in canal.

8.2.2 Sudden drawdown condition

Due to impermeability of BGM layer, the water will not enter the embankment before drawdown. So, no water table is considered in the model before and during drawdown condition.

SRF (strength reduction factor) is computed for sudden drawdown condition.
Figure 9. Model of stage-2: BGM layer installed as liner under drawdown condition.
Figure 10. Output: Failure surface with displacement contours under drawdown condition. (FOS=1.74).
Figure 11.   Output: Deformation vectors showing the potential failure direction.

9   RESULTS AND DISCUSSION

Following are the output of stability analysis in terms of Factor of safety obtained under various conditions of analysis.

Table 5.   Factor of safety against various loading conditions.

Condition	Factor of Safety	
	With CNS Layer & concrete lining	With BGM Layer
Sudden Drawdown	1.55	1.74

The embankment soil is high to medium plastic clay, hence the value of Skempton's pore pressure parameter, "B" was kept as 1 in the software to simulate the rise in pore pressure actually taking place during drawdown in the canal. The routine lowering of water taking place in the canal can be considered as sudden drawdown keeping in view the rate of lowering of water vs the slow dissipation of pore pressure due to low permeability of soil.

9.1   *Analysis of embankment with CNS layer*

It can be clearly seen from the results that in case of normal condition, the embankment has found to be safe in slope stability, whereas under drawdown condition, the Factor of Safety (FOS) reduces further due to reduction of effective stress in embankment soil. Further, the erosion of embankment soil due to flowing water led to removal of "toe" material and the seepage of water into the soil lead to loosening of soil, and these two phenomenon combinedly lead to failure of canal slope. This phenomenon of seepage through concrete lining joints, erosion of CNS layer, swelling of expansive clay and cracking of concrete lining thereof has already been explained in 3 Canal Behavior with Plain Cement Concrete lining.

9.2   *Analysis of embankment with BGM layer installed*

The installation of BGM layer forms an impermeable barrier (all around the inner surface of canal and along the top width of embankment up to half of embankment top width. This layer prevents the seepage of canal water to enter the embankment fill and at the same time during rains, the rainwater is also prevented to percolate into the half width of the embankment top. Thus, the moisture variation almost ceases to take place in the canal embankment and hence no excess pore pressure develops during drawdown condition. Also, the provision of BGM layer rules out any possibility of soil erosion by flowing water. These rules out the major failure causing factors due to provision of BGM layer in the canal. Thus,

as expected, software analysis gives the critical failure surface on the slope of embankment opposite to the canal side, but with FOS more than minimum required. In actual practice also, these is no failure anywhere at the site on outside slope of canal. Hence the system is completely safe with BGM layer.

10 CONCLUSION

This type of embankment having swelling characteristics with provision of CNS layer also are not able to prevent the erosion of CNS layer and embankment fill from flowing water in canal after cracking of rigid concrete slab. A flexible, impermeable membrane having tensile strength is required to be installed to take care of all the issues like seepage into embankment fill, concrete slab cracking, surface erosion, moisture variation etc. Bituminous Geomembrane meets all the technical requirement to address the adversities in the stability of embankment along the canal.

Repairs of dam components subjected to dynamic loads with application of geosynthetics: Case studies from India

Vivek Kapadia
Government of Gujarat, Gandhinagar, India

ABSTRACT: Dam is a complex hydraulic structure having many components subjected to dynamic loads. Such components periodically manifest signs of distress and require repairs especially in case of aging dams. Conventional methods for repairs are mainly based on usage of impact resistant materials. As an alternative, solutions with geosynthetics are designed as impact resistant systems rather than depending merely on material properties. Such solutions not only help effectively repair the damaged components but also enhance their performance in several ways besides cost economy, faster execution and longevous life. The paper outlines main issues related to various dam components due to dynamic loads and presents case studies of aging Indian dams whose distressed components have been restored or are being restored with application of geosynthetics.

1 DAM COMPONENTS SUBJECTED TO DYNAMIC LOADS

1.1 *Upstream face of earthen and rockfill dams*

Waves are generated on the top surface of the reservoir under the effect of the wind. They tend to dislodge the soil particles resulting in to erosion of the earthen dam. As the reservoir level varies, such erosion takes place at different levels of the earthen dam. Such an erosion becomes dangerous when it is progressive. In case of rockfill dams, the wave action may result in to loss of mechanical bond between the adjacent rocks due to penetration of water causing displacement of rocks.

1.2 *Upstream and downstream faces of spillways*

Discharge from reservoir is released and regulated through spillway and gates and therefore the crest on its upstream and downstream faces is subjected to severe loading conditions. Under the effect of heavy dynamic water loads, cavity formation on the downstream face is a common problem which may result in to pitting or delamination of the concrete surface. Such forces are so severe in some cases that the reinforced concrete lamination of masonry structure gets disintegrated.
Figure 1.   Components of a typical dam - upstream view.

1.3 *Hydraulic gates and supporting structure*

Hydraulic gates and supporting structure resting atop the spillway crest are subjected to heavy dynamic loads as they govern the discharge from over the spillway. Gates are usually made up of steel and they undergo various types of deformations including warping under such loads. The entire system has to take severe vibrations and therefore they undergo fatigue at times. Embedded parts in to concrete elements are of utmost importance and fatigue in concrete members affects them.

1.4 *Energy dissipation portion*

Downstream of the spillway is the energy dissipation portion which is also subjected to high magnitude dynamic loads as its basic function is to dissipate the energy within the falling water and to streamline the flow to the best possible extent. Concrete gets badly distressed in many cases are frequent repairs are usual. In some cases, residual energy in the downstream of the energy dissipation portion is so much so that erosion takes place for a long distance in the riverbed.

1.5 *Power channel and divide bund/ wall*

Dams equipped with hydropower turbines have a divide bund/ wall separating tail race channel of hydropower units and the spillway channel. Conduce hydraulics of the tail race channel is required for efficiency of the hydropower units. Spillway channel streamlines the flood water in to the river gorge. Both these functions are exclusive and hence the divide bund/ wall is designed to ensure distinct hydraulic behavior on either side. It has to take different types of dynamic loads on both of its sides. In some cases, where the divide bund/ wall is not on a straight alignment, it has to act as a river training work. In such cases, it has to take heavy impacts and requires frequent repairs.

2 CASE STUDY OF UKAI DAM: RESTORATION OF DIVIDE BUND

2.1 *Overview of Ukai dam and distress observed in its divide bund*

Ukai dam is located in Gujarat state of India. It was constructed on Tapi river in 1972 with live storage capacity of 6730 million m^3. Total length of the dam is 4926 m of which 4058 m is an earth dam and 868 m is the spillway which is a masonry gravity dam with 22 radial gates whose discharge capacity is 37,865 m^3/s. There are 4 riverbed hydropower turbines of 75 MW each.

Divide bund acts as a groin on the spillway channel side, and, during the spillway operation, it is subjected to severe dynamic loads when it contracts the flow. Here, the original construction was in the form of an earthen bund covered with thick stone pitching. In spite of periodical repairs, signs of serious distress were observed in 2019. Near the hook-shaped nosing (Figure 2),
Figure 2. Layout of Ukai dam (Kapadia 2022).

Figure 3. Distressed divide bund (Kapadia 2022).

not only the stone pitching was disintegrated but also the stones were ruptured (Figure 3) and the surface of the earthen bund was found badly eroded. Riverbed though made up of monolithic basalt rock was found eroded badly to the extent of 5 m in depth and 8 to 10 m in width. Heavy erosion in rocks may cause undesirable changes in hydraulic behavior of flow.

2.2 *Method of estimation of buffeting forces*

While making original design of the divide bund, a three-dimensional laboratory model was used for deciding its alignment and profile which could take care of the impact due to water splashes during release of the flood water from the spillway. In order to fast converge to the right proposition of the model, wave characteristics were captured through a flume model. For this purpose, simple principles of dynamics were used.

$$p = wv^2/g \qquad (1)$$

where p is pressure at the striking point, w is the weight of unit volume of water and v is the velocity. As shallow water waves are dominant in such cases,

$$v \approx 3.16\sqrt{h} \qquad (2)$$

As the surface is inclined and some additional safety is required, design pressure p = 1.7wh was considered. In such a case, the pressure-time diagram for each wave contains a spike representing the primary impact component followed by a well spread secondary pressure component. As the tarin of waves is a series of waves with a short lag during high discharge from the spillway, only the primary impact component is considered and the aggregate impact is estimated for the design purpose considering maximum 7 cycles in a wave train.

2.3 *Impact resistant system using geosynthetics and its execution*

Usual practice for protecting earthen bund from impacts due to water waves is to provide a hard surface on it which may be in the form of thick rubble pitching or concrete blocks. Requirement of frequent maintenance of rubble pitching and limitations of compacting techniques to prepare the subgrade suggested that redoing the rubble pitching was not a promising solution. Therefore, as an alternative, a solution was designed in the form of a multilayer impact resistant system using geosynthetics. Three layers – hard, semi-flexible and flexible in sequence from top to bottom were chosen such that stagewise dispersal of impact occurs resulting in to a very low pressure on the earthen bund. Concrete slab as the outer most layer, gabions as the middle layer and biaxial geogrid with tensile strength of 40 kN/m and polypropylene non-woven geotextile as the bottom layer were provided. Filling of eroded riverbed with local rocks near hook-shaped nosing of the divide bund was also done followed by providing a layer of gabions as a lid. The entire system of restoration was designed such that the anti-slide key required at the toe of the divide bund was formed by the filling of the eroded river bed using its existing natural profile (Figure 4).
Figure 4. Restoration details - cross section (Kapadia 2022).

2.4 *Performance during floods*

Flood water release for three consecutive years during monsoon has given an opportunity to appraise the effectiveness of the solution. It is observed that the solution has been very effective from hydraulic and structural performance points of view (Figure 5).
Figure 5. Performance after divide bund after restoration (Kapadia 2022).

3 CASE STUDY OF KADANA DAM: SECONDARY APRON

3.1 *Overview of Kadana dam and distress in energy dissipation portion*

Kadana dam was constructed in 1978 on Mahi River in Gujarat state of India. Its storage capacity is 1542 million m^3. Its main spillway is 406 m long and is constructed of rubble masonry with reinforced concrete lamination. Its design flood is 31,063 m^3/s. Ogee fall height from the crest of the dam is 37 m and energy dissipation is of solid roller bucket type with exposed basalt floor in the downstream. Roller bucket type energy dissipator is preferred when tailwater depth is high (greater than 1.1 times sequent depth preferably 1.2 times sequent depth) and river bed rock is sound (IS7365 2010).

In the solid bucket, all of the flow is directed upward by the bucket lip to create a boil on the water surface and a violent ground roller on the riverbed. The severity of the high boil and the ground roller depends upon tail water depth. Low tail water produces the most violent boils and ground rollers (Peterka 1984). During initial operation of the spillway, such a situation prevails.

Originally, there was a pit in the riverbed approximately 42 m away from the toe of the roller bucket which was not actually that serious as it was away from ground roller and hydraulic jump. However, in 2017 it was observed that the pit that was 12 m deep had undergone retrogression in length but not in depth. The pattern of retrogression suggested that after formation of the surface roller, the balance energy used to be of high magnitude
Figure 6.   Progressive retrogression of pit in downstream of roller bucket (Kapadia 2020).

causing erosion of the riverbed. Such issues of riverbed erosion in downstream of the roller bucket are usual and require periodical inspection followed by restoration as per need. Here, it was observed that the change in profile of the riverbed had caused undesirable changes in the hydraulic behavior of the flow.

3.2   Methodology for estimation of impact on rocky riverbed

Ground roller occurring on the rocky riverbed followed by hydraulic jump required estimation of impact at the time of designing the dam. Theoretical estimation of impact due to ground roller is not advisable for design purpose in case of a very high ogee spillway and therefore physical model was used.

Hydraulic jump dissipates the energy which can be estimated from the Froud number. Froude number is defined as

$$F = \frac{v}{\sqrt{gy}} \tag{3}$$

where F is the Froude number, v is the velocity of water, y is the height of water and g is the gravitational force. In this case, the Froude number being in range of 2.5 to 4.5, energy dissipation may occur between 20 to 40%. Specific energy before and after the jump is E_1 and E_2.

$$E_1 = y_1 + \frac{v_1^2}{2g} \tag{4}$$

$$E_2 = y_2 + \frac{v_2^2}{2g} \tag{5}$$

where y_1 is the initial depth of water, v_1 is the initial velocity, y_2 is the water depth after jump and v_2 is the velocity after jump. Difference between E_1 and E_2 is the energy dissipated. E_2 in case is too high, the flow tends to scour the riverbed. Pressure on floor at different points can be estimated from the velocity i.e. v = q/y where q is the discharge per unit width and y is the height of the water. During various combinations of gate operations, values obtained from these equations may differ from actual ones, and, therefore, design of the bucket and energy dissipation measures was made using results of physical modeling. Retrogression on the riverbed had altered the hydraulics.

3.3   Secondary apron using geosynthetics

Retrogression of the riverbed after long years of operation of the dam required a treatment of the riverbed such that the hydraulics is more congenial and impact is properly resisted. Secondary apron was designed for both these aspects.
Figure 7. Schematic details of secondary apron as an impact resistant mechanism (Kapadia 2020).

Secondary apron was designed as a multilayer load dispersion system. The top layer of reinforced concrete slab, the middle one a composite layer of coarse aggregate and cement sand mix and the bottom as the biaxial geogrid with tensile strength of 30 kN/m to act as a separator cum basal reinforcement. This entire system was extended to cover the entire pit which was duly filled with graded rubbles. Conventional concrete apron resists impact mainly by its hardness. The solution designed here is a system that takes the impact with sharing its components amongst its members. Thickness of the reinforced concrete apron is required much less than in case of conventional solution because a part of the total impact is taken by it. This results in to a significant cost saving and should give better performance. This solution is in execution stage.

Figure 8. Execution of multistage secondary apron (Kapadia 2020).

4 LEARNINGS AND CONCLUSIONS

Severity of impact depends on stiffness of the material resisting it. Single member impact resistant surface has to take all the impact. Incremental interrelationship between stiffness and severity of impact requires very thick and stiff shield of rubble or concrete in a conventional solution. On the other hand, in multilayer system, impact is shared by the layers, and, therefore, lesser stiffness is required and hence the impact is less severe. Considering long life and importance of dams, application of geosynthetics have a huge scope in their construction and restoration.

Rehabilitation project of a reservoir in Italy

G. Gatto & F. Bisci
Studio Speri, Rome, Italy

M. Scarella
Carpi, Balerna, Switzerland

A. Frezza
Enel Green Power, Rome, Italy

ABSTRACT: In 2020 Studio Speri was engaged by Enel Green Power in the design of the maintenance project of the Sillico reservoir, located in Tuscany, in the district of Lucca (Italy). The aim of the work is the rehabilitation of the reservoir impervious facing. The existing facing, made of concrete slabs, has failed due to differential foundations settlements. The reservoir has already experienced cracking of the concrete facing several times in the last years, without solving the problem definitively. The present designed and built solution consist in waterproofing by a flexible geosynthetics impervious facing system. The impervious facing is composed by a composite geomembrane liner (PVC geomembrane + geotextile) coupled with a composite geodrain (geonet + geotextile).

1   INTRODUCTION

In 2020 Studio Speri was responsible for the design of the maintenance project of the Sillico reservoir from Enel as the structure's owner. On May 28th 2020, the reservoir experienced a collapse of the impervious system, composed by concrete slabs, with the subsequent complete release of the stored water.

2   SILLICO RESERVOIR

2.1   *Location*

Sillico reservoir, constructed in 1940, is located in Lucca, Tuscany, Italy (Figure 1). The structure is a small reservoir off the river that collects water from the diversion works near the area. The reservoir has a maximum storage volume of almost 8'000 m^3 and provides a 51 m constant hydraulic head for the downstream hydropower plant and it works as a run-of-the-river hydropower power plant. The installed power is 1'600 Kw.

2.2   *Main features*

The main features of the reservoir are reported in Table 1.

   The reservoir has been built partially with the excavation of natural ground and slopes and partially through the construction of a small embankment (Figure 2). The slopes and the bottom are protected with a waterproof facing, composed of concrete slabs with the following dimensions: 4.0 × 4.0 × 0.30 m. Water stops ensure the waterproofness of the facing joints.

Figure 1. Sillico reservoir.

Table 1. Main features of Sillico HPP and reservoir.

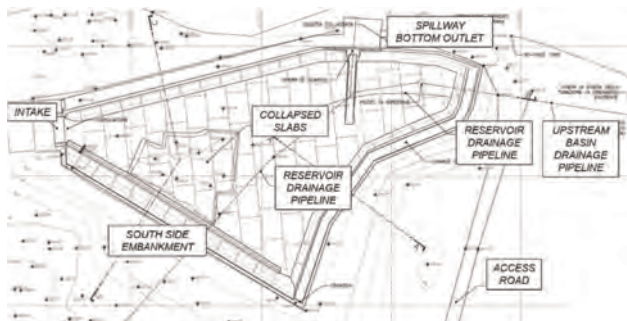
Feature	Unite	Value
IP	kW	1'600
Maximum storage volume	m^3	8'000
Maximum hydraulic head	m	51
Upstream face slope	v/h	1.0/1.0
Downstream face slope	v/h	1.0/2.0
Maximum height of slopes	m	4.1
Crest length	m	220
Crest width	m	0.70–3.60
Crest elevation	m a.s.l.	435.00
Maximum regulation level	m a.s.l.	434.80


Figure 2. General plan of Sillico reservoir.

Because the reservoir is located into a natural pond at the end of a small ravine, a drainage system to bypass the reservoir was built (Figure 3). The system is composed of an underground pipeline that crosses the reservoir from the upstream north-east zone to the downstream south-west zone. This system is also collecting the leaks of the reservoir.

The outlet structures, bottom outlet and ungated spillway, are located into the northern side of the reservoir.

Figure 3.   Plan of the drainage system.

The intake structure is at the west side of the reservoir.

The site being examined is entirely set on terraced alluvial deposits of poorly cemented and heteromeric conglomerates. Both are matrix and clasto supported, and subordinately by gravel and sands, sometimes silty-clayey (Figure 4).
Figure 4.   Geological longitudinal section of the drainage system.

2.3   *Story of the multiple failures of the waterproofing system*

In 1985 some slabs on the bottom of the reservoir have collapsed due to differential settlement of the foundation. In 2006 a similar damage has ben occurred in the central part of the concrete facing of the reservoir. The rehabilitations have been done always through the restauration of the original rigid impervious facing. It is not well documented what is has been done to prepare the foundation plan neither what type of details.

On May 28th 2020 the structure, once more, experienced severe damage, due to the collapse of a vast number of concrete slabs both on the bottom and on upstream toe of the embankment at the north side of the reservoir (Figure 5). Whitin a few hours during the night the reservoir has lost throughout the foundation almost 8'000 m^3 of water. This failure has caused no casualties or damage.

During the subsequent site inspections, it was evident that the failure has been caused by the differential settlement of the concrete slab in foundation. Notwithstanding the presence of joints, this type of waterproofing system is susceptible to foundation's movement. Moreover,

Figure 5.   Pictures of the 2020 failure.

over the years, the reparation works executed have disregarded the presence of the original movement joints, casting monolith slabs, reducing even more the flexibility of the facing.

Once removed the cracked slabs, the soil in foundation was showing an important internal erosion (Figure 6). The loss of waterproofing, the internal erosion of the foundation and the settlements are coupled and evolutive phenomena that brought to the collapse of structure. However, the original cause of this mechanism was not clear. A camera inspection into the lower bypass drainage system made evident a collapse of the small masonry tunnel just below the area of the failure. Most probably this collapse, due to aging of the old structure, has incepted a small creak into the foundation slabs and the subsequent leakage toward the drainage system has finalized the failure.

Figure 6.   Internal erosion of foundation under the removed damaged slabs.

All the historical damages of the reservoir have been caused by an evolutive phenomenon as-sociated to differential foundation settlements and progressive internal erosion of foundation soil, due to the infiltration of water from the cracks of the concrete facing. The loss of waterproofing, the internal erosion of foundation and the settlements are coupled and evolutive phenomena that could bring to the collapse of a rigid structure as it happened.

3   REHABILITATION PROJECT

3.1   General description

Following the lesson-learned of the previous failure cases, the designer proposed the adoption of facing made of a flexible geomembrane liner, in order to provide a higher standard of safety, a predictable resilience, a higher durability and a stringent quality control procedure during construction. The geomembrane liner is characterized by an outstanding flexibility, largely more reliable than the existing rigid facing.

In detail, the main features of the rehabilitation project are:

- Construction of a new abutment against the existing degraded by erosion;
- Restoration of the reservoir foundation in the area of the observed collapse;
- Installation of a new flexible composite geomembrane, also known as geocomposite, made of a flexible PVC geomembrane thermally bonded to a non-woven geotextile, on the entire surface of the reservoir;
- Installation of a new drainage system below the geomembrane liner;
- Construction of a new protective lean concrete cover in the reservoir bottom above the geomembrane liner, in order to allow transit of maintenance equipment and installation of a new decoupling and anti-puncturing non-woven geotextile in between the lean concrete cover and the geomembrane liner to avoid damage during casting and transmission of stresses in case of further settlements;
- Minor maintenance works to the gates.

3.2 *New impervious facing*

The most important aspect of the rehabilitation project is the design of a new impervious facing, that can provide a better response than the original solution with concrete slabs to the critical foundation contest of the structure. The impervious facing essentially consists of a flexible geomembrane liner. In general, flexible facings guarantee a higher level of imperviousness than concrete slabs and can absorb the deformations induced by foundation settlements.

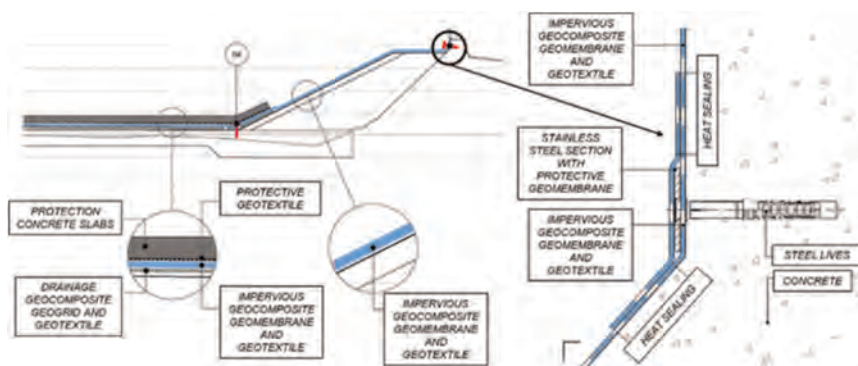
The new impervious facing is placed both upon the existing concrete slabs (in the zones where they are not damaged or collapsed) and upon granular soil material or new concrete slabs (in the zones where the existing concrete facing has failed). The total waterproofed area is almost 2'700 m^2 (Figure 7).


Figure 7.   Section of the new abutment with the new facing and detail of the perimetric anchorage system.

The facing is composed by an impervious composite geomembrane coupled with a composite geodrain to control any potential water leakage and to dissipate the sub pressure. The impervious composite geomembrane is made of a 2.5 mm PVC geomembrane thermally bonded during fabrication with a 500 g/m^2 non-woven geotextile. The composite geodrain is made of a geonet core (made of polyethylene) thermally bonded during fabrication with a 140 g/m^2 non-woven geotextile with filter behavior.

The choice of a PVC geomembrane is related to the intrinsic characteristics of the polymer. PVC geomembranes are distinctly the most flexible and resistant synthetic liners and are suitable for installation on irregular surfaces. From a statistic point of view, designers have selected a PVC geomembrane in nearly 59% of the installations on dams (ICOLD 2010). PVC geomembranes show a permeability coefficient k in the order of 1×10^{-12} m/s and a service life of more than 100 years in continental climates and exposed position. This statement is supported by the experimental results from the laboratory tests conducted at the Geo-synthetics Institute (GSI) with accelerated aging devices (ICOLD 2010).

In general, geomembranes exhibit a better performance when bonded with a geotextile to form a composite geomembrane (or geocomposite). The geotextile increases puncturing and tensile resistance, improve the dimensional stability, and minimize the formation of wrinkles due to the thermal deformation of the geomembrane liner. Composite geomembranes made of PVC polymers have been tested with success in international laboratory and are recommended by USACE for hydraulic installations (ICOLD 2010).

The seaming of the geomembrane sheets (2.0 m width) is made during construction at site by means of seaming machines, which can be either automatic double track or manual single track. Seams can be tested with the procedures and tools indicated by the international standards (ASTM and EN UNI). Single track seams can be tested with the method of the static pin (ASTM D4437-08 2013), while double track seam can be tested with the method of the pressurized air (ASTM D7177/D7177M-21 2021).

The impervious facing is fixed with an anchorage system with the scope of stabilize the facing subjected to wind and water loads (Figure 7). The face anchorage on the reservoir slopes is composed by stainless steel batten plates fixed to the concrete subgrade and covered with an additional strip of geomembrane. The perimeter seal around openings (intake, bottom outlet, spillway, etc.) is composed by stainless steel batten plates fixed to the concrete subgrade and made watertight under water in pressure by means of an additional rubber gasket and epoxy resin. The upper fixation along the top of the reservoir slopes, at an elevation higher than the full supply level, is composed by stainless steel batten plates fixed to the concrete subgrade and made watertight under water not in pressure (rainfall and waves) by means of an addition-al neoprene gasket.

3.3 *Construction works*

The construction has begun in July 2022 and are almost concluded, with the end of construction expected in November 2022. Studio Speri was engaged from Enel Green Power in the supervision of construction. Construction activities and particularly installation of new facing have been carried out extremely quickly. The geocomposite installation activities are reported in the following pictures together with the testing on sealing system (Figure 8).

Figure 8. Photo of the geocomposite placing activities.

4 CONCLUSION

In May 2020 Sillico reservoir concrete facing has collapsed due to differential settlements of the foundation. Historically the reservoir has been subjected to similar damages.

Studio Speri has been engaged from Enel Green Power, as owner of the structure, to carry out the rehabilitation project. The adopted design solution, with the scope to avoid other damages like the past ones, mainly consists in the installation of a new flexible geosynthetic im-pervious facing system, which comprise a composite geomembrane liner coupled with a composite geodrain. The geosynthetics have been selected and designed according to the best international standards.

Construction activities has begun in July 2022 and has been completed in November 2022, confirming that the installation of a geosynthetics facing is usually simple and quick.

Angkor Wat west embankment - restoration and strengthening of the backfill by means of a composite geotextile

V.M. Santoro & V. Gallinaro
IGeS.World srl - International Consulting Engineering, Italy

ABSTRACT: The paper illustrates the restoration and stabilization of a moat embankment portion of the Angkor Wat Temple, Cambodia, in a World Heritage Site context. The earth strengthening was realized with a composite geotextile fabric, providing drainage and reinforcement to the backfill. The implementation of key geotechnical concepts proved to be effective in the middle run since its realization 20 years ago in a low technology environment within a low budget, involving local staff. The requirement of a low impact solution was a key issue in the adoption of the Intervention.

1   INTRODUCTION

1.1   *Historical setting*

The Angkor Wat Temple, located in Siem Reap, Cambodia, counts among the most astonishing monuments of the World Heritage listed sites. Built in the XII century A.D. during the golden age of the ancient Khmer Civilization during the reign of the king Suryavarman II, it is widely praised for the quality of the craftsmanship, as well as for its architectural and cultural value and has long surged to an iconic status. To the present days the Temple Complex maintains its strong link to the local population as a cultural and religious venue, and represents a major resource for the development ambitions of the whole Nation.

1.2   *Hydraulic network and general layout of the area*

Recent studies have been unveiling that the ancient Khmer Civilization designed a complex hydraulic system in the greater Area of the Angkor Royal City, in order to manage the local monsoonal rains.

Canals, water reservoirs, artificial lakes, barriers and dikes are all part of this system that stretches from the Khulen mountains in the north to the lows of the Tonle Sap riverbanks.

The realization of extensive expansion basins at the same time protected the population from the dangers of flooding and provided a manageable water resource to its agricultural economy. The network probably served also as a waterway through the landscape of the Royal city of Angkor and the natural basin of the Tonle Sap lake farther south to the open sea.

The Angkor Wat Temple compound itself, as part of this hydraulic network is surrounded by a rectangular moat, stretching 1.3 km along the east and west sides, and 1.5 km along the north and south sides. The ditch is 190 meters wide, and runs outside the outermost enclosure wall.

1.3 Intervention context

The Restoration Project involved a stretch of the moat embankment located on the west side of the Temple, aside its main entrance. Originally conceived as a stepped slope for the crowds to be seated, the embankment shore maintains to these days its role as a major cultural venue during water festivals and ceremonial occasions.

The intervention on the collapsed embankment involved a length of approximately 60 meters, a stretch located between two abutments of the south side of the moat, on its east shore, its inner perimeter. The project consisted in the reconstruction of the collapsed steps and in the strengthening of its backfill.

Table 1. Key data of the intervention.

Reference	(UM)	(Q)
Intervention length	(m)	60
Earth Volume moved	(m^3)	1050
Geocomposite surface	(m^2)	5000
Final slope inclination	(^{0})	45

Figure 1. Intervention area during the rehabilitation intervention.

The restoration project on the Angkor Wat front steps have been realized in the framework of an international co-operation Program sponsored by UNESCO, and were planned together with the relevant local Authorities with the involvement of local staff, intending to preserve Cultural Heritage through tourism promotion and cultural interchange, along with the development of human potentials through on-field training.

2 ANALYSIS

2.1 Previous restorations of the embankment

Along the last century, at least three times a reconstruction of this portion of embankment was recorded. The Conservation of Angkor- the local Authority responsible for the Maintenance of the Archaeological Area- intervened in 1909 and 1915 for the repositioning

of the steps to their original location, substituting some of the missing heavy stones steps on the front of the slope. A major intervention is documented in the French period with the reconstruction of this part of the embankment in the early 1960's.

In this latest intervention a drainage system from the superficial waters was provided at the back of the embankment. Remains of discharge RC pipes running through the landfill into the moat had been detected already prior to the intervention among the debris of the landslide and further recovered during the excavations of the embankment.

The common feature of these works was possibly a poor prevention of the water action from the backfill. A strengthening of the embankment was also not implemented according to the records.

2.2 *Back analysis of the damage and design approach*

The steps of this moat embankment portion last collapsed on September 27th 1997, following a torrential rain. The project on-site activities started in January 2002.

According to the Reports relating on the collapse event, a substantial water head mounted on the north half of the moat ditch with respect to the south half, where the moat steps are located.

Evidence of filtration paths leading to the steps, was also found in the earth just behind the collapsed wall. Saturation of the soil volumes involved in the landslide may also have played a major role in the instability of the landmass.

Even though there are clear signs of awareness of the potential disruptive effect of the water in the previous Restoration Interventions on the embankment, prevention measures were only limited to a superficial draining system, only capable of conveying runoff waters into the moat through the installed discharge pipes.

For what regards the implementation of a reinforcement of the embankment earth body, there is no sign that it went beyond the compaction of the available soil recovered from the landslide and repositioned behind the steps.

During the onsite survey was furthermore noticed that the laterite and sandstone blocks shielding the embankment slope downstream were assembled on a bedding mortar in the latest restoration intervention, a procedure unknown to the original Khmer constructors. Such sealing of the joints between adjacent stone blocks represented than a barrier to the free water flow from the body of the embankment into the moat.

Figure 2. Adjacent portions of the steps showed a different behavior due to different boundary conditions. Left: dry assemblage of the steps; Right: Joint sealing (gray cementitious mortar) preventing drainage.

The back analysis of the collapse causes pointed out to two possible concurring phenomena.

The pouring rainwater that was falling in the area prior to the landslide, on one side resulted in a sudden relevant increase of the free water surface in the moat, on the other side soaked into the soil, in a more gradual filtration process.

During the first phase of the rain downpour the rising water level in the moat possibly started a filtration process towards the embankment fill, where the water table level lagged behind, as to generate destabilizing upward forces against the foundation basement, in a siphonage path lead by the water gradient.

With the peak downfall fading, the runoff water conveyed into the moat was then readily driven away downstream through the open canals, while the pore overpressure in the backfill was still building up, due to the much slower development of the filtration process.

In this second phase the infiltrating rainwater exerted then an outward thrust against the steps, not balanced any more from the moat water level.

As the rising water level lowers the soil friction bearing capability, the horizontal destabilizing force behind the wall increases.

Under these conditions, chances to trigger a landslide phenomenon drastically increase.

Prevalent could have been one or the other phenomenon, depending on the water level rising rate in the adjacent basins during the rain.

The proposed restoration was then based on the previous considerations, as to ease water pressure behind the wall, and enhance at the same time the friction resistance of the soil.

The design criteria were based on the traditional procedures in use at the project time (Corbet S. & King J. 1993), then revised with the up-to-date ones (Koerner R. 2016).

3   DESCRIPTION OF THE INTERVENTION

3.1   *Introduction*

The idea of reinforcing a weak soil through the insertion of an extraneous material was long since exploited, even before recorded history, often through natural and degradable inclusions such as timber, organic fabrics, or bushes. Though, such interventions could not have been fully reliable and effective in the long term, due to the natural decay of the reinforcements.

Durability remained the major problem for this kind of stabilization till the late 1960's, when the first applications of soil reinforcement based on a rational theory first appeared.

The need for a better durability is nowadays satisfied by synthetic man-made products coming from the plastic industry, namely the polymers, whose characteristics are often improved with additives by the chemical industry, guaranteeing the product from most decay phenomena for "permanent" applications, according to the international standards (up to 100 years).

Typical protection of these materials includes sheltering from UV ray attack, and stabilization from soil aggression, that might result in precocious oxidation and wearing of the polymer chains. The final products are usually guaranteed, and comply with international testing standards.

The first patented usage of a reinforcing geotextile in civil engineering dates back to 1964, but in more recent years the expansion of such products has been enormous, with applications covering reinforcement and drainage in a number of different choices offered by the material's specific characteristics. Target products are often manufactured according to the customer's particular performance requirements.

These materials represent today a low impact and relatively low cost solution to many slope stability problems.

The introduction of a restoration method based on geotextiles, represented an occasion to introduce into Cambodia a viable solution to the slope instability.

3.2 *Details of the intervention*

The soil reinforcing was realized through the insertion of a geotextile into the body of the embankment fill, so to realize strengthened earth.

A drainage system, both at the interior of the embankment and at the surface level was also provided, in addition to the reinforcing of the backfill.

The filtering drainage tissue included in the package deployed inside the earth mass, is meant to drive the waters into transversally positioned draining ditches, specifically realized with graded granular soil.

For a proper functioning of the drainage system in the long term, a filter, placed at the interface between these drainage wells and the reinforced earth, prevents the migration of smaller soil particles.

The available original stone blocks, were recovered from the slide muds and repositioned alongside the moat, so to provide a protection against erosion.

The reinforcement fabric was assembled in horizontal layers intercepting the potential sliding surface, and so dimensioned to provide adequate anchorage length to the compacted stable soil behind.

Soil compaction during the phase of the embankment refilling served to improve force transmission to the reinforcement layers through friction, and avoid settlements of the backfill.

A series of transversal drainage ditches are hydraulically connected to the moat waters, crossing the layers perpendicularly. The soil inside these drainage shortcuts was specifically graded as regards its permeability characteristics.

Service conditions with people surcharging the embankments during a crowded celebration day have been considered, allowing a proper safety factor.

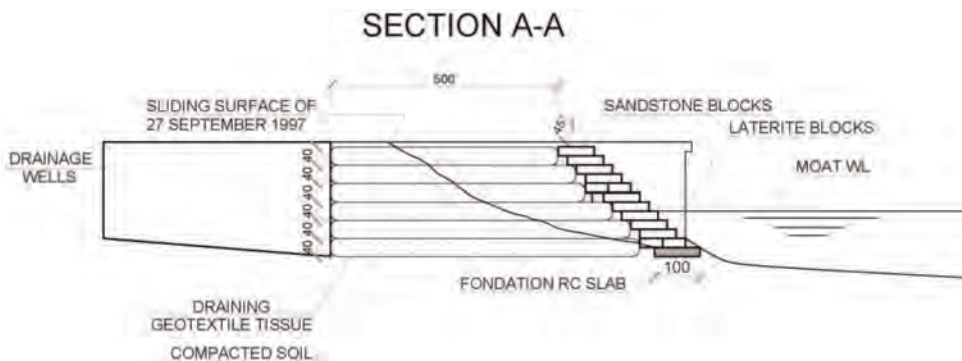
Heavy weather conditions have also been considered, as the drainage system implemented in the works prevents a water head from acting behind the steps.


Figure 3.   Restoration intervention- Geotextile package assemblage in the embankment section.

Figure 4.   Overview of the working site and detail of the filling of the slurry trench.

3.3 Technical characteristics of the adopted materials

3.3.1 Geotextile

As regards its drainage characteristics, the geotextile was specifically studied to drain the waters from the neighboring soil, with permeability values 3-4 orders of magnitude greater of the local soil, that is 1,000 to 10,000 times greater of the natural surrounding material. Once placed on site, these drainage sheets work as drainage pipes within the existing soil mass.

Specific care in the design of the draining sheets was devoted to prevent undesired occlusion, with a proper geometrical distribution of the pores throughout the geotextile.

The process of bonding together the polymer filaments is organised in such a way to prevent both surface covering (blinding), due to the transportation of smaller soil particles, and inside obstruction of the 'mattress' during the filtration process, or clogging. The needle-punching bonding process, that follows the extrusion of the polypropylene filaments, in comparison to the resin or heat assembly method, gives the geotextile a greater mass, resulting in better drainage properties. Only a minor contribution to global strength of the geo-composite comes from the geotextile.

3.4 Geo-grid

On the other hand, the geo-grid plays the major role in the resisting force of the final product.

Service temperature is well beneath the transition glassy temperature of the Polyester fibers (120°), giving the material a more rigid behaviour under service conditions, compared to that of the Polyoefine (Polypropylene (PP) and Polyethylene (PE)), which would be working above the transition glassy temperature of the material in normal environmental conditions, with a rubber-like behaviour and greater deformations.

4 CONCLUSIONS

Extreme weather conditions have long been characterizing monsoon regions, exposed to peak events in short seasonal periods. A changing climate is now exposing always larger areas worldwide to the challenge of protecting built and natural slopes.

Even though awareness of the water influence in triggering soil instability can be recognized already in the classical times, a full understanding of its role dates back to the last century, whilst effective and viable technical solutions in this respect appeared as recently as within the last decades.

The stabilization intervention on the Angkor Wat moat embankment showed that an effective solution based on key geotechnical concepts can be successfully adopted in low technical contexts, under the restrictive design constraints of a prominent World Heritage Site.

With always larger areas dealing with slope instability problems, and new materials specifically tailored to the most diverse requirements being introduced in the market, a broader application field for this type of interventions is opening.

Under this perspective, the restoration represented a pilot project for approaching a current problem in heavy rain environments, through a low impact approach.

Numerical analysis of geo-filters with reference to an Italian case-history

L. Frigo
Comune di Chiampo,Vicenza, Italy

P. Pavanello & P. Carrubba
Dipartimento ICEA, Università degli Studi di Padova, Padova, Italy

ABSTRACT: Geotextile filters are geosynthetic tubular containers, which are filled by pumping a fluid mixture of water and soil: the permeability of the geosynthetic allows the water to drain so that at the end of the installation a relatively solid nucleus can be obtained. Taking advantage of this feature, geo-tubes have been widely used for the storage of sludge of various types and origins. The paper presents a case-history of an application in Northern Italy, where fine sediment accumulated on the bottom of an artificial basin, Valdaora lake, in Alto Adige (Italy) was removed to ensure the correct functioning of the bottom spillway of the dam. Approximately 2,500 m³ of sediments were stored six geo-tubes, organized in a stacked configuration. At the end of the dewatering process, they were left in situ and used as storage containers, after having covered them with earth, thus becoming an integral part of the slope. Given that there are not closed-form solutions available for the stacked configuration, a numerical analysis was performed by means of the Flac 2D code, in order to evaluate the stress level in the geotextile during the various construction phases and to highlight critical aspects of this composite structure.

1 INTRODUCTION

The geosynthetic tubular elements are widely used for various purposes, including the construction of bank or submerged barriers, artificial dunes, for the dewatering and the storage of dredged sediments or for the treatment of sewage of industrial processes. This paper presents a case study of the application of geo-filters for the dewatering of sediments dredged from the bottom of a reservoir. The dewatering procedure has the purpose of separating the liquid phase from the solid one in order to minimize the residual volume, allowing the transport and the storage of the consolidated solid fraction for its final disposal. It should be noted that besides geo-filters (Grzelak *et al.* 2011; Mastin *et al.* 2008; Satyamurthy *et al.* 2011), various other technologies can be applied for the sludge dewatering, including plate and frame presses, belt filter presses (Novak 2006; Wakeman 2007), centrifuges (Lin *et al.* 2001; Rees *et al.* 1991).

The dewatering of sludge through the use of tubular geotextile filters is a recent technique that has multiple aspects of interest: high process efficiency, rather simple management of the construction site, reduced handling of materials and consequently low costs. Moreover, the filtering element could also constitute the container for long-term storage of the sediment, as in the case presented in this paper. The area of intervention is located in the Alto Adige region of Italy, at Valdaora Lake, in Pusteria Valley. It is an artificial basin for the production of hydroelectric energy, created with the construction of an arch dam, with a height of about 35 m and a crest length of 140 m which was built in 1958. The dam is equipped with two spillways on the right hydrographic side, which convey the water into a circular tunnel with a diameter of 5.0 m through two separate pipes. An emergency spillway, on the left side, and a water intake gallery next to the control room, on the right side, completed the hydraulic connection of the reservoir.

The dredging operation was necessary due to the partial obstruction of the two bottom spillways, caused by the deposition over time of sediments transported by the river that feeds the lake. For safety reasons these materials had to be removed, but their high water content required the adoption of a dewatering technique in order to easily manage and store these sediments. The solution with the geo-filters was chosen by the managing body because it allowed the on-site disposal of the sediments, minimizing transportation costs and allowing a good integration with the environment.

2 THE CASE HISTORY

The geo-filters are tubular containers, made of polypropylene by sewing a series of woven geo-textile elements, in order to reach the dimensions required by the project. They were placed on the left side of the lake, near to the dam; preliminary used for the dewatering of the dredged slurry, after the densification of the solid fraction, they were re-employed for the final storage of the retained sediments. In this last phase, the geo-filters were covered with natural soil, thus achieving both the purposes of remodeling the profile of the slope and making them no longer visible. To optimize the storage capacity and to minimize the occupied area, a pyramidal configuration of the tubular containers was adopted, with a cross section formed by two elements at the base and a third element, of larger dimensions, placed above them. Each geo-filter was 30 m long and the pyramidal configuration was repeated twice in length, for a total number of 6 geo-filters (four at the base and two superimposed) and a total extension of 60 m, able to store up to 2,500 m^3 of consolidated sediments. The four geo-filters at the base had a circumference length of 15.7 m, with a maximum design height of 1.7 m, while the larger two upper geofilters had a circumference of 25 m and a height of 1.9 m. The selected woven geotextile had a tensile strength of 100 kN/m and a velocity index of 25 mm/s. The sediments were removed by means of a submersible pump, equipped with disruptors. This dredging unit was moved and controlled by a floating pontoon, so as to be able to suck up the sediment at the required depth of about 20–25 m. The dredged material was pumped through a floating pipe, approximately 250 m long, to the geo-filters (Figure 1).

The average daily productivity was of 150 m^3 of solid material, corresponding to about 300 m^3/h of flowing slurry, with a solid content of about 6%, pumped over an 8-hour work shift. The dredged material was a slightly sandy clayey silt, with a granulometry composed by 12% of sand, 77% of silt and 11% of clay. Its on-site unit weight, before the dredging operations, was of about 16 kN/m^3, while, the slurry obtained by mixing the sediments with the water, during the pumping process, had an average density of 11.8 kN/m^3. To facilitate the separation of the solid fraction in the dewatering phase, an automatic station for dosing an anionic polyelectrolyte was
Figure 1. Aerial view of the site.

provided before introducing the mixture into the geo-filters. The intervention was developed in different executive phases which can be summarized as follows:

(1) preliminary excavation: the natural slope was excavated to create a platform about 20 m wide and 65 m long, for the subsequent positioning of the geofilters, with a slight slope (0.6%) towards the lake, to facilitate the flow of water (Figure 2a);
(2) creation of a drainage layer: at this phase about 200 mc of gravel were used to made a drainage layer with a thickness of about 15 cm, separated from the soil in situ by a layer of nonwoven geotextile, having a weight for unit area of 600 g/m^2 (Figure 2b);
(3) installation and progressive filling of the four geo-filters located at the base of the structure: the filling takes place via a series of hoses connected to the 3 outlets with which each geo-filter is equipped (Figure 2c);
(4) installation and subsequent filling of the two upper geo-filters (Figure 2d), over a leveling layer of granular material placed as drain between the first and the second layer of geo-filters;
(5) At the end of the dredging and filling of the geo-filters, all the equipment was dismantled and the containers were subsequently covered with a layer of topsoil, with an average thickness of 50 cm (Figure 2e).

At the end, the geo-filters are no longer visible and the result is a perfect integration of the intervention into the natural environment (Figure 2f). The works, from the initial phase of removing the sediments to the final stage of covering of the geo-filters, took a total of about six months.
Figure 2. a) step 1: preliminary excavation of the site; b) step 2: drainage layer; c) step 3: filling of the geo-filters at the bottom; d) step 4: installation of the two upper geo-filters; e) step 5: covering of the geo-filters with topsoil; f) final configuration of the slope with geo-filters no longer visible.

3 NUMERICAL MODEL

The design requires the check of the stability of the system in the various executive phases. While the global stability can be evaluated with the usual limit equilibrium methods, the stress and strain state of the geo-filters is more complex to analyze. In fact, there are several analytical solutions for the design of a single geo-filter (Leshchinsky *et al.* 1996) but there are no simple solutions for the case of stacked geo-filters, given that the solution strictly depends

on the geometry adopted, i.e. on the size and relative position of the various elements. The study was performed with a simplified numerical model, implemented in the Flac 2D code (Itasca 2016), based on the finite difference method. The objective of the numerical analysis was to investigate the behavior of the geo-filters, in terms of stress and deformation, during the different operating phases and considering, among the various loads, also the lateral pressure exerted in the final phase by the filling soil placed behind the textile containers.

The model, for plane-strain state analyses, represents a typical cross section, formed by three geo-filters, two at the base and one superimposed (Figure 3). Each geo-filter is discretized with a grid made up of 117 zones, having an average height of 0.2 m and an average width of 0.6 m. The upper geo-filter is modelled with the same number of zones, but the average sizes in this case are equal to 0.21 m in height and 0.87 m in width. The foundation soil is represented as an elastic medium, due to the negligible settlement expected, and corresponds to a grid composed by 432 zones. A summary of the parameters adopted in the numerical model for the geotextile, the slurry and the soil is reported in Table 1.

Various steps are considered in this analysis: first of all, the first geo-filter at the base is materialized. At this phase, the filling slurry is modeled as an elastic material, almost incompressible, and, after the application of the gravity acceleration, the geo-filter assumes its correct configuration. Even if the filling phase is not properly simulated, previously analyses (Pavanello *et al.* 2019b) demonstrated that the results, in terms of stress in the geotextile and shape of geo-filter, are very good and comparable with those provided by analytical calculation methods. At the second step, the change of status of the filling material, from fluid to solid, is simulated by changing the mechanical properties of the inner material. In detail, the medium passes from an elastic behavior to an elastic-plastic behavior characterized by a Mohr-Coulomb yield law. In the subsequent third and fourth phases the previous two phases are repeated to materialize the second tubular container at the base of the structure. Lastly, the simulation of the third tubular container is carried out, again with
Figure 3. Flac numerical model of the staked geo-filters (final configuration).

Table 1. Input data for Flac model.

	Symbol	Value
Unit weight of slurry [kN/m]	γ_{sl}	11.77
Bulk Modulus of slurry [Pa]	K_1	2.0E7
Shear Modulus of slurry [Pa]	G_1	1.0E3
Stiffness (geotextile) [Pa]	E_g	1.15E9
Frictional angle foundation soil-geosynthetic [deg]	$\delta_{g,f}$	20
Frictional angle slurry-geosynthetic [deg]	$\delta_{g,s}$	0.1
Frictional angle consolidated slurry-geosynthetic [deg]	$\delta_{g,c}$	16
Bulk Modulus of consolidated slurry [Pa]	K_3	6.67E6
Shear Modulus of consolidated slurry [Pa]	G_3	4.00E6
Unit weight of consolidated slurry [kN/m]	γ_{sl}	13.72
Friction of consolidated slurry [deg]	φ	25
Cohesion of consolidated slurry [Pa]	c	1000

a first phase in which the filling material is considered in the fluid state and a subsequent one corresponding to a solid state. Finally, in the last phase the lateral stress, due to the filling soil behind the tubular containers, is applied, as a horizontal active pressure, acting on the right side of the structure. For the evaluation of this additional horizontal stress, an average height of the ground to the right of the geofilters greater than one meter compared to the top of the upper geo-filter was considered. In addition, the following soil parameters have been hypothesized: γ = 18 kN/m3, φ' = 30°, c' = 0 kPa, ka = 0,33.

4 RESULTS

The first result regards the stress during the filling phase of the single geo-filter: at the end of the first step of the analysis, when the inner material is simulated as a incompressible fluid medium, the model provides a maximum tensile stress equal to 11.0 kN/m. The same results are obviously obtained for the second geo-filter at the base of the structure. When the third upper tubular container is materialized in the model (Figure 4), the tensile stress of the lower geo-filters shows a significant increase, of about 70%, rising from maximum values of 11.0 kN/m up to 18.6 kN/m. Due to the different dimensions and the irregular support surface, also the tensile stress in the upper geo-filter is much higher than in the previous case, reaching maximum values of about 24.8 kN/m in the "saddle area", in correspondence with the axis of symmetry. Moreover, in the lower side of the geo-filter at the base, the axial forces are close to zero, thanks to the stabilizing contribution of the friction force between the geosynthetic and the foundation soil, which discharges the stress acting in the tubular container (Pavanello *et al.* 2019b).

This analysis scheme can be considered to be in favor of safety, as the gap between the base geo-filters can be reduced by backfilling it with soil. Reducing the space reduces the deformation, and therefore the stress of the upper tubular container; from an operational point of view it corresponds to what was actually done on site, as shown in Figure 2.
Figure 4.   Tensile stress of the geo-filters at the final configuration (in absence of the lateral stress).
Figure 5.   Tensile stress of the geo-filters at the final configuration (in presence of the lateral stress).

As final step, the effect of the lateral filling soil acting on the right side of the model have been investigated (Figure 5). By comparing the distribution of tensile stresses on the geo-filters with (Figure 5) and without (Figure 4) the action of lateral stress, it can be seen that the variation of stress is very limited and only affects the geo-filter at the base, on the side opposite the lake, where a decrease of the tensile force in the geotextile was recorded, due to the stabilizing effect of the action of the lateral soil. On the other hand, there is no percep-tible deformation of the structure and consequently, the configuration of the system can be considered stable even in the presence of the lateral pressure exerted by the backfill soil.

5 CONCLUSIONS

This paper presents a case-history of application of geo-filters for the dewatering and the final storage of dredged sediments. The interaction between the three geotextile tubular container has been modelled with Flac numerical code in order to evaluate the stress state in the geo-sinthetics and the deformed configuration reached by the geo-filters. The interaction between the stacked geo-filters shows that the upper element presents higher tensile stress than the lower ones, especially in correspondence of the "saddle zone", between the two lower con-tainers. Furthermore, the presence of backfill soil on the side of the structure leads to an imperceptible deformation of the structure and to a small decrease of the tensile stress in the geofilter at the base, on the upstream side. The good behavior of the structure in situ indirectly demonstrates the adequacy of the analysis for sizing the geofilters in the design context, although the model has analyzed the backfilling and consolidation phases in a simplified form.

ABSTRACT: The Central Luzon Link Expressway (CLLEx) is a four-lane expressway linking several existing expressways in the Central Luzon region of the Philippines to shorten the travel time between main cities, mitigating the severity of traffic congestion. To minimize interruptions to the local communities and economic activities, abutment embankments are constructed for overpass bridge structures. Geotechnical problems such as embankment instability and excessive post-construction settlements of the embankment were the primary concerns in the project. Among several ground treatment methods, geosynthetics solution was chosen by the Department of Public Works and Highways (DPWH) due to ease of construction and cost effectiveness. High stiffness geotextile is used as a basal reinforcement to enhance the embankment stability and bearing capacity. Prefabricated vertical drains (PVDs') together with surcharge fills is used to accelerate the consolidation settlement of the soft foundation. This paper also discussed the construction sequences of the embankment.

1 INTRODUCTION

The Central Luzon is the third largest region in the Philippine Republic located at the north of the Manila; the capital of the Philippines. It serves as an administration region in the Philippines comprising 7 provinces including Aurora, Bataan, Bulacan, Nueva Ecija, Pampanga, Tarlac and Zambales, as well as 12 cities and 118 municipalities. It is known as the Central Plains of Luzon as it has the longest contiguous area of lowlands surrounded by mountains, active volcanoes, farmlands, sea harbors, etc. The strategic location of the Central Luzon between the Metro Manila and the Northern Luzon turns it into a center gateway, connecting the two regions for land transportation of people and goods, and thereby contributing to the formulation of industrial space and local economic development.

The population in the Central Luzon has tremendously increased from 8 million to 12.5 million people over the past 20 years, contributing more than 10 percent of the total population in the Philippines. Increased population in the region has raised the concern of traffic congestion that worsens the problems of environmental air pollution, local economic efficiency, etc.

2 PROJECT BACKGROUND

Central Luzon Link Expressway (CLLEx) is located at the north of Manila, the capital of the Philippines. The CLLEx is a newly constructed four-lanes expressway linking several existing expressways in the Central Luzon region of the Philippines to shorten the travel time between main cities. The CLLEx is divided into two phases, with Phase I consists of 30 kilometers long expressway connecting Tarlac City to Cabanatuan City and Phase II consists of 35.7 kilometers long expressway connecting Cabanatuan City and San Jose City passing through the municipalities of Talavera and Llanera in Nueva Ecija. Figure 1 shows the layout plan of the CLLEx in Central Luzon Region III.

Figure 1.   Layout plan of the CLLEx in Central Luzon Region III (blue line – phase I; red line – phase II).

The terrain at the central region of Central Luzon is generally flat with an average altitude of 200 m, having mountains and hills with peak altitude up to 2000 m located on its left and right. Its strategic location has stimulated local population growth, property development, economic activities, etc. Apart from urban development, rural development such as agricultural farms to produce rice and sugarcane were also promoted in the rural areas in Central Luzon due to its natural advantages of having fertile soils and river channels.

The new CLLEx expressway traverses existing roadways, as well as rural areas where local rivers and farm roads intersect the CLLEx alignment. To minimize interruptions to the local communities and economic activities, abutment embankments are constructed for overpass bridge structures.

3 SOIL PROFILE

The subsurface soil profile along the length of the CLLEx varies from place to place. The poorest soil condition consists mainly of soft clay layer varying in depth from 2 m to 8 m, whereas some other areas consist of a thick liquefiable fine sand and/or sand and clay mixture layer. The soft clay has an overconsolidated surface crust in the region above the ground water level (GWL). Under this upper soft clay layer is a medium stiff silty clay stratum followed by dense sand layer.

In many locations the ground surface is fully saturated with high ground water table, resulting in a low undrained shear strength (c_u) of 20 kPa near the ground surface increased to

30 kPa at 8 m depth of the soft clay layer with an increasing cu-rate of change of 1 kPa/m along the depth. Under the 8 m depth of soft clay, the cu increased from 30 kPa to 70 kPa over 12 m depth with a higher increasing cu-rate of change of 2.667 kPa/m along the depth. Figure 2 shows the overall soil profile for ground treatment design throughout the CLLEx project.
Figure 2.   Overall soil profile adopted for ground treatment design throughout CLLEx project.

4   EMBANKMENT DESIGN

When soft clay foundation is loaded with embankment fills during construction, the soil deforms over time, mobilizing shear resistance that helps to support the load applied (Yee 2005). The lateral earth pressure from embankment fills exerts an outward shear stress to the foundation, lowering the bearing capacity of the foundation (Jewell 1996). At the same time, the soft foundation may experience significant vertical deformation that mainly caused by the self-weight of embankment fill added onto the foundation. If post construction settlement of embankment is neglected, pavement failure due to excessive differential settlement of the embankment may happen.

The reinforced embankments in CLLEx project varying in height from 5 m to 7 m. The embankment side slope has a gradient of 1 vertical : 2 horizontal proposed with hydro-seeding at the end of construction to facilitate green facing. Figure 3 shows the typical cross section of the reinforced embankment in CLLEx project.

The contribution of geotextile reinforcements in improving embankment stability over soft soil is determined first in terms of stress and force equilibrium, follow by deformation and failure mechanisms (Jewell 1996). Two design approaches were adopted for the reinforced embankments in CLLEx, which are the bearing capacity improvement design and settlement design respectively.

Due to confidentiality of the project, the detail design and calculation performed for the reinforced embankment will not be discussed in this paper.
Figure 3.   Typical cross section of the reinforced embankment in CLLEx project.

4.1 Bearing capacity improvement

For bearing capacity improvement, the reinforced embankments were designed using the limit state design in accordance with BS8006-1 2010 for the internal stability, whereas the external stability was checked using limit equilibrium method. To enhance the bearing capacity of the reinforced embankments during construction stages, geotextile reinforcements were proposed to lay across the entire embankment base, providing the tensile capacity required to achieve a safety factor of minimum 1.5 as per project requirement.

A minimum design life of 60 years is required for the reinforced embankments. Hence, a long-term design strength based on 60 years design life of the PET high strength woven geotextile reinforcements was considered in the analysis. The long-term design strength of geotextile reinforcement can be derived using Equation 1 below:

$$T_D = \frac{T_u}{f_{cr} \times f_{id} \times f_{en}} \tag{1}$$

where, T_D is the long term design strength of the geotextile reinforcement; T_u is the initial tensile strength of the geotextile reinforcement; f_{cr} is the material reduction factor relating to creep effects over the required life of the reinforcement; f_{id} is the material reduction factor relating to installation damage of the geotextile reinforcement; and f_{en} is the material reduction factor relating to environmental effects over the required life of the geotextile reinforcement.

Based on the calculations, a geotextile reinforcement with minimum characteristic initial tensile strength of 600 kN/m is required. The Mirafi® PET600-50 high strength woven geotextile reinforcements having tensile strength of 600 kN/m in machine direction and 50 kN/m in cross-machine direction is adopted in this project. Refer Table 1 for the long-term design strength of PET600-50 high strength woven geotextile reinforcements.

Table 1. Long term design strength of PET600-50 high strength woven geotextile reinforcements.

Property	Unit	PET600-50
Characteristic initial tensile strength (machine direction)	kN/m	600
Material reduction factor – creep effect	1.41	
Material reduction factor – construction damage	1.10	
Material reduction factor – environmental effects	1.03	
Long-term design strength (60 years)	kN/m	376

4.2 Settlement calculation

For settlement design, primary consolidation theory was applied together with prefabricated vertical drains (PVDs') design to calculate the accelerated settlement within an acceptable waiting time.

A settlement design with PVDs' was carried out to determine the waiting time required for ground consolidation to achieve a total 1 m depth of settlement at site. With a design PVDs' spacing of 1 m apart in triangular pattern down to 8 m installation depth together with 2 m high of surcharge fills, a settlement up to 1 m were expected over a duration of 5 months. The design was carried out by the Department of Public Works and Highway (DPWH) for the PVDs' ground treatment method.

5 EMBANKMENT CONSTRUCTION

The construction of embankments began with removal of any vegetation, rock particles and/ or debris on the existing ground that may protrude or damage the geotextile. Ground levelling

was then carried out to prepare an even surface for the laying of separator geotextiles. After the separator geotextiles are laid, a 500 mm thick sand drainage blanket was directly placed on top of the geotextiles (see Figure 4), used to remove the excess pore water pressure at the base of the embankment at the same time serve as a stable working platform for the PVDs' installation machines. After the PVDs' had been installed, PET high strength geotextile reinforcements were laid in a continuous length across the embankment width in the principal direction. The geotextile reinforcements were joined together with adjacent panels onsite with double stitching J-seam method, to provide an overall coverage at the base of the embankments. Subsequently, a 1m thick gravel layer was placed and compacted on top of the geotextile reinforcements (See Figure 5). The gravel and embankment fills were well compacted to 95% Standard Proctor as per the project requirement. Lastly, the expressway pavement structures were then constructed on top of the completed embankments, with side slopes of the embankments hydroseeded to provide vegetation growth. Figure 6 shows the CLLEx completed with pavement constructed on top of the reinforced embankment.

Figure 4.   Placement of drainage sand blanket layer prior to placement of geotextile reinforcements.

Figure 5.   PET high strength geotextile reinforcements laid with principal strength direction across the embankment, followed by placement of gravel layer on top.

The installation of geotextile reinforcements which supplied in roll form are relatively easy to construct compared to other methods. Despite that, detailing such as jointing between geotextile panels and laying direction are critically important during installation, to ensure the functionality of geotextile reinforcement in bearing capacity improvement.

Figure 6.   The CLLEx completed with pavement constructed on top of the reinforced embankment.

5.1 *Jointing*

The two common jointing methods used in geotextile laying are overlapping and seaming methods. Selection of jointing greatly depends on the practicality and appropriateness of using overlap under specific site condition, as well as the comparative costs incurred between overlap and seaming. In general, seaming may be more economical than overlapping in term of geotextile material quantity, especially when the ground is very soft says CBR is less than or equal to 1 % where large ground movement is expected, large overlapping distance up to 1 m may be required. Nevertheless, seaming is usually more time consuming than overlapping due to the on-site stitching process thus increasing the labor cost.

With conservative approach, a J-seaming method was used to join the geotextile reinforcement panels together in this project, ensuring a well coverage of the geotextile reinforcements along the base of the embankment.

5.2 *Laying direction*

The geotextile reinforcements are generally manufactured with principal strength direction along the roll direction, whereby the laying direction must be corresponded to the principal stress direction in the reinforced embankment. In this case, the PET high strength woven geotextiles are laid with principal strength direction across the embankment to enhance the bearing capacity of the soft foundation.

6   CONCLUSION

A successful case study of using PET high strength woven geotextile reinforcements for soft ground bearing capacity improvement and PVDs' for accelerated soft ground consolidation was discussed in the paper. Both reinforcement and settlement consolidation mechanism are equally important for an embankment constructed over soft foundation to ensure the long-term performance of the infrastructure constructed on top.

Five decades of combined knowledge on geosynthetic clay liners

B. Herlin
Terrafix Geosynthetics Inc., Canada

K. von Maubeuge
Naue, Germany

ABSTRACT: The authors of this paper have over five decades of combined knowledge on Geosynthetic Clay Liners (GCLs). This paper will cover both the engineering and performance capabilities of GCLs but also provide readers the dos and don'ts experienced by the authors over the course of their work exposure while working on GCLs on various projects worldwide since the early 90s. Kent von Maubeuge has been directly involved with GCLs since the early 90s when needlepunched GCLs were entering the market and has seen the growth of this geosynthetic material used on various applications while providing assistance on various research studies and testing done on GCLs over the course of the last three decades. Bruno Herlin has been directly involved with GCLs since 2000 with the direct responsibility of overseeing GCLs for his organization and has witnessed what, where, when, who, and why a GCL should be used and how they should be used but also the dos and don'ts of their installation techniques. The paper will also cover the myths of GCLs. Both authors have had a history of sharing information between themselves on GCLs over the last two decades and are now going to share this information for the next generation to have in their GCL 'bag of tricks' to avoid mistakes made in the past but to also feel confident that GCLs do indeed work and can performance effectively as a proven barrier.

1   INTRODUCTION

Geosynthetic Clay Liners (GCLs) began in the 1980s as a simple thin layer of bentonite sandwiched between two textiles with little to no connection between the two textiles. Into the late 1980s and early '90s, manufacturers started to stich bond and/or needlepunch (patented by Naue GmbH & Co. KG in 1987) the upper textile with the bottom textile while interlocking the bentonite between the two textiles to allow the use of GCLs in slope applications. These GCLs are called multi-directional, shear-strength transferring hydraulic barriers. Later the stitch-bonding was added as a method of interlocking the two geotextile layers together. However, the stitchbonding only transferred shear strength in the direction of the stitch-bonding. Over the decades since, GCL manufacturers have provided various types and grades of GCLs by either increasing or decreasing the top and bottom fabric thickness, used various amounts of bentonite, added polymers to the bentonite for added chemical reaction protection to the bentonite and/or to lower the permeability capabilities of the bentonite itself. In the past couple of decades, manufacturers have added lamination thin polymeric geomembranes and/or coated polymeric geofilms to one geotextile side of the GCL - the bottom fabric textile., These GCL types also are known as multi-component GCLs, to not only provide an additional protection to the bentonite layer but also to expand the use of GCLs in various complex applications to ensure a low permeability is provided while long-term performance is upheld.

A special GCL worthwhile to note is a special bentonite composite lining system featuring an additional sand ballast layer that is integrally encapsulated by needle-punched nonwoven geotextiles. The sand layer performs several functions which includes ballasting this special GCL from floating when installed under water - even where there are high water currents, or turbulences caused by ship propellers (however, it should be noted that GCLs do not in theory float due to the shear weight of the material – the bentonite). Due to the needle-punching of the GCL, the sand layer also has the effect of providing a counterpressure to the natural swelling properties of the bentonite, providing more uniform activation of this layer. Consequently, this GCL can remain underwater without additional load or cover for longer periods of time - without loss of performance. During the subsequent placement of stone or other covering layer, this integrated sand ballast layer evenly distributes the load and prevents installation damage to the product.

GCL manufacturers continuously provide new types of GCLs due to design engineers requesting additional safety factors in their project lining designs. It should be noted that new GCLs are not being created because the original GCLs are not working (they are working) but are being made based on new research findings but also as mentioned, due to complex applications that GCLs are being used in to provide additional safeguards to protect our environment.

2 GCL APPLICATIONS

In environmental critical applications GCLs are used in combination with a geomembrane (HDPE/LLDPE) liner as a composite liner system in e.g., landfill base and caps or mining applications. However, they can also be used as a single liner in landfill cap applications, pond lining opportunities, and various other applications where any type of low permeability liner is required, typically to replace a compacted clay liner or low permeable soil. When used as a single liner, GCL type and selection is critical depending on the application, site conditions, possible weather elements, and experience of the contractor with or without previous lining deployment experience. Not every GCL is alike and some GCLs can withstand physical abuse while lower grade GCLs are unable to withstand conditions beyond those provided in the installation guidelines set out by various GCL manufacturers.

2.1 Ponds

When using a GCL in a pond application with soil cover (e.g., not with concrete), the following three rules must exist before using a GCL as a liner. The pond area must be at least 2,000 square metres in size, the slopes must be no greater than 2.5(H):1(V), and the cover soil thickness over the GCL must be 0.3 m (better 0.5 m) at minimum. GCLs are a great liner selection for Stormwater Managements Ponds (SWM Ponds), golf course ponds, and recreational ponds and lakes when the proper type of GCL is selected depending on the subgrade conditions on site during time of deployment. Anchor trenches for the GCL liner are required when used in slopes of greater than 7(H):1(V) to ensure no movement of the liner during cover soil placement, especially when the cover soil operations are being done from the top of the pond to the bottom of the pond (preferred cover soil installation guidelines state that the cover soil operations over the GCL liner be done from bottom to top of the liner, however in some pond application projects, the cover soil material source is located outside the pond hole cavity).

2.2 Pond size

As mentioned above, a GCL is a great liner selection to line a pond if the size of the pond is greater than 2,000 square meters in size. Do not use a GCL if the pond is smaller than

2,000 square metres in size. Why? The GCL requires one foot of cover soil. Most small ponds less than 2,000 square meters in size have slopes greater than 2.5(H):1(V) and will not be able to keep and maintain the minimum 0.3 m cover soil thickness that the GCL needs to act as a liner. The bentonite inside the GCL needs weight to act as a liner. The more weight (e.g., 0.5 m), the lower the permeability, hence the better for the GCL to act as a liner.

Small ponds require greater attention to detail and to be honest most contractors and installers sometimes do not read nor pay attention to lining installation guidelines provided by GCL manufacturers. Pond lining areas greater than 2,000 square metres offer the GCL a proper gentle slope subgrade to rest on and the 0.3 m cover soil minimum thickness required for the bentonite in the GCL to act as a liner. This 0.3 m minimum confining stress is needed to prevent the GCL of free swelling and likely loosening the internal shear strength of the needle punched fibres.

2.3 Subgrade conditions

When selecting a GCL type for a pond application, the subgrade conditions must be known prior to a GCL being deployed. A subgrade for a GCL liner (any liner for that matter) must be dry and well compacted for a low-grade type of GCL to be used (a low grade GCL being where the bottom fabric of the GCL is only a woven fabric). Subgrade conditions in pond applications are rarely dry and well compacted. In conditions where the subgrade is wet and soft, the GCL selection type should be a higher grade GCL. The authors of this paper highly recommend that the GCL in pond applications must be a double-nonwoven GCL where the bottom non-woven must be scrim-reinforced (having the presence of a woven fabric). Double nonwoven scrim-reinforced GCLs are far more robust that GCL that only have a simple woven bottom fabric. Double nonwoven scrim-reinforced GCLs can withstand weather events and maintain their high peel strength values than lower grade GCLs. Weather conditions such as rain and snow on uncovered GCL sheets/rolls can severely affect the strength of low peel strength GCLs versus GCLs that have a high peel strength. Double nonwoven scrim-reinforced GCLs as mentioned with their original manufactured higher peel strength can be left exposed for longer periods prior to cover soil placement. In areas where precipitation will be and/or is an issue then multi-component GCLs should be used with the geofilm/coating portion of the GCL being placed facing up to avoid having the bentonite to be hydrated prior to soil confinement over the GCL.

In applications, where the subgrade is a coarse material, e.g., gravel, it is recommended not to use a stand-alone GCL, as likely under high hydraulic gradients (high water heads in the pond) can cause bentonite piping and therefor weakening the barrier performance of the GCL. In applications with high water heads (approx. > 1m and gravely subgrades) a multicomponent is the best option for a barrier system. Never use a double nonwoven GCL that isn't scrim-reinforced in hydraulic head conditions. Always use a double nonwoven GCL where the bottom fabric nonwoven is scrim-reinforced, hence a scrim-nonwoven bottom fabric – already mentioned, however being repeated herein again, since both authors have seen failures of double nonwoven GCLs where the bottom fabric did not contain a woven (scrim).

2.4 Slopes (pond applications)

GCLs can be used in steep slope applications and certain GCLs can be used in vertical applications, however when used in pond applications, do not use a GCL as a pond liner when slopes are greater than 2.5(H):1(V). GCLs need confinement, the overlaps in GCLs need confinement, and as such will not act as a liner in pond applications where the slopes are too steep. The 0.3 m minimum cover soil placement is required over the GCL to act as a ballast for the bentonite in the GCL to act as a low permeability liner.

2.5 *GCL selection*

When a geosynthetic liner is required on a project, sadly some design engineers will just add a line in their drawings with a mention that a liner is required with no specific details provided. If a GCL is required and used, the specifications will sometimes simply say 'GCL is required' with nothing more provided. GCLs come in many forms since they were created in the 1980s. The top fabric of the GCL (usually a nonwoven fabric) can be supplied in various weights. The bentonite sandwiched between the geotextiles can be supplied in different amounts of kilograms per square metres, the bentonite can also have an enhanced polymer added to protect the bentonite from various liquids that might attack it in a particular application or just improve poor bentonite quality. The bottom fabric of the GCL can either be a single geotextile or contain more than one geotextile as well as having a geofim added to the geotextile(s). It is the authors opinion that all GCLs should have a scrim-nonwoven geotextile as a bottom fabric in a GCL. Double nonwoven scrim-reinforced GCLs provide not only a more robust fabric than a simple nonwoven or woven fabric but they provide a high resistance to internal bentonite erosion in high hydraulic head conditions compared to bottom single geotextile GCLs. Having a bottom scrim-nonwoven fabric GCL also provides an added safeguard to poorly prepared subgrades on a construction site. Double nonwoven scrim-reinforced GCLs also provide a higher peel strength retention when a GCL is involved in bad weather conditions during deployment/exposure prior to cover soil placement and/or other geosynthetic materials applied over it.

3 ADVANCEMENTS IN GCLS

Over the last decade, coated GCLs (multi-component GCL) have been selected over standard GCLs since they provide an added safeguard on projects against badly prepared subgrades and/or harsh working conditions. It should also be mentioned that coated GCLs should not be said to be the same as membrane added GCLs. Membrane added GCL (laminated multi-component GCL) are glued to a GCL and hence have an added angle of friction that should be dealt with and/or paid attention to. Additionally, nothing sticks in the long-term to an PE laminated membrane, so that during the project life-time this interface can become the critical interface in a slope and worse, create a downhill sliding of the cover soil A coated GCL is a melted polypropylene or polyethylene that becomes an integral part of the bottom fabric and hence does not contain an added slip zone to deal with when used in slope applications. However, coated GCLs should undergo a friction angle test to determine the friction of angle between the coating and the adjacent subgrade and/or cover soil material if the coated side of the GCL is facing up during installation. Some project engineers and/or project site can gain an advantage by having the coating facing up due to various conditions that may present on a particular site/project.

3.1 *GCL myths*

GCLs are easy to deploy, too easy in fact, hence 'one should not use them' has been heard many times as a manufacturer of GCLs. They are indeed easy to deploy, and no experience is required to deploy them. When to use an unexperienced geosynthetic deployment contractor and when to use one with an extensive experience is all based on the application that the GCL is being used in. For example, deploying a GCL in a large pond/lake application doesn't necessarily require a contractor with GCL experience. The GCL manufacturer or distributor can provide initial assistance. Other applications such as a GCL being used along with a geomembrane in a composite lining system in a landfill application should require an experience geosynthetic contractor since the project is deemed to require more attention to

details when dealing with liquid leachates. However, overall, a GCL deployment does not require much experience whatsoever. It only requires a contractor who cares about their workmanship to follow GCL deployment guidelines and understands the principle and concept of a GCL.

3.2 Winter deployment myths

Can a GCL be deployed in the winter? A question that is heard every winter for the last 4 decades. A GCL that is made with a dry bentonite of less than 12% moisture content can be deployed in the winter without any concern to the performance of the GCL. Geotextiles are dry and are widely used during the winter without concerns. Hence the only other item of concern is the bentonite itself. If a GCL is manufactured with a dry bentonite and remains dry prior to deployment as it should, there should then be no concerns once installing the dry GCL under cold winter temperatures. GCL material selection should also be considered if it known that the GCL will be deployed in the winter in harsh conditions and with a badly prepared subgrade. Design engineers should select a higher grade GCL such as double nonwoven scrim-reinforced GCL if deployment will occur in the winter to ensure an added safeguard to the performance of the GCL. There's no doubt at all that double nonwoven scrim-reinforced GCL are more robust than the standard nonwoven(top)/woven(bottom) GCLs or a double nonwoven GCL that lacks a scrim-reinforcement.

Figure 1.   Winter deployment and GCL rolls being stored over the winter until deployment. A GCL made with a dry bentonite can be stored without any concern over the winter season outside until required for deployment.

3.3 Can one drive over a GCL?

GCL guidelines state that one should not drive directly over a GCL. However, if the GCL is made with dry bentonite then one in theory can drive directly over the GCL without concern compared to a GCL made with a wet paste bentonite. Any load applied over a wet paste bentonite GCL will in fact squeeze the bentonite away at the point in contact and in fact offer a GCL without any bentonite at the point of contact. Hence one here should also inform themselves if they have a GCL made with a dry bentonite or one with high moisture (wet) bentonite. ASTM 6102 is also very specific on this: "Although direct vehicular contact with the GCL is to be avoided, lightweight, low ground pressure vehicles (such as four-wheel all-terrain vehicles) may be used to facilitate the installation of the overlying geosynthetic. It is recommended that a test pad be constructed on a site-specific basis to evaluate the feasibility and effect of direct vehicular traffic."

3.4 Can a GCL be deployed in water?

A GCL should always be deployed in dry conditions, however construction sites are never timed according to perfect weather conditions. If the application of a GCL is for a pond application, then one can deploy a GCL in stubborn groundwater without any concerns if the appropriate GCL is used in such conditions. One requires that the GCL will maintain a high peel strength when fully submerged in water, i.e... use a double nonwoven scrim-reinforced GCL.

Figure 2. Fully hydrated and/or stubborn groundwater GCL applications in Dyke and/or Canal and/or Pond Applications. Double nonwoven scrim-reinforced GCL being deployed. These GCLs are more robust to installation stresses, have a higher peel than other low grade standard GCLs, and are more weather resistant.

3.5 Is bentonite mass per unit area important?

This answer must immediately be answered with yes. While the GCL permeability of a GCL with a low bentonite mass per unit area (approx. less than 3,500 g/m^2) can be the same as a high bentonite mass per unit area (approx. 3,600 – 8,000 g/m2) the flux value is directly influenced by the bentonite mass per unit area (von Maubeuge *et al*. 2014). GCLs with more bentonite mass per unit area have lower flux values, basically a lower amount of water flowing through the GCL as it is thicker. Therefore, it is recommended to specify GCLs, as recommended in GRI-GCL3 with a minimum mass per unit area of 3,600 g/m^2 at 0% moisture content.

3.6 Buyer beware

Too many times a low grade GCL is used and/or specified on a project where a higher grade GCL should been used instead. GCLs used in vertical applications should never be a low grade GCL (for example: Nonwoven/woven GCL). Vertical applications require a GCL that have a high peel strength (for example: Nonwoven/Scrim-Nonwoven GCL). Never use a double nonwoven GCL unless the bottom the bottom fabric of the GCL is scrim-reinforced, i.e... a scrim-nonwoven. Using a double nonwoven GCL with a scrim-reinforcement can lead to an internal erosion of the bentonite if the subgrade is badly prepared. Water pressure will force the bentonite out through the nonwoven fabric, whereas a scrim-nonwoven bottom fabric in the GCL can withstand a much higher hydraulic head without failure. Failures of double nonwoven GCLs (GCLs that do not contain a scrim) have been known in pond applications over the years. (Scrim = woven).

Needlepunched GCLs have had four full decades of research review and successful deployments, however from time to time a few deployments have gone wrong but for known reasons (no cover soil applied over the GCL for weeks/months following deployment). Installation guidelines are provided and are sometimes not followed. When guidelines are

available due to the unique application in which the GCL is being used, the manufacturers should be contacted to ensure that the GCL selected is the proper one. Too many times a GCL distributor and/or a project specifier will supply a low grade GCL for a project that requires a higher grade GCL (for example: Steep slopes where a low peel GCL is being used). High grade GCLs include coated GCLs and/or where enhanced protective polymers are added to the bentonite to protect the bentonite from being chemically attacked and/or to provide a long-term low permeability performance from the GCL. Going forward some GCLs will be made with higher grade geotextiles.

With needlepunched GCLs currently in their fifth decade of use, research of new higher grade GCLs is currently underway to ensure that our environment at large is protected from these unique thin liners that have over and over shown that they do indeed work and perform as required. However, ensure the proper GCL is being used and that installation guidelines are followed. As with all geosynthetic liners, they can and will perform as intended, however from time to time they are promoted with an exaggerated performance for only a sale to be made without any testing reviews (for example: Shear box testing and/or puncture testing). Geosynthetic Clay Liners come in various forms as mentioned, different types of geotextiles, different amounts of bentonites sandwiched between textiles, coated & geofilm added, enhanced polymers, and at different peel and tensile strengths. All can be supplied for various different applications and requirements, however the bulk of GCL specifications continue to be GCL products made in the 1980s. Needlepunched GCLs have advanced in the last decades since their inception. Unfortunately, as mentioned, some engineers and designers still see lining requirements as an added line in their drawings without doing a full review of what is currently available from manufacturers, a full four decades from where they started.

ABSTRACT: Globally temporary working platforms are an underrated element of almost every construction site. Geogrids have been installed in the temporary working platforms for decades now, as they offer contractors large cost, time and carbon savings compared to alternative solutions. The use of hexagonal, multiaxial stabilisation geogrids and square, biaxial geogrids is by far the most common method for the cost-effective solution. However, designing temporary working platforms using geogrids constitutes a challenge, as broadly available methods (e.g. BR470) present a conservative approach for incorporating geogrids in the designs that results in non-cost effective design. Moreover, geosynthetics manufacturers methods are validated only for specific manufacturers products (e.g. 45° load spread or T-value method). This paper discusses the importance of temporary working platforms design methods full scale validation and lists ideal site conditions for full scale validation tests. Also, it reviews recently undertaken site tests that aimed at testing temporary working platforms full bearing capacity and examining the design methods.

1 INTRODUCTION

To create a safe working surface for construction site plants, an accurately designed and adequately constructed temporary working platform is required. Most of site personnel is aware that using geogrids in their platforms brings costs savings due to the reduced amount of aggregate required for platform construction. It is not the only benefit, reduction of carbon footprint and time required to construct the platform are also significant when using geogrids.

The most widely known and utilised guidance on temporary working platforms design is BR 470 (2004), which was first published in 2004. At the time the guidance was required in the UK as a high number of site accidents was occurring, due to insufficient ground support for the site plants. Nearly 20 years after the guidance introduction in the UK, accidents on sites involving large construction machinery still happen, however only small proportion of them is associated with temporary working platforms performance.

Over the time the guidance gained a reputation of being conservative compared to other methods. Specifically, geosynthetics manufacturers challenged the approach of considering geosynthetic element in the calculation that BR470 endorses. The shortcomings relating to geosynthetic element consideration in the guidance was then reviewed and in 2011, an amendment was created to allow for other methods to be approved and accepted under BR470 requirements. This is, for example, where specific geosynthetics manufacturers design methods are permitted for use. However, BR470 guidance sets specific requirements for these methods before they get applied in real sites conditions, these are:

Objective of safety is preserved

Which means that any considered alternative method needs to be safe for use. It is obvious that risk reduction is the main purpose for installation of a temporary working platforms. Hence, appropriate safety measures need to be implemented within the method.

Based on credible and representative research

This aspect dictates that the method needs to have sufficient theoretical & technical consideration. It needs to be credible scientifically and academically.

Validation by well documented case studies

The alternative design method must be tested and validated in real scale before it can get applied in practice. The validation element of any new method is critical in providing evidence that the method works. Full scale validation of a platform is not an easy task. To fully validate a design method, it is of importance to drive a platform to a full bearing capacity failure. This allows direct comparison of the design method against experimental results at failure. It also allows to quantify and verify required factor of safety.

Whilst there are various methods available to design temporary working platforms with variable level of credibility or applicability for use in this specific application (e.g., not recommended Ev_2 approach), BR470 clearly lists conditions that a method needs to fulfil before it gets utilised on an actual live project. This paper presents a range of recent approaches applied for full-scale testing of temporary working platforms.

2 VERIFICATION TESTING - REQUIREMENTS

Performing a site trial, test or an experiment on a full-scale platform is a challenging task. Some of the typical requirements for these tests include:

Homogenous ground conditions

Seams or layers of a quality or competent soil may contribute to results showing increased bearing capacity at the surface. To obtain unaffected results for design method validation, especially if the method is designed to consider only one subgrade layer, homogenous conditions are required

Deep soft deposits

Pressure applied at the surface has a limited influence on the deposits with depth. At certain depths the excess pressure becomes negligible. That depth is called 'zone of influence'. For practical reasons, zone of influence is typically considered as approximately: two to three times width of the load (2-3xB) applied at the surface (this is practical rather than scientifical consideration). On a trial project, homogenous subgrade deposits should extend deeper than the influence zone. This is to ensure that deep seated competent deposits do not provide extra strength to the overall performance of the system. Also, this allows to limit number of variables required in the back analysis of the results.

Soil strength

In addition, it is worth considering the strength properties required for the trial project. The stronger subgrade the more surface load will have to be applied to the platform surface to ensure generating sufficient deformations to achieve platform failure. In semi competent ground significant tonnage of load must be applied. This may not be practical or achievable due to site constraints. Then, on very soft subgrades stability and safety of testing equipment that won't affect the results must be considered.

Load source

Often, this depends on the contractor that is engaged in the project. The case studies reported in this article utilised four different sources of load: bespoke loading frame, pile testing reaction frame, large cranes counterweight, site plant (e.g. excavators) to provide sufficient counterweight. There is a balance that must be met, e.g: if the desire is to test a very soft subgrade with relatively thin platforms, it needs to be ensured that the platform can support the machinery and/structure that constitutes the reaction load. The thicker the platform the larger the plant/reaction load is required.

Load footprint

The surface load footprint and soil strength are the elements that influence degree of reaction load needed to fully test the platform. The footprint should realistically reflect footprint of typical site plant's track or outrigger size. For example, it is not adequate to run plate load test with 300mm plate and pressures at the level of 1.2 times the design load if the track width is 950mm wide and 4000mm long. However, using 600mm PLT with 600mm track width or a specific case might be considered suitable for 600mm wide drill rig track.

From the Author's experience, it is challenging to find a site with correct site conditions as many sites (e.g. in the UK) are covered by made ground with fairly competent properties (multi-layered subgrades), or subgrades with strength properties that will require considerable level of counterweight, that might be difficult to obtain from typical construction site machinery.

Resulting from this, each project requires careful consideration and analysis of construction and testing processes. Development of full bearing capacity failure in the platform will require considerable load and high deformation, therefore specialised equipment and broader technical consideration should address the above points to obtain valuable results.

3 FULL SCALE VALIDATION TESTING

Table 1 below presents a summary of large-scale tests undertaken for both commercial projects and full research projects. The purpose of the listed tests was to investigate

Table 1. Summary of full-scale temporary working platforms tests.

Project Name/ year performed	Country	Load Footprint & Max Load	Comment
Saskatchewan University 2019–2022	Canada	1m^2 square	Series of controls and stabilized platforms, Su 30-60kPa. Failure through excessive deformation
Wieringemier 2020	Netherlands	8m by 12m	Stabilised platform with 1m geocells on peat subgrade. Failure through excessive deformation.
University of Stuttgart 2019	Germany	5m by 6m 280 t	Reinforced platform 0.9m thick, qc<0.2MPa. Failure through excessive deformation (Moorman 2019)
Krakow Phase I 2022	Poland	1m DIA 1000kN @15%DIA deformation	Stabilised platform 0.25m thick Cu<60kPa. Failure assumed at @15% plate DIA deformation
Krakow Phase II 2022	Poland	1m DIA 460kN	1 x control, 3 x stabilised platform 0.3m–0.6m thick, Cu <20kPa Failure through excessive deformation
San Diego 2022	USA	0.610m DIA 198kN	Cu 16-24kPa. Failure through excessive deformation
Great Yarmouth 2022	UK	0.610m DIA 203kN- 539kN	Stabilised platforms thickness variable Cu – variable approx. 12kP and above No failure achieved

temporary working platforms bearing capacity. The below comprise tests undertaken on all: non stabilised, stabilised, and reinforced platforms.

The Saskatchewan University, Krakow, San Diego and Great Yarmouth tests where run to support and verify compatibility of the T-value design method (Lees *et al.* 2019) for TriAx and InterAx products only. These tests were performed to ensure design method compatibility with the stabilising geogrids installed in the tested temporary working platforms. To Author's knowledge both novel and traditional temporary working platforms design methods for geosynthetics, require verification of compatibility of the methods with a proposed geosynthetic. Considering variety of geosynthetic products available on the market, it is not safe to replace a product with another one that has not gone through rigorous testing and validation process. Such instances may result in undermining safety of the given design.

3.1 *Saskatchewan University, Canada 2019-2022*

Tensar Ltd in cooperation with Saskatchewan University performed validation testing of the T-value temporary working platforms design method (Lees 20019). The site in the Saskatoon Region, Canada was underlaid by weak soils. A layer of more competent crust had to be removed from the site.

A purpose-built temporary bridge (with loaded trucks), was used to create a reaction weight. The plate comprised a steel square 1m by 1m. Several tests were undertaken for the purpose of failing the platform and investigating its full bearing capacity. For each testing location the temporary bridge had to be relocated. Figure 1 (Left) shows the generic set up of the test. Trench that was excavates and marks of the previous tests – square mark on the ground surface in front of the temporary bridge. Figure 1(right) shows the view of the plate used in the test.

Figure 1. Saskatchewan University full scale temporary working platforms testing (Left: general set up, right: platform after the test).

3.2 *University of Stuttgart, Germany 2019 & Wieringemier, Netherlands 2021*

By far an ideal validation for design method comprises a test that replicates the load, contact pressures and footprint that correspond with the actual site project parameters. Large research project was led by Stuttgart University (Moorman 2018). This investigated performance of platforms, examined number of design methods, validate design assumptions, and provided important site observations.

The test was run utilising large timber crane mats stacked in two layers with second layer being installed perpendicular to the bottom layer for better load transference through the layers of the matts. In addition, these tests utilised cranes steel counterweights (made of cast iron) – which is typically used by large cranes to increase their capacity.

Figure 2. Stuttgart University full scale temporary working platforms testing (Moorman 2018).

It is not uncommon for large windfarm projects to conduct a 'routine' validation test of the temporary working platforms designs. That was the origin of the tests undertaken at Wieringemier project in Netherlands 2019 (Figure 3). Developments in wind industry leads to larger and heavier equipment being installed to construct a wind turbine. This leads to designs of temporary platforms that have to withstand excessive surface pressures (e.g. STOWA 2019).

Figure 3. Wieringemier project – general view of the full-scale test.

The Authors are aware of mats up to 8m dimension (timber, steel/iron or concrete). However, it is recognised that when increasing mat dimension (under e.g., 1.2m width track), the effectiveness of the load spread may decrease significantly. Similarly, when using too thin steel plates. Aim of the large mats is to distribute the load over a larger footprint which will reduce the surface pressures. However, if they are too thin, they may start flexing and their efficiency drops.

3.3 Krakow Phase I & II, Poland, May & September 2022

The two phases of tests undertaken in Krakow, Poland 2022, utilised piles testing equipment. The testing equipment comprised a loading frame that is mounted to reaction piles or column (Figure 4 left). Here, each tested platform had installed four DSM columns that allowed capacity of up to 2MN of reaction load to be applied on the platform. The tests in

Figure 4. Left: Reaction frame; Right: Load cell.

Poland were performed on uniform subgrade 6m of natural deposits with Cu values of approx. 60kPa for the Phase I, however Phase two included 4 sections in another location with subgrade strength of Cu< 24kPa. This comprised perfect conditions for this type of testing (addressing all requirements from Section 2).

3.4 *San Diego, USA 2022 & Great Yarmouth, UK 2022*

By far the most cost effective and easy to arrange are standard Plate Load Tests (PLTs). These are readily available across the European continent, less popular outside of it. The main drawback of these tests, however, is that these tests are typically performed using 300mm DIA plate. It is well recognised that to test temporary working platforms' ultimate bearing capacity larger plates are required. In the UK or Germany common sizes are 762mm DIA, France 600mm DIA, which depending on a case may be considered acceptable. The size of the plate should reflect at least the width of the track of the plant that is to utilise the platform. Most common widths of piling rig tracks and construction sites tracked cranes start at approx. 400mm and can go as far as exceeding 1.2m–2m. Further timber/steel mats (called crane mats, bog mats or load spread mats) can reach dimensions exceeding 2m.

Figure 5 presents San Diego USA 2022 PLT using 0.610mm DIA plate. Note that PLT testing equipment was not adequate for testing using low chassis of the excavator. There was

Figure 5. Left: Sand Diego USA 2022 PLT test; Right: Great Yarmouth, UK 2022 PLT.

not sufficient clearance for the testing hydraulic jack to be installed between the plate and the excavator. Hence, small berms had to be constructed to create a clearance for testing apparatus. This type of a solution is not ideal, as this adds complexity to the back-analysis of the results. The berms comprise a surcharge to the sites that adds a degree of additional capacity to the platform. Careful back-analysis needs to be undertaken to consider the effect on design calculations validation.

4 CONCLUSIONS

This paper provided a review of recent large-scale tests on temporary working platforms. Whilst many methods exist to design a temporary working platform (e.g. TWf 2019, Moorman, 2018), there exist very little data to evaluate their accuracy. There exist even less information specifically investigating full scale performance of platforms using stabilising or reinforcing geogrids. This article highlights current industry and research state-of-the-art methods for new and old design methods validation. It should be recognised that introducing a new design method, or a new geosynthetic product to already calibrated method (e.g. T-value method) or novel consideration for a design method (e.g. non-conservative properties to existing methods e.g. BR470), a full scale verification needs to be undertaken to evaluate the systems response to the proposed changes and to ensure safety of the design. The full-scale experiments allow back analysis and verification of factors of safety resulting from more optimal designs. Temporary working platform act as a composite system, with elements i.e. subgrade, geosynthetic element, aggregate and surface pressure interacting in micro and macro-scale. To introduce efficiencies in one element of the analysis, the response of the whole system should be verified in a full-scale setting.

Case study of the use of a piled embankment system with geosynthetic as reinforcement for soft soil subgrade at the Kadusirung Flyover's approach slabs, Banten, Indonesia

N.A. Anindita, D.A. Nurjannah, F. Widhiastuti & D.S. Harninto
P.T. Geoforce Indonesia, Central Jakarta, Indonesia

ABSTRACT: This paper presents a case study of piled embankment system with geosynthetic as reinforcement for soft soil subgrade at the Kadusirung Flyover's approach slabs, Banten, Indonesia. The embankment was reinforced with GSRW (Geoforce Segmental Retaining Wall) system with height of up to 9 metres. GSRW is a retaining wall construction that consists of a compacted layer of backfill and has a facing made of precast concrete and reinforced using polyester strip. Due to the low bearing capacity of the subgrade, piled embankment with geosynthetic system was chosen to reinforce. To help transfer load to the pile and to consider the soil arching ratio, a combination of small pile cap and high tensile strength geogrid was used. From design perspective, the system improves safety factor above the criteria stated in Indonesian National Standard for Geotechnical Design Requirements which is above 1.50 and design with pseudostatic earthquake load which is above 1.10.

1   INTRODUCTION

The construction of the Kadusirung Flyover's approach slabs in Banten, Indonesia will span up to 185 meters and will be carried out as high as 9 meters. The construction of the flyover will be done on soft soil subgrade. The approach slabs' embankment will be reinforced using Geoforce Segmental Retaining Wall (GSRW). This structure's technology combines concrete facing and polyester strip as a locally sourced reinforcement and is anchored from the facing to the body embankment according to the design calculations. Soil investigations results such as SPT drill showed that the subgrade is dominated by soft soil approximately until the depth of 11 meters. The piled embankment system was then selected as the subsoil's reinforcement. Using geosynthetic, geogrid material can be incorporated as the load transfer platform by reducing the pile cap's dimension.

Figure 1.   Kadusirung Flyover, Banten, Indonesia.

2 APPROACH SLABS EMBANKMENT'S REINFORCEMENT USING SEGMENTAL RETAINING WALL SUPPORTED BY PILED EMBANKMENT SYSTEM WITH GEOSYNTHETIC REINFORCEMENT AS LOAD TRANSFER PLATFORM

2.1 *Geoforce segmental retaining wall*

This flyover used Geoforce Segmental Retaining Wall (GSRW) as the approach slabs' embankment reinforcement. GSRW is an earth retaining wall system that consists of layers of compacted backfill material and facing element made from high quality precast concrete, also reinforced with belt or known as GI-Strip. The distinction between GSRW and other product lies in the robustness of the structure which has been tested, the competitiveness of the price compared to the similar segmental product, the fast and easy installation of the structure that affects the time efficiency of the project, and the aesthetic aspect that capable of adding the enticing aspect of the constructed segmental system.

The GSRW system is reinforced with the friction belt made out of high tenacity polyester yarn namely GI-Strip. The strip has been specially designed to generate reinforced belt with high tensile strength and friction coefficient. This component is what makes the structure robust. The selection of the tensile strength type is adjusted with the design calculation from the GSRW construction which will be built. Another advantage from GI-Strip is the high durability of the material, resistance from organic bacteria and acidity from the backfill material. The GSRW system is shown in Figure 2.

Figure 2.   Construction of geoforce segmental retaining wall system.

2.2 *The piled embankment system combines with geosynthetic reinforcement*

Piled embankment system is one of soil improvement technique that can minimize massive settlement problem. This system is done by installing piles that reaches into certain depth and space depends on load, subsoil type and take advantage of geosynthetic's tensile strength to reduce the need for large pile caps and raking piles. According to The British Standard "Code of practice for strengthened/ reinforced soils and other fills" (British Standards Institution 1995) the general idea of geosynthetics reinforcement utilization can be understood through the soil arching mechanism. This way, the load that is acting on the soft soil will be transferred to the piles by tension in geosynthetics. This mechanism is used to determine the required tensile strength of the geosynthetics. The construction of piled embankment system combines with geosynthetic reinforcement is shown in Figure 3.

Figure 3. Geosynthetics reinforcement scheme in piled embankment system.

3 DESIGN METHODOLOGY

3.1 *Geotechnical investigation*

During the initial phase, soil investigation was carried out with as many as six SPT bore holes equipped with soil laboratory data. Based on the SPT results, it can be concluded that the area is dominated by clay-silt soil with consistency soft to medium at the surface until the depth of 11 meters. This is where the problem lies. This layer of soft to medium clay silt possesses low shear strength and hence, low bearing capacity. Without proper subsoil improvement, the construction of GSRW system will leave massive deformation. Here is shown the SPT graph result.
Figure 4. Geotechnical profile for BH-1 until BH-6.

3.2 *Geosynthetic in piled embankment design process*

The design for the GSRW needs to be assessed internally and externally. Internally, the reinforcement belt's (the GI-Strip) tensile strength and length needs to be designed properly. The GI-Strip tensile strength and length must withstand the load from the embankment itself, the dead load from the road, the live load from traffic and earthquake load. Externally, the GI-Strip must be safe from the possibility of failure through sliding, overturning, and must check the bearing resistance. The safety factor used is 1.50 for condition without earthquake and 1.10 for condition with earthquake, in accordance with Indonesian National Standard for Geotechnical Design Requirements.

After the GSRW design process, the piled-on embankment system design is carried on determining which type of geosynthetic is appropriate for the system. The calculation for the pile length and type was done before the calculation of the required geosynthetic. The piles are required to reach a depth of 12 meters with a square mini pile type measuring 25x25 cm

and contiguous bored pile with a diameter of 60 cm under the leveling pad. The calculation for the geosynthetic requirement is as followed:

1. Basic data

   Fill Data:
   Unit weight $= \Upsilon_{fill}$ = 12.6 kN/m^3
   Angle of internal friction $= \phi'_{fill}$ = 28°
   Cohesion $=$ c' = 30 kPa
   Load Data:
   Embankment load   = 117.68 kPa
   Life load   = 15 kPa
   Dead load   = 12 kPa

2. Calculating maximum pile spacing

$$s = \sqrt{\frac{Q_{pall}}{\gamma_e}} H \tag{1}$$

$$\gamma_e = \left(\gamma_{fill} + \frac{q}{H}\right) \tag{2}$$

   where Q_{pall} = allowable capacity of the pile; Υ_e= effective unit weight of the embankment; and H = height of the embankment.
   s = maximum pile spacing = 7.5 m, adopted pile spacing = 1 m

3. Calculating the ratio of vertical stress on pile (or pile caps) to vertical effective stress in fill

$$\frac{p'_c}{\sigma'_v} = \frac{p'_c}{\gamma_e H} = \left(\frac{a_c d}{H}\right) = \left(\frac{((1.70 \times H/d) - 0.12)d}{H}\right) \tag{3}$$

   where p'_c = vertical stress on the pile (or pile cap); σ'_v = vertical effective stress at the base of the fill; d = width or diameter of the pile (or pile cap); and a_c = arching coefficient and is dependent upon the height of the fill, the width of the pile (or pile cap), and the rigidity of the pile.
   p'_c / σ'_v = 2.87

4. Calculating the distributed load which the geosynthetics reinforcement, W_t, must support between the piles (or pile caps)

$$W_t = \frac{s\gamma_e H}{s^2 - d^2}\left[s^2 - d^2 \frac{p'_c}{\sigma'_v}\right] \tag{4}$$

   where W_t = distributed load acting on geosynthetics.
   W_t = 54.6 kN/m

5. Calculating tensile load (required working strength)

$$P_{rp} = \frac{W_t(s-d)}{2d}\sqrt{1 + \frac{1}{6\varepsilon}} \tag{5}$$

   where P_{rp} = required working strength.
   P_{rp} = 53.05 kN/m

6. Calculating ultimate breaking strength

   The value of the tensile strength of the geogrid material above must be reduced to factors as shown in the equation below:

$$T_{design} = \frac{T_{ult}}{RF_c \times RF_{id} \times RF_d} \tag{6}$$

   where T_{ult} = ultimate breaking strength; RF_c = reduction factor creep (2); RF_{id} = reduction factor for installation damage (1.3); RF_d = reduction factor for durability (1.2).

T_{ult} = 165.5 kN/m

For that, the geosynthetic used as load transfer platform is Geogrid with 175 kN/m in tensile strength.

3.3 Global stability analysis

As the last design step, global stability's safety factor check was assessed with PLAXIS 3D software. The analysis was done with the highest embankment which is 9 meters. According to the design, the piles were installed in the first stage of the design. After the piles, the pile caps and geosynthetic were activated. Next, the backfilling of soil, installation of the concrete precast facing and GI-strip were done. The whole system was then assessed with the activation of the 20 kPa traffic load. The soil parameter is as shown in Table 1, as for the geometry model is as shown in Figure 5 and the analysis yield results as shown below in Figures 6 and 7.

According to Figure 5, the static safety factor for GSRW of Kadusirung Approach Slab is 2.031. This safety factor fulfills the criteria in Indonesian National Standard for Geotechnical Design Requirements which is above 1.50. After that, the analysis combines with the pseudo-static load which was adopted from design response spectrum in Map of

Table 1. Hardening soil model parameter.

Soil type	Υ_{unsat} $[kN/m^3]$	Υ_{sat} $[kN/m^3]$	c' $[kPa]$	φ' degrees	E_{50}^{ref} $[kN/m^2]$	E_{oed}^{ref} $[kN/m^2]$	E_{ur}^{ref} $[kN/m^2]$
Silty clay, soft (0-5 m)	15	17	2.5	22	10000	7000	30000
Silty clay, medium (5-11.5 m)	16	18	5	28	20000	14000	60000

Figure 6.   Estimation of static failure mode of GSRW of Kadusirung approach slabs supported by geosynthetic and piled embankment system.
Figure 7.   Estimation of pseudo-static failure mode and safety factor of GSRW of Kadusirung approach slabs supported by geosynthetic and piled embankment system.

Indonesia Earthquake Sources and Hazards in 2017. The Peak Ground Acceleration value is 0.426 g and multiplied by the amplification factor of 1.1 and 0.5, which results in horizontal acceleration 0.23g. The pseudo-static load analysis yields safety factor 1.131. This safety factor also fulfills the criteria in Indonesian National Standard for Geotechnical Design Requirements for embankment with seismic load which is above 1.10.

4   CONCLUSION

The Kadusirung Flyover Approach Slabs was constructed with Geoforce Segmental Retaining Wall system on soft soil and needed subsoil reinforcement. The selected reinforcement system was piled embankment, as it is the easiest, fastest and most robust system to implement. Nevertheless, this system requires massive pile cap as a load transfer platform. Geosynthetic can reduce the need for pile cap, and in this case, Geogrid has successfully done that. In Kadusirung Flyover Approach Slabs the geogrid uses 175 kN/m tensile strength to spread and distribute the dead and live load to the piles. The global stability was then analyzed using PLAXIS 3D software and yield safety factor 2.031 for static analysis and 1.131 for pseudo-static analysis.

Using of geosynthetics on foundation of residential complexes and low height buildings on stabilized fillings from municipality of Bucharest

S. Mustatea, L. Talos, A. Barariu & Ali Naji
S.C. Geostud S.R.L. Bucharest, Romania

ABSTRACT: Due to the restriction of the perimeters with good foundation lands in Bucharest, which are also very expensive, a need arose to base on fillings, especially for residential complexes and some low-rise building. Although these houses transmit lower pressures to the foundation lands, due to the inhomogeneity of the fillings, differentiated settlements appear, which in the end can destroy the building. Consequently, in addition to the well-known solution to completely remove fillers – a solution that involves excavation work transportation, storage in specially designed spaces, activities that require approvals, environmental protection work, high costs – Geostud specialists have found alternative technologies consolidation and stabilization of these fillers, based on the use of geosynthetics. The article presents the technologies, including the theoretical basis and examples of works where they have been used.

1 INTRODUCTION

In the Municipality of Bucharest, there are areas where the fillings have thicknesses from 3,5 m to 15 m consisting of pieces or slabs of concrete, bricks, metals, vegetable, or textile residue, deposited over time in an unorganized way and which, from a geotechnical point of view, constitute a difficult foundation ground (according to table A13, NP 074/2014). All this the high level of water table, which is practically contained in the fillings, is added to Filled areas exist both in the inner city and in the outer city of the municipality.

Due to the narrowing of the perimeters with good foundation ground, which are also very expensive the need for foundations on the fillings appeared, especially in residential complexes as well as in some low-rise buildings. Although these buildings transmit lower pressures to the foundation grounds, due to inhomogeneity of the fillings, differential settlements occur, which can eventually destroy the building.

Hence, in addition to the well-known solution of completely removing the filling material - a solution that involves excavation works, transport, storage in specially designed spaces, activities that require approvals, environmental protection works, high costs – our specialists have found alternative consolidation technologies and stabilization of these filling materials.

Among these solutions, the promoted and recommended ones by S.C. Geostud S.R.L. are the following:

– foundation on ballast/crushed stone cushion, reinforced with geogrids and covered in geotextile
– consolidation through the execution of successive layers of soil geotextile reinforced soil.
– consolidation with 'rigid inclusions'.

Each solution has a theoretical basis, a specific technology that involves excavating the filling material to a certain depth, usually between $1 \div 1.5$ m for the cushion, $1.5 \div 2.5$ m

for consolidation with successive layers of reinforced soil, and 2.5 ÷ 3.5 m for strengthening with rigid inclusions. In any case, the level of the excavation must be stopped at least 1m above the water table.

Next, the first two technologies based on the use of geosynthetics are summarized.

2 FOUNDATION ON BALLAST /CRUSHED STONE CUSHION, REINFORCED WITH GEOGRIDS AND COVERED WITH GEOTEXTILES

This technology is based on working together between geogrids, ballast, and geotextiles.

Geogrids are synthetic materials made of high-strength polyethylene, formed by an empty aperture, which allows the penetration of ballast/crushed stone grains, with which they achieve an interlock (Figure 1), thus considerably reducing the tendency of lateral and vertical displacement of the grains. In this way, a web is formed that takes the tensile stress, which the foundation ground cannot take over, uniformizes the distribution of the loads, the stress concentrations disappear, increasing the angle of distribution of loads at the same time and finally the bearing capacity of the foundation ground increases.
Figure 1.   Geogrid empty aperture.

The geotextile has the role of separation between the surrounding heterogeneous filling, preventing the penetration of aggregates into the filling and the penetration of fine soil particles from the filling into the cushion, removing the clogging. It also has a filtering and drainage role. The ballast also has the role of breaking capillarity so that the water does not rise above the cushion, thus canceling the under pressure on the base of the building's foundation, also evenly distributing the loads. Since the width of the mattress is bigger than the width of the foundation, the load distributed on the foundation soil is smaller. Thus, the foundation soil can safely take over the loads transmitted by the construction.

The required number of layers, geogrids included, can be dimensioned as follows:

$$T = (G + q \cdot l)/l \qquad (1)$$

where T = the total force transmitted by the structure, kN; G = the building weight, kN; q = uniformly distributed mobile loads (snow furniture, people etc.), kN

$$n = \frac{T}{R_t} \qquad (2)$$

where n = amount of geogrids / number of layers; R_t = tensile strength of one geogrid, kN

– it is chosen constructively:
– The thickness of the mattress d =1.0 m
– The width of the mattress L = l + 2 0.5 m
– l = the width of the building foundation

Usually from experience, the maximum number of layers is 4 and the thickness of one layer is 0.25m (after compaction).

This solution was proposed in the geotechnical study for the construction of the residential complex Green Lake Residence, plot H, where the fillings are up to 7 m thick, and from 3 m deep contains large concrete slabs embedded in the heterogeneous mass of rubble and soil.

At the moment, the residential complex is partially finished (Figure 2).

Figure 2.   The green lake residence.

3   CONSOLIDATION AND STABILIZATION OF FILLINGS BY THE EXECUTION OF SUCCESSIVE LAYERS OF EARTH REINFORCED WITH GEOTEXTILES

The technology of consolidation and stabilization of fillings consists of:

– plotting the location of the building
– excavating the filing material to the level established by the project
– removal from the excavated surface of all blunt materials (bricks, pieces of concrete, iron bars), roots, vegetable remains textiles, etc.
– leveling and compacting the resulting surface.

On the surface thus prepared, the first layer of geotextile is spread (consisting of strips over-lapping a width of at least 20 cm), after which a layer of loose soil of approximately $25 \div 35$ cm thickness is laid and compacted to a degree of compaction between $96 \div 98\,\%$, thus creating the first elementary layer of reinforced soil. The procedure continues to be carried out successively up to the projected elevation, which becomes the foundation elevation of the building.

The stabilization and reinforcement effect are achieved by mobilizing shear forces at the soil-geotextile contact (Figure 3) as follows:

Compaction, with vertical stress (σ), induces a stretching stress in the geotextile (T), given by the resistance mobilized at the contact between the soil and the reinforcement (τ_s). Thus, a mobilized resistance (τ) appears in the composite soil, whose value is:

$$\tau = \tau_s + \frac{T}{d} = \tau_s + T \cdot D \tag{3}$$

$$D = \frac{1}{d} \tag{4}$$

where D = armature frequency or armature density; d = distance between reinforcements. In this way, an extra cohesion appears in the soil (additional cohesion Δcs), whose value is:

$$\Delta c_s = D \cdot T \tag{5}$$
Figure 3.   The stabilization and reinforcement effect of the geotextile.

when under stress, the soil breaks first,

$$\Delta c_s = \frac{D \cdot T}{m_s} \tag{6}$$

$$m_s = \frac{\tau_s}{\tau} \tag{7}$$

when under stress, the geotextile breaks first.
This additional cohesion is highlighted in the graph below (Figure 4):
Figure 4.   Additional cohesion.

Under these conditions, the shear strength increases in the reinforced layer and further in the entire package of layers and is a direct function with the distance between the reinforcements (d), respectively with the density of the reinforcement (D). Thus, the last reinforced layer is reached, the foundation conditions are practically homogenized on a filling whose geotechnical characteristics vary in plan, reducing the settlements to a minimum, while increasing the bearing capacity.

In conclusion, this solution ensures the distribution of loads in the field at the level of admissible pressures. This technology was successfully applied to the foundation of a building in the Colentina area, where the thickness of the filling layer is over 10 m.

4   MATERIAL AND SOIL QUALITY CONTROL

Before commissioning, all materials and soils included in the works must meet all the conditions established by European and National norms. However, in order, to ensure the quality and durability of the works, the ballast/crushed stone, geotextile, geogrid, and soil must meet the following minimum conditions:

- For ballast/broken stone:
  - granularity $0 \div 70$ mm and falling within the prescribed areas
  - uniformity coefficient Un $\geq$ 15
  - capillary height: 15–20 cm
  - degree of compaction: D = $90 \div 100\%$, normal Proctor

- For geotextile:
  - tensile strength: $T_{max} \geq 300$ kN / m
  - the normal permeability coefficient: $K_n \geq 5 \cdot 10^{-3}$ cm / s
  - longitudinal permeability coefficient: Kl $\geq 2 \cdot 10\text{-}3$ cm / s
  - elongation at break: $\varepsilon_{max} = 6\%$

- For geogrids:
  - tensile strength on main direction Tmax $\geq$ 200 kN / m
  - elongation at break: $\varepsilon_{max} = 6\%$

The soils in the layers are of a cohesive type without blunt elements that can pierce the geotextile and at least the following characteristics must be checked before commissioning:

- continuous granulometric curve: Un $\geq$ 15
- upper limit of plasticity $w_L = 30 \div 40$ %
- dry density $\rho_d \geq 1.65$ g / cm3
- humidity at commissioning, w = $w_{opt} \pm 3$ %
- where w_{opt} = optimum moisture content obtained from compaction test
- content of organic materials, maximum 1 %
- carbonate content, maximum 1%

After compaction, each layer must be 20–25cm thick, reaching a degree of compaction of D = $96 \div 98\%$ and D = 100 % on the last three layers. Also, on each layer, the bearing capacity will be checked with the static plate, and the homogeneity with the dynamic plate.

5 CONCLUSIONS

Of particular importance in these buildings founded on fillings is the in-situ monitoring of both the behavior of the filling and of the buildings themselves.

Thus, for fillings, it is necessary to install topographic markers to monitor subsidence and to install piezometers to monitor fluctuations in the groundwater level. For the building itself, it is necessary to mount settlement gauges, visually monitor and measure any cracks, as well as their development over time.

Beforehand, it is necessary to design a surveillance and monitoring program, which must contain:

- the frequency with which the measurements must be made;
- location of landmarks and piezometers;
- proposals for values that characterize the normal operating state and limit values for 'attention', 'warning' and 'alarm';
- proposals for measures in the event of settlement in the foundation, cracks in the walls and raising the groundwater level that may endanger the building.

Sinotech Engineering Consultants, Taipei, Taiwan

ABSTRACT: In 1999, the Chelungpu fault in central Taiwan triggered the deadly 921 Chi-chi earthquake, which measured 7.3 on the Richter scale. However, because of specific technical influences, the project reported herein has to pass through the Chelungpu active fault through a high-fill embankment. Due to the fault-induced movement bound to produce severe differential deformation and surface rupture, the structure must be earthquake-resistant to ensure its safety. Considering the particular requirements of this section, after exploring several probable solutions, the designers finally determined to apply geosynthetics reinforced soil structure (GRS) to build the reinforced foundation and the reinforced embankment to restrain the differential movement caused by active faults to the greatest extent. The adjacent slopes have also been stabilized carefully. The analysis results show that the safety factors of the GRS embankment and its adjacent slopes all meet the requirements of safety and service functions.

1 INTRODUCTION

Taichung City is located in the center of western Taiwan, where the population and economy are concentrated. It has frequent industrial and commercial activities and a dense population, thus with a high demand for traffic development. The government actively promotes transportation construction in central Taiwan and constructs a complete highway network system. It also aims to provide convenient transportation services to the Great Taichung metropolitan area and promote the mutual development of the metro area and surrounding cities.

Taiwan is located at the boundary of the Eurasian plate and the Philippine plate, resulting in 51 faults on this island. The numbers of earthquakes caused by these faults are almost countless, posing a significant threat to people's lives and property. For example, the 1999 Chi-chi earthquake, triggered by the Chelungpu fault in central Taiwan, caused about 14,000 deaths and injuries and toppled more than 100,000 houses (Wikipedia 2022). This fault is distributed from north to south along the foothills of the hilly eastern area of the Taichung Basin. The extension project of National Highway No. 4, the case study presented in this paper, must meet the Chelungpu fault at the stations of 23k+242 to 23k+410 under the overall considerations of service function, topography, and highway alignment. According to historical information, the surface rupture caused by the Chi-chi earthquake triggered by the Chelungpu fault was about 85 kilometers long, the vertical displacement was about 4~5m in this area, and the horizontal displacement was about 2.5~5m in some areas.

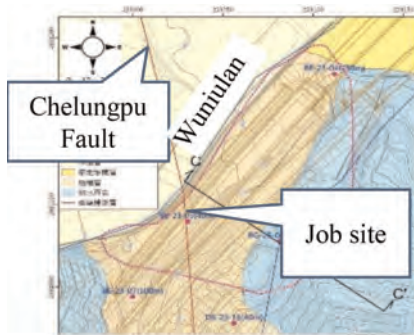
As shown in Figure 1, the surface fracture zone intersects with the designed highway at an angle of about 60 degrees, and the surface rupture caused by the hanging wall on the site was relatively moved up about 3 m. The evidence indicated that there had been serious fault misalignment, which resulted in severe damage to the nearby reinforced concrete revetments of Wuniulan Creek at that time (Figure 2). Because of the severe impact of the fault, if a similar movement occurs again in the future, it will undoubtedly cause severe damage to the structure of this section. Therefore, the design strategy of this project must consider the earthquake-resistant requirements of the structure in this area to ensure the necessary safety. Also, well-organized emergency countermeasures must be available after the disaster.


Figure 1. The intersection of the site and Chelungpu fault (Sinotech engineering sonsultants, Ltd. 2017).
Figure 2. Failure of reinforced concrete revetments caused by Chelungpu fault (Chiang *et al.* 2022).

2 PHOTOGRAPHS AND FIGURES SITE CONDITIONS

The presented case runs through the hilly area of the foothills region in western Taiwan. The surface terrain changes significantly, with elevation along the route fluctuating between 300~450m. The toe at the west slope of the highway is close to Wuniulan Creek. The east side of the highway is a steep slope consisting of debris formation and only allowing for a very narrow proximity for construction. Since this section must match the longitudinal slope variation of the adjacent tunnel, as well as the geometric planning of the highway spaces at the tunnel's entrance, the design elevation of the embankment section has shown up to 20m different from the original ground surface. Therefore, retaining structures must be used to ensure the safety of the embankment. As shown in Figure 3, based on the site investigation, the shallow geological formations at the site consist of colluvium and gravel with poor engineering properties. Bedrocks below the site consist of shale, sandy mudstone, and alternate layers of sandstone and shale with well-developed shear fractures attributed to the Chelungpu fault. The strength of rock mass is poor due to these fractures.

3 SOLUTIONS

The traditional geotechnical engineering solutions for fault areas include:

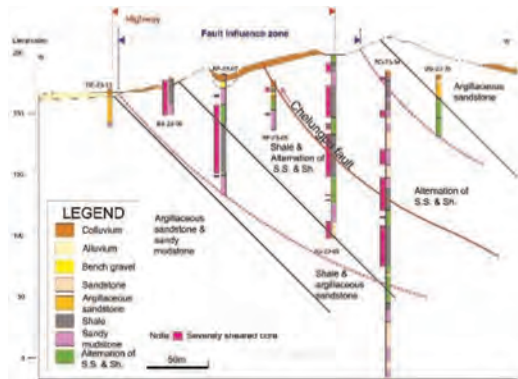
1. Rigid foundations or structures
2. Embedded retaining structures or buffer trenches
3. Placement of ductile engineering fills


Figure 3.   Geological section of the site (Sinotech Engineering Consultants, Ltd. 2017).

The first solution involves using high-rigidity structures such as thick mats to counter-balance the fault ruptures. The second solution suggests installing a diaphragm wall, soil-bentonite mixtures, or ground improvement to divert the propagation of shear rupture beyond the boundaries of the target facilities. Alternatively, buffer trenches filled with lightweight expanded polystyrene (EPS) can provide spaces to accommodate fault-induced ground movement. The third measure involves the use of seismic-resistant engineering fills such as geosynthetic reinforced structure (GRS) to distribute the fault movement over a wider zone to reduce angular distortion at the ground surface and thus maintain the stability of the overlying structures (Ashtaiani et al. 2017; Bartlett et al. 2015; Chiang et al. 2021; Rasouli & Fatahi 2020, 2021; Yang et al. 2020).

Because of the elevation requirement, the sections across the fault zone must be embankment or viaduct structures. However, rigid reinforced concrete viaduct structures will be costly and time-consuming. It is also tough to promptly repair the damages caused by the induced ground movement after severe shaking.

The optional embedded retaining structures and buffer trench consist of flexible or light-weight materials mainly applied to underground systems such as utility facilities (Bartlett et al. 2015; Ra-souli & Fatahi 2020). In addition, this construction commonly involves deep excavation and complicated retaining structures. Therefore, it does not meet the application requirements of this project.

Geosynthetic reinforced soil structures (GRS) consist of geosynthetic materials that are flexible structures capable of presenting a higher damping properties to absorb the energy released by earthquakes (Chiang et al. 2022). This kind of structure has been extensively used in the construction of embankments, and its effectiveness has been validated in earthquake areas proving that the correctly designed GRS has excellent seismic resistance (Dobie 2006; Taheri & Hadiani 2019). Studies have also indicated that GRS has significantly mitigated the damages caused by fault movement (Ardah et al. 2018; Bray 2001; Chiang et al. 2021).

Yang et al. (2020) and Chiang et al. (2021) studied the effect of fault movements on GRS foundations using a series of sandbox model tests and finite element numerical simulations. The results indicate that, compared to the unreinforced foundations, the reinforcement acts as a tension membrane, creating tension along with the displacement caused by the fault. Its vertical component supports the overlying soil, thus minimizing the influence of surface settlement.

When the fault movement increases and thus initiates an enormous shear force within the GRS, the reinforcement can effectively impede the development of the shear zone and prevent the shear plane from reaching the surface to form surface rupture and reduce the angular distortion by up to 60% on average at the ground surface. Such reinforced earth mechanism can be identified as the shear rupture interception effect. Because of this inter-ception effect, the intense shear strain develops horizontally and extends along the bottom

reinforcement layer. The initiated shear strain reduces with the increased distance from the fault tip, indicating that the energy of fault movement is progressively dissipated by the resistance provided by the soil–reinforcement interaction. However, relevant studies have also noted that reinforcement pullout in the top reinforcement layer could occur in the case of short reinforcement. Because of the effect of reinforcement pullout, it is very likely that the shear rupture will be transmitted upward and passed through one end of the reinforcements due to the fault movement. Secondary settlement at the ground surface will be initiated through the end of the reinforcement, indicating that the verification of the pullout resistance of the reinforcement is essential (Chiang *et al*. 2021).

Factors that affect the overall stability and safety of this project: (1) narrow site proximity, (2) high embankment, (3) significant differential deformation due to fault movement, and (4) the need for timely repair of earthquake damage. In addition to these site relevant conditions, the designer also considered the design principle of building structures for earthquake damage control: (1) no damage for a small earthquake, (2) repairable for a medium earthquake, and (3) no collapse for a strong earthquake (Construction and Planning Agency 2022).

The designer finally adopted geosynthetic GRS in this section to build a 168 m-long embankment. The slope near Wuniulan Creek was shaped as a steep slope to solve the problem of narrow proximity at the site. In addition, the design of the GRS embankment can also reuse a large amount of excavated material from the Fengyuan No. 3 tunnel near the site. It dramatically benefits by reducing the output transportation of unwanted earth materials and saving shipping costs. It is also more in line with the highest principle of energy conservation, carbon reduction, and sustainable development of the project.

4 ANALYSIS AND DESIGN FOR GRS EMBANKMENT

4.1 *Stability analysis*

The static stability analysis of the GRS embankment should first consider the safety of external stability under various conditions such as normal, seismic, and storm, including sliding, overturning, and bearing capacity. For overall slope stability, the SLIDE 6.0 program was used to analyze the safety factor of slope stability by the limit equilibrium analysis method. The internal stability analysis, including the safety of geogrid pullout and tensile strength, was also confirmed. Based on the analyses, the design scheme and configuration of the GRS embankment and the effective embedded length and spacing of the geogrid are described in Section 4.2.3 (Sinotech Engineering Consultants Ltd. 2017).

The seismic coefficient of dynamic analysis was based on the "Code for Seismic Design of Highway Bridges" issued by the MOTC (2018). The applied horizontal seismic coefficient (k_h) was 0.182, and the vertical seismic coefficient (k_v) was 0.091. The seismic analysis results are shown in Table 1, indicating that the designed GRS embankment was stable under all conditions, and all safety factor values meet the code requirements. In addition, the analysis also should consider the emergency backfill to repair the surface rupture caused by the fault

Table 1. The results of stability analyses for GRS embankment under seismic condition.

Condition of Analysis		Factor of Safety
External Stability	Sliding	1.21
	Overturning	3.71
	Bearing Capacity	1.82
	Overall Stability	1.42
Internal Stability	Tensile Strength	1.84 (min.)
	Pullout Resistance	59.8 (min.)

movement. The weight of the backfill has been included in the study to ensure the safety of the GRS embankment. Detailed results and discussions are presented elsewhere and will not be given herein (Chang *et al*. 2022).

4.2 GRS design

4.2.1 Foundation improvement

Because the GRS embankment is located on the colluvium with poor engineering properties, its bearing capacity needs to be improved. Chiang *et al*. (2022) also recommended restraining the fault zone displacement from the foundation tended to achieve a better reinforcement effect. Therefore, the weak soil under the embankment shall be treated with a GRS foundation. It can be done by removing the underlain weak shallow colluvium and replacing it with the GRS foundation.

As shown in Figure 4, 150kN/m geogrids were placed in a crisscross pattern. Two geogrid layers were laid in the warp direction with a vertical spacing of 0.6m (perpendicular to the highway direction). Then a layer of geogrid was laid in the direction of parallel latitude (parallel to the highway direction) at a space of 0.3m. Backfill for the GRS foundation was compacted to at least 95% of the modified Proctor maximum dry density. The total length of the replaced GRS foundation was about 140m, and the replaced depth has reached the gravel stratum or bedrock with sound engineering properties ranging from 3 to 5m.
Figure 4.   Design configuration of the GRS foundation (Sinotech engineering consultants Ltd. 2017).

4.2.2 GRS embankment

Figure 5 shows the schematic design of the GRS embankment. Due to the limited space, the slope aspect ratio was 1: 0.2 (vertical : horizontal). It was divided into three stages, each stage was 5m high, and the width of the step-back platform was 1.5m. The GRS embankment was used for highway support, which has the highest level of function and safety. The configurations of geogrid were thus correspondingly designed carefully. The geogrid was placed with a vertical spacing of 0.3m at the lowest stage and 0.5m for the other two higher stages. The embedded lengths of the geogrid, from lower to upper layer, were 20m, 18.8m, and 17m, respectively.

The backfill material was the excavated materials from the adjacent tunnel. It should be compacted to more than 95% of the modified Proctor maximum dry density. In addition, permeable material, 0.5m thick, and high-density polyethylene (HDPE) drainage pipes should be installed at the bottom of each stage of the GRS embankment to improve the overall drainage efficiency and safety for seepage and heavy rainfall. GRS embankment was designed with geobags facing, which was attached to the embankment using the geogrid wrapped-around method. Geobags contain formulated seed, fertilizer, and organic soil that
Figure 5   The design scheme of the GRS embankment (Sinotech engineering consultants Ltd. 2017).

facilitate vegetation growing and greening the surface of the embankment (Sinotech Engineering Consultants Ltd. 2017).

4.3   *Protections for adjacent slopes*

As shown in Figure 5, the site materials surrounding the embankment are weak colluvium and fractured bedrock. The designer decided to build a permanent pile-supported retaining structure at the toe of the GRS embankment adjacent to Wuniulan Creek. The diameter of the pile used was 1.5m and closely spaced 2m to ensure the stability of the toe of the huge embankment. The pile-supported retaining structure also protects the safety of the existing riverbank of Wuniulan Creek.

For safety, the upper slope was first shaped to a gentle slope of 1:2.5(V: H). It was then covered by reinforced concrete lattice girders, plus 40 tons of preloaded anchors 25m in length, spaced 2.5m in the X and Y direction (Figure 5). The protection system has been verified to fulfill all code safety requirements under various conditions, such as normal, rainstorms and earthquakes.

5   CONCLUSION

Fault movement has a significant impact on the safety of structures. However, because of many technical limitations, the case reported herein must pass through the Chelungpu active fault. After discussing several possible countermeasures, the GRS embankment has been considered the most suitable solution. Detailed safety considerations and analyses have been conducted with the key points summarized below.

1. The weak subsoils of the GRS embankment have to be replaced using GRS foundation to improve the bearing capacity and stability. It also provides a better restrain for the displacement of fault zone.
2. The results of static and dynamic analyses of the GRS embankment have shown that the designed structure is stable under various conditions, and all safety factors meet the specification requirements. However, further studies are recommended to explore detailed mechanisms of GRS structure relevant to fault movement.
3. Various slope stabilization methods have been applied to safeguard the safety of the adjacent slope for the GRS embankment. These treatments further warrant overall protection for the targeted facility.
4. The site was adjacent to the tunnel construction. Thus the design of the GRS embankment can also reuse a large amount of tunnel excavated materials, reducing the cost of dumping unwanted earth materials.

reinforcement of embankments"*

A case study of geosynthetic basal reinforcement techniques in Japan

Y. Miyata
National Defense Academy, Yokosuka, Japan

J. Hironaka
Mitsui Chemicals Industrial Products, LTD, Saitama, Japan

ABSTRACT: Both excessive subsidence and slippage are crucial concerns when constructing embankments and retaining walls on soft soil foundations. Geosynthetic basal reinforcement is a powerful solution. This study introduces Japanese design methods for related techniques and reports a case study conducted in Japan.

1 INTRODUCTION

Excessive settlement and slippage failure are crucial concerns in soft-soil foundation engineering. Various techniques can be employed to overcome these problems. Namely, geosynthetic basal reinforcement is an effective solution (Koerner 2012).

In Japan, popular geosynthetic basal reinforcement methods include 1) reinforcing the surface layer of super soft soil foundations, 2) reinforcing the embankments over soft soil foundations, and 3) combining basal reinforcement with deep mixing (Miki 1996). Their effectiveness has been verified in practice, and a corresponding design manual is well-prepared (PWRC 2000). However, the current techniques should be further improved for broader applicability and advanced design concepts, such as performance-based design. The authors addressed this challenge by investigating the actual performance of a geosynthetic basal reinforcement approach. This study briefly introduces the current Japanese design methodology for basal reinforcement technology, as well as a Japanese case study. Finally, the authors present their thoughts on technical issues considering reliability and deformation/damage analysis regarding the transition from a specific-based design to performance-based design.

2 REINFORCING THE SURFACE LAYER OF A SUPER SOFT SOIL FOUNDATION

2.1 Outline

In super soft soil foundations, such as dredged soil reclamation sites, the water content is significant, and shear strength is very low. In such foundations, even simple construction machinery cannot be moved on-site because of the lack of bearing capacity. Therefore, to effectively utilize super soft soil foundations, it is necessary to improve their bearing capacity before attempting ground improvements, such as vertical drainage or deep mixing. In such cases, geosynthetic reinforcement for the surface layer, as shown in Figure 1, is effective. In this technique, geosynthetics are placed on super soft foundations and covered with soil. This simple process ensures that the construction machines can safely traverse the site.
Figure 1. Geosynthetic basal reinforcement applied to the surface layer of a super soft soil foundation.

In Japan, this technology was initially adopted using a polyvinyl sheet as the soil reinforcement material (Fukuzumi & Nishibayashi 1970). At about the same time, Yamanouchi *et al.* (1968) proposed using plastic nets as the soil reinforcement material.

Subsequently, geogrids and geostraps with high tensile stiffness and strength characteristics have been started being used until the present day.

2.2 *Design method*

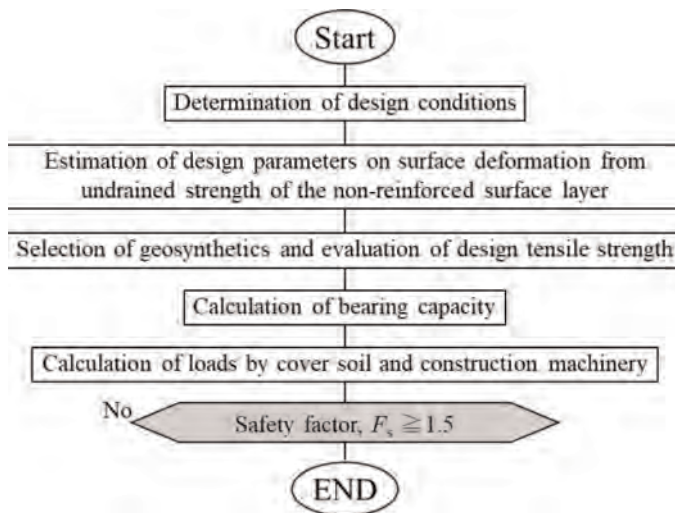
The design of the geosynthetic reinforcement applied to the surface layer of a super soft soil foundation is based on the idea that the ground reaches its ultimate limit state when the geosynthetics break (PWRC 2000). The design flow is illustrated in Figure 2, where the geosynthetics required to ensure the target bearing capacity is appropriately selected, and soil cover thickness is set accordingly.


Figure 2. Design flow of geosynthetic reinforcement applied to the surface layer of a super soft soil foundation.

During the design, three effects of geosynthetics are considered: 1) the tensile force effect, 2) the confining effect, and 3) the membrane effect, as shown in Figure 3. The following equation proposed by Yamanouchi (1979) is used to evaluate the bearing capacity:

$$q_d = \alpha c N_c + \frac{2T \sin \theta}{B} + \frac{T}{r} N_q + \gamma D_f N_q \qquad (1)$$

where q_d is the ultimate bearing capacity (kN/m^2), α is the shape coefficient of the foundation (in this case, = 2/3), c is cohesion (kN/m^2), N_c and N_q are bearing capacity factors, T is the designed tensile strength of the geosynthetic (kN/m), B is the loading width (m), θ is the

Figure 3. Geosynthetic reinforcement effects on the surface layer of a super soft soil foundation.
Figure 4. The geometry parameters observed in the bearing capacity formula stated in Eq.1 (from Sasaki *et al.* 1990). (a) Construction machine traversing a reinforced foundation (b) Connecting geosynthetic materials during construction

(a) Construction machine traversing a reinforced foundation (b) Connecting geosynthetic materials during construction
Figure 5. Case history of geosynthetic reinforcement applied to the surface layer in Japan.

angle between the deformed geosynthetic and horizontal plane near the loading edge (°), r is the radius of the circle (m) when the geosynthetic deformation near the loading edge can be captured as a circle, γ is the unit volume weight of the soil (kN/m^3), and D_f is the penetration displacement of the surface layer (m).

When evaluating the bearing capacity using Eq. (1), it is important to appropriately set the geometric parameters of the geosynthetic-laid surface layer of soft soil foundations. Sakai *et al.* (1990) measured this shape in various fields and summarized it, as shown in Figure 4. PWRC (2000) recommends conducting these measurements to obtain the required geometric parameters. Bearing capacity is generally evaluated based on the foundation geometry before loading. For geosynthetic-reinforced very soft foundations, the bearing capacity is evaluated based on the ground geometry after loading.

2.3 *Case history*

Figure 5 shows a construction machine traversing a reinforced foundation and the process of connecting geosynthetics during a Japanese construction project conducted on a very soft soil foundation.

3 REINFORCING THE EMBANKMENT OVER SOFT SOIL FOUNDATION

3.1 *Outline*

Embankments on soft soil foundations can cause excessive settlement and lateral flow. When an embankment is constructed on such a foundation, a certain treatment to reduce the settlement and lateral flow of the foundation is required. In this case, the geosynthetic basal reinforcement technique, shown in Figure 6, is effective. In this technique, one or multiple layers of geosynthetics are placed on the soft soil foundation to construct the embankment. In Japan, geogrids are primarily used under single-layer conditions. Currently, geosynthetics with higher strength and stiffness, such as geostraps and geocomposites, are also used. Recently, geosynthetic mattress foundations have been used. Therefore, it is necessary to evaluate the safety factor of the unreinforced embankment before confirming the applicability of geosynthetic reinforcement. When selecting and placing geosynthetics, two failure modes are considered: the overall stability of the reinforced embankment and the sliding stability of the embankment placed on the reinforced foundation, as shown in Figure 8.

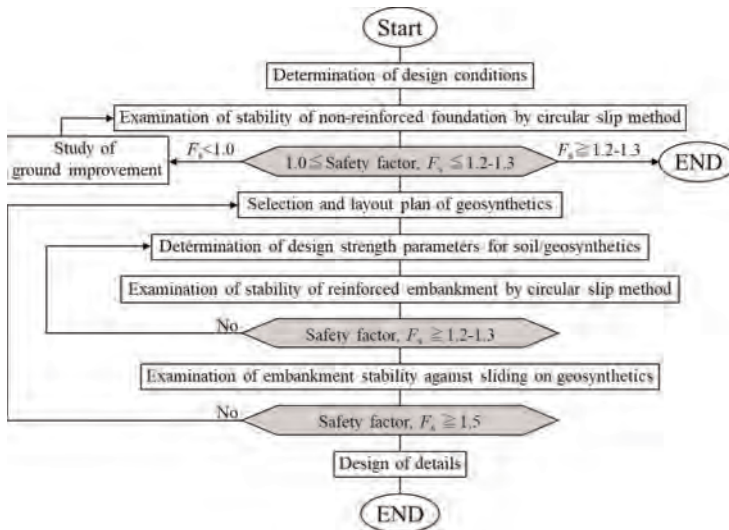
Figure 6. Geosynthetic reinforcement applied to an embankment over a soft soil foundation.
Figure 7. Design flow of geosynthetic reinforcement applied to an embankment over a soft soil foundation.


Figure 8. Considered limit states when designing a geosynthetic reinforced embankment over a soft soil foundation. (a) Geogrid-reinforced case (b) Woven geotextile-reinforced case

3.2 Design

The design flow of this technology is illustrated in Figure 7. Geosynthetic reinforcement is not considered to be very effective in stabilizing embankments where the foundation is extremely soft. Accordingly, the safety factor for embankments on the unreinforced ground is less than 1.0.

3.3 Case study

Figure 9 shows a construction machine traversing a reinforced foundation and the process of connecting geosynthetics during a Japanese construction project conducted on a very soft soil foundation.

(a) Geogrid-reinforced case   (b) Woven geotextile-reinforced case

4 BASAL REINFORCEMENT COMBINED WITH DEEP MIXING AND GEOSYNTHETICS

4.1 Outline

Residual settlement is a key issue observed when engineering embankments constructed on soft ground. It is effective in improving the foundation of embankments with cement mixing. In this case, the improvement area should be as minimal as possible to reduce the improvement costs. However, an overly small improvement causes differential settlement between the soil cement columns and unimproved areas, which results in cracks at the embankment surface and overall slippage in the embankment. Geosynthetic basal reinforcement combined with deep mixing, as shown in Figure 10, is an effective solution to this engineering problem. In Japan, geogrids and woven geotextiles have been used in this technique; however, using geostraps with higher strength has become increasingly popular recently.

4.2 Design

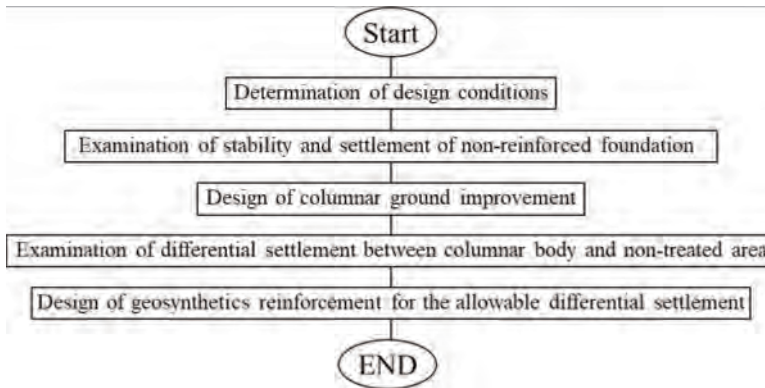
The design flow of the geosynthetic basal reinforcement combined with deep mixing is shown in Figure 11. After designing the cement mixing process, the geosynthetic reinforcement
Figure 10.   Geosynthetic basal reinforcement combined with deep mixing.


Figure 11. Design flow of geosynthetic basal reinforcement combined with deep mixing.
Figure 12. Design chart plotting the required geosynthetic tensile stiffness (from PWRC 2000) (a) After cement mixing (b) Connecting geosynthetic during construction

condition is determined such that the differential settlement between the soil cement column and the unimproved area is less than the allowable threshold (PWRC 2000). During the design process, the required tensile stiffness for geosynthetics is evaluated, considering that the ground improvement by cement mixing is three-dimensional. Figure 12 shows the design chart used to evaluate the required stiffness. This is prepared after summarizing many numerical analysis results by three-dimensional FE analysis considering nonlinear constitutive equations for soil and geosynthetics, in which coefficient a is expressed by the following equation:

$$\beta = \frac{1}{2}\frac{P}{S_a}\left(\frac{S_a}{S_b} - 1\right) \tag{2}$$

where P is the vertical stress acting on the foundation, S_a is the estimated differential settlement for cement mixing only, and S_b is the target differential settlement for the combined reinforced case.

4.3 *Case study*

Figure 13 shows photographs of a case where a combination of deep mixing treatment based on columnar improvement and geosynthetics is applied to stabilize an embankment constructed on soft ground.

Figure 13.   Applications of basal reinforcement combined with deep mixing in Japan.

5   TECHNICAL CHALLENGES IN GEOSYNTHETIC BASAL REINFORCEMENT

In Japan, the design of recently developed infrastructures has increasingly adopted a performance-based design process. In performance-based design, the limit states for frequent actions may be verified by reliability analysis, and those for accidental actions may be checked by deformation/damage analysis. In reliability design, partial safety factors must be reasonably determined by conducting statistical analyses with actual data for the load and resistance sides. Because geosynthetic basal reinforcements are implemented before the main construction phase, their importance has not been carefully investigated owing to a lack of sufficient collected data. Establishing reliable design models and determining partial safety factors to control structural safety, which is an important engineering challenge, should be addressed for future applications.

A three-dimensional analysis is required to estimate the deformation and damage characteristics of reinforced foundations. To analytically reproduce the consolidation behavior of soft soil ground, a soil skeleton-water coupled analysis is required. Rational constitutive laws for clay and geosynthetics are required to analyze the nonlinear behavior of natural ground. In the case of applying numerical analysis at a high level, engineers who conduct the analysis and the governor who controls the project are required to have professional knowledge regarding the topic. Therefore, human resources should be effectively developed. The International Geosynthetics Society, especially its technical committees, should play an important role in addressing these issues.

The design of embankments on soft soil, over piles and over areas prone to subsidence to BS8006

P.J. Naughton
Atlantic Technological University Sligo, Ireland

ABSTRACT: BS8006-1 (2016) is the UK code of practice for strengthen /reinforced soil and other fills. The code provides design guidance for metallic and polymeric reinforced soil walls, reinforced steep and shallow slopes and embankments on soft soil, over piles and over areas prone to subsidence. This code was one of the first design documents on geosynthetic reinforcement applications and first appeared in 1995 (BS8006 1995). The last revision of the code was in 2016. This paper reviews the design of embankments on soft soil, over piles and over areas prone to subsidence to that code. Key aspects are discussed, rather than providing a recipe for design.

1 INTRODUCTION

BS8006-1 (2016) is the UK code of practice for strengthen/reinforced soils and other fills. The code provides design guidance for metallic and polymeric reinforced soil walls, reinforced steep and shallow slopes and embankments on soft soil, over piles and over areas prone to subsidence. This code was one of the first design documents on geosynthetic reinforcement applications and first appeared in 1995 (BS8006 1995). The last revision of the code was in 2016.

Eurocode 7 (EN1997-1 2004) does not consider reinforced soil techniques. The UK National Annex to EN1997-1 (2004) specifies the use of BS8006-1 for the design of reinforced soil structures in the UK. While BS8006-1 is not fully EN1997-1 compliant, it does align with that code and stipulates its use for calculation of overall stability in many applications. For the design of reinforcement, BS8006-1 uses limit state principles in design and has different sets of partial factors to EN1997-1. The partial factors for each application are based on previous experience and have been calibrated to maintain consistency with current practise (BS8006-1 2016).

This paper reviews the design of embankments on soft soil, over piles and over areas prone to subsidence. Key aspects are discussed, rather than providing a recipe for design.

2 PARTIAL FACTORS AND DESIGN LIFE

2.1 *Partial factors for embankments on soft soil, over piles and over areas prone to subsidence*

The partial factors for use in design of reinforcement for embankments on soft soil, over piles and over areas prone to subsidence are presented in Table 1. These factors are used when checking limit states where the tension in the reinforcement is a contributor to stability. In some limit states, where the reinforcement is not a contributor, the partial factors from EN1997-1 (2004) are used. In the UK, the National Annex specifies that Design Approach 1 shall be used.

Table 1. Partial factor for embankments on soft soil, over piles and over areas prone to subsidence, BS8006-1.

	Partial factor		Limit state	
			Ultimate	Serviceability
Load factors	Soil unit weight	f_{fs}	1.3	1.0
	External dead load	f_f	1.2	1.0
	External live load	f_q	1.3	1.0
Soil materials	Angle of friction, ϕ'_{cv}, applied to $\tan\phi'_{cv}$	f_{ms}	1.0	1.0
	Apparent cohesion, c'	f_{ms}	1.6	1.0
	Undrained shear strength, c_u	f_{ms}	1.0	1.0
Reinforcement interaction factors	Sliding across the surface	f_s	1.3	1.0
	Pullout resistance of reinforcement	f_p	1.3	1.0

2.2 Reinforcement material factors

The reduction factors for reinforcement base strength are listed in BS8006-1 and use a different terminology to ISO TR 20432 (2007). However, Annex A of BS8006-1 presents the reduction factors from ISO TR 20432 (2007) and these are typically used in design. In addition to material reduction factors, a partial factor for the ramifications of failure is given in BS8006-1. The magnitude of this partial factor increases with the consequences of failure, Table 2. In embankment support applications the ramifications of failure are typically considered high and this factor is taken as 1.1. The reduction factors, including the partial factor for the ramifications of failure, are applied to the short-term characteristic strength of the reinforcement.

Table 2. Partial factor for the ramifications of failure, BS8006-1.

Category	Partial factor, f_n	Example of structures
1 (low)	1.0	Retaining walls and slopes less than 1.5m high
2 (medium)	1.0	Embankments where failure would result in loss of service
3 (high)	1.1	Embankments supporting motorways, roads and railways

2.3 Design life for embankments on soft soil, over piles and over areas prone to subsidence

The design life of embankments on soft soil is typically 5 – 10 years, in which time the foundation soil should have gained sufficient strength to support the embankment without reinforcement. The actual design life can be determined using consolidation theory, considering the change to foundation soil strength and any ground improvement techniques employed.

For embankments over piles the design life is typically 60 years (embankments only) or 120 years where the system is supporting retaining walls or other structures. The design life for earthworks in the UK is 60 years, while structures (retaining walls and abutments) is 120 years (BS6031 2009). However, typically embankments over piles are designed for a 120 year design life, as for most reinforcement materials there is only a marginal difference in the magnitude of reduction factors for a 60 and 120 year design life.

The design life for an embankment with basal reinforcement over an area prone to subsidence is based on the design strategy and proposed remedial works. BS8006-1 does not

specify a minimum design life for these structures. Where the remedial strategy is to immediately repair the embankment area once subsidence occurs, the design life is typically less than five years. The repair of the embankment is dealing with the cause of the subsidence issues, rather than just repairing the surface deformation. A 60 – 120 year design life is typical for cases with no planned intervention.

3   EMBANKMENTS ON SOFT SOIL

Reinforcement can be placed at the base of an embankment on soft soil to improve stability. In this situation settlement of the embankment is of secondary concern. The role of the reinforcement is to prevent shear failure both in the embankment fill and in the foundation soil. The reinforcement stabilises the embankment by preventing lateral spreading of the fill, extrusion of the foundation soil and rotational failure. The reinforcement is installed at the base of the embankment normal to its centre line.

BS8006-1 states that the following ultimate limits states should be checked: local stability, rotational stability through the embankment, overall stability of the embankment, lateral sliding of the embankment fill and foundation extrusion. In addition, the reinforcement strain and foundation settlement must be checked for the serviceability limit state. Foundation settlement is outside the scope of BS8006-1 and is typically checked using conventional soil mechanics methods.

Reinforcement at the base of the embankment can be used in conjunction with ground improvement techniques, such as vertical drains, or construction techniques like surcharging and berms. However, no guidance on the design of these systems is given in BS8006-1.

BS8006-1 states that the long-term design tensile strength of the reinforcement should be the greater of:

1. The maximum tensile force to resist the rotation limit state, or
2. The maximum tensile force to resist lateral sliding plus the maximum tensile force to resist foundation extrusion.

BS8006-1 allows rotational stability to be checked using conventional slip surface analysis, plasticity solutions (as a preliminary design tool) and finite element and finite difference techniques.

For lateral sliding the reinforcement is required to resist the full lateral thrust from the embankment fill. BS8006-1 also requires that the length of the reinforcement is sufficiently long under the side slope of the embankment to generate sufficient interaction to resist the long-term tension in the reinforcement due to lateral thrust.

For foundation extrusion, the length of the embankment side slope needs to be a minimum length to resist the lateral loads developed in the foundation soil. Equations for determining the length of the side slope are presented in BS8006-1 for a constant and linearly increasing undrained shear strength in the foundation soil. The short-term tensile force to resist foundation extrusion is proportional to the undrained shear strength, with foundation soils of higher undrained shear strength having higher reinforcement requirements. However, this will be counterbalanced by higher strength foundation soil requiring shorter embankment side slope lengths.

BS8006-1 suggests that the short-term allowable strain in the reinforcement should not exceed 5% and that for soft sensitive soil the maximum strain should be limited to 3%. No guidance on what constitutes a soft sensitive soil is given. A design strain of 5% is suitable for most reinforcement materials on the market.

The maximum tensile force to be resisted by the reinforcement should ideally be provided in a single layer of reinforcement. Where multi-layers are used, they should be of equal strength and stiffness. A coefficient, with a value less than unity, should also be applied to the second and subsequent layers to account for inefficiencies in a multi-layer system, Rowe & Li (2003).

4 EMBANKMENTS OVER PILES

Embankments over piles are used where control of both embankment stability and settlement are required. In the BS8006-1 design approach, piles are installed on a square grid with square or circular pile caps. No other geometries are permitted. There is no restriction on the type of pile used, but for arching to be mobilized there should be sufficient differential settlement between the piles and the surrounding soft soil. The pile should also have adequate bending resistance to resist lateral forces at the pile head. Two layers of reinforcement are installed, the first longitudinally along the embankment length and the second transversely across the embankment width. The longitudinal reinforcement must transfer the vertical embankment loads to the piles. In the transverse direction the reinforcement must also transfer the vertical loads to the pile caps and also resist the outward lateral thrust of the embankment.

BS8006-1 lists several limit states that should be considered in design: pile group capacity, pile group extent, vertical load shedding (arching), lateral sliding and overall stability, reinforcement strain and foundation settlement. Pile group capacity is not covered in BS8006-1 and the designer is referred to EN1997-1 (2004) for guidance. Foundation settlements, which are not covered in BS8006-1, should also be considered with pile group capacity.

Overall stability is discussed but the designer is again referred to EN1997-1 (2004). The overall stability is difficult to check using conventional stability software, as it is not common to include vertical piles. Where stability is checked, the partial load factors from EN1997-1 (2004) should be used rather than the partial factors listed in Table 1. Guidance is provided in BS8006-1 on the extent of the pile group. As a rule of thumb, the outer most pile should be located at least halfway between the crest and the toe of the embankment. Jennings & Naughton (2010 & 2011) showed that the greater the pile group extent the lower the lateral loads in the individual piles.

Vertical load shedding is a key element when designing embankments over piles. BS8006-1 provides two load shedding calculation methods: Marston's formula and the Hewlett and Randolph method. The designer is free to use either method.

Marston's method (John 1987; Spangler & Hardy 1973) is based on positive projecting subsurface conduits, a plane strain approach that was modified for the three-dimensional nature of embankments over piles. Mathematically it is difficult to reconcile the two- and three-dimensional equations (van Eekelen & Bezuijen 2008). Marston's method assumes that full arching is mobilised once the height of the embankment is greater than 1.4 times the clear spacing between adjacent pile caps. This approach has been part of BS8006 since it was first published in 1995.

The Hewlett and Randolph method which was introduced to BS8006-1 in 2010, is based on the observed mechanism from model tests conducted in sand (Hewlett & Randolph 1988). The method considers a series of hemispherical domes and considers that the system should fail either at the crown of the arch or at the pile cap. Generally, for lower height embankments, failure is at the crown of the arch and as the embankment height increases failure occurs at the pile cap. The transition between failure at the crown and failure at the pile cap is not fixed but depends on the geometry.

Once vertical load shedding is determined the tension in the reinforcement can be established. BS8006-1 assumes that the load on the reinforcement is uniformly distributed and that no support from the underlying foundation soil is considered. This results in the deflected shape of the reinforcement been a parabola. Where the embankment height is greater than 0.7 times the clear spacing between pile caps, the design strain in the reinforcement can be up to a maximum of 6%. Where the height is less than 0.7 times the clear spacing, the design strain should be limited to a maximum value of 3%. This is to ensure the reinforcement has adequate stiffness (reinforcement strain limit state) and has been shown to be an important property in controlling surface deformations (Lawson 1995).

The approach for vertical load shedding adopted in BS8006-1 assumes that the pile caps are square in plan. Where circular pile caps are used, the diameter of the pile cap should be reduced to produce an effective pile cap width, equal to an equivalent square pile with the same plan area as the circular pile cap. This reduces the width of the circular pile cap by 12% and increases the span between adjacent pile caps.

BS8006-1 also specifies a minimum distributed load acting across the reinforcement, corresponding to 15% of the embankment load. This minimum load requirement is specified to overcome deficits in the understanding of vertical load shedding and in particular the impact of dynamic and cyclic loading on load shedding. These effects are not currently considered in vertical load shedding theories.

Figure 1 shows the distributed load on the reinforcement and long-term tension determined in the longitudinal direction using Marston's method and the Hewlett & Randolph formula for embankment heights between 1 – 10m. This data is for a pile spacing, s, of 2.5m c/c, a square pile cap size, a, of 1m, 20kPa surcharge and a weight density of the embankment fill of 19kN/m^3. The total reduction factor for the reinforcement was taken as 1.77 and a design strain of 6% was used. For Marston's method, the distributed load and reinforcement tension both increased to a maximum value at an embankment height of 2.1m, corresponding to 1.4(s-a). For embankment heights greater than this, full arching was assumed and the distributed load and reinforcement tension remain constant. With the Hewlett and Randolph formula the distributed load and reinforcement tension reduced to a minimum at an embankment height of 4m, before increasing proportional to the embankment height. In this case, failure at the crown occurred until an embankment height of 8m, after which failure occurred at the pile cap. For this geometry and embankment heights between 3m and 6m both methods gave similar reinforcement tensions. For embankment heights less than 3m, Marston's method predicted higher tension and for heights greater than 6m Hewlett & Randolph formula predicted the higher tension.
Figure 1. Distributed load, W_t, and long-term reinforcement tension in the longitudinal direction, T_{rp}, determined using Marston's formula and Hewlett and Randolph method in BS8006-1.

BS8006-1 does not explicitly forbid support from the foundation soil between piles. However, no method is given in BS8006-1 for incorporating subsoil support. Russel & Pierpoint (1997) and Russel et al. (2003) have shown that even partial support from the subsoil can significantly reduce the reinforcement requirement in embankments over piles. BS8006-1 does, quite rightly, caution against incorporating partial subsoil support into design and warrants that any partial support used must be available over the entire design life of the structure, typically 60 – 120 years.

In the transverse direction BS8006-1 assumes that the reinforcement will resist the total outward lateral thrust from the embankment. The tension required to resist lateral thrust is proportional to the square of the embankment height. This results in anisotropic strength requirements, particularly in high embankments. In all cases the transverse reinforcement will have a greater strength than that in the longitudinal direction. This is not reflected in the vertical load shedding calculation. Numerical analysis reported by Russel & Pierpoint (1997), Lally & Naughton (2012) and Jennings & Naughton (2012) have shown that the BS8006-1 approach is very conservative, leading to higher transverse reinforcement strengths than may actually be required.

Jennings & Naughton (2010 & 2011) and Ahern and Naughton (2022) have shown that the piles under an embankment can be displaced laterally. BS8006-1 states that the piles should be designed to resist a minimum lateral load equivalent to 10% of the tensile load needed to resist the outward thrust of the embankment multiplied by the longitudinal pile spacing, distributed proportionally between the piles under the sloping edge of the embankment. EN1997-1 should be used for the design of the piles for axial and lateral loads as this is not covered in BS8006-1.

5 EMBANKMENTS OVER AREAS PRONE TO SUBSIDENCE

Subsidence is the sinking, or caving in, of the ground, essentially due to the removal of support beneath the ground surface. The cause of subsidence is normally due to the collapse of a void below the ground surface. These voids can result from either natural processes, soil erosion in karstic areas or the leaching of subterranean salt deposits, or from man-make processes such as ground water pumping or mining.

Reinforcement can be used to limit surface deformations. While reinforcement can be used both internally within the embankment fill and reinforcement at the base of the embankment, BS8006-1 only deals with reinforcement at the base of the embankment. Where a longitudinal void could form, a plane strain analysis is undertaken and the potential void is spanned over the shorter distance by a single layer of reinforcement. Where a circular void could form, an axisymmetric analysis is conducted and two mutually perpendicular layers of reinforcement are required, with each layer having the same short-term tension capacity.

The BS8006-1 approach has two principal assumptions:

1. Constant volume of soil in the zone of depression, with the zone of deformation taken as a truncated wedge for plane strain analysis or a truncated cone for axisymmetric analysis, Figure 2(a). This assumption allows the maximum design strain in the reinforcement to be determined, while still restricting deformation at the embankment surface over the void.
Figure 2. (a) A plane strain representation of the design situation, adopted from BS8006-1 (2016) and (b) The design geometry and definition of parameters in BS8006-1 (2016).

2. No soil arching within the embankment fill. Numerical analysis and physical models have demonstrated that arching does occur in fill over an area experiencing subsidence (Britton & Naughton 2011; Potts & Zdravkovic 2008). However, there is no agreement between arching theories at what stage either partial or full arching is fully mobilised (Britton & Naughton 2010; Naughton 2007).

A plane strain representation of the design situation is shown in Figure 2(a), while the design geometry and definition of parameters in BS8006-1 is presented in Figure 2(b).

The design assumptions in BS8006-1 lead to conservatism in design (Potts & Zdravkovic 2008). The design process given in BS 8008-1 is covered in the following steps:

1. Determine the maximum acceptable surface deformation limits for the pavement or embankment. For motorways the maximum differential surface deformation is limited to 1%, while for lower class highways it is limited to 2%. At these limits traffic can still traverse the deformed area, at speed, without danger. Higher differential surface deformations can also be used in other locations, while more stringent deformation limits are required for railways (Alexiew *et al*. 2002; Villard *et al*. 2000).
2. Determination of a suitable design value for the cavity diameter, D.
3. Using the values determined in Steps 1 and 2, the embankment fill properties and fill height to determine a maximum allowable strain to ensure that the maximum surface deformations remain within the specified limits set in Step 1. The design strain is the lesser of the calculated maximum allowable strain or 6%. The maximum allowable strain is determined based on the geometry of the truncated wedge for plane strain analysis or a truncated cone for the axisymmetric case.
4. Determination of the tensile strength required in the reinforcement to support the embankment and any surcharge loads, while ensuring that the reinforcement has suitable properties to guarantee that the maximum working extension is less than that derived in Step 3. In BS8006-1 it is assumed that the reinforcement is subject to a uniformly distributed load at the base of the embankment and that the deflected shape of the reinforcement is parabolic.

The geosynthetic reinforcement tension given by BS8006-1 is very dependent on both the design strain, Figure 3(a) and the ratio of embankment height, H, to cavity diameter, D, Figure 3(b). At design strains less than 1% there is a rapid increase in the long-term strength requirements, Figure 3(a). At small strains it should also be noted that the short-term

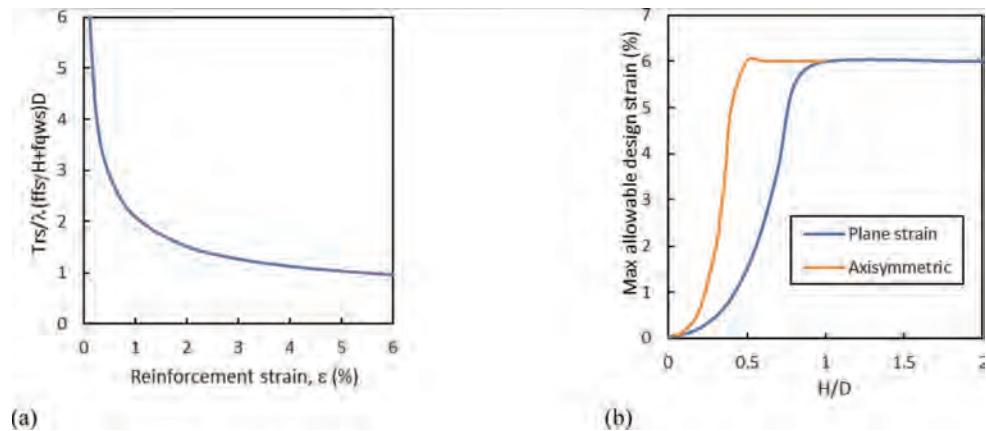
(a) (b)


Figure 3.   (a) Relationship between reinforcement strain and normalized reinforcement tension and (b) Relationship between the ratio of embankment height, H, and void diameter, D, and maximum allowable design strain.

strength of the reinforcement is dictated by strain compatibility considerations rather than just the application of reduction factors to the long-term strength.

Figure 3(b) presents the relationship between maximum allowable design strain and the H/D ratio for both plane strain and axisymmetric conditions. In plane strain, once the embankment height and void diameter is unity or less, the maximum design strain reduces rapidly resulting in an increase in the long-term reinforcement strength requirements. For axisymmetric conditions, this change occurs at approximately H/D = 0.5, when the void diameter is twice the embankment height.

Figure 4 presents the long-term tension, maximum design strain and reinforcement bond length for a void forming under a 5m high embankment. The weight density and angle of friction of the embankment fill was 20kN/m^3 and 30° respectively. A traffic surcharge of 10kPa was applied to the embankment surface. The differential surface limit was taken as 1% and was designed using the plane strain and axisymmetric approach given in BS8006-1 (2016). Limiting the maximum short-term capacity of the reinforcement to 1500kN/m would indicate that a longitudinal void of 7m and a circular void of 14m diameter could be accommodated, Figure 4(a). The design strain would be 4% and the reinforcement bond length would be 20m and 25m for the longitudinal and circular voids respectively, Figure 4 (b). Theoretically, larger voids could also be accommodated, however both the short-term strength requirements and bond length would be excessive. Multi-layers of overlapping reinforcement could be used. However, care is needed in laying multi-layers to ensure every part of the site is protected, particularly at overlap joints between layers.

It is not possible to design at extremely small strains, as the reinforcement tension requirements exceed the maximum grades of reinforcement currently manufactured, Figure 4(a). Consideration must also be given to the required anchorage length, which is proportional to the design tension, Figure 4(b). At very high tension it is not practical to manufacture a roll of geosynthetic reinforcement to facilitate installation. High strength reinforcement is bulky necessitating shorter rolls than lighter strength grades.

6 CONCLUSIONS

A review of the partial factors and limit states considered by BS 8006-1 (2016) was presented. Key aspects of the design of embankments on soft soil, over piles and over areas prone to

subsidence were also presented. The impact of geometry on the required reinforcement in embankments over piles and over areas prone to subsidence were discussed and recommendations made on these from a design perspective.

Design of basal reinforced embankments on soft soils at short and long term

P. Rimoldi
Civil Engineering Consultant, Milan, Italy

G. Lugli & F. Trovato
Officine Maccaferri Spa, Bologna, Italy

ABSTRACT: The stability of embankments on soft foundation soil is often critical during the construction period; geosynthetic reinforcements placed across at foundation level enhance the short-term stability of an embankment over soft soil by preventing lateral sliding of the fill and extrusion of the foundation soil. For each of these limit states the associated reinforcement strength and bond length should be checked to ensure that the required tensile load can be generated in the reinforcement. While the consolidation of the soft soil develops, geosynthetics for basal reinforcement are progressively subject to out-of-plane deformations, which trigger the tensioned membrane mechanism. Hence the long-term design of geosynthetics requires the calculation of the final and constant tensioned membrane strength, which has to be compared with the long-term tensile strength of the geosynthetics for getting the associated long-term Factor of Safety.

1   INTRODUCTION

The design of basal reinforcement of embankments on soft soil at short term has been addressed by Romeo *et al* (2021), while the design of basal reinforcement of embankments on soft soil at long term has been addressed by Rimoldi *et al* (2022). The present paper aims to present the overall design method for basal reinforcement of embankments on soft soil at short and long term. Additional details may be found in the two above referenced publications.

2   DESIGN AT SHORT TERM

2.1   *Lateral sliding*

Lateral sliding is a limit state which involves only the equilibrium entirely within the embankment fill: the direct sliding mechanism along the upper surface of the reinforcement layer has to be examined (Figure 1). Sliding would result if the available resistance at the reinforcement interface is lower than the lateral thrust from the fill. Hence the anchorage length L_e, shown in Figure 1, shall be determined, together with the tensile strength T_{ds} generated by the lateral sliding mechanism.

The tensile force per metre run in the reinforcement, T_{ds}, can be determined as:

$$T_{ds} = 0.5 K_h H \left(f_{fs} \gamma_1 H + 2 f_q w_s \right) \tag{1}$$

where: K_h is the horizontal earth pressure coefficient; H is the height of the embankment; γ_1 is the unit weight of the embankment fill; w_s is the surcharge on top of the embankment; f_{fs} is the partial factor for soil unit weight; f_q is the partial factor for external applied loads.

While generating the tensile load T_{ds} in the reinforcement, the embankment fill should not slide outwards over the reinforcement. Hence, to prevent the horizontal sliding the minimum reinforcement bond length, L_e, is:

$$L_e = \frac{0.5 K_h H \left(f_{fs}\gamma_1 H + 2f_q w_s\right) f_s f_n}{\gamma_1 h \frac{f_{ds}\tan\varphi'_{cv}}{f_{ms}}}$$ (2)

where: f_s is the partial factor for reinforcement sliding resistance; f_n is the partial factor governing the economic ramifications of failure; h is the average height of embankment fill above the reinforcement length L_e; f_{ds} is the interaction coefficient relating the embankment fill/reinforcement bond angle to $\tan\varphi'_{cv}$; φ'_{cv} is the angle of friction at large strains of the embankment fill under effective stress conditions; and f_{ms} is the partial material factor applied to $\tan \varphi'$.

Note: f_{ds} can be obtained from direct shear tests, according to EN ISO 12957-1, or derived from published default values for the specific reinforcement and fill (see Koerner 2012).

The anchorage length L_e obviously starts from the toe of the side slope: since the basal reinforcement extends to the whole embankment base, the available reinforcement length is usually well in excess of L_e; hence the required length to resist direct sliding usually is not a limit state.

The easiest way for evaluating K_h is to use the well-known Coulomb's formula for the coefficient of active thrust with inclined wall face; in case of horizontal top the formula can be written as:

$$K_h = \frac{\cos^2\left(\varphi' - \lambda\right)}{\cos^2\lambda \cdot \cos\left(\lambda + \delta\right) \cdot \left[1 + \sqrt{\frac{\sin\left(\delta + \varphi'\right)\cdot\sin\varphi'}{\cos(\lambda+\delta)\cdot\cos\lambda}}\right]^2} \cdot \cos\left(\lambda + \delta\right)$$ (3)

where: λ is the angle of the slope to the vertical, δ is the friction angle along the line a-b shown in Figure 1. For the embankment the slope angle λ in Equation (3) is negative and is equal to $(\beta - 90°)$, while the friction angle δ can be assumed equal to φ'.

Note that, to be consistent with equations (1) and (2), Equation (3) shall be used with the friction angle of the fill equal to φ'_{cv}.

2.2 Foundation extrusion

Vertical embankment loading causes an increase in the vertical stress in the foundation soil and a corresponding increase in the horizontal stress. Therefore, a lateral thrust develops in the foundation soil beneath the embankment crest which can eventually cause the foundation soil beneath the embankment side slope to displace laterally. If we assume that extrusion starts from the slope crest (where the vertical load decreases), to prevent this extrusion the side slope length of the embankment, L_s, should be enough to develop adequate lateral confinement (Figure 1).

2.2.1 Foundation soil of uniform strength and limited depth

With reference to Figure 1, by integrating the equation expressing the horizontal equilibrium balance for a soft foundation soil with uniform undrained shear strength, c_u, and limited depth, D (with respect to the embankment width), underlain by a rigid stratum, with the boundary conditions $z = 0$ and $z = D$, we get the minimum side slope length $L_{s,min}$ required to support the weight of the embankment:

$$L_{s,min} = \frac{\left(f_{fs}\gamma_1 H + f_q w_s - \frac{4c_u}{f_{ms}}\right)D}{\frac{c_u(1+\alpha_{bc})}{f_{ms}}} f_n$$ (4)

where: c_u is the undrained shear strength of the foundation soil at the underside of the reinforcement; α_{bc} is the interface coefficient relating the soil/reinforcement adherence to c_u, $L_{s,min}$ is the minimum distance from the embankment toe to the edge of the embankment crest; f_n is the partial factor governing the economic ramifications of failure.

For obvious physical and geometrical reasons, if Equation (4) provides a minimum side slope length $L_{s,min} \leq 0$, the foundation extrusion cannot occur. This condition can be given as follows:

$$f_{fs}\gamma_1 H + f_q w_s \leq \frac{4c_u}{f_{ms}} \tag{5}$$

Equation (5) represents the cut-off value for the allowable bearing pressure for the soft foundation soil of uniform strength c_u. If the inequality (5) is satisfied, the foundation extrusion limit state is satisfied as well, and basal reinforcement is not needed.

Equation (5) can be used also to determine the limit time when the basal reinforcement will be no more required: since c_u increases while consolidation progresses, the limit time t_{lim} for the need of basal reinforcement can be obtained from the consolidation theory, as $t_{lim} = t_c$, where t_c is the consolidation time at which:

$$c_u(t_c) = \frac{f_{ms}}{4}\left(f_{fs}\gamma_1 H + f_q w_s\right) \tag{6}$$

From Figure 1, the tensile load per metre run generated in the basal reinforcement, T_{rf}, due to outward foundation shear stress is:

$$T_{rf} = \frac{\alpha_{bc}c_u}{f_{ms}} \cdot L_{s,min} \tag{7}$$

Note that α_{bc} could be obtained only from large scale unconsolidated undrained triaxial tests on both reinforced and unreinforced soil specimens, which are not easily available; moreover, no default values for α_{bc} are included in BS8006:2010. Hence, in absence of direct measurements or published default values of α_{bc}, it is suggested to assume $\alpha_{bc} = 0.50$.
Figure 1.   Scheme of lateral sliding and foundation extrusion mechanisms (modified from BS 8006:2010).

Assuming Equation (4) for $L_{s,\min}$, the tensile load T_{rf} generated in the basal reinforcement due to foundation extrusion becomes:

$$T_{rf} = \frac{\alpha_{bc}c_u}{f_{ms}} \cdot \frac{\left(f_{fs}\gamma_1 H + f_q w_s - \frac{4c_u}{f_{ms}}\right)D}{\frac{c_u(1+\alpha_{bc})}{f_{ms}}} f_n \tag{8}$$

Note that if the minimum side slope length $L_{s,\min}$, from Equation (4), is equal to zero, also the tensile load T_{rf} generated in the basal reinforcement, from Equation (8), is equal to zero.

2.2.2 Foundation soil with strength increasing with depth

The solution described above can be adapted to the problem of soft soil with strength increasing linearly with depth, that is with $c_u(z) = c_{uo} + \rho z$, where c_{uo} is the undrained shear strength of the foundation soil at the underside of the reinforcement and ρ is the increase of undrained cohesion per unit depth. The overall equilibrium between the unloaded toe and the load to be supported at a distance L_s from the toe is now examined (see Figure 1).

In this case the depth of the equilibrium block has to be determined. The same assumption about the horizontal and shear stresses acting on the block are made.

The resulting critical depth z_c is obtained from the solution of the quadratic equation

$$z_c = \frac{-b + \sqrt{\Delta}}{2a} \tag{9}$$

where: $\Delta = b^2 - 4ac$.

The coefficients a, b, and c are:

$$a = \frac{2\rho^2}{f_{ms}^2}; \quad b = \frac{4c_{uo}(1+\alpha_{bc})\rho}{f_{ms}^2}; \quad c = -\left(f_{fs}\gamma_1 H + f_q w_s\right)\frac{c_{uo}(1+\alpha_{bc})}{f_{ms}} + \frac{4c_{uo}^2(1+\alpha_{bc})}{f_{ms}^2} \tag{10}$$

A critical depth $z_c > 0$ is obtained if $-b + \sqrt{\Delta} > 0 \Leftrightarrow \Delta = b^2 - 4ac > b^2 \Leftrightarrow c < 0$.

Reinforcement is required, for the foundation extrusion limit state, only if the inequality (11) is satisfied:

$$f_{fs}\gamma_1 H + f_q w_s > \frac{4c_{uo}}{f_{ms}} \tag{11}$$

Adding the partial factor f_n governing the economic ramifications of failure, the minimum side slope length is:

$$L_{s,\min} = L_s(z_c) = \frac{\left(f_{fs}\gamma_1 H + f_q w_s\right)z_c - \frac{4}{f_{ms}}\left(c_{uo}z_c + \rho\frac{z_c^2}{2}\right)}{\frac{c_{uo}(1+\alpha_{bc})+\rho z_c}{f_{ms}}} f_n \tag{12}$$

where z_c shall be calculated with Eqs. (9) and (10).

It is important to note that Equation (11) can be used also to determine the limit time when the basal reinforcement will be no more required: since c_{uo} increases while consolidation progresses, the limit time $t_{\lim}$ for the need of basal reinforcement can be obtained from Equation (6), using $c_{uo}(t_c)$ in place of $c_u(t_c)$.

From Figure 1, the tensile load per metre run generated in the basal reinforcement T_{rf} due to outward foundation shear stress is:

$$T_{rf} = \frac{\alpha_{bc}c_{uo}}{f_{ms}} \cdot L_{s,\min} = \frac{\alpha_{bc}c_{uo}}{f_{ms}} \cdot L_s(z_c) \tag{13}$$

As in the previous case, in absence of direct measurements or published default values of α_{bc}, it is suggested to assume $\alpha_{bc} = 0.50$.

Adopting Equation (12) for $L_{s,\min}$, the tensile load in the basal reinforcement T_{rf} becomes:

$$T_{rf} = \frac{\alpha_{bc}c_{uo}}{f_{ms}} \cdot \frac{\left(f_{fs}\gamma_1 H + f_q w_s\right)z_c - \frac{4}{f_{ms}}\left(c_{uo}z_c + \rho\frac{z_c^2}{2}\right)}{\frac{c_{uo}(1+\alpha_{bc})+\rho z_c}{f_{ms}}}f_n = \frac{\alpha_{bc}c_{uo}}{f_{ms}} \cdot L_s(z_c) \qquad (14)$$

Therefore, in the case of soft soil with strength increasing linearly with depth, the required tensile strength of basal reinforcement can increase or decrease, in a non-linear way, as function of the values of the undrained shear strength parameters of the soft foundation soil, c_{uo} and ρ.

2.3 Design of the basal reinforced embankment at short-term

The design of geosynthetic reinforced embankments on soft soil at short-term requires the definition of the minimum side slope length and of the tensile strength of reinforcement. As above said, the side slope length does not depend on the direct sliding mechanism, hence it shall be assumed equal to $L_{s,\min}$, that is the length of the side slope required to prevent foundation extrusion.

The design tensile strength of reinforcement, T_D, is the sum of the tensile strengths required for the direct sliding and foundation extrusion mechanisms:

$$T_D = T_{ds} + T_{rf} \qquad (15)$$

According to ISO/TR 20432, the minimum required $T_{ult,lt}$ is:

$$T_{ult} = T_D \cdot (RF_{ID} \cdot RF_{CR} \cdot RF_W \cdot RF_{CH}) \qquad (16)$$

where: T_D = design tensile strength of the reinforcement (kN/m); $T_{ult,lt}$ = ultimate tensile strength of the reinforcement (kN/m) required at short term; RF_{ID} = reduction factor for installation damage; RF_{CR} = reduction factor for creep (= 1 at the end of construction); RF_W = reduction factor for long term weathering exposure (= 1 if the reinforcement is covered with soil within 1 day exposure time); RF_{CH} = reduction factor for long term chemical and biological degradation.

3 DESIGN AT LONG TERM

3.1 Long term deformations

While the consolidation of the soft soil develops, the base of the embankment is subject to non-uniform settlements, usually higher at the centre of embankment and progressively decreasing towards the toes of the lateral banks (Figure 2.a). Hence geosynthetics for basal reinforcement are progressively subject to out-of-plane deformations, which trigger the tensioned membrane mechanism. When consolidation ends, the related out-of-plane deformations become constant over time, and the tensioned membrane force produced in the geosynthetics also become constant.
Figure 2. a) The out-of-plane deformation along the settlement curve triggers the tensioned membrane mechanism in geosynthetics for basal reinforcement; b) Scheme for calculating the primary consolidation settlement of a layer of cohesive soil.

This means that the long-term design of geosynthetics for basal reinforcement of embankments on soft soil requires the calculation of the final and constant tensioned membrane strength, which has to be compared with the long-term tensile strength of the geosynthetics.

In the long term, the soft soil below the embankment yields under the weight of the embankment itself. The geosynthetic reinforcement slightly decreases the settlement (5 – 10 % less) but the reinforcement cannot control the settlement by imposing a certain reinforcement strain ε.

Instead, it is the settlement that imposes the long term strain ε to the reinforcement, as a function of the out-of-plane deformation that triggers the tensioned membrane mechanism.

Therefore, for the check of the basal reinforcement at long term, it is first necessary to calculate the settlement of the embankment at the time t necessary for at least 90 % consolidation, the related force in the basal reinforcement, and the related strain $\varepsilon(t)$; then calculate the required ultimate strength $T_{ult,lt}$ at long term, based on the isochronous curves of the geosynthetic reinforcement and all reduction factors at time t.

3.2 Consolidation settlements

Calculation of the total settlement due to primary consolidation can be performed using the parameters obtained from oedometric tests: if one-dimensional consolidation is considered, it is possible to calculate the settlement of a soil layer under a uniformly distributed load $\Delta\sigma_v$.

Especially in the presence of thick and non-homogeneous layers, it is advisable to divide the soft soil layer into several sub-layers, possibly differentiating the soil compressibility parameters. In the more general case of over-consolidated soil, with reference to the symbols in Figure 2.b, the overall settlement ΔH of the soft soil is expressed as:

$$\Delta H = \sum_{i=1}^{n} \frac{H_{0i}}{1 + e_{0s}} \cdot \left(c_u \cdot \log \frac{\sigma_{ci}}{\sigma_{v0i}} + C_{ci} \cdot \log \frac{\sigma_{v0i} + \Delta\sigma_{vi}}{\sigma_{ci}} \right) \tag{17}$$

As an alternative to the parameters C_c and C_s, it is possible to refer to the volume compressibility coefficient m_v, or to the compressibility coefficient a_v:

$$\Delta H = \sum_{i=1}^{n} H_{0i} \cdot \Delta\sigma_{vi} \cdot m_{vi} = \sum_{i=1}^{n} \frac{H_{0i}}{1 + e_{0s}} \cdot \Delta\sigma_{vi} \cdot \sigma_{vi} \tag{18}$$

where the pressures and compressibility parameters refer to the centre line of each of the n sub-layers, each one of thickness H_{0i}.

In the hypothesis that the load, q, applied to the surface, is uniformly distributed and infinitely extended, the increase in the total vertical stress, $\Delta\sigma_v$, is equal to the applied load ($\Delta\sigma_v = q$). In case the load q is distributed over a surface of limited dimensions, the value of $\Delta\sigma_v$ is reduced as the depth increases and varies in a horizontal direction. As a first approximation, in the case of load q uniformly distributed over a rectangular area, the value of $\Delta\sigma_v$ can be estimated assuming that the load spreads with a 2V: 1H ratio. At depth z, therefore:

$$\Delta\sigma_v(z) = \frac{q \cdot L \cdot B}{(L + z) \cdot (B + z)} \tag{19}$$

A better evaluation of the vertical pressure increase $\Delta\sigma_v(Z = H/2)$ can be obtained using the Boussinesq equations for rectangular loaded area (see Rimoldi & Simons 2013), assuming the load as applied to a rectangular area of the same width B of the embankment at top and length L = 1 m.

The total settlement can be evaluated also with the modified Winkler model (as example, according to Rimoldi & Pagotto 1986, or Shukla & Chandra 1995) or with validated numerical methods.

3.3 Oedometric consolidation theory

According to Terzaghi's theory of oedometric consolidation, the dimensionless variable T_v (Time Factor) is defined as:

$$T_v = \frac{C_v \cdot t}{H_d^2} \tag{20}$$

where H_d is the drainage height, i.e. equal to the maximum vertical path that a water particle need to run to exit the layer (in case of a double drained layer it is equal to half the height of the layer, in case of drainage on one side only it is equal to the thickness of the whole layer).

There are analytical expressions that provide an approximate estimate of the solution for the case of initial isochronous constant with depth, for example the following formula by Terzaghi, valid for $U_m > 60\%$:

$$T_v = 1.781 - 0.933 \cdot \log(100 - U_m) \tag{21}$$

where U_m is the considered average degree of consolidation (in % of total consolidation).

3.4 Strain in basal geosynthetic

According to Giroud (1995), a geosynthetic subjected to a normal stress follows the out-of-plane deflection in the supporting soil (see Figure 3.a). As a result of the out-of-plane deflection, the geosynthetic elongates and a tensioned membrane force is generated.

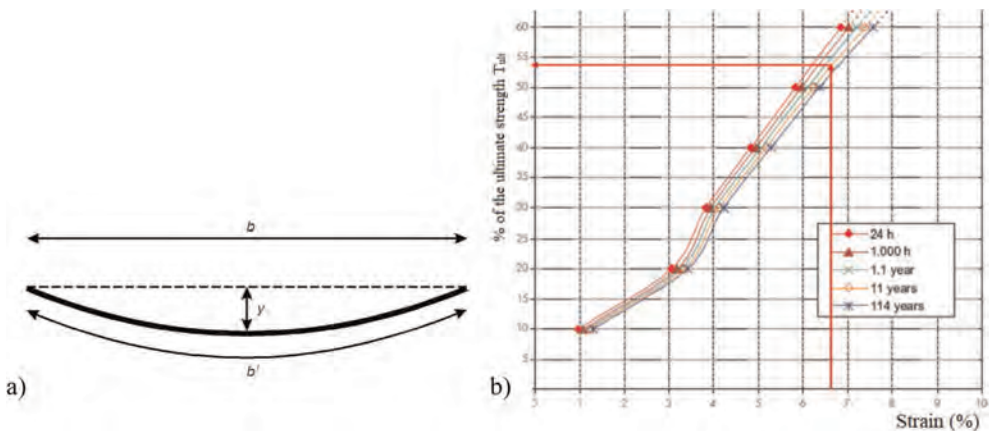
If the shape of the geosynthetic after deflection is a smooth curve in a considered cross section, the elongation of the geosynthetic can be determined mathematically by assuming that the shape is a curve with a known equation, such as a parabola. Then, if it is assumed that the geosynthetic strain ε is uniformly distributed, it is possible to derive the strain from the elongation (b'- b), shown in Figure 3.a.


Figure 3. a) Geosynthetic deflection (from Giroud 1995); b) example of isochronous curves of geogrids.

Mathematical tables give the following expression of ε from the length of a parabola (see Figure 3.a):

$$\varepsilon = \frac{1}{2}\sqrt{1 + 16(y/b)^2} + (1/8) \cdot (b/y) \cdot \ln\left(4(y/b) + \sqrt{1 + 16(y/b)^2}\right) \quad (22)$$

3.5 Calculation procedure

The proposed method is based on the following procedure.

The average degree of consolidation U_m is set (i.e. $U_m = 90\ \%$) and T_v is calculated with Equation (21).

From Equation (20), assuming drainage only towards the top, therefore with $H_d = H$:

$$t = T_v \cdot c_v \cdot H^2 \quad (23)$$

$\Delta\sigma_v(Z)$ is calculated with Equation (19) or with Boussinesq equations for rectangular loaded area (as wide as the embankment width at crest, B, and 1 m long).

The total settlement ΔH is calculated with Equations (17) or (18), or with the modified Winkler model (according to Rimoldi & Pagotto 1986, or Shukla & Chandra 1995) or with validated numerical methods.

The total settlement with basal reinforcement is assumed to be equal to 95 % of total settlement without reinforcement (see Rimoldi & Pagotto 1986, or Shukla & Chandra 1995):

$$\Delta H_r = 0.95 \cdot \Delta H \quad (24)$$

It is assumed that at time t the settlement at the centre of the embankment with basal reinforcement is:

$$\Delta H_r(t) = \Delta H_r \cdot U_m \quad (25)$$

Setting $y = \Delta H_r(t)$ and $b = B$ in Equation (22) we get $\varepsilon(t)$, the strain in reinforcement at time t.

A geosynthetic reinforcement (e.g. a specific geogrid) is chosen; the value t (example: 50 years) from formula (23) and the value $\varepsilon(t)$ from formula (22) are used to obtain $T_{\varepsilon(t)}$, that is the tensile strength related to the strain ε at time t, in % of the ultimate strength T_{ult}, from the isochronous curves of the reinforcement (see Figure 3.b).

The required tensile strength at long term $T_{req,lt}$ (kN/m), that is the strength corresponding to the tensioned membrane force generated at time t, shall be calculated with the modified Winkler model (according to Rimoldi & Pagotto 1986, or Shukla & Chandra 1995) or with validated numerical methods.

Then, according to BS8006 and ISO TR 20432, the ultimate tensile strength at long term, $T_{ult,lt}$, is:

$$T_{ult,lt} = \left(T_{req,lt}/T_{\varepsilon(t)}\right) \cdot RF_{ID} \cdot RF_W \cdot F_{CH} \cdot RF_{CR} \cdot f_n \quad (26)$$

The geogrid shall be selected with the design tensile strength $T_{ult,D}$:

$$T_{ult,D} = \max\left[T_{ult,lt};\ T_{ult,st}\right] \quad (27)$$

3.6 Anchorage length

The average vertical stress on width B_s of side slopes (see Figure 2.a) is:

$$\sigma_v = 0.5 \cdot \gamma_f \cdot H \quad (28)$$

where γ_f is the unit weight of fill (kN/m^3) and H is the height of the embankment.

The pullout shear stress (kPa) along the contact subsoil–geosynthetic reinforcement is:

$$\tau_{gs} = f_{pos} \cdot \sigma_v \cdot \tan \varphi_s \qquad (29)$$

The pullout shear stress (kPa) along the contact geosynthetic reinforcement–fill is:

$$\tau_{gf} = f_{pof} \cdot \sigma_v \cdot \tan \varphi_f \qquad (30)$$

where f_{pos} and f_{pof} are the pullout factors between the reinforcement/subgrade interface and the reinforcement /fill interface.

Hence the minimum anchorage length (m) is:

$$L_{po} \geq \frac{FS_{po} \cdot T_{red,it}}{(\tau_{gs} + \tau_{gf})} \qquad (31)$$

where FS_{po} is the factor of safety for anchorage, which usually can be assumed as 1.30.

Basal reinforcement on piles and on voids according to EBGEO

D. Alexiew
Alexiew Geoconsulting, Gescher, Germany

ABSTRACT: EBGEO is the present German code for the design of geosynthetic reinforced systems. The abbreviation means "Empfehlungen für den Entwurf und die Berechnung von Erdkörpern mit Bewehrungen aus Geokunststoffen" (Recommendations for Design and Analysis of Earth Structures using Geosynthetic Reinforcements). The latest German version was issued in 2010, and the corresponding English one in 2011. Among others, EBGEO includes chapters dealing with the so-called piled embankments and with systems bridging voids. These two chapters are shortly presented inclusive of history and background which cannot be found in the original document. The author is member of the EBGEO working group.

1 INTRODUCTION

Until the early nineties there was in Germany no specialized document handling the design of geosynthetic reinforcements. Due to the increasing demand for such solutions based on the global, European and German development on the field of geosynthetics, the German Geotechnical Society (DGGT) established the working group AK 5.2 to create such design guidelines. The group consisted of designers, consultants, academics, producers, contractors and representatives of official German institutions. The concept was to create not a standard, but "recommendations" being a quite popular and less formal class of documents in German geotechnics: they may include also e.g. calculation examples and/or execution references which is of practical importance especially for innovative topics.

The first EBGEO was published in 1997 and included the most popular applications e.g. embankments on soft soils, retaining walls, slopes, foundations, landfills, temporary roads etc. Experience and documents from both former Western and Eastern Germany were used. The growing demand from engineering practice and the progress on the field of geosynthetic reinforcements necessitated the reactivation of AK 5.2 which started working on a new EBGEO, completely reworked, based on the partial safety factors concept in the sense of Eurocode 7 (EC 7) EN 1997-1 and significantly extended by several new or more extensive chapters. Two of them are shortly described below. The work took several years. Every chapter includes not only design procedures, but beside a list of references also a detailed calculation example. The new present EBGEO includes 300 pages and was published in 2010 (EBGEO 2010), thirteen years after the first one.

Due to the significant interest across Europe the DGGT and the publisher Ernst und Sohn decided to publish also an English version in 2011 (EBGEO 2011). The only difference is that some German terms were switched to new "English" terms according to the Eurocode 7 (EC 7) EN 1997-1 terminology.

A next EBGEO is already planned, but this process will depend among others on the progress of the new next generation EC7.

2 PILED EMBANKMENTS

Officially this Chapter 9 in EBGEO is called "Reinforced earth structures over point or linear bearing elements". Background for this wider definition: the supporting elements can

be not only piles, but also columns of different types such as compacted gravel columns, mixed-in-place columns, geotextile encased columns etc. Supporting elements can be also diaphragm walls being linear, typically parallel to the embankment axis.

2.1 Overview

The system under consideration is shown in Figure 1.
Figure 1. Illustration of system and geometries (diameter d, width b, spacing between supports s, supporting area A_S, h* etc).

2.2 Historical and technical background

First projects of piled embankments started in Germany in the early nineties for the Deutsche Bahn (DB) (German Rail). The trigger was the German reunification, DB had to build new links to the former Eastern Germany and to upgrade existing ones there for higher speeds and loads.

Time became a very important factor, and piled embankments were identified as a good option due to the eliminated consolidation time. Piles/columns capacities were available, woven geotextiles with up to 800 kN/m and geogrids with up to 200 kN/m as well. The missing link was a proper design. At that time no design procedure (e.g. the Swedish Method, the BS 8006, the Guido Method etc.) took into consideration the shear strength of

the embankment fill, say, the methods delivered the same results in terms of reinforcement for sand and crushed gravel. This seemed not realistic and not acceptable to the German geotechnical community.

As a first step the arching method of Hewlett *et al.* (1988) was adopted to estimate the load distribution between piles and soft subsoil. The first projects (e.g. Alexiew & Gartung 1999; Alexiew & Vogel 2001) were designed combining the "arching" from Hewlett *et al.* (1988) with the "hanging rope" parabolic shape under uniform load approach in BS 8006 (1995). However, this was believed to be a compromise, and intensive research started resulting in a better understanding of the "inner life" of the system inclusive of two PhD-Theses (Heitz 2006; Zaeske 2001). German and international experience, German research and measurement programs (e.g. Alexiew & Gartung 1999) were the base for the new Chapter 9 (Alexiew 2004; Kempfert *et al.* 2004) in EBGEO (2010).

2.3 *Some most typical assumptions, conditions and recommendations*

The design procedure is valid for a relation of compression stiffnesses of "pile" to soft soil >75, otherwise the "arching" assumed could not take place.

A multi-spherical "arching" is assumed for evaluating the load distribution between piles and soft soil (difference to Hewlett *et al.* 1989), Figure 2, left.
Figure 2.   Overview of concept, multiple arching, spacings and counterpressure.

An upwards counterpressure is assumed from the soft soil resulting from and depending on the deflection of reinforcement between piles (Figure 2, right).

The reinforcement collects the load from the area between the piles and transfers it to fictive "strips" between piles (Figures 1–2). These "strips" control the design.

The distribution between both reinforcement directions depends not only on the pile pattern geometry (Figure 1) but also on the reinforcement moduli J in both directions.

The strip load on the reinforcement between the piles is assumed to be triangular: max value in the middle, zero on the supports.

As spacing s (Figures 1–2) the maximum (diagonal) axial distance is set. Because the design is de facto based on second order theory (interdependence of deformations and forces) and due to the deformation-dependent counterpressure for the solution differential equations have to be solved. Because the EBGEO philosophy is that computational programs and numeric must not be mandatory, graphs are included allowing a read out by hand (Figure 3). Due to brevity the symbols cannot be explained herein.

A key parameter of reinforcement is the tensile stiffness J (time-dependent due to creep).

The reinforcement should be installed as deep as possible.

Maximum two reinforcement layers are allowed. They can be uniaxial, biaxial or mixed.

There are geometrical limitations for s, d, A_S and for the ratio $h^*/(s-d)$ (Figure 1). They are more conservative (smaller s and higher ratio $h^*/(s-d)$) for high variable loads of dominant importance.

A post-construction creep strain of maximum 2% is allowed if there are no stricter limitations due to SLS.

A multi-staged time-dependent design has to be performed. Embankment height is increasing (thus the efficiency of "arching"), loads differ from compaction to traffic, and the tensile modulus J is decreasing.

Assuming an upwards counterpressure is allowed only if the contact between reinforcement and subsoil is guaranteed for the entire design life (e.g. no change in groundwater level).
Figure 3. Principle of read-out of strain during design (strongly reduced for clarity, 1 & 2 are normalized dimensionless input parameters).

The tensile force results from calculated strains and assumed J in both directions and has to be checked versus available design strength.

Two very specific points more:

– for the lateral trust (spreading) which can control the choice of reinforcement perpendicular to embankment axis, reduced values are allowed if a thick well-compacted working platform is available (Figure 4);
– for partially cohesive natural or artificial fills the use of an equivalent angle of internal friction considering cohesion – natural or artificial – is allowed (the background is to open the door for the use of local or industrial fills in the sense of sustainability).
Figure 4. Concept with reduced lateral trust.

Usually, the design procedure consists of a series of calculations: choose J of reinforcements in both directions based on experience, calculate, check and repeat until all requirements are met in both directions inclusive of spreading.

A very detailed calculation example for a multi-staged design is presented.

Execution recommendations are also included at the end of the chapter although formally EBGEO is a design code.

3 BRIDGING VOIDS

Officially this Chapter 11 in EBGEO is called "Overbridging systems in areas prone to subsidence". The background is to use a more general formulation due to the different geological phenomena behind with different genesis.

3.1 Overview

Typical problems demonstrating the importance of the topic are shown in Figure 5.

Figure 5. Examples for sinkholes and their consequences.

3.2 Historical and technical background

Similar to the piled embankments (Chapter 1.2) the problem became acute in Germany after the German reunification. New roads and railroads had to be built or existing ones upgraded. Many of them were positioned in areas prone to subsidence due to natural (e.g. karst) or "artificial" (e.g. mining) reasons.

As a temporary solution the BS 8006 was used for design, at the beginning even in its draft stage. The first German void bridging was designed in 1993 in this way (Alexiew 1997).

Due to the increasing demand from engineering practice the AK 5.2 decided to create an extensive chapter in EBGEO. The story was similar to the piled embankments story: AK 5.2 started an intensive search for international design procedures, and a research program inclusive of tests started as well. This resulted among others in a PhD-Thesis and in a specific German design method called BGE (Schwerdt 2004; Schwerdt *et al.* 2004).

Finally, the Chapter 11 in the new EBGEO 2010 included a wide range of models and design procedures depending on geometrical and geomechanical factors and on the reinforcement concept as well. From this point of view EBGEO is quite unique. Numerous significant German projects for highways, motorways and railroads bridging voids were designed and executed according to these recommendations using already the EBGEO in its Draft stage.

3.3 Some most typical assumptions, conditions and recommendations

Four structural behavior models are taken into consideration assuming failure and non-failure conditions (Figure 6).

The methods available as options are the British BS 8006 (1995), the German BGE (Schwerdt 2004; Schwerdt *et al.* 2004), GIROUD (Giroud *et al.* 1990), the French RAFAEL (Blivet *et al.* 2001, 2002), the German AST (Ast *et al.* 2001). For models taking into account the lateral shear resistance around the collapsing body the silo theory of Terzaghi (Terzaghi 1943) is used.

There is a useful overview of the typical characteristics and limitations of all methods (Figure 7)

Design recommendations concerning the most applicable methods depending on the load transfer model and on the type of reinforcement are given (Figure 8). Isotropic: equal tensile stiffness J in both directions. Extremely anisotropic: J in the one direction is at least ten times higher than in the other one.

Design recommendations concerning the anchorage length outside the void bridged are given depending on the same circumstances (Figure 9), and also concerning possible overlaps (not shown here).

The practical issue of overlaps design of reinforcement layers in both directions is also handled.

It is a mixed ULS/SLS design. On the one hand the surface deflection (leading criterium) and consequently the strain in reinforcement have to be controlled (SLS). On the other hand, a critical state in the fill is assumed in most cases, partial safety factors for ULS are applied (even for formally non-failure models), and the tensile force has to be compared with the ultimate design strength (ULS).
Figure 6. Failure and non-failure models.

Figure 9. Anchoring lengths depending on transfer directions and on type of reinforcement.

Notes are included concerning monitoring and warning systems.

Execution recommendations are also included at the end of the chapter although formally EBGEO is a design code.

4 FINAL REMARKS

EBGEO (2010, 2011) has in the meantime a longer history starting with the previous EBGEO (1997). It is intentionally formulated not as a standard but as a "recommendation" being a popular less stringent format in Germany. This allows to include not only design/calculation procedures but also detailed calculation examples and execution recommendations. It is believed that this is more useful for the geotechnical community.

It includes twelve chapters and three hundred pages, and is a National Application Document to EC7.

Many professionals participated in the working group AK 5.2 of the German Geotechnical Society (DGGT) over the years, the author is only one of them.

The two chapters herein are be presented only shortly and cannot substitute the originals. These chapters belong to the most sophisticated in EBGEO. The author has taken the liberty for himself of adding some history and background to the best of his knowledge.

Note that EBGEO (2010, 2011) being still valid presents in fact the German state-of-the-art about 2005–2009.

In the years passed practice and experience has confirmed it as useful and reliable, inclusive of the two chapters here, although some aspects are maybe conservative.

A next EBGEO is already planned, but this process will depend among others on the progress of the new next generation EC7.

ABSTRACT: The current design methods for Geosynthetic-Reinforced and Pile-Supported embankments disregard on one side the effect of the embankment construction and on the other one the stiffness of embankment, foundation soil, column and geosynthetics. What is missing nowadays is a simplified design method capable of taking all these aspects into account. To this aim, in this paper the authors present the results of a series of numerical analyses simulating the embankment construction. In particular, the evolution during construction of embankment displacements is discussed and the maximum tensile force in the geosynthetic reinforcements is compared with the one suggested by the most popular standards. To clearly highlight the mechanical processes taking place in the embankment, an ideal problem is considered: the pile shaft is assumed to be smooth, the piles to be founded on a rigid bedrock and the embankment construction to take place under drained conditions.

1   INTRODUCTION

Piled foundations are commonly employed to reduce settlements of artificial earth embankments on soft soil strata, and geosynthetic reinforcements are installed at the embankment base to increase pile spacing, that is to reduce construction costs. Despite the well documented effectiveness of this technique, the mechanical processes developing during the construction are not fully understood and the current design approaches, based on very simplified assumptions, ignore them.

In the scientific literature, the problem is usually tackled in the light of Ultimate Limit State (ULS) theory and the mechanical response of Geosynthetic-Reinforced Pile-Supported (GRPS) embankments, that is the vertical stress transfer to piles (arching effect) and the arising of the plane of equal settlements (plane above which differential settlements are negligible), is interpreted by assimilating it to the trapdoor problem. Nevertheless, experimental data (Iglesia 1991; Reshma *et al.* 2020; Terzaghi 1936) have shown that (i) the arching effect is strongly affected by both geometry and embankment mechanical properties, and (ii) the stresses acting on the foundation soil significantly depend on the differential displacements imposed at the base. All these observations put in evidence the crucial role played by the material deformability and, therefore, the unsuitability of trapdoor-based approaches to investigate the serviceability conditions of GRPS embankments (Mangraviti 2022; Mangraviti *et al.* 2022a).

Therefore, in the last decades, numerical studies, considering the presence of the foundation soft soil stratum (absent in the trapdoor geometry), were performed by using either finite element or finite difference (Flessati *et al.* 2022; Han & Gabr 2002; Mangraviti *et al.* 2022b; Stewart &

Filz 2005) codes or both (Jennings & Naughton 2012). It worth mentioning that in general these studies (i) do not focus on the effects of the embankment construction, (ii) do not take large displacements into account and (iii), thus, disregard the membranal behavior of geosynthetics.

In this paper, the authors discuss the results of a series of finite difference numerical analyses simulating the construction of the embankment under drained conditions, by accounting for the membranal mechanical behavior of the geosynthetic layer. Since the final goal of this research is to conceive a simplified mathematical "meta-model" to evaluate settlements at the top of the embankment during construction, the problem considered here in the following is ideal: (i) a unit axisymmetric cell of the embankment is analyzed (boundary effects are not accounted for), (ii) the pile shaft is assumed to be smooth and (iii) the pile are assumed to rich a rigid underneath bedrock.

The paper is structured as it follows: in §2 the numerical model is described; in §3 the results in terms of maximum tensile force and settlements at the top of the embankment are discussed and in §4 what learnt is briefly summarized.

2 NUMERICAL MODEL

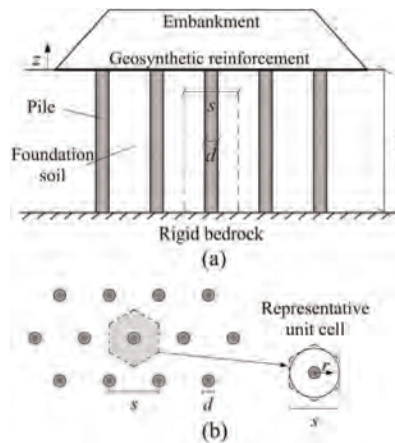
In this paper, the authors considered the effects of embankment construction on the central part of GRPS embankments. Therefore, the problem schematized in Figure 1a (where z is the vertical coordinate) is reduced to the analysis of one central axisymmetric cell (Figure 1b, where r is the radial coordinate). The unit cell of diameter s, assumed to be equal to the pile spacing (to each pile disposition a suitable definition for the unit cell diameter has to be assigned) includes: (i) the pile of diameter d and length l, (ii) a homogeneous foundation soil stratum of thickness l resting on a rigid bedrock, (iii) an embankment, whose height h evolves during the construction phase and (iv) the geosynthetic reinforcement laid at the embankment base. As previously mentioned, the pile shaft is assumed to be smooth and the construction process to take place under drained conditions.


Figure 1. (a) Problem geometry in transversal section; (b) Pile disposition in plan and representative axisymmetric unit cell.

The unit cell of Figure 1b has been modelled as illustrated in Figure 2. The numerical problem has been solved by using a finite difference numerical code (FLAC3D 6.0, Itasca 2017). A large displacement approach has been used and the spatial discretization has been optimized by choosing smaller elements close to the pile, where strains are expected to localize.

Normal displacements are not allowed along both the lateral boundaries and the bottom of the model. The pile is assumed to be elastic and, analogously to what done by many authors in

the literature, the soil has been modelled by means of a non-associated elastic-perfectly plastic constitutive relationship with a Mohr-Coulomb failure criterion. This constitutive relationship, despite of its simplicity, can capture the main aspects of the mechanical processes taking place in the considered spatial domain (Mangraviti *et al.* 2022c). The geosynthetic reinforcement has been modelled as an elastic isotropic membrane of axial tensile stiffness J.
Figure 2.   FLAC3D numerical model layout and spatial discretization.

Between pile and foundation soil, smooth interface elements are inserted. Along normal direction, under compression, the interface elements are "quasi rigid" (the elastic stiffness is sufficiently larger than the soil one, equal to 4e5 kN/m^3), whereas under tension perfectly fragile. Between the geosynthetic and the surrounding soil, frictional interface elements quasi-rigid along the normal direction are introduced. The interface friction angle is imposed to coincide with that of the soil (in agreement with the experimental findings by Moraci *et al.* (2014)).

The layer-by-layer embankment construction is subdivided in single stages, each one corresponding with the deposition of 0.25 m of granular material (for the sake of simplicity, both pile installation and soil compaction are not reproduced). At each construction stage, a new stratum of elements is added on the current position of the embankment top. This allows to reproduce, in contrast with what done by Han & Gabr (2002) and Jennings & Naughton (2012), although in a simplified way, the real loading path followed by the system during the embankment construction.

To study the mechanical processes taking place during the embankment construction, a parametric study, in which different geometries and mechanical properties have been considered, was performed. The results differ from a quantitative point of view but are qualitatively consistent. As a consequence, for the sake of brevity, the numerical results will be discussed here in the following by considering only a reference case of fixed geometry ($s = 1.5$ m, $d = 0.5$ m, $l = 5$ m) and given mechanical properties of materials (Table 1).

Table 1.   Mechanical properties of the materials for the reference case.

	Unit weight kN/m^3	Young modulus MPa	Poisson ratio -	Friction angle °	Cohesion kPa	Dilatancy angle °	J kN/m
Foundation soil	18	1	0.3	30	0	0	-
Embankment	18	10	0.3	40	0	0	-
Pile	25	30000	0.3	-	-	-	-
Geosynthetic reinforcement	-	-	0.3	-	-	-	1000

3 RESULTS AND DISCUSSION

Analogously to what already observed by Han & Gabr (2002), the distribution of the total tensile force per unit thickness within the geosynthetic is not uniform and varies along the radial coordinate (Figure 3a). In this figure, the tensile stress is integrated along the current circumference, reducing with r. For this reason, although the tensile stress is maximum at the pile edge, the tensile force has a maximum for $r = 0.3$ m. The numerical results from this study (Figure 3a, solid line) are compared with the value of maximum tensile force assessed (for the reference case and $h = 5$ m) by according to what suggested by one of the most popular standard in the field (BS8006-1 2010), that assumes an unrealistic uniform distribution of tensile force in the geosynthetic (Figure 3a, dotted line).

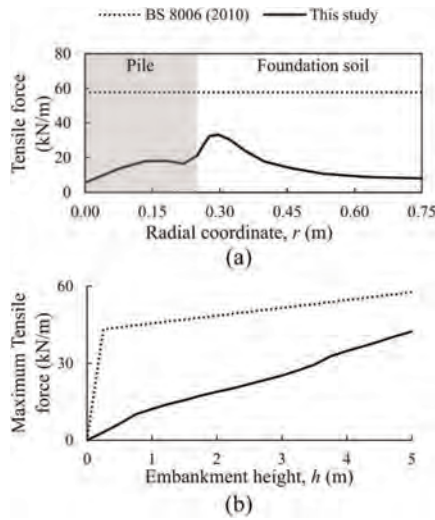
The values of the maximum tensile force calculated for different values of h by using BS8006-1 (2010) were found to be always larger than the ones obtained in this study (Figure 3b). This result is consistent with the hypothesis at the base of the standards. In fact, as was already observed by Bhasi & Rajagopal (2015), ULS approaches lead to an extremely conservative estimation of the maximum tensile force in the geosynthetic.


Figure 3. Comparison between numerical analyses from this study and BS8006 (2010) for the reference case: (a) Tensile force within the geosynthetic along the radial coordinate for $h = 5$ m; (b) Maximum tensile force of the geosynthetic reinforcement calculated for different values of h.

To better understand the mechanical behavior of GRPS embankments, the evolution of irreversible deviatoric strain contours during construction was analyzed: Figures 4 a-c refer to three representative values of h. The results show that deviatoric strains localize in a cylindrical crown (defined as "process zone", in agreement with what suggested by (di Prisco *et al.* 2020a, 2020b) close to the pile edge, while in the rest of the spatial domain deviatoric strains are negligible. For small h values, the height of the process zone (h_p) coincides with the embankment height, but, when the embankment height gets a threshold value ($h_p = h^* = 1.1$ m, for the reference case), h_p stops evolving. As a result of the parametric study, it was found that h^* is a function of: (i) geometry (s, d and l); (ii) embankment soil friction and dilatancy angle; (iii) relative stiffness between pile, foundation soil and embankment soil and (iv) J.

As in Mangraviti *et al.* (2022b), the numerical results in terms of average and differential settlements at the top of the embankment have been plotted (Figure 5). Average ($u_{t,av}$) and differential ($u_{t,diff}$) settlements at the embankment top are calculated as:

$$u_{t,av} = \frac{u_{t,f}\left(s^2 - d^2\right) + u_{t,p}d^2}{s^2} \text{ and } u_{t,diff} = u_{t,f} - u_{t,p} \tag{1}$$

where:

$$u_{t,p} = \frac{2\pi \int_0^{d/2} u_t(r)dr}{\pi d^2/4} \quad \text{and} \quad u_{t,f} = \frac{2\pi \int_{d/2}^{s/2} u_t(r)dr}{\pi(s^2 - d^2)/4} \tag{2}$$

are the weighted average values of $u_t(r)$ above the pile (for $0 < r < d/2$) and the foundation soil ($d/2 < r < s/2$), respectively. $u_t(r)$ is the vertical displacement accumulated during construction at the top of the embankment.

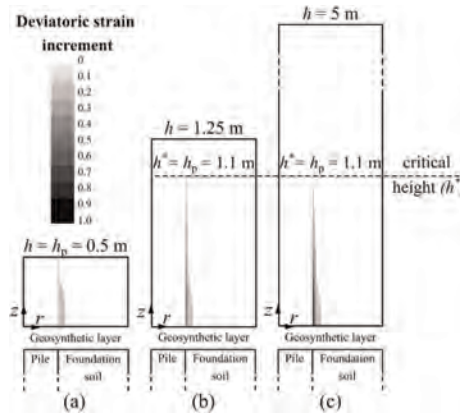
Once the height of the embankment becomes larger than h^*, differential settlements stop increasing, regardless of the final height of the embankment (Figure 5). h^* can also be interpreted as a "critical height" and is analogous to the height of the plane of equal settlements observed by Terzaghi (1936) and Han & Gabr (2002).


Figure 4. Contour of deviatoric strains in the embankment during construction for the reference case and evolution of process height, h_p, for three representative h values: (a) $h = 0.5$ m; (b) $h = 1.25$ m; (c) $h = 5$ m.
Figure 5. Average and differential settlements at the top of the embankment during construction for the reference case.

4   CONCLUSIONS

In this paper, the results of a finite difference numerical analysis campaign, modelling an ideal axisymmetric unit cell of Geosynthetic-Reinforced and Pile-Supported embankments are

discussed. For the sake of brevity, only the results concerning a reference case are illustrated. The results, in terms of both maximum tensile force in the membrane and settlements at the top of the embankment during drained construction of the embankment have been discussed. In particular, the numerical results highlighted the importance of taking into consideration the stiffness of the materials involved for a reliable estimation of the critical embankment height. Furthermore, the authors emphasized the importance of considering the layer-by-layer embankment construction to properly reproduce the mechanical processes progressively developing within the embankment and, therefore, to correctly estimate: (i) the tensile force acting in the membrane and (ii) average and differential settlements at the top of the embankment.

According to the authors, the very conservative approach of current design methods, based on ultimate limit state theory and not accounting for staged construction processes, lead to a significative overestimation of the force acting in the membrane. This does not allow for an adequate optimized and sustainable design of GRPS embankments from a serviceability limit state perspective.

ABSTRACT: Recent work has shown that GCL hydration by subgrade is influenced by a series of variables related to GCL characteristics, as well as subgrade initial moisture content, particle size and mineralogy. Another major variable is the effect of GCL exposure to daily thermal cycles during the landfill construction phase. Additionally, tropical climate conditions, such as in Brazil, result in the occurrence of lateritic fine soils, which present high moisture content and a particular mineralogy. The present study evaluated the GCL hydration by two lateritic subgrades (clay and clayey sand) under isothermal conditions and heating/cooling cycles. The isothermal analysis confirmed the influence of subgrade initial moisture content on GCL hydration since both soils with the highest moisture content showed 50% higher GCL hydration. GCL samples exposed to heating and cooling presented poor hydration, even at a higher subgrade moisture content, confirming the influence of thermal conditions on GCL hydration and properties. In comparison with studies of literature, lateritic soils showed higher GCL hydration speed than soils formed in temperate climates.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) are often used as a solution in different applications that demand fluid or gas barriers. The extremely low hydraulic conductivity, higher swelling potential and cation exchange capacity of bentonites result in an excellent material when enveloped by geosynthetics. Additionally, the ease of installation, reduced thickness, the potential of self-healing in face of punctual stresses, and cost-effectiveness explains the current use of GCLs (Bouazza *et al.* 2017; Kerry Rowe R 2020; Touze-Foltz 2020). However, in the last years, many researchers demonstrated a recurrent problem with the correct hydration of GCL from the underlying soils (Acikel *et al.* 2018; AbdelRazek & Rowe 2019; Rowe *et al.* 2019), which can adversely affect GCLs performance.

The GCL hydration by the subgrade can be affected by the granulometry of soil, subgrade moisture, bentonite characteristics, and structure of the GCL. These parameters have been studied in the last years in many literature studies. A study conducted by Rayhani *et al.* (2011) reported better hydration levels of GCLs in contact with sands compared to silt soils. Acikel *et al.* (2018) demonstrate that the insufficient hydration of GCLs from subgrades can

*Corresponding Authors: josewilsonbatistadasilva@gmail, ncorreia@ufscar.br and fportelinha@ufscar.br

be explained by subsoil grain size distribution and mineralogy. The initial moisture of soil affects significantly the GCL hydration, showing that even a small increase of 2% of soil moisture content can improve the hydration levels (Acikel *et al.* 2018; Bouazza *et al.* 2017; Kerry Rowe R. 2020; Rayhani *et al.* 2011). Research developed by Anderson *et al.* (2012) and Sarabian and Rayhani (2013) and Rowe *et al.* (2022) suggests that exposition to thermal conditions affects GCL hydration. All these studies were conducted using temperate soils as a subgrade and demonstrated that the hydration process can be influenced by a significant range of variables. Therefore, there is a lack of studies related to soil formed in tropical regions (lateritic soils). This paper will examine the hydration behavior of three GCLs in contact with lateritic soils when exposed to isothermal and heating/cooling conditions (tropical climate), varying initial foundation moisture content and GCLs structure.

2 MATERIAL AND EXPERIMENTAL PROCEDURE

2.2 *Geosynthetic Clay Liners (GCLs)*

Table 1 summarizes the properties of the three different GCLs examined in this research, all GCLs contain similar thickness, dry mass per unit area, saturated hydraulic conductivity (k) and plasticity index (PI). However, important properties are different, cation exchange capacity (CEC), swell index (SI), and fluid loss properties. The initial moisture content and the maximum hydration gravimetric water content (w_{ref}). Similar tests were conducted to estimate w_{ref} using the water-rising process (Anderson *et al.* 2012; Acikel *et al.* 2018; Rayhani *et al.* 2011; Sarabian & Rayhani 2013) under 1 kPa of vertical stress.

Table 1. Properties of the GCLs.

Material	Properties	GCL1	GCL 2	GCL 3
Bentonite	Plastic Index (%) (ASTM D4318 2017)	252	253	273
	Avg. Dry mass /area (g/m) (ASTM D5993 2018)	4964	3878.5	4375.1
	Swell Index (ml/2 g) (ASTM D5890 2019)	25	20	25
	Fluid Loss (ASTM D5891 2019)	18	32	28
	Smectite content (%) *	80	80	80
	Cation Exchange capacity (meq/100 g)**	140	110	163
Carrier	Type	WGT	WGT	WGT
Cover	Type	NWGT	NWGT	WGT
GCL	Thermally treated	yes	yes	no
	Bonding	NP	NP	ST
	Thickness (mm) (ASTM D1776 2020)	7.0	7.0	6.0
	Initial gravimetric water contents	21	10	11
	Reference gravimetric water content (%) (ASTM D2216 2019)	182.7	214.2	267.7
	Hydraulic conductivity (m/s) (ASTM D5887 2020)	1.2×10^{-11}	1.2×10^{-11}	4.8×10^{-11}

*Maximum values as provide by manufacturers.
**Cation exchange capacity (CEC) tests were conducted using the methylene blue adsorption test. The complete characterization of these GCLs was described by Silva *et al.* (2022).

2.2 *Subsoils*

Two lateritic soils were used to hydrate the GCLS in this investigation. The clayey sand and a high plastic clay were selected as typical lateritic soils found in the Brazilian territory and in other tropical countries. The complete characterization of these soils was described by Silva

et al. (2022). According to the Unified Soil Classification System (USCS) (ASTM D2487 2017), clayey sand is classified as SC soil, and sandy clay is classified as high plasticity clay (CH) soil. Although the lateritic CH soil is clay, it also has a significant percentage of fine sand (36%), a common characteristic of lateritic soils.

2.3   *GCL hydration test under isothermal and simulated field conditions(heating/cooling)*

Polyvinyl chloride (PVC) cells of 250 mm in diameter and 500 mm in height were used to investigate the hydration of three GCLs installed over lateritic subsoils (Figure 1a). For each subsoil, compaction moisture contents adopted were at optimum (OMC) and 2% above optimum (OMC+2%). The cells were compacted using a 95% degree of compaction in relation to the maximum dry density of soil based on the Standard Proctor Compaction Test to ensure the same void ratio of the subgrade. GCL samples with 250 mm of diameter were placed over the compacted subsoil with the initial gravimetric moisture content (Table 1). Then, the system was sealed, and the tests were conducted under environment-controlled conditions of 21°C. Tests were conducted with GCL1 hydrated by both lateritic soils at two moisture values (OMC and OMC+2%). Additionally, two others GCLs (GCL2 and GCL3) were tested at each lateritic soil, only in OMC+2% condition.
Figure 1.   Physical models: (a) Isothermal test cells; (b) Thermal test box.

To investigate GCLs hydration by the subgrade when exposed to heating/cooling cycles a physical model was constructed using the same liner used in the PVC cells. Both materials (GM and GCL) were restrained longitudinally to simulate the anchorage found on field. Similar models have been used in several laboratory studies and in the physical model studied by Rowe *et al.* (2013). A heating period of 8 hours was imposed with a temperature of 57±4 °C, followed by a cooling period of 16 hours, leading to a minimum of 30±4 o C of temperature in a day cycle. This temperature range is consistent with the conditions found in Brazilian landfills (Costa *et al.* 2019; da Silva *et al.* 2020; Portelinha *et al.* 2020). The study with heating/cooling cycles was conducted only using the GCL1 hydrated by CH subsoil at OMC, GCL1 hydrated by SC subsoil at OMC+2% condition, and GCL1 hydrated by CH subsoil at OMC+2% condition. The complete description of the models used for isothermal and simulated field conditions tests is described by Silva *et al.* (2022). The GCL gravimetric moisture contents in both conditions were monitored weekly, weighing the samples using a digital scale of 0.01 g precision.

3 RESULTS

3.1 *Effect of subsoil type and moisture content on GCLs hydration under isothermal conditions*

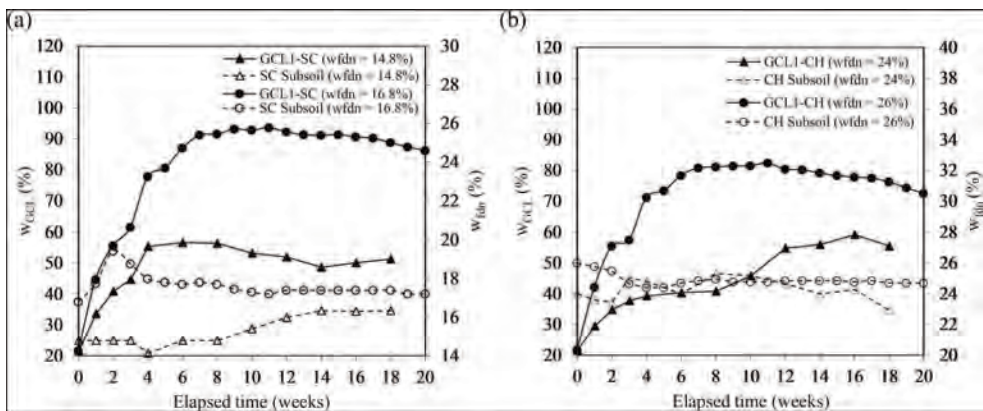
Figure 2 presents the changes in gravimetric moisture content for three different GCL1 (w_{GCL}) when hydrated from lateritic SC and CH subsoils under isothermal conditions and at different water foundation moisture contents (w_{fnd}). After 18 weeks of hydration, both lateritic subsoils significantly increased the moisture content of the GCL to approximately 60% in the OMC condition. The hydration of GCLs was higher when hydrated by subsoils with a higher initial moisture content (OMC+2%). An impact of soil type was also observed on the hydration rate of GCLs. The lateritic SC soil, with granular characteristics, showed a higher hydration rate than CH soil (fine soil). However, the GCL1 when hydrated by the SC soil at OMC condition showed moisture loss after 12 weeks of testing. Similar results were found by Rayhani *et al.* (2011) regarding the difficulty of GCLs to hydrate from fine-grained subgrades reported by Rayhani *et al.* (2011). A possible explanation for this behaviour is the initial suction level of subgrades and the hydraulic conductivity of soil (Acikel *et al.* 2018). Soil moisture data measured along the GCL hydration tests are also plotted in Figure 2. The soil moisture was stable during GCL hydration, except for the lateritic SC soil compacted at OMC which presented small variations.


Figure 2. GCL1 hydration under isothermal conditions: (a) SC subgrade; (b) CH at OMC+2%.

3.2 *Effect of heating/cooling cycles on GCL hydration*

Figure 3 compares the hydration of GCL1 from lateritic SC and CH under isothermal and heating/cooling conditions. The exposition to thermal cycles affected significantly the GCL hydration. Similar results were as also observed by Rowe *et al.* (2011), Anderson *et al.* (2012) and Sarabian and Rayhani *et al.* (2013). At simulated field conditions the sand soil (SC) was not capable of hydrating the GCL1 after 8 weeks of testing, even considering soil compaction at OMC+2%. The reduction in SC subsoil moisture content without increases in GCL moisture indicates a limitation of upward flow from the soil to GCL. Figure 4 shows the specimens of GCLs after hydration, showing less hydration in the GCL1 subjected to thermal cycles.

3.3 *Analysis of GCL properties after hydration*

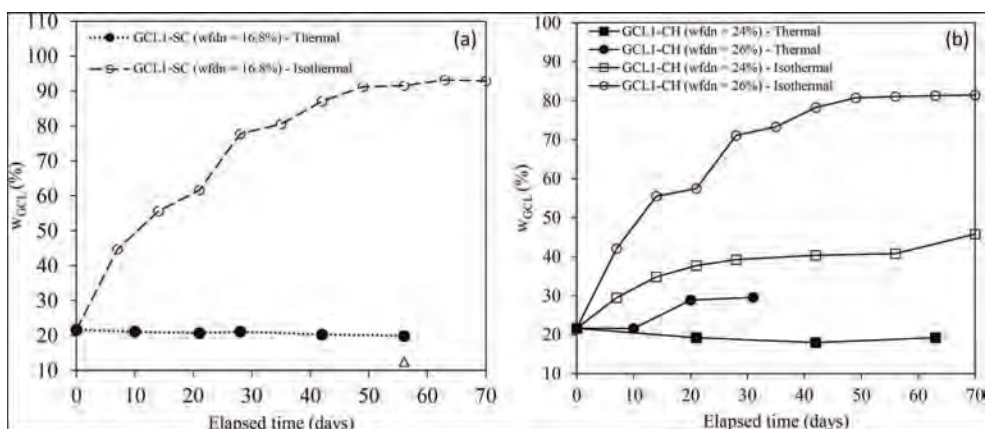
At the end of hydration, tests were conducted to investigate GCL's hydraulic conductivity, swell index, and cation exchange capacity. All these parameters are presented in Table 2 for tests conducted for isothermal (I) and heating/cooling cycles (T) for all GCLs examined.


Figure 3. Hydration of GCL1 from SC and CH subgrades under isothermal and heating/cooling conditions.
Figure 4. GCLs after hydration under isothermal conditions: (a) GCL1 in the SCwót+2% subgrade; (b) GCL2 in the SCwót+2% subgrade; (c) GCL3 in the SCwót+2% subgrade; (d) GCL1 after hydration under heating/cooling cycles conditions.

Based on the current guideline to qualify GCLs (GRI GCL3 2016) all the results of SI found are lower than the minimum required to ensure good bentonite swelling properties. The hydraulic conductivity of all GCLs studied suffered an increase for both soils, with the main changes occurring at isothermal conditions. A possible explanation for this is the fact that under isothermal conditions, continuous water redistribution and water content changes in the subsoils were observed, resulting in a possible cation exchange between the subgrade and GCL. This hypothesis is explained by Acikel *et al.* (2021), cation distribution due to self-diffusion in bentonites is favoured by wetting, which leads to more significant changes in GCL properties. Different behaviour occurred for heating/cooling cycles tests, due to the capillary break moisture changes between soil and GCL were limited. Without water flow, cations exchange decreases, and as a result, fewer alterations in hydraulic conductivity. The influence of thermal conditions on CEC can be assed in Table 2, all GCLs presented values greater than the minimum of 70 meq/100 g required (Guyonnet *et al.* 2009).

Table 2. GCLs properties after isothermal and heating/cooling cycles hydration tests.

		Virgin samples			After hydration		
Hydration Test	w/w_{ref} (%)	SI (mL/2 g)	CEC (meq/100 g)	k_s (m/s)	SI (mL/2 g)	CEC (meq/100 g)	k_s (m/s)

I – Isothermal condition; T - heating/cooling condition.

4 CONCLUSIONS

This paper has examined the hydration of three GCLs from two lateritic subsoils exposed to isothermal and heating/cooling conditions. Complementary tests were conducted for exhumed samples to evaluate the influence of hydration on GCL properties. Based on these results this paper suggests the following conclusions:

- Under isothermal conditions, lateritic subsoils were not able to provide the maximum hydration possible for the GCLs in both soils and at the two moisture contents (optimum and +2%). Although the lateritic soils did not provide the maximum hydration, the result found for the hydraulic conductivity of the GCLs is in accordance with the guidelines.
- Results in this study reaffirms that heating/cooling cycles influence the GCL hydration. In this tests, lateritic clayey soils promoted equal or better conditions to hydrate the GCLs than sandy soils (dehydration), as opposed to isothermal test results.
- GCLs hydrated at isothermal conditions presented more alterations in the swelling index, cation exchange and hydraulic conductivity than when exposed to heating/cooling cycles. These results can be a result of cation exchange between the soils and bentonite facilitated by the continuous water flow at isothermal conditions.

ABSTRACT: An embankment underlain by permafrost foundation was reinforced with woven geotextiles at its side slopes to reduce slope displacements when the compacted frozen fill used to construct the embankment thaws. The fully-instrumented embankment along the Inuvik-Tuktoyaktuk Highway in the Northwest Territories, Canada has thermistor strings to monitor soil temperatures as well as ShapeAccelArrays installed at the midslope of the embankment to measure displacements. Four years of monitored data shows reduction in slope movements compared to an unreinforced embankment. A numerical model was developed in a commercially-available finite element software to simulate the thermal and mechanical behaviour of this embankment and further understand the benefit of using geotextiles in cold regions environment. Multi-layer woven geotextiles with varying reinforcement length and vertical spacing were also investigated. The monitored performance and the model results presented will help optimize embankment design in cold regions environment using geotextiles.

1 INTRODUCTION

Highway embankments in the Arctic are usually constructed during winter conditions to preserve the permafrost foundation and minimize environmental impacts. They are typically designed to provide adequate ground insulation and minimize permafrost degradation (Argue et al. 1981) under known climatic conditions. The construction of embankments inevitably results to thermal disturbance of the underlying permafrost. The permafrost will degrade if the insulating effect provided by the embankment fill is less than the insulating effect of the original active layer. On the other hand, the permafrost can rise into the embankment if the insulating effect of the embankment fill is greater than the insulating effect of the original active layer. However, there is limited understanding on the mechanical behaviour of embankments that are initially compacted with frozen fill and experienced natural thawing and settlements during the spring and summer seasons following winter construction (De Guzman et al. 2021).

A test section that is 20 m long was constructed along the Inuvik-Tuktoyaktuk Highway (ITH) in the Northwest Territories, Canada in April 2015 and instrumented to monitor temperatures and displacements. This section is reinforced with layers of wicking woven

geotextiles to minimize localized thaw-settlements under the shoulders and side-slopes of the embankment created in combination with the depression of the permafrost table at the toe of the embankment (De Guzman et al. 2021). It was conceptualized they will provide drainage paths for the melt water during spring and summer seasons when the embankment undergoes thawing. This wicking geotextile has been successfully used for moisture management and drainage applications (Sikkema & Carpita 2016; Zhang et al. 2014). De Guzman et al. (2021, 2022) reported the field performance of this reinforced embankment supported with numerical modelling results, which are briefly presented here prior to investigating multi-layer wicking geotextiles with varying reinforcement lengths and vertical spacing. This paper aims to demonstrate the benefit of using wicking geotextiles as slope reinforcement for embankments in cold regions environment.

2 FIELD PERFORMANCE

2.1 *Embankment construction and instrumentation*

The embankment height of the test section is 5.3 m with a slope of 3H:1V. The location of the instrumentation installed and the geotextile layers at the test section is shown in Figure 1. The geotextiles are at elevations 1.8, 2.7, 3.6, and 4.5 m above the natural ground surface. Frozen fill material was taken from the nearest borrow pit source with an average moisture content of 16%. Two thermistor strings were laid out horizontally at the top (TS-R1) and along the base (TS-R2) of the embankment, and another two vertically installed through the foundation at the centreline (TS-R3) and at the toe (TS-R4). The base thermistor is 600 mm above the natural ground surface, while the top thermistor is 500 mm below the road surface. The vertical ShapeAccelArray, SAA, (SAA-RV) is located at an offset of 12 m from the embankment centreline, with its first node 400 mm below the slope surface. SAA-RV was anchored at the frozen foundation soil. Similarly, the horizontal SAA (SAA-RH) was anchored inside the embankment either sitting on top of compacted frozen soil at the core of the embankment or below the 0°C isotherm. The instrumentation cables were connected to a DAQ at an offset from the toe of the embankment which can be remotely accessed through satellite connection. The wicking geotextile layers are 8.4 m long and were laid out horizontally at every 900 mm from initial placement of fill material on both sides of the embankment. The same instrumentation and layout were used in a control test section (unreinforced), which is directly beside this reinforced embankment.
Figure 1. Instrumentation installed in the embankment cross-section with wicking geotextiles installed. Location of thermistor strings and ShapeAccelArrays (SAAs) in the test section. All units are in metres.

2.2 Temperatures

Temperature readings at different time steps are shown in Figure 2 from the horizontally-laid thermistor string along the base (Figure 2a) and the vertically-laid thermistor string at the foundation centreline (Figure 2b) of the embankment. TS-R2 shows that from the embankment centreline to about 11.5 m towards the toe, the core of the embankment has remained frozen since end-of-construction, while beyond this distance the seasonal temperature fluctuations occur on the embankment slopes. TS-R3 at the foundation centreline remained below -3°C for the monitoring period. Warming in the foundation was observed for the month of December but the thickness of the fill material for the test sections provided adequate insulation preventing permafrost thaw from the centreline to the shoulder.

2.3 Displacements

Recorded lateral displacements for the test section is shown in Figure 3a. The largest displacements occurred at the SAA node closest to the slope surface during the first thawing season after construction. Although the temperature of the SAA nodes P6 and P7 were recorded to be between $-1°C$ and $0°C$ as reported by De Guzman et al. (2021, 2022), there were movements observed in the monitoring period. The thickness of the soil from the base of the embankment that has not moved is approximately 0.75 m based on the SAA readings where the temperatures are less than -2°C. As air temperatures were warming, the seasonal depth of fluctuation increased and thus initiated for displacements to develop at deeper nodes. Initial displacements were required before the geotextile fabric can provide resistance against lateral movements. De Guzman et al. (2021) reported that the geotextiles provided the most resistance against lateral movements during the first thawing after construction. There are minimal to almost no displacements during the winter months until the spring season of the following year. Since end-of-construction of the test section, the embankment was able to consolidate for three thawing seasons before the highway was officially opened to traffic in November 2017. Although these displacements are increasing due to thawing at the slopes, the cumulative displacements of the reinforced test section at different elevations are considerably less than that of a comparable unreinforced section, confirming that the geotextiles are providing reinforcement to the high fill section (De Guzman et al. 2021), as shown in Figure 3b.

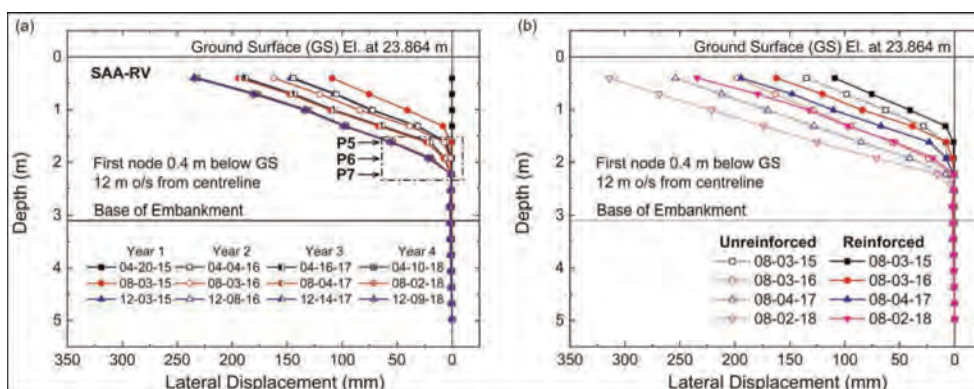

Figure 3. Lateral displacements at (a) different time steps recorded from SAA-RV and (b) comparison with unreinforced test section.

3 NUMERICAL MODELLING

3.1 *Field measurements vs. model results*

De Guzman (2020) and De Guzman et al. (2022) presented the material properties, boundary conditions, and modelling procedure for the reinforced embankment using the commercially-available general finite element software ABAQUS Version 6.14 (Smith 2014). The geotextile has a tensile strength of 15.8 kN/m at 2% strain. The interface friction angle was assumed to be high when the soil is frozen, and taken as 5.8° based on pullout tests at 0°C. The friction angle of frozen soil is 52.1°, and taken as 27.0° when the soil is thawed at 0°C. The model is sequentially built, where the temperature field is first solved for the entire period of analysis, followed by a deformation model referencing the temperature field to call material properties in a frozen or unfrozen state. The sequential approach used in the model is primarily due to the presence of the geotextile (membrane element) and the pore pressure degree of freedom available in the software. A similar embankment but without the wicking geotextiles was studied by De Guzman (2020) using a coupled thermal-mechanical model where the heat transfer (thermal) and stress and deformation (mechanical) occurring on the soil elements are solved simultaneously in a single analysis. In this type of analysis, the soil is modelled using coupled elements with displacement, pore pressure, and temperature degrees of freedom at its nodes. The hydraulic component was limited to best-fit parameters by running several model simulations that would result to closer values with the measured lateral and vertical displacements from the field.

The horizontal displacements from the model compared to recorded field data of SAA-RV is shown in Figure 4a. The horizontal displacement of the soil between Layer 1 (GL1, 1.8 m) and Layer 2 (GL2, 2.7 m) from SAA-RV shows a linear variation of displacement with depth accumulating over time. The model displacements on the other hand show this to be curved, with the top node of the layer observed to be less than the recorded one. With respect to depth, the horizontal displacements just above L1 from August 2015 to August 2017 show that it is slightly overestimated by 5 to 10 mm, but this difference increased to 50 mm in August 2018. These displacements are related to temperatures modelled in a pure heat transfer analysis. Additional thawing will occur at the toe of the embankment when a coupled thermal-mechanical model is used (De Guzman 2020) since both the heat transfer and stress and deformation occurring on the soil elements are solved simultaneously in a single analysis. The underestimated displacements below L2 are offset by the overestimation in displacements above L1.

A comparison of the horizontal displacements from the reinforced sequential model with the results of an unreinforced sequential model is shown in Figure 4b. Both models are using the thermal regime in the embankment fill and foundation soil from a pure heat transfer

2123

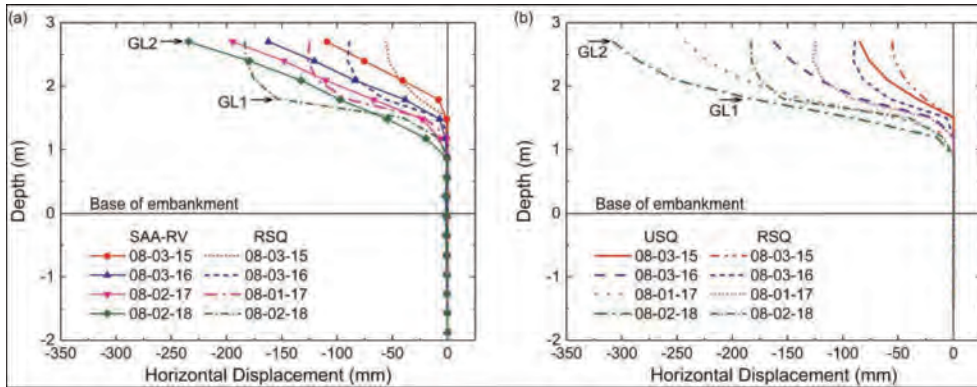
analysis and as expected the depth of seasonal freezing and thawing and its corresponding thickening over time are the same. The displacements in both directions are reduced with the use of these geotextile reinforcements. The results provide confidence that the interface shear strength (derived from pullout tests) and tensile strength from tensile tests are contributing in reducing lateral displacements (De Guzman 2020).


Figure 4. Comparison of horizontal displacements (a) between measured field values and model results for reinforced section and (b) model results between unreinforced (USQ) and reinforced (RSQ) analysis.

3.2 *Effect of reinforcement length*

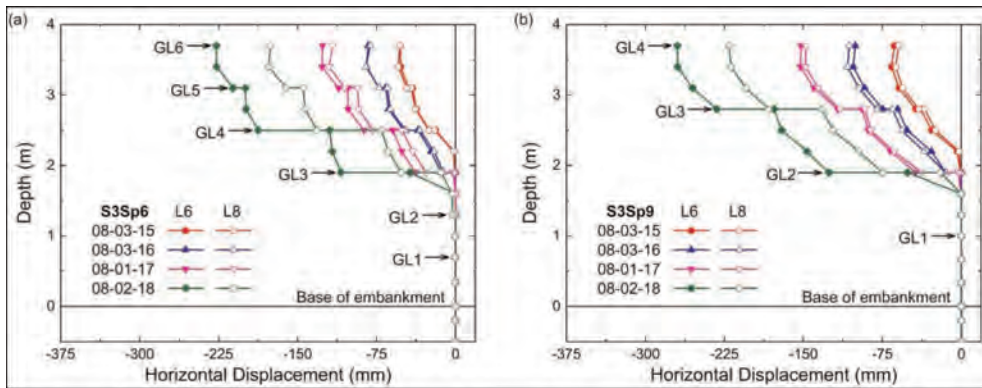
The extent of the thawed core for S3 (3H:1V) is shown Figure 5. A fictitious line is super-imposed in this figure to show the conceptual embedment of the geotextile in the model. The vertical spacing shown is 0.9 m (Sp9), but these were also done for the 0.6 m (Sp6) case. Figure 6 shows the horizontal displacements for the S3 models using two reinforcement lengths considering Sp6 (0.6 m spacing, Figure 6a) and Sp9 (0.9 m spacing, Figure 6b). The plots are relative to the midslope of the embankment. This change in slope configuration will change the thermal regime of the model embankments and therefore the length of the geo-textile embedded in the frozen core. S3Sp6 and S3Sp9 using 6 m have all layers of reinfor-cement within the seasonal thaw depth at the slope. These geotextile layers, although only embedded outside the frozen core, provided 33% and 20% reduction in horizontal dis-placements for Sp6 and Sp9, respectively, compared to an unreinforced embankment of the same configuration. For S3Sp6 and S3Sp9, lengthening the reinforcement to 8 m intercepted the frozen core with an embedment length of 2 m. With an additional geotextile length of 2 embedded in the frozen core, the Sp6 model showed a reduction in horizontal displacements by 53%, and the Sp9 model showed 38%.
Figure 5. Extent of thawed core where reinforcements were installed for 3H:1V.


Figure 6.   Model horizontal displacements at midslope of embankment for (a) s = 0.6 m and (b) s = 0.9 m using two reinforcement lengths with 3H:1V slope configuration.

3.3   *Effect of reinforcement spacing*

Figure 7 show the horizontal displacements at the midslope for S3 with the reinforcement length held constant. For all cases, a larger vertical spacing (Sp9) resulted in larger horizontal displacements along the midslope. With the reinforcement embedded in the frozen core (Figure 7b), the displacements were reduced by 23% for the soil between elevations 2.8 m and 3.7 m, and by 53% for the soil between 1.9 m and 2.8 m above the original ground surface.

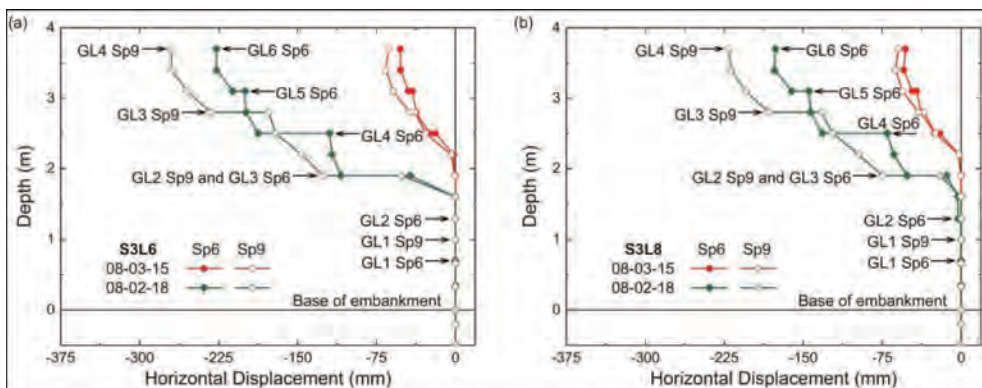
The S3 models demonstrated that addition of geotextiles in thawing slopes can reduce the horizontal displacements for a similar unreinforced embankment. A combination of tighter vertical spacing and longer reinforcement embedded in the frozen core provided the most benefit in limiting displacements as the slopes undergo seasonal freezing and thawing cycles. It should be noted that a tighter vertical spacing will require quality control as each soil lift is compacted under frozen conditions and may delay project delivery time, while reinforcement layers (woven geotextiles) have to be long enough to intercept the potential location of a frozen core.


Figure 7.   Model horizontal displacements at midslope of embankment for 3H:1V slope configuration using (a) L = 6 m and (b) L = 8 m.

4 SUMMARY AND CONCLUSIONS

The recorded field data from the thermistor strings and SAAs were used to calibrate a numerical model using a sequentially-coupled approach. The model results slightly under-estimated the horizontal displacements at the midslope. A comparable unreinforced section showed that the geotextile layers installed reduced the horizontal displacements by as much as 40% in August 2018 (three years after the end of construction). The large displacements occurring during the summer following winter construction was reduced by 31% using wicking geotextiles. Similar to the recorded field data, the largest incremental displacements occurred during the summer following winter construction. It is recognized that there is an overlapping influence of warming air temperatures and thermal disturbance on the perma-frost underneath the embankment due to embankment construction.

Results from parametric reinforced models indicate that reducing the slope inclination is the most plausible option in mitigating the development of large horizontal displacements for thawing slopes. With prohibitive project costs to accommodate gentler slopes, geotextiles can be used as an alternative strategy to have steeper slopes yet reduce embankment dis-placements. The benefit of installing geotextile layers for cold regions embankment appli-cations is realized as long as there is a region where the geotextiles are still embedded within a frozen core and designed using a tighter vertical spacing between reinforcement layers.

Predicted performance of geogrid-stabilized unbound aggregate layers using confined soil-geosynthetic composite stiffness

S. Subramanian & J.G. Zornberg
University of Texas at Austin, USA

ABSTRACT: Selection of geosynthetics, for stabilization of unbound aggregate layers in pavements, involves the unconfined properties of geosynthetics and/or the large displacement confined properties. However, geogrids within a pavement system are neither unconfined nor undergo large displacements. This study proposes using the confined Soil-Geosynthetic composite stiffness (K_{SGC}), obtained from Soil-Geosynthetic interaction (SGI) tests, to predict pavement performance when using geogrid-stabilized road bases. A series of identical one-third scale accelerated pavement tests (APTs) were performed on pavement test sections stabilized with various geogrids, diverse in terms of geometry and materials. The rutting from these sections was compared to that in the non-stabilized (control) section to evaluate the Traffic Benefit Ratio (TBR) at failure rut depth for each geogrid. The TBR obtained showed a strong linear correlation to the soil-geosynthetic composite stiffness (K_{SGC}) of the corresponding geogrid obtained from the SGI tests. It is concluded that K_{SGC} is a particularly good indicator of the performance of pavements with geosynthetic-stabilized road bases.

1 INTRODUCTION

Stabilization of unbound pavement layers involves the inclusion of geosynthetics within an unbound aggregate layer and/or at the interface between layers. This is aimed at improving pavement performance by increasing the aggregate layer stiffness through transfer of stresses to the geosynthetic material. In paved roads, this transfer of stresses, to tension-bearing geosynthetic materials, limits the lateral movement of the stabilized pavement layer. This "lateral restraint", which can be mobilized under relatively small deformations, is considered the dominant mechanism of performance improvement for geosynthetic-stabilized paved roads.

Engineering projects specify for geosynthetics based on their index properties such as tensile strength & stiffness, and their performance properties that govern their interaction with surrounding soils such as pull-out resistance or interface shear strength (Zornberg and Christopher (2007)). While these properties are particularly relevant in many engineering applications such as earth-retaining walls, embankments, or slope stability, they are not well suited for the design of stabilized road bases. These properties capture either the small-strain, unconfined behavior (as in the case of tensile stiffness or flexural rigidity) or the large-displacement confined interaction of the geosynthetics with the surrounding soil. However, under serviceable limits for surface pavement, the geosynthetic is under confined conditions but does not undergo large displacements. AASHTO-R50 (2009) recommends performing full-scale tests with geosynthetics to predict their field performance. Some researchers have also developed correlations between geosynthetic properties and their field performance in stabilization (Christopher *et al.* (2008), Archer & Wayne (2012)). However, these correlations lack a mechanistic basis since they are based on properties that do not capture the geosynthetic behavior under serviceable limits for surfaced pavements. In this study, the soil-geosynthetic composite stiffness (K_{SGC}), that captures

the confined small-strain interaction of geosynthetic with soil, is proposed to predict the stabilized pavement performance.

2 ACCELERATED PAVEMENT TEST

In order to access the performance of pavement sections with stabilized base course, reduced-scale pavement sections were constructed in the laboratory under controlled environmental conditions. These sections comprised of identical pavement configuration but with four different types of geogrids (GG1 to GG4 – Figure 1), different in their material and geometric properties (Table 1). One section without any stabilizing geosynthetic was also constructed to serve as the control. All 5 pavement sections consisted of a 15 cm clean uniform sand subgrade placed at 67% relative density, 12.5 cm gravel base conforming to AASHTO#8 gradation and placed at 85% relative density, and 2.5 cm hot mix asphalt (HMA) ride surface from a thin overlay mix – type A (TxDOT SS3239 (2004)). The entire structure was built above grade in two modular frames, each 15 cm tall. The pavement structure was 180 cm (72″) in length and 180 cm in width with a total depth of 30 cm as shown in Figure 2. The geogrid in stabilized sections was placed at 7.5 cm below the HMA surface within the base.
Figure 1. Geogrids used in the SGI test and for stabilization of base course in APTs.

Ultimate Tensile Strength (kN/m)	19.0	24.2	23.3	–
Junction Efficiency (%)	93	–	–	93
Figure 2. Cross-section of the pavement test section.

Accelerated pavement tests (APTs) were conducted on all 5 sections using the model mobile load simulator (MLS11 – Figure 3) by applying repeated, unidirectional, rolling-wheel loads of 2.1 kN at 620 kPa tire pressure. The pavement structure was subjected to 7200 load repetitions per hour. Additional details about the loading equipment and its capabilities can be found in previous studies such as Epps Martin *et al.* (2003).

A laser distance meter (LDM), attached to the carriage on an actuator, was used to profile the

Figure 3.   Model Mobile Load Simulator (MLS11) trafficking the pavement test section.

surface deformations as shown in Figure 4. By controlling the LDM sampling rate and actuator velocity, the vertical distance from the actuator to the pavement surface was captured every 5 mm of horizontal actuator displacement. This allowed for the generation of transverse surface profiles with 360 sample points. The pavement was painted white, at the locations of profiling, in order to improve the reflectivity of the laser. The surface profiles post-trafficking is compared to the initial surface profile to determine rutting at any given number of passes.
Figure 4.   Profilometer mounted on the section (Highlighted in green is the laser distance meter).

3   SOIL-GEOSYNTHETIC INTERACTION TEST

The Soil-Geosynthetic Interaction (SGI) tests is a novel variation of a conventional pull-out resistance test that involves the measurement of internal nodal displacements of the geosynthetic in addition to the external pull-out load and the corresponding frontal displacement of the geosynthetic (Roodi & Zornberg 2017). The SGI tests, performed for this study, involved sandwiching each of the four geogrids (GG1 to GG4) with the clean AASHTO#8 gravel base material, used in the APTs, at 21 kPa confining pressure, and pulling them out as their internal nodal displacements under the applied tensile load were measured. A total of 5 tests were conducted for each geogrid and three nodal displacements were measured per test. Thus, the soil-geosynthetic composite stiffness (K_{SGC}) was calculated as the slope of the square of the unit tension (in (kN)/m) at each node vs. nodal displacement (in mm) of the corresponding node. The K_{SGC} of each geogrid was taken as the

mean of the 15 K_{SGC} values determined as discussed above. In their theoretical formulation of K_{SGC}, Zornberg *et al.* (2017) showed that this slope of the unit tension squared at the node vs. nodal displacement is the same as,

$$K_{SGC} = 4 \cdot J_c \cdot \tau_y \tag{1}$$

where J_C = confined stiffness of the geogrid; and τ_y = yield shear strength.

Therefore, K_{SGC} of the geogrid is a measure that combines the in-isolation stiffness of the geogrid under confined conditions with the interaction of the geogrid with the surrounding soil. A high K_{SGC} indicates that the geosynthetic under consideration is not only stiff but is also capable of significant stress transfer between the soil and the geosynthetic. This implies that K_{SGC} is particularly well suited in determining how well geosynthetics would perform under stabilization of bases where transfer of stresses from the soil to the geosynthetic is expected along with resistance to those transferred stresses (high stiffness).

4 RESULTS

The performance of the various pavement sections is measured in terms of rutting. Rutting is measured from the post-trafficking surface deformation profiles, after correcting for pre-trafficking surface, as the maximum depth from the top of the heave next to the wheel path to the path of the trough under the wheel path as shown in Figure 5. These rut measurements were taken periodically after a pre-determined number of wheel passes. Figure 6 shows the rut measurements taken till failure of all five pavement sections with and without geogrid stabilization.
Figure 5. Typical rutting profile with 360 sample points from the laser profilometer.

4.1 *Traffic benefit ratio*

The improvement in pavement performance due to the stabilization of the base course can be quantified using the traffic benefit ratios (TBRs) obtained by comparing the rutting in the geogrid stabilized sections (GG1 to GG4) to that in the control section. This is possible because the only difference between the four geogrid stabilized sections and the control is the presence of geogrid. Thus, TBRs of each stabilized section is a direct measure of the improvement due to the corresponding geogrid.

For the purposes of this study, TBR due to geogrid stabilization may be defined as the ratio of the number of load repetitions to failure in the stabilized section to that in the control section, given identical pavement structure with the exception of the geogrid. From Figure 6, the number of wheel passes to various levels of rut are determined and their TBR is determined as follows.

$$TBR_{RD} = \frac{N_{GSS}}{N_{Control}} \tag{2}$$
Figure 6.   Progression of rutting with trafficking on all test sections.

where TBR_{RD} = Traffic Benefit Ratio at failure defined as rut = RD; N_{GSS} = Number of
Figure 7.   TBR as a function of rut for geogrid stabilized sections.

wheel passes to failure rut, RD, in geogrid stabilized section; and $N_{Control}$ = Number of wheel passes to failure rut, RD, in control section.

Thus, TBR for the various stabilized sections can be expressed as a function of the rut depth as shown in Figure 7. The TBR starts at 1.0 for very small values of rutting, increases rapidly to a maximum in the 2.5 mm to 5 mm rut range, decreases and asymptotes to a constant around 10 mm to 15 mm rut depth. This is likely due to the high relative density (85%) of the base layer within which the geogrid is placed. As the pavement surface is trafficked, the dense base layer begins dilating in the control section. But in geogrid stabilized sections, the dilatancy is reduced (Chen *et al.* 2018; Sweta & Hussaini 2018), resulting in increased TBR. As the deformations increase, the base material reaches the critical state, thus benefits from geogrid reduces and asymptotes to a constant value of TBR.

4.2   *Soil-geosynthetic composite stiffness and TBR*

Figure 8 compares the traffic benefit ratio obtained at critical state for each geogrid stabilized section with the soil-geosynthetic composite stiffness obtained from SGI tests between
Figure 8.   Traffic Benefit Ratio Vs. K_{SGC}.

the same geogrid and base material. Each circle represents the (TBR, K_{SGC}) pair of the particular geogrid. The dashed line is the linear regression line through the datapoint. It can be seen that the TBR of any stabilized section is linearly correlated with the K_{SGC} of the base course-geogrid composite used in the stabilized section. The high degree of linear correlation ($R^2 = 0.9994$) between TBR and K_{SGC} values shows that K_{SGC} is a direct measure of the improvement to pavement rutting performance due to the inclusion of the geogrid and is thus a strong justification for the use of K_{SGC} as a critical parameter in the selection of geogrids to be used as for base stabilization.

5 CONCLUSIONS

Reduced-scale accelerated pavement tests and soil-geosynthetic interaction tests were conducted with AASHTO#8 base material and four different types of geogrids. The K_{SGC} of the base material-geogrid composite for each geogrid was determined from the SGI tests and found to be over a range from 9 $(kN/m)^2/mm$ to 20 $(kN/m)^2/mm$. The traffic performance enhancement facilitated by the inclusion of the geogrid was evaluated by comparing it to a control section without geogrid stabilization as Traffic Benefit Ratio. It was found that traffic benefit ratio due to stabilization by any geogrid is a function of the failure rut depth. The TBR was found to increase with increasing failure rut depth up to a certain rut value and then decrease to an asymptotic value. This interesting behavior of stabilized sections is attributed to the dilation of the base material and the varying levels of reduction in dilatancy facilitated by the stabilizing geogrid.

It is also found that the asymptotic TBR of the stabilized sections differs by the type of geogrid used and is highly linearly correlated to the base material-geogrid composite stiffness determined from the SGI tests. Thus, K_{SGC} can be used to predict the performance of geogrid stabilized base layers in flexible pavements and therefore be used in the selection of geogrids for the application of stabilization.

ABSTRACT: The objective of this study was to analyse the short-term tensile response of a geocomposite (a geotextile and a geogrid overlapped) and apply hyperbolic models to describe its load-strain tensile curves. Data from specimens submitted to mechanical damage, abrasion, and mechanical damaged followed by abrasion were analysed. Reduction factors were proposed by comparing data from damaged specimens with those from undamaged specimens. The experimental results were compared with those fitted by the constitutive models to validate the model. The constitutive models demonstrated good fitting capacity. For any mechanical condition, the model parameters could be estimated by relating the experimental tensile properties of the geocomposite with adjustment coefficients, which allowed for describing the tensile load-strain curves with good accuracy. The reduction factors for the specimens subjected to mechanical damage followed by abrasion were lower than the values which would be obtained if the damages were considered individually.

1   BACKGROUND

The mechanical response of geosynthetics combines the typical behaviour of an elastic solid, viscous liquid, and plastic, and depends mostly on the temperature (McGown et al. 2004). Determining the behaviour of geosynthetics is a complex task due to several variables involve, such as environmental conditions, type of polymer, soil confinement, and level, rate and duration of loading (Greenwood et al. 2012). The performance of geosynthetics deteriorates with time due to changes in mechanical properties before, during and after installation (Shukla 2016).

Assessment of durability is based on experimental observations and tests performed to simulate damages and degradation expected during the design life of a geosynthetic. Among the durability mechanisms for soil reinforcement, tensile creep, abrasion and damage associated with installation stand out (Greenwood et al. 2012). The effects of mechanical damage on geosynthetics may be assessed by performing field tests or inducing damage in a laboratory. Mechanical damage associated with installation is relevant for all applications of geosynthetics; it has been reported by several authors, e.g Fleury et al. (2019), Domiciano et al. (2020) and Lombardi et al. (2022). Continuous dynamic loading may cause abrasion damage, as in coastal protection and road applications (Greenwood et al. 2012). The effects

of abrasion on the tensile response of geosynthetics were reported by different authors, e.g. Huang et al. (2007) and Pinho-Lopes & Lopes (2015).

Allen & Bathurst (1994) stated that the tensile load-strain curve of a damaged geosynthetic (Y) can be obtained using scaling factors applied to the tensile load-strain curve of the undamaged geosynthetic (X), and then drawing the remaining parts of the damaged curve parallel to the undamaged one, as illustrated in Figure 1a. In this sense, the ultimate tensile strength (T_{max}) is adjusted by R_T (Equation 1), the strain at maximum load (ε_{Tmax}) is scaled by R_ε (Equation 2), whereas the secant stiffness (J) is adjusted by R_J (Equation 3). The reduction factors RF_T, RF_ε, RF_J are defined as the inverse of R_T, R_ε and R_J respectively; RF_T is most commonly applied in the design of geosynthetics for soil reinforcement, as indicated in EN ISO 20432 (ISO 2007).

$$R_T = \frac{T_{\max}(Y)}{T_{\max}(X)} = \frac{1}{RF_T} \tag{1}$$

$$R_\varepsilon = \frac{\varepsilon_{T_{\max}}(Y)}{\varepsilon_{T_{\max}}(X)} = \frac{1}{RF_\varepsilon} \tag{2}$$

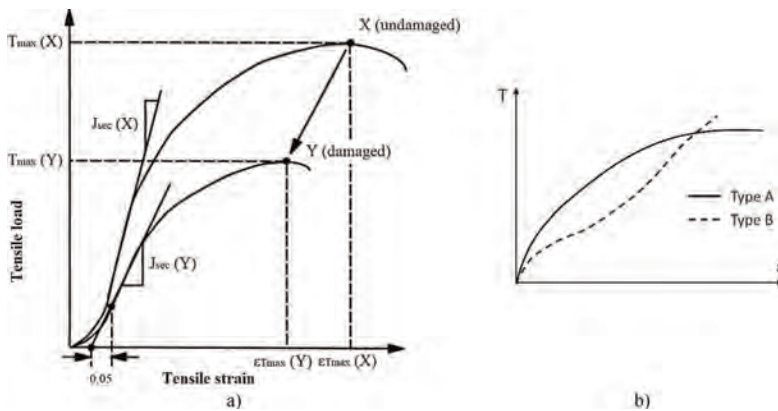
$$R_J = \frac{J_{sec}(Y)}{J_{sec}(X)} = \frac{1}{RF_J} \tag{3}$$


Figure 1.   a) Illustration of changes in load-strain response after damage (Allen & Bathurst 1994) – adapted; b) Typical tensile load-strain curves of geosynthetics (Paula & Pinho-Lopes 2018).

According to Liu & Ling (2006), short-term load-strain curves can be fitted by hyperbolic-based models depending on the tensile response of the geosynthetic: Equation 4 for a response of type A, and Equation 5 for a response of type B, as shown in Figure 1b. For type B geosynthetics, the nonlinear function combines a hyperbola for low strains with an exponential function for high strains. The tangent stiffness J_A and J_B are given by Equations 6 and 7. T_{max} is given by Equation 8 when ε tends to ε_{Tmax}. The initial stiffness (J_i) given by Equation 9 is obtained by imposing boundary conditions on Equations 6 and 7. As reported by Lombardi et al. (2022), the adjustment coefficients C_T and C_J are included in Equations 8 and 9, respectively, in order to relate the experimental properties with the corresponding model parameters.

$$T_A = \frac{\varepsilon}{a + b \cdot \varepsilon} \tag{4}$$

$$T_B = \frac{\varepsilon}{a + 2b\varepsilon} + \frac{1}{2b} \cdot e^{-c[\varepsilon - \varepsilon_{\max}]^2} \tag{5}$$

$$J_A = \frac{dT_A}{d\varepsilon} = \frac{a}{(a + b \cdot \varepsilon)^2} \tag{6}$$

$$J_B = \frac{dT_B}{d\varepsilon} = \frac{a}{(a + 2b\varepsilon)^2} - \frac{c[\varepsilon - \varepsilon_{\max}]}{b} \cdot e^{-c[\varepsilon - \varepsilon_{\max}]^2} \tag{7}$$

$$T_{\max} = C_T \frac{1}{b} \quad \varepsilon \to \varepsilon_{T_{\max}} \tag{8}$$

$$J_i = C_J \frac{1}{a} \quad \varepsilon \to 0 \tag{9}$$

where a, b and c = parameters of the constitutive models.

2 MATERIALS AND METHODS

The geocomposite (GCR) studied was formed by overlapping a PET woven geogrid (GGR) on a PP nonwoven geotextile (GTX), of which the nominal properties are presented in Table 1. The test procedures adopted were the ones reported by Rosete et al. (2013). The tensile strains were measured using a video extensometer, and the full tensile load-strain curves were available. The geocomposite presented two peaks of strength, but only the first was considered.

Table 1. Nominal properties of the geosynthetics used to form the geocomposite.

Property			Geotextile (GTX)	Geogrid (GGR)
Structure			Nonwoven	Woven
Constituent polymer			PP	PET
Ultimate tensile strength[a]	T_{nom}	kN/m	55	55
Strain at maximum load[b]	ε_{nom}	%	105.0	10.5
Mass per unit area[d]	μ_{nom}	g/m^2	1000	–
Thickness[e]	t_{nom}	mm	7.2	1.7
Grid spacing	–	mm^2	–	25 x 25

[a]EN ISO 10319 [b]EN ISO 11058 [c]EN ISO 12956 [d]EN ISO 9864 [e]EN ISO 9863-1

Some specimens of the geocomposite were damaged by synthetic aggregates at 1 Hz for 200 loading cycles ranging from 5 kPa to 500 kPa (EN ISO 10722:2019). Another group of specimens was damaged by abrasion using a P100 abrasive (EN ISO 13427:1998), and another one was submitted to mechanical damage followed by abrasion. For each mechanical condition, five specimens were subjected to wide-width tensile tests (EN ISO 10319:2015), and the results were used to characterize the tensile properties of the material, namely: $J_{0.5\%}$ and $J_{2\%}$ (secant stiffness for 0.5% and 2% strain, respectively), T_{max} and ε_{Tmax}. Due to the difficulty to obtain reliable data at the beginning of the tests, herein experimental J_i was adopted as experimental $J_{0.5\%}$.

Data from damaged specimens were compared with those from undamaged specimens so that reduction factors were proposed. The reduction factor for the mechanical damage followed by abrasion was compared with those obtained by multiplying the individual reduction factors to assess the synergy between them.

Curve fittings were performed in SPSS® based on the tensile response: type A or type B; intact specimens (INT) and specimens after mechanical damage (MEC) presented a response of type B,

whereas specimens after abrasion (ABR) and mechanical damage followed by abrasion (M + A) presented a response of type A. The parameter estimates were given with 95% confidence bounds using nonlinear regressions. The adjustment coefficients were determined by linear regressions between experimental tensile properties and model parameters from curve fittings, as per Equations 8 and 9. Once C_T and C_J were determined, the model parameters were estimated by relating the experimental tensile properties and the adjustment coefficients using Equations 8 and 9.

3 RESULTS – ANALYSIS AND DISCUSSIONS

The mean experimental and fitted tensile properties are summarized in Table 2. The mean estimates of the model parameters a, b and c are given in Table 3. Table 4 gives the reduction factors (Eq. 1–3), as well as the adjustment coefficients C_T and C_J (Eq. 8 and 9). Table 3 gives the model parameters a^* and b^* estimated relating experimental J_i and C_J, and experimental T_{max} and C_T, respectively. Table 4 gives the tensile properties $T_{max}{}^{\#}$ and $J_i{}^{\#}$ estimated using C_T and C_J and the model parameters b and a, respectively. The experimental and fitted tensile load-strain curves are shown in Figure 2, in which the curves were plotted using the parameters a and b, and a^* and b^*.

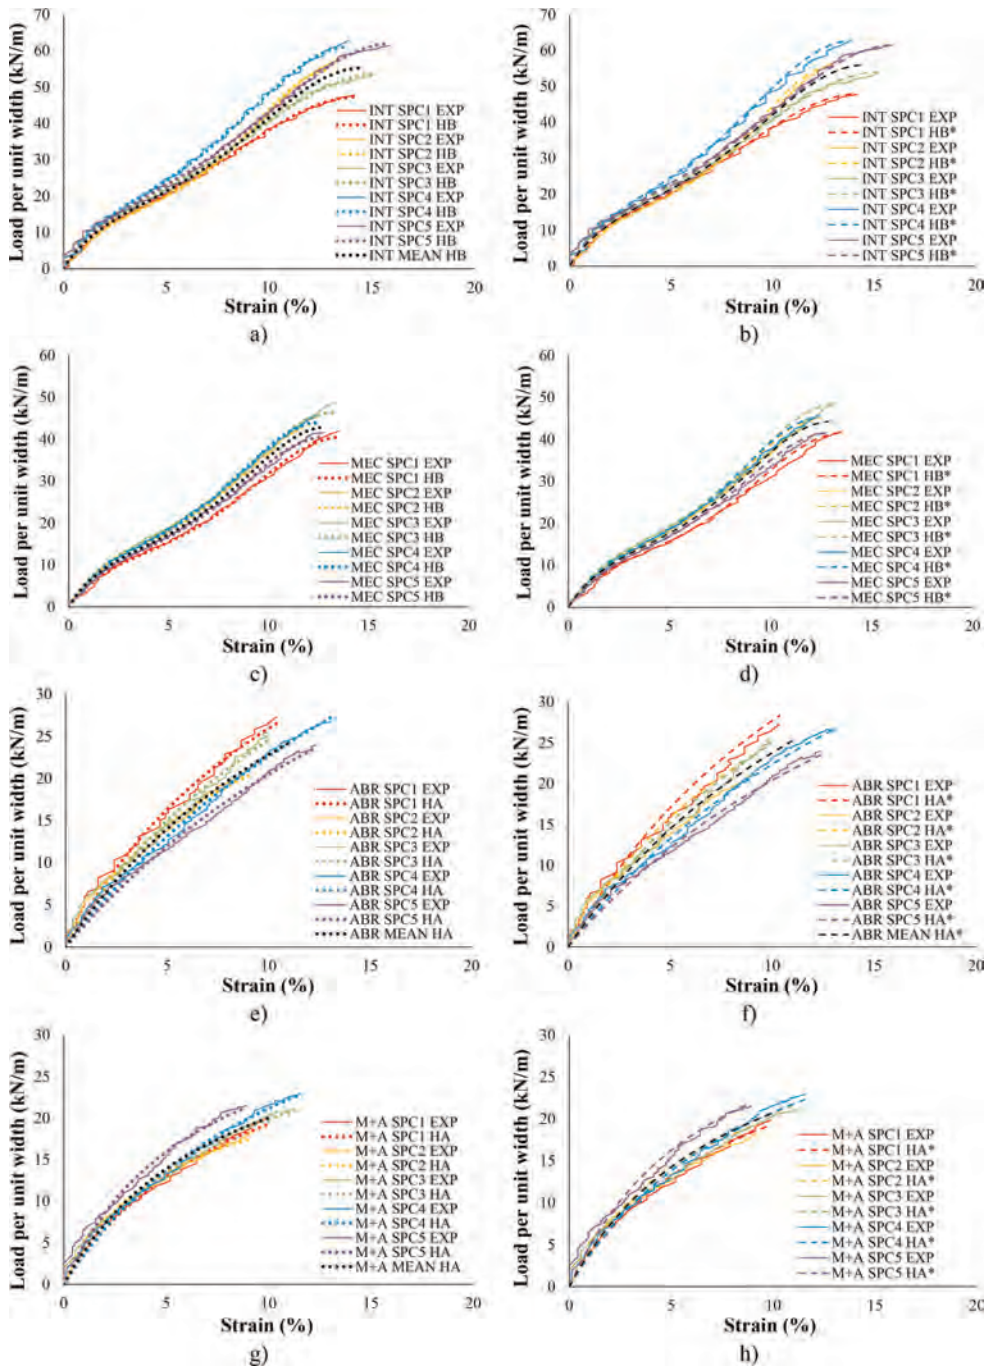

Figure 2. Experimental and fitted tensile load-strain curves of the geocomposite (GCR). a) and b): INT; c) and d): MEC; e) and f): ABR; g) and h): M + A. H_A and H_B: curves obtained using the parameters a and b from curve fitting (Table 3); HA* and HB*: curves obtained using the parameters $a*$ and $b*$. (Table 3).

The constitutive models presented good fitting capacity, whether in terms of qualitatively describing the tensile load-strain curve or providing accurate estimates of the tensile properties. The mean curves given in Figure 2 were able to qualitatively represent the experimental curves as well as to provide accurate estimates for the tensile properties, either using mean model parameters a and b or a^* and b^*. As expected, the parameters a and b produced slightly more precise results if compared to those obtained using the parameters a^* and b^*.

Intact specimens of the geocomposite and those submitted to mechanical damage presented a type B tensile response, whereas the specimens after abrasion and mechanical damage followed by abrasion presented a type A response; thus, the effects of abrasion damage were very pronounced in the material to the extent of changing the shape of the tensile curve.

For intact and damaged specimens, the tensile properties estimated by relating the model parameters and the adjustment coefficients were notably similar to the experimental values. For any mechanical condition, the model parameters estimated by relating the experimental tensile properties of the geocomposite with the adjustment coefficients allowed for describing the tensile load-strain curves of the geocomposite with good accuracy.

The reduction factors for the specimens subjected to mechanical damage followed by abrasion were lower than those which would be obtained if the damages were considered individually, i.e. the synergy between the damage effects proved to be less harmful to the material than superimposing the effects separately, as usually done in the design of geosynthetics.

4 CONCLUSIONS

The objective of this study was to analyse the short-term tensile response of a geocomposite and apply hyperbolic models to describe load-strain tensile curves. Data from specimens submitted to mechanical damage, abrasion damage, and mechanical damage followed by abrasion were analysed. The results of the study are summarized as follows.

- The constitutive models presented good fitting capacity in terms of qualitatively describing the load-strain curve or providing accurate estimates of the tensile properties.
- Using mean model parameters to describe a representative tensile curve has shown to be effective either for the parameters a and b (curve fitting) or a^* and b^* (statistical approach).
- The tensile properties estimated by relating the model parameters and the adjustment coefficients were similar to the experimental values for intact and damaged specimens.
- The effects of abrasion damage in the geocomposite were very pronounced to the extent of changing the shape of the tensile load-strain curves.
- The reduction factors for the specimens subjected to mechanical damage followed by abrasion were lower than those which would be obtained if they were taken individually.
- The model parameters could be estimated by relating the experimental tensile properties of the geocomposite with the adjustment coefficients for intact and damaged specimens.
- Using load-strain curves after damage allows for considering realistic responses of geosynthetics in design, rather than the intact responses and reduction factors as traditionally.

ABSTRACT: The finite element method is a powerful tool that can be used to analyse problems including complex geometries and material properties. In this study, the general-purpose finite element software ABAQUS was used to investigate the load-strain response of a biaxial geogrid under in-isolation tensile loading. A 3D model was developed, accounting for different thickness of geogrid elements and their nonlinear response. Then, TOSCA module was used to investigate an alternative design of a junction profile. The geogrid was submitted to uniaxial and biaxial tensile loading, simulating a wide-width tensile test and a biaxial wide-width tensile test. Validation was performed by comparing the numerical model with experimental data. Optimization results showed that it was possible to reduce the junction volume profile by 53% with a compromise of 3% in maximum bearing capacity.

1 INTRODUCTION

Numerical modeling of the tensile response of geosynthetics can be a challenging task. For geogrids, the complex geometry and the nonlinear response of the polymeric material are the main causes of complexity for numerical implementation. To explore alternative geometry designs, 3D numerical simulations can be used to map the stress distribution within the geogrid elements, aiding to the understanding on how the geogrid works and how it can be improved. In this paper, experimental data was used to calibrate a numerical model of a biaxial geogrid. The objective was to use the validated model to assess a more efficient design for the junction profile of the studied geogrid under tensile loading.

Geogrid reinforcement is an effective method to improve the performance of earth structures by transferring the tensile load from the soil to the reinforcement. Thus, the design of geogrid reinforcements are mainly determined by their tensile resistance. Numerical methods have been developed to model geogrids both in-isolation (Amirhosseini *et al.* 2022) and in soil-geosynthetic applications (Chen *et al.* 2021; Gu *et al.* 2017; Leonardi & Suraci 2022; Perkins 2000; Perkins & Edens 2003; Shen *et al.* 2019; Yang *et al.* 2020). These studies have focused on the general response of the reinforcing elements under various conditions, often recurring to simplified models for the geometry and material properties.

A 3D elasto-plastic finite element (FE) model was studied using the general purpose FE software ABAQUS (2021). The in-isolation tensile response of the geogrid was analysed.

The model was initially calibrated with experimental data on the machine direction (MD), wide-width tensile test (ISO-10319: 2015). Then, a topology optimization study was carried out to produce an alternative profile for the geogrid junction.

2 CALIBRATION OF THE 3D FEM MODEL

2.1 Model development

Geometry and boundary conditions: The geometric details were directly created in ABAQUS considering the 3D solid features of the geogrid. The studied geogrid had a ultimate tensile strength of 40 kN/m for a peak strain of 10% (nominal values for the MD). The cross-section of the longitudinal and transversal ribs were, respectively, 2.5 x 2.2 mm^2 and 2.2 x 1.4 mm^2. The curved junction profile was 5.8 mm thick. The specimen was composed by 5 longitudinal and 5 transversal ribs and had total dimensions of 132 x 132 mm^2 between rib centres (Figure 1). The boundary conditions emulated those of the experimental tensile test. Both ends had translation constraints along the Y direction (perpendicular to the applied force), with one end being fixed along the X direction (parallel to the applied force). The numerical test was carried out by applying a prescribed displacement at the other end of the geogrid model with the same strain rate of 20%/min (0.44 mm/s) used in the experimental test. Only half of the longitudinal bars were modeled utilizing symmetry for enhanced computational performance.
Figure 1. Geometry and boundary conditions of the geogrid. All dimensions are in mm.

Constitutive model: The experimental data available referred to wide-width tensile tests, carried out according to BS EN ISO 10319 (ISO-10319: 2015), which was used to compose a nonlinear elasto-plastic material model. A isotropic material was composed using the experimental data on the MD direction (Figure 2), where T_{max} is the maximum tensile load and e_{max} is the corresponding strain. The experimental load per unit width/strain curve shows a nonlinear behaviour, even for small strains. Default elasto-plastic material with isotropic hardening from ABAQUS was used, with an Young's modulus of 1190 MPa (obtained from the initial tangent response on the MD direction) and a Poisson's ratio taken as 0.3 (Perkins 2000), together with the elastic component deduced from the experimental load-strain response. Stresses and strains were evaluated using a von Mises yield criterion.

2.2 Stresses and strains in the geogrid

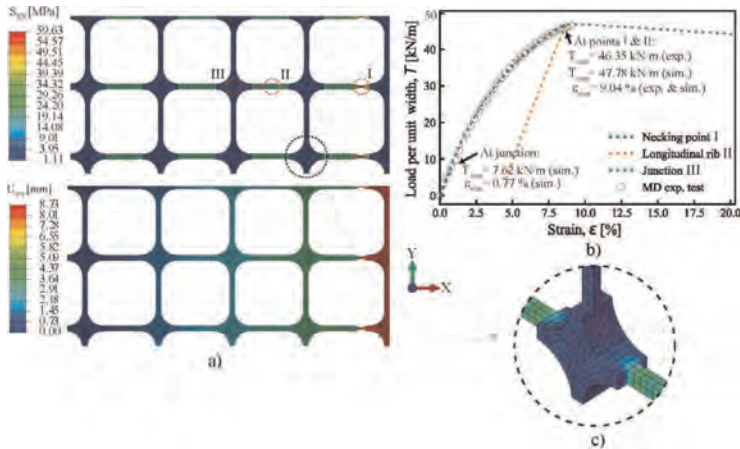
The modeling results for an axial displacement of 8.7 mm are shown in Figure 3a. This displacement is relative to a 20 s test time under a strain rate of 10%/min where the maximum plasticity occurred. Displacements were linearly distributed along the geogrid, with a null deformation at the left end (where it was constrained) and the maximum displacement at
Figure 2.   Experimental uniaxial load per unit width/strain curve for the MD direction (EN ISO 10319:2015).


Figure 3.   Simulation results for the tensile test simulation: a) stresses and strains at maximum plasticity (8.7 mm displacement) in terms of true stress/strain; b) load per unit width/strain curve of experimental (exp.) data and simulation (sim.) at three points (I, II & III), in terms of nominal stress/strain; c) 3D detail on the stress distribution in the junction.

the right end (where the prescribed displacement was applied). The axial stress plot Sxx showed an equally distributed tension under the longitudinal ribs, whereas the junctions and perpendicular ribs showed significantly less stress concentration. The necking effect spotted at point *I* was in line with experimental tests, where failure at the longitudinal ribs near the clamps often occurs. The load-strain overlay between experimental and numerical tests is shown in Figure 3b. The model was able to accurately reproduce the tensile test with a slight overestimation of the maximum load (3% error), whereas the maximum strain was the same in the physical and in the numerical tests. The results were also in good agreement with the nominal properties reported by the manufacturer. Figure 3c shows a corner junction with the respective critical stresses at maximum plasticity. Specially close to the perpendicular rib, the junction profile had little to no stresses or relative strains.

It is important to notice that the differences in magnitude results between the ABAQUS plots (Figure 3a) and the load per unit width/strain curves (Figure 3b) were due to the fact that ABAQUS results are in terms of true stresses/strains, while traditional tensile tests are reported in terms of nominal (engineering) stresses/strains. For geosynthetics the response is quantified ignoring the thickness of the material (as it can vary with confinement).

3 TOPOLOGY OPTIMIZATION OF A GEOGRID JUNCTION UNDER IN-ISOLATION TENSILE LOAD

3.1 Model development

A continuous structure submitted to a topology optimization process can be regarded as a material (volume) distribution problem (Bendsoe & Sigmund 2003; Pang & Fard 2020; Saleem *et al*. 2008). For this particular problem, the optimization target was to find an alternative minimum volume distribution within the boundary constrains for the maximum global stiffness. In ABAQUS, TOSCA module was used to search iteratively for a minimized strain energy (to maximize global stiffness), while taking into the consideration boundary conditions and applied forces for a reduction in volume where stresses are not critical. The goal was to find the optimal volume configuration for the junction profile that saves on material, while still being able to perform the same tensile test.

Model development and boundary conditions: A simplified unit of the geogrid was used to run the TOSCA algorithm for two scenarios: 1) the geogrid was submitted to a axial displacement similar to that of the original tensile test; 2) the geogrid was submitted to a biaxial prescribed displacement, in order to explore the optimization results. Since a prescribed displacement was applied (velocity), the strain energy was set to be maximized, while the volume constraint was set to be less or equal to 50% than that of the initial value. Both of these rules were applied to only the junction section. The two optimization layouts are illustrated in Figure 4, with two symmetry axes (only a quarter of the part was modeled).
Figure 4.   Topology optimization layout: a) uniaxial test; b) biaxial test. Only a quarter of the unit was modeled utilizing symmetry.

3.2 Optimization results

Results of the topology optimization are shown in Figure 5. The curved profile of the junction was nearly removed for both uniaxial and biaxial simulation tests. Results for the unixial test (Figure 5a) showed that a junction with a reduction of 55% of lateral thickness could still sustain the axial loading applied. The stress distribution in a biaxial scenario was more critical, allowing for a lateral thickness reduction of 36% (Figure 5b).
Figure 5.   Topology optimization results: a) optimized section for uniaxial loading; b) optimized section for biaxial loading. Only a quarter of the unit was modeled utilizing symmetry.

3.3 An alternative junction profile

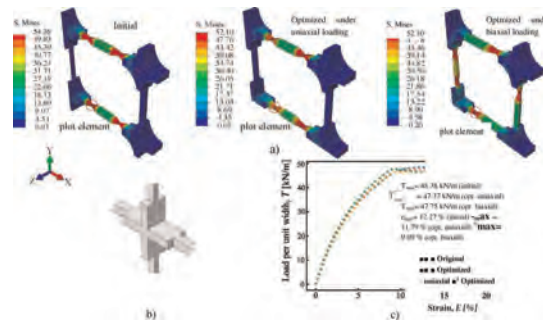
The theoretical results produced by topology optimization algorithms can provide insights on how to improve the geometry of geogrids. From the results described in Section 3.2, a new optimized junction profile was studied, matching the thickness of the ribs without the original curved profile (Figure 6b). Although the results in Section 3.2 allowed for a theoretical lateral thickness of the junction smaller than the ribs (Figure 5), continuity was maintained to avoid excessive distortion of the mesh. The same thickness of 5.8 mm was preserved from the initial profile, generating a volume reduction of 53%. The von Mises stress distribution for both initial and optimized junctions under uniaxial load are shown in Figure 6a. The load per unit width/strain comparison between initial and optimized profiles are shown in Figure 6c. A good agreement between the topology results and the actual stress distributions of the optimized junction was found. The stress distributions showed little variation between the two simulations, whereas the maximum load for the optimized model was 2% smaller than the initial model. This could be due to the lateral thickness reduction, since the initial model has a thicker rib-junction interface.


Figure 6. Comparison between initial and optimized junction profiles: a) von Mises stresses (true stresses) for maximum plasticity; b) 3D view of optimized junction; c) Load per unit width/strain curve for identified plot element (engineering stress/strain).

3.4 Limitations and potential

The optimization described herein considered the in-isolation response under uniaxial and biaxial tensile loadings. On the one hand, depending on the application, the loading can be more complex. On the other hand, in real applications, geogrids are confined in soil. Thus, the response of the composite material will be affected by factors related to the soil. Examples include: the particle size distribution and its relation to the geogrid openings; the relative movement of the geogrid and the soil. The soil-geosynthetic interaction is a function of the geogrid area, hence, changes in geometry will affect the mechanisms of load distribution within the junction and the reinforcement as a whole. The isotropic assumption affects the predicted resistance of the interface between ribs and junctions, that can also influence the optimization in this area.

Future models incorporating these aspects can utilize the non-destructive and easily-parametrized advantages of numerical simulations to propose more realistic optimized geometries for geogrids. As demonstrated, a general-purpose FE tool is an effective method to analyse geosynthetics, being able to generalize 3D stresses and strains from uniaxial tests.

4 CONCLUSIONS

In this study, numerical tensile tests of a geogrid were carried out, followed by a topology optimization to propose an alternative design of a junction element in a biaxial geogrid. First, a numerical model capable of simulating the tensile response of the in-isolation geogrid was

developed using ABAQUS. The model featured a 3D geometry and an isotropic elasto-plastic constitutive model that was calibrated with experimental data from in-isolation tensile tests (MD). The results from the calibrated model allowed a deeper understanding on the stress distribution at the junction elements, where part of the profile was not contributing to the load bearing and local stability.

The TOSCA framework was then applied to optimize the topology of the junction profile, with a design domain set for material removal. The results obtained from the optimization design showed that the lateral thickness of the junction could be reduced in 55% (uniaxial loading) and 36% (biaxial loading), without compromising the initial stiffness and stability. The geometry produced by the optimization algorithm was used to propose an alternative junction profile with 53% less material that was also capable of resisting the same load conditions with a 3% resistance margin. These initial results are promising and can be extended to scenarios where a geogrid and the surrounding soil are modeled.

This study has demonstrated how a calibrated numerical model could be used to extend the physical element analysis through simulation (non-destructive) methods. The contribution of topology optimization in simplifying element shapes was also proved to be a suitable framework in finding new design solutions without compromising structural performance and integrity.

ABSTRACT: Geosynthetics are widely adopted within the asphalt layers to enhance the pavement performance through various functions such as reinforcement, stiffening, and moisture barrier. Specifically, these functions help retard the reflective cracking, formation of rut and permanent deformation, and fatigue cracking in the asphalt layers. However, a major concern of adopting geosynthetic reinforcements is the reduction in interlayer shear resistance between the asphalt layers. In this study, the impact of various geosynthetic-asphalt interface characteristics on the interface shear resistance was evaluated by testing cores obtained from an in-service highway. Specifically, the Leutner shear device was used to test seven interfaces including an unreinforced (control) interface and six asphalt-geosynthetic interfaces that were formed by different types of geosynthetic reinforcements including both polymeric and fiberglass products. Although the Leutner shear test results indicated reduced interface shear resistance in all geosynthetic-reinforced specimens, the percentage reduction was found to be particularly affected by the composition of the reinforcements. Specifically, the reinforcement materials (glass or polymer) and form (grid or textile or composite) were found to significantly affect the asphalt-reinforcement bond strength. Additional factors affecting the geosynthetic-asphalt interface characteristics included tack coat application rates, characteristics of the apertures, and the thickness of the geosynthetic reinforcements.

1 INTRODUCTION

Geosynthetics have been widely used within or as the interface between pavement layers to enhance roadway performance. Reinforcement inclusions in asphalt layers have been reported to mitigate reflective cracking and enhance pavement structural performance (e.g., Brown *et al*. 2001; Ferrotti *et al*. 2012; Kumar & Saride 2018). However, geosynthetic inclusion can compromise the bonding between the asphalt layers through interlayer de-bonding effect. This effect is described as a condition where the adhesion between two adjacent asphalt layers weakens and the two layers may eventually separate under excessive

DOI: 10.1201/9781003386889-289

horizontal stresses (e.g., Brown *et al*. 2001; Kumar & Saride 2018). Debonding may undermine the design benefits from geosynthetic interlayers and dissuade owners on using them. With the development of a wide range of geosynthetic interlayers with various designs and textures, understanding the asphalt-geosynthetic bonding strength and extents of potential debonding has become crucial.

A wide variety of experiments have been developed to characterize various aspects of bonding strength between two asphaltic layers. The most common experimental method for evaluating interlayer bonding strength involves direct shearing of the interface and various experimental setups have been adopted to generate such shear loading on the interface. A few examples include the Leutner shear test (Leutner 1979), the Layer-Parallel Direct Shear (LPDS) test, the Florida Department of Transportation (FDOT) shearing device (Sholar *et al*. 2002), Ancona Shear Testing Research and Analysis (ASTRA) (Canestrari *et al*. 2005), and large-scale interface shear strength test device (Kumar *et al*. 2017). The variations among the shear mechanisms involved in the tests has made comparison of test results particularly difficult. However, several experimental studies could identify the most important parameters that impact the bond strength as temperature, aggregate gradation, and surface roughness, normal pressure, tack coat type, and tack coat application rate among others (e.g., Canestrari *et al*. 2005; Correia *et al*. 2022; Kumar *et al*. 2017; Kumar & Saride 2018; Roodi *et al*. 2017; Sholar *et al*. 2002; West *et al*. 2005).

While most experimental studies on asphalt-geosynthetic bonding strength involved remolded samples, comparatively limited research has been conducted on asphalt cores obtained from roadways that have been constructed with geosynthetic reinforcements. Testing of such field samples that had subjected to construction impact provides more realistic insights into asphalt-geosynthetic bonding strength. This paper presents results of asphalt-geosynthetic bond testing program that aimed at understanding the various parameters affecting the bond strength, including impacts from construction damages. Asphalt cores were collected from an unreinforced and six geosynthetic-reinforced roadway sections and their interface bond strength was tested using the Leutner shear tester. Geosynthetic reinforcement included different polymeric and fiberglass products with different forms of grids, textiles, and composites. Factors affecting the geosynthetic-asphalt interface bonds were evaluated.

2 PROJECT BACKGROUND

As part of Texas Department of Transportation (TxDOT) rehabilitation program, a 32-km-long stretch of State Highway (SH) 21 was restored by treatment of distresses in the pre-existing asphalt surface followed by construction of a 75-mm-thick structural overlay. The original overlay design included geosynthetic interlayer to be placed between the existing asphalt and the new overlay. To establish basis for future expansion in the use of geosynthetic interlayers, TxDOT retained the research team to investigate the effectiveness of various geosynthetic interlayers in enhancing roadway performance. A 1.34-km-long section of the four-lane highway was split into 34 test sections that were constructed with different designs in plan and profiles. Geosynthetic-reinforced sections were constructed side-by-side and along with unreinforced sections to compare their performances under similar conditions.

Seven of the test sections, including an unreinforced section and six geosynthetic-reinforced sections, were selected for more robust investigation that involved installing various types of sensors and conducting controlled traffic loading on sensors (Kumar *et al*. 2022). To complement the investigation and provide insight into the bonding strength between asphalt and various geosynthetic types, several cores were collected from each test section two months after construction. Figure 1 shows design profile of the rehabilitated test section along with an example picture of cores depicting various asphalt layers. As shown in the figure, the asphalt layers included approximately 150 mm of preexisting asphalt and level-up layers, with geosynthetic interlayer installed on applied tack coat at the interface,

and overlain by 75 mm asphalt overlays placed in two layers including a 50-mm-thick dense-graded asphalt mixture (Type D) and a 25-mm-thick wearing-course asphalt mixture (TOM). The asphalt mixtures (Type D and TOM) were adopted from TxDOT standard specifications for construction and maintenance of highways, streets, and bridges (TxDOT 2014).

3 MATERIALS AND METHODS

3.1 Geosynthetic reinforcements

Six different types of geosynthetic reinforcements including three each of polymeric and fiberglass products were adopted as asphalt reinforcements in this study. Specifically, the geosynthetic reinforcements were adopted based on their material composition, tensile, and physical characteristics. Figure 2 presents the three polymeric products evaluated in this study, which includes two polyester geogrid composites and a polyvinyl alcohol geogrid composite. The product GR-1 (Figure 2a) is a geocomposite made up of high modulus polyester geogrid and a woven fabric, while GR-2 (Figure 2b) is a geocomposite made up of high modulus polyester geogrid and an ultra-lightweight non-woven fabric. The third product, GR-3 (Figure 2c) is a geocomposite made up of a high modulus polyvinyl alcohol geogrid and an ultra-lightweight non-woven fabric. All the three products are completely coated with a binder to enhance the bonding characteristics. The three fiberglass products evaluated in this study are as shown in Figure 3, which includes two fiberglass geogrid composites and a fiberglass geogrid. The product GR-4 (Figure 3a) is a geocomposite made up of high strength fiberglass filaments and an ultra-lightweight non-woven fabric that is completely coated with binder, while GR-5 (Figure 3b) is a geocomposite comprising fiberglass filament yarns incorporated into a thick nonwoven polypropylene paving fabric. The final product, GR-6 (Figure 3c) is a self-adhesive geogrid made up of high strength fiberglass filaments that are completely coated with elastomers. The physical and tensile properties of the geosynthetic reinforcements evaluated in this study is summarized in Table 1.
Figure 2. Polymeric Geosynthetic Reinforcements evaluated in the study: a) GR-1; b) GR-2; and (c) GR-3.
Figure 3. Fiberglass Geosynthetic Reinforcements evaluated in the study: a) GR-4; b) GR-5; and (c) GR-6.

Table 1. Properties of geosynthetic reinforcements and tack application rates.

Geosynthetic Reinforcements	Mass/ unit area (g/m^2)	Aperture size (mm)	Ultimate tensile strength (kN/m)	Strain at elongation (%)	Asphalt retention capacity (l/m^2)	Melting point (°)	Tack application rate (l/m^2)
GR-1	275	34 × 34	50	12	0.47	250	0.54
GR-2	270	40 × 40	50	10	0.47	250	0.54
GR-3	210	40 × 40	50	5	0.47	235	0.54
GR-4	596	30 × 30	100	3	0.47	300	0.54
GR-5	678	38 × 38	115	3	1.2	800	1.35
GR-6	432	25 × 25	100	3	–	232	–

3.2 Asphalt and tack

Two different types of asphalt mixtures were used as asphalt overlays that included a dense-graded asphalt mixture (Type D) overlain by a thin asphalt overlay mixture (TOM). However, it is important to note that the geosynthetic reinforcements were installed below the Type D layer in the reinforced sections using a polymer modified asphalt cement (AC-15P) applied at different rates, per geosynthetic manufacturer recommendations and prior trials. While, a cationic, slow-setting, low-viscosity, and comparatively hard residue emulsion (CSS-1H) was applied at a residual rate of 0.27 l/m^2 on the level-up course prior to the placement and compaction of Type D layer in the unreinforced (UR) section. Table 1 provides the tack application rates for different geosynthetic-reinforced sections evaluated in this study and as shown, the tack application rates of all the geosynthetic reinforcements except GR-5 and GR-6 was 0.54 l/m^2, since GR-5 had the maximum rate of 1.35 l/m^2, while GR-6 did not require tack during the installation.

3.3 Core extraction and specimen preparation

Several cores were collected from the 7 test (6 geosynthetic-reinforced and 1 unreinforced) sections considered for evaluation in this study. Specifically, about 2 months after the completion of the overlay construction, cores were extracted from the test sections using a trailer-mounted core drill with inside diameter of 150 mm. The core heights were extended from the pavement surface to the bottom of the old asphalt as shown in Figure 1b. The top and the bottom of the specimens were trimmed to obtain a height that was consistent with the dimensions of the Leutner shear tester device and the interface plane will be aligned with the applied shear plane imposed by the device. Careful attention was paid to ensure that the

interface where the reinforcement layer is located has remained intact during drilling, transportation, and trimming of the specimens.

3.4 *Leutner shear test*

Leutner shear test is one of the most common interlayer shear tests that applies a constant rate of shearing displacement between the two asphalt interfaces to determine the bond strength between them. The cores extracted from the unreinforced and geosynthetic-reinforced test sections were tested using the Leutner shear tester to determine their interface shear strength characteristics. Specifically, the Leutner shear tester was used in an Instron 8872 loading machine and a monotonic load was applied at a displacement of 50 mm/min until failure or displacement of 12.5 mm, at a temperature of 22°. Additionally, a width of 2.5 mm was maintained between the two shearing rings of the Leutner shear tester matching the interface zone of the core specimens being tested. Similar conditions were maintained and recommended by Correia *et al.* (2022).

4 RESULTS AND DISCUSSION

The results from Leutner shear tests are obtained in the form of shear load vs relative shear displacements. The interface shear strength is then determined by the ratio of shear load and the cross-sectional area of the specimen tested and the variation of interface shear strength with displacements are plotted. Figures 4a and b show the variations of interface shear strengths with displacements respectively, for unreinforced and geosynthetic-reinforced (GR-3) specimens tested in this study. As shown in the figures, the interface shear strengths increased with increasing displacements and reached a peak value and reduced thereafter with further increase in the displacement values for both the specimens (UR and GR-3). However, the geosynthetic-reinforced specimen witnessed a lower peak interface shear strength value compared to that of the unreinforced specimen, suggesting a reduction in the interface shear strength with the inclusion of geosynthetic reinforcements. In addition, the displacement corresponding to the peak interface shear strength increased in the geosynthetic-reinforced specimen compared to that of the unreinforced specimen tested in this study. The peak interface shear strength values for different interface (6 reinforced and unreinforced) conditions were determined from multiple cores tested in this study and reported in Figure 5. As shown in the figure, the peak interface shear strengths for all the specimens tested in this study ranged between 0.44 MPa and 0.87 MPa, which is similar to that recommended in the literature for mostly unreinforced asphalt layers.
Figure 4. Typical interface shear strength trends: (a) Unreinforced specimen and (b) Geosynthetic-reinforced (GR-3) specimen.
Figure 5. Peak Interface shear strength for different interfaces tested.

On the other hand, FGSV 770 (2013) suggested that the minimum bond strength required between two asphalt layers is about 10 kN (0.56 MPa for a specimen with 150 mm diameter). While, it is important to note that the unreinforced specimen had a highest interface shear strength value of 0.87 MPa compared to that of the geosynthetic-reinforced specimens tested in this study. In other words, the interface shear strength of all the geosynthetic-reinforced specimens were lower than the unreinforced specimen confirming the reduction in bond strength with the inclusion of geosynthetic reinforcements between the asphalt layers. Among the geosynthetic-reinforced specimens, GS-3 had the maximum interface shear strength of 0.82 MPa, followed by GR-2 (0.81 MPa), GR-4 (0.69 MPa), GR-1 (0.50 MPa), GR-6 (0.48 MPa), and finally GR-5 (0.44 MPa). However, it is important to note that the tack application rates for GR-5 and GR-6 were different from the rest of the geosynthetic products evaluated in this study.

The reductions in interface shear strengths were on the order of 42.61% (GR-1), 6.13% (GR-2), and 5.63% (GR-3) for the polymeric products, and 20.57% (GR-4), 49.42% (GR-5), and 44.12% (GR-6) for the fiberglass products respectively. It is evident that polymeric products performed better than the fiberglass products, in terms of bond strength, especially GR-2 and GR-3 specimens. The high bond strengths witnessed in GR-2 and GR-3 specimens may be due to their aperture sizes and the ultrathin nonwoven backing that can promote through hole bonding to enhance the interface bond strength. In addition, the products GR-2 and GR-3 were completely coated with a binder to enhance their interface bonding characteristics. While the other polymeric product, GR-1 had a fabric woven into the polymeric grids that did not promote through hole bonding and hence, reduced bond strength. On the other hand, among the fiberglass products, GR-4 performed better than GR-6 that performed better than GR-5. The variations in the performances may be due to the thickness of geotextile backing (especially in GR-5) and the presence/absence of tack (especially in GR-6). In addition, the apertures of GR-6 were smaller in comparison to GR-4, while the apertures of GR-5 were not significant because of the thick geotextile backing. Overall, it can be summarized that the interface bond strength is crucial for the performance of geosynthetic-reinforced asphalt layers and depends on multiple factors including the tack type and application rates, nominal aggregate size of the asphalt mix, and geosynthetic properties including the aperture size, presence/absence of geotextile backing, and the thickness of geotextile backing among others.

5   CONCLUSIONS

In this study, the impact of various geosynthetic-asphalt interface characteristics on the interface shear resistance was evaluated by testing cores obtained from an in-service

highway. Specifically, the Leutner shear device was used to test seven interfaces including an unreinforced interface and six asphalt-geosynthetic interfaces that were formed by different types of geosynthetic reinforcements including both polymeric and fiberglass products. The following conclusions can be drawn from the study.

The geosynthetic reinforcements reduced the interface shear strength between the asphalt layers and the reductions were on the order of 42.61% (GR-1), 6.13% (GR-2), and 5.63% (GR-3) for the polymeric products, and 20.57% (GR-4), 49.42% (GR-5), and 44.12% (GR-6) for the fiberglass products evaluated in this study, respectively.

The reduction was found to be particularly affected by the composition of the reinforcements. Specifically, the reinforcement materials (glass or polymer) and form (grid or textile or composite) were found to significantly affect the asphalt-reinforcement bond strength. Additional factors affecting the geosynthetic-asphalt interface characteristics included tack application rates, aperture size, and the thickness of geosynthetic reinforcements.

Interface shear bond analysis of different geosynthetic paving interlayers

M.P.S. Silva, K.M. Santos & N.S. Correia
Federal University of Sao Carlos, Sao Carlos, Sao Paulo, Brazil

ABSTRACT: Different variables shows to affect shear bond performance of geosynthetic paving interlayers. The correct evaluation of the interface shear bond is fundamental to estimate design parameters and the service life of the pavement. The present study evaluated five types of geosynthetics, including four different geogrids and a paving fabric, using Leutner shear tests. In addition, the influence of geosynthetics characteristics on interface shear bond parameters was analyzed. Double-layered asphalt specimens were prepared in the laboratory considering the same binder impregnation rate of 600 g/m^2. Geogrids showed overall superior interface shear strength behavior compared to geocomposite, although inferior to control samples. Furthermore, the geogrid aperture size played an important role in shear bond results, corroborated by the through hole bonding mechanism. The presence of bituminous coating contributed to interface shear bond results. Interface shear stiffness and accumulated energy analyzes showed that large geogrids aperture sizes presented similar behavior to control samples.

Keywords: Geosynthetics, Pavement interlayer, Asphalt layer, Interface shear strength, physical characteristics

1 INTRODUCTION

Advanced rehabilitation techniques and sustainable pavement solutions have been used to control reflective cracking (Nithin Sudarsanan et al. 2020). Geosynthetics have been effective in minimizing the damaging effects caused by reflective cracking propagation in asphalt pavements (Safavizadeh et al. 2022; Wargo et al. 2017), providing waterproof barrier (Solatiyan et al. 2020) and controlling pavement deformations (Correia & Zornberg 2018; Kumar et al. 2021; Lee et al. 2019). In extension, geosynthetics used in pavement rehabilitation depicts an economic and sustainable choice considering it allows the replacement of lower thickness of asphalt layers, therefore reducing the asphalt concrete amount that must be discarded and produced, in consequence, reduces emission as well as the intervention time, making opening to traffic faster (Spadoni et al. 2021). However, different variables have shown to affect shear bond performance of paving interlayers, such as geosynthetic type and characteristics, binder type and rate, type of asphalt mixture, surface texture, temperature, among others (Correia & Mugayar 2021; Correia et al. 2022; Kumar & Saride 2017; Noory et al. 2019; Walubita et al. 2018).

According to Canestrari et al. (2022), the correct evaluation of the interface shear bond is fundamental to estimate the service life of the pavement. For this reason, it is very important to understand which are the variables that affect interface shear bond behavior to obtain the optimal binder impregnation of each geosynthetic interlayer condition. The present study evaluated five types of geosynthetics, including four different geogrids and a paving fabric, using Leutner shear tests. In addition, the influence of different physical characteristics of geosynthetics on interface shear bond parameters was analyzed.

2 MATERIALS AND METHODS

2.1 Geosynthetics

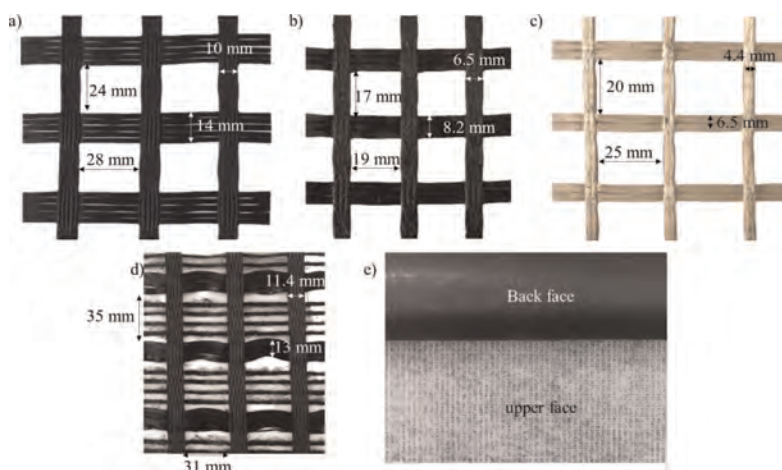
Figure 1 shows the different types of geosynthetics used in the current research to analyze the influence of geosynthetics physical properties on the shear bond behavior of pavement interlayers. The geosynthetics were selected based on coating characteristics, presence of aperture size, aperture size dimension, rib width and tensile properties.


Figure 1. Geosynthetic reinforcements used in the study: (a) GG1; (b) GG2; (c) GG); (d) GG4; and (e) GC.

GG1 is a fiberglass geogrid coated with modified bitumen, knitted to form a bi-axial grid having aperture size of 28 mm x 24 mm. GG1 has longitudinal (L) rib width of 10 mm and transversal (T) rib width of 14 mm, while the ultimate tensile strength is 120 kN/m in both machine (MD) and cross-machine direction (CMD), at an elongation break of 3%. GG2 is a fiberglass geogrid coated with bitumen with aperture size of 17 mm x 19 mm. GG2 presents rib width of 6,5 mm (L) and 8,2 mm (T), with ultimate tensile strength of 120 kN/m in both MD and CMD, at an elongation break of 3%. GG3 is a fiberglass geogrid that has a polymeric coating and an adhesive on the back face, as well as an ultimate tensile strength of 75 in MD and 95 kN/m in CMD, at an elongation strain of 3%. GG3 presents an intermediate aperture size of 20 mm x 25 mm and rib width of 4,4 mm (L) and 6,5 mm (T). GG4 is a fiberglass geogrid coated with bitumen. GG4 presents a mesh size of 31 mm x 35 mm and rib width of 11,4 mm (L) and 13 mm (T), with ultimate tensile strength of both 130 kN/m in MD and CMD, at an elongation break of 3%. and contains small strips of nonwoven geotextile crossing the opening of the mesh in the CMD. GC is a waterproofing paving mat manufactured by embedding micro fiberglass meshes into high polyester (PET) mat, coated with an elastomeric product. GC had an ultimate tensile strength of 25 kN/m (MD) and 30 kN/m (CMD) at an elongation strain of 7%.

2.2 Hot mix asphalt and tack coat

The hot mix asphalt (HMA) used in the current research consist of a nominal aggregate size of 19 mm and had binder with a penetration of 31 dmm (ASTM D5 2020), an optimum bitumen content of 4.3% by weight of aggregates, indirect tensile strength of 1.9 MPa (ASTM D6931 2017) and a flow value of 1.8 mm (ASTM D6927). The tack coat employed at the interface is a straight asphalt having a penetration value of 51 dmm (ASTM D5 2020) and softening point of 52°C.

2.3 Double-layered specimens' preparation

The specimens for interface shear test were prepared using adapted Marshall compacted method. Specimens with diameter of 150 mm were prepared, as indicated in the literature for geosynthetic-reinforced asphalt systems (FGSV 770 2013). To determine the corresponding number of blows for 150 mm samples, a height of 40 mm compaction was established, totalizing 213 blows. The second adaptation concerns the method of compression for double-layered specimens. Blows in only one face were applied in each HMA layer. This adaptation was based on literature research with double layered specimens with 100 mm in diameter (D'Andrea et al. 2013; Tozzo et al. 2014, 2015).

After the production of the inferior HMA layers, the specimens were extracted from the molds and the asphalt binder was applied at the interface at 135 °C. The application rate of 600 g/m^2 was used for all paving interlayers evaluated herein. A metal spatula and heat gun were employed to spread the binder on the interface before the geosynthetics installation. Then, the inferior layers were inserted in the mold and the upper HMA layers were compact. This procedure was based on Safavizadeh et al. (2022) method. Figure 2 shows double layered specimens' preparation.
Figure 2. Specimen preparation: (a) applying asphalt binder tack coat; (b) lower layer surface after tack coat application; (c) geosynthetic installed; (d) double layered specimen.

2.4 Leutner shear test

The interface bonding properties of the asphalt overlay can be evaluated as per prEN 12697-48. To measure interface bond strength characteristics, Leutner shear tests were carried out under displacement rate of 50.8 mm/min using a servo-controlled testing machine and at a temperature of 20°C. The load was applied until complete failure. Figure 3 shows typical results of an interface shear bond test, such as maximum interface shear strength, interface shear stiffness and accumulated energy after failure. When using a geosynthetic interlayer, the German Working FGVS 770 establishes a minimum shear bond force of 10 kN for 150 mm diameter specimens extracted from the field, which corresponds to a minimum interface shear strength of 0.56 MPa.
Figure 3. Leutner shear test: (a) testing device; (b) typical result of an interface shear bond test.

3 TEST RESULTS AND DISCUSSIONS

Figure 4 shows the results obtained in interface shear tests. Figure 4(a) presents typical interface shear stress (ISS) curves for control and geosynthetic interlayers. As shown in the figure, the ISS behavior depends on the presence or absence of geosynthetic, as well as geosynthetics characteristics. Control samples presented higher values of peak ISS when compared to geosynthetic interlayers.
Figure 4. Results of interface shear tests: (a) typical ISS curves; (b) comparison of average ISS for different geosynthetics and control samples.

Figure 4(b) shows a comparison of average values of ISS obtained for the different paving interlayers tests. ISS values ranged between 0.90 and 1.93 MPa. Overall, specimens reached minimum required ISS of 0.56 MPa as indicated in (FGSV 770 2013). However, Canestrari et al. (2022) recommend an increase in the minimum accepted value of ISS by 50% when using laboratory-produced specimens. In this case, the minimum ISS corresponds to 0.84 MPa. As observed in Figure 4(b), all paving interlayers achieved the minimum limit. It can be observed that among different geosynthetics interlayer, the highest ISS value was obtained in the case of GG1, followed by GG2, GG3, GC and finally GG4. The difference in ISS values can be attributed to the different characteristics of geosynthetics and their compatibility to bond the adjacent HMA layers. The presence of geogrid apertures in the cases of GG1, GG2, and GG3 has showed to enhance ISS with the help of through hole bond (THB) mechanism described by Sudarsanan et al. (2018a). The THB mechanism was not observed in the geocomposite sample (GC) due to the absence of apertures. In this case, the bonding strength of GC is attributed to the adhesion mechanism. The inferior result of ISS showed by GG4 could be explained by the presence of small strips of geotextile crossing the opening of geogrid mesh, which may have partially activated both THB and adhesion mechanism. Similar observations of THB and adhesion mechanisms were observed by Kumar and Saride (2017), Sudarsanan et al. (2018a), Sudarsanan et al. (2018b), and Correia et al. (2022). Another important aspect that may have corroborated the superior performance of GG1 and GG2 is the presence of a bituminous coating present in both materials.

Figure 5 presents additional interface shear analysis. Figure 5(a) depicts the interface shear stiffness (k) trends for different paving interlayer conditions. This parameter is a useful variable to understand the behavior of interface adhesion until failure condition and to evaluate the effects of different levels of adhesion on the stress-strain distribution of the pavement (Yang et al. 2021). According to Canestrari et al. (2013), the k value assures an ideal bonding between asphalt layers and varies between 10^{-2} MPa/mm (fully sliding) and 10^2 MPa/mm (fully bonding). Therefore, all the specimens evaluated in this study are within an adequate interface shear bonding condition. As shown in Figure 5a, GG1, GG2, and GG3 presented similar behavior to control samples. Overall, superior interface shear stiffness was observed for GG1, which may be attributed to both higher aperture size and presence of bituminous coating.

Figure 5(b) presents the accumulated energy after failure for control and geosynthetic interlayer conditions. This result indicates post-failure interface shear behavior. It can be observed
Figure 5.   Additional interface shear analysis: (a) interface shear stiffness (k); (b) accumulated energy after failure.

that GG1 and GG2 presented very similar behavior to control sample, demonstrating that the presence of a geosynthetic interlayer did not influence residual shear bond behavior. These results present the same order of magnitude as the results observed by Lee et al. (2019).

4   CONCLUSIONS

In this study, the interface shear properties of control and geosynthetic interlayers were analyzed by performing Leutner shear tests and the following conclusions can be summarized below:

- Unreinforced (control) specimens presented higher values of peak interface shear stress when compared to geosynthetic interlayers.
- The presence of geogrid apertures in the cases of GG1, GG2, and GG3 has shown to enhance interface shear stress due to the through hole bond (THB) mechanism when compared to geocomposite (GC) and geogrid with less aperture size (GG4). The strips present in GG4 had a negative influence on the behavior of interface shear bond.
- The presence of bitumen coat on some geosynthetics may have influenced the results, since geogrids GG1 and GG2 presented higher interface shear stress values than GG3, even with similar opening mesh sizes.
- Interface shear stiffness (k) values were found in the order of 10^{-1} MPa for all evaluated interfaces, highlighting GG1 which presented a k higher value when compared to control sample.
- Analyzes of accumulated energy have shown that geogrids GG1 and GG2 presented very similar behavior to control samples, demonstrating that the presence of a geosynthetic interlayer did not influence residual shear bond behavior.

Evaluation of connection loads between a geogrid and concrete blocks based on laboratory tests

P.V.C. Figueredo, F.H.M. Portelinha & J.G. Zornberg
Federal University of São Carlos, at São Carlos, Brazil

ABSTRACT: Internal stability analysis of segmental geosynthetic reinforced soil walls includes the verification of connection strength at the geosynthetic-block interface. The calculation of the connection load (T_o) has been a hard task as mechanisms are still not completely understood. This paper presents an evaluation of geogrid-modular blocks connection forces based on a laboratory test device developed to simulate load transfer mechanism at the face of geosynthetic reinforced soil walls. A reinforced system with a sand backfill, a woven geogrid and concrete blocks were subjected to incremental vertical loads while lateral earth pressures, horizontal displacements at the face, as well as reinforcement strains and load at the geogrid-block interface were monitored. and the strains of the reinforced layer were monitored. Results show differential settlements of the backfill and the facing wall leading to a down-drag effect on the reinforcement. This effect associated to face wall displacements led to a significant impact on connection loads at geosynthetic-blocks connection.

1 INTRODUCTION

The use of geosynthetic reinforced soil structures has gained increasing popularity, being used in containment systems, slope stability, load-bearing walls, or for bridge abutments. This type of structure stands out for the flexibility of project design, being adaptable to various environments, having a fast execution process, without the use of skilled labor, due to its low complexity, besides having a good cost benefit (Ngo 2016) The good performance of this type of structure depends on many variables, of which the backfill soil, type of face and the reinforcements have been reported to have significant influence (Brugge *et al.* 2012; Liu *et al.* 2009, 2011; Portelinha *et al.* 2014; Saghebfar *et al.* 2017).

In this type of structure, the geosynthetics are connected to the face in some way. In case of segmental reinforced soil walls this connection occur often by friction and extend to the anchorage zone. When reinforcements are loaded, stresses are developed at the geogrid-block connection (Soong & Koerner 1997). The structure must be able to generate sufficient interlock between the face and the reinforcement to resist the horizontal forces in the soil mass in the connection zone (Collin 1997). Morsy (2021) reports the importance of the type of face and how it affects the distribution and magnitude of stresses at the face, where connection loads tend to be greater in rigid than flexible faces.

Currently, design recommendations, such as BS-8006 (2010) and FHWA-NHI-10-024 (2009), treat connection stresses in a simplified manner, suggesting percentages of 50% to 100% of the maximum mobilized tension in the reinforcements (Tmax), depending on the structure configuration. The present study is part of a large experimental program that investigates the mechanisms involved in the connection loads at the interface between geosynthetic reinforcements and face elements. Specifically, this paper presents results of a

laboratory test conducted to investigate connection loads developed in a sand reinforced with geogrid in modular block reinforced system.

2 MATERIALS AND METHODS

2.1 Materials

In this study the soil used was a well-graded medium sand with friction angle of 33.2°, dry density of 17.2 kN/m^3 and maximum and minimum voids index of 1.10 and 0.6, respectively. Figure 1 shows the grain size distribution of the sand. The geosynthetic reinforcement was a polyvinyl alcohol polymeric (PVA) geogrid with properties indicated in Table 1. As facing revetments, commercial concrete masonry units (CMU) were used, with a compressive strength of 3.0 MPa, with dimensions of 390 X 150 X 190 mm (width X length X height).

with internal dimensions of 600 X 760 X 800 mm (width X length X height) where one of the lateral walls of the box is made of transparent glass and the others are stationary, all walls were lubricated to minimize frictions between then.

The MSE wall were constructed above two plates, one fixed and one that was able to move horizontally with bearings that run internally along rails. The mass of soil was compacted in layers to 98% of density, the reinforcement was placed between the soil mass and had been connected to wall only by attractive forces. The blocks were able to move free and independently.

The working system of the equipment is to apply vertical pressure in the top of the reinforced soil unit, thereby inducing a horizontal stress on the front moving wall. For that, were used an airbag system up to 180 kPa.

The instrumentation includes measurements of tensile loads, geosynthetic internal displacements and horizontal and vertical soil pressure. A load cell was attached to the reinforcement at that back wall of the model to measure the mobilized load on it. For the internal displacements were used seven potentiometer-type 'tell tales', with 100 mm spacing, to be possible capture the displacement inside of the wall, which were used to calculate internal strains. Figure 1a show an illustration of the equipment and the instrumentation used during tests and 1b shows the physical model before the start of the test. PIV (Particle Image Velocimetry) technique was used to capture the displacement field from the lateral transparent wall. Figure 2 shows the lighting system used during tests.

Figure 2. Lightning and recording system.

3 RESULTS

Figure 3 shows the tensile load mobilized by the geogrid at 20, 60, 100, 140 and 180 kPa of vertical loadings. Tensile loads along the on the reinforcement were calculated based on reinforcement strains obtained from the tell-tales technique and the corresponding value of tensile load using wide-width tensile test results. It should be observed that tell-tales measurements generate total strains. The peak tensile load was registered to occur close to the connection between the geogrid and the modular block at the face with a value of 9.16 kN/m under 180 kPa of loading. It was observed because tell-tale points were located inside the modular blocks which is not usual. Otherwise, peak loads would be around 400 mm from the facing, which corresponded to the location of the potential failure surface. This result agreed with the images taken during the procedure and the results using the PIV methodology as indicated in Figure 4.
Figure 3.   Tensile load mobilized by geosynthetic versus distance from the face.
Figure 4.   Displacements field from the PIV-Lab at the end of loading of: (a) 20 kPa; (b) 60 kPa; (c) 100 kPa; (d) 140 kPa; and (e) 180 kPa.

Figure 4 shows the displacement field at the end of each loading stage. It can be observed the formation of displacement zones that intensified near the wall facing, which is intensified with loading increasing. A very relevant fact was the creation of a small area of displacement concentration under the connection of the geosynthetic to the wall. This zone is a void created by the down-drag effect on the geosynthetic as reported by Morsy (2021).

In order to capture the down-drag effect, Figure 5 shows the total displacements of the reinforcement in each loading stage. The reinforcement has a maximum settlement of 2.3 mm close to the face due to the down-drag effect, and it was noted that the trend is that the settlement values reduce as more distant from the face. This type of deformation described as asymmetric deformation occurs due to the relative difference of rigidity of reinforced soil and block facing wall (Soong & Koerner 1997). It is observed that this effect is relevant for the connection load even in small magnitude, in this case, 2.3 mm.
Figure 5.   Total displacements of the geosynthetic inside of the soil mass for 20,60,100,140 and 180 kPa load stage.

Figure 6 compares the tensile load measured by the load cell with that calculated at the connection in each loading stage. This comparison aims to evaluate the magnitude of the
Figure 6.   Comparison between stresses requested on the geosynthetic measured by the load cell, the tell-tale farther from the blocks face and the tell-tales at the connection.

connection load in respect to the maximum along the potential failure surface. Usually, design standards recommend a percentage of T_{max} to obtain the connection load, which is between 50% and 100%, depending on the type of the face wall and the capacity of movements at connection. Note that for loading up to 80 kPa, the test results follow the same design recommendation of 1.0 of T_o/T_{max} indicated in the BS-8006 (2010). Lower vertical stress turn this relation greater than 1.0 because of the down-drag effect.

4 CONCLUSIONS

The testing system and the physical model consist of innovative methodology to evalu-ate the connection loads in geosynthetic reinforced soil walls. The drown-drag effect was observed to be the main factor for the high values of loads at the connection between the reinforcement and the face wall, resulting in an asymmetric deformation behavior of the reinforcement, it is important to point out that the drown-drag effect is also due to the relative settlement of the reinforced soil mass and the modular blocks. The use of digital im-age analysis programs proved to be very valuable for this type of study. The most relevant aspect observed herein is that the connection load can be greater than the maximum tensile load at the potential failure surface, which is dependent of the relative settlement between block facing and reinforced soil.

ABSTRACT: The growing concern regarding waste and water management is pushing the worldwide geomembrane market, thanks to its excellent technical and economical solutions. They have contributed greatly to the completion of many projects, such as reservoir storing water. Geomembranes are not designed to provide structural resistance but frequently undergo mechanical actions that may mishandle their impermeable properties. For instance, the contact between a geomembrane and a drainage (granular) layer increases the risk of puncture. In this study, we adopt an original multiscale view of a geomembrane to relate microstructural features to its macroscopic mechanical properties. A micromechanical model has been developed based on the discrete element method (DEM) to derive the mechanical response of a Polyvinyl chloride (PVC) geomembrane from the modeling of its microstructure. Such an approach offers the potential to understand the elementary mechanisms responsible for the mechanical response and the puncture failure mode of PVC geomembranes.

1 INTRODUCTION

In the past few years, Europe has been hit by a climate-driven drought crisis, which has increased interest towards the sustainable management of water resources. Geomembranes assist with water stock management by limiting water loss along irrigation canals, and through reservoirs. However, they are highly susceptible to mechanical actions, which can lead in a perforation and consequently to a loss of waterproofing property. This results in severe consequences ranging from the water losses to the failure of the structure.

Geomembrane damage is most of the time the consequence of punctures due to contacts with underlying angular stones that may generate localized irregularities in the membrane settlement, when vertical compression is applied.

Therefore, several regulations have been enacted, based on experimental studies, to minimize the risk of puncturing, including stone dimensions specifications and the installation of a protective layer like geotextile beneath the geomembrane. Many works attempted to interpret the puncturing phenomena using a theoretical approach (Koerner *et al.* 1996; Stark *et al.* 2008; Marcotte *et al.* 2009). Furthermore, several analysis were performed on different geomembrane types and thicknesses, protected by various geotextiles, using truncated stone under hydraulic pressure (Koerner *et al.* 2010; Stark *et al.* 2009), or with different drainage layer under high loads (Athanassopoulos *et al.* 2008; Stoltz *et al.* 2013). The

consequence of these design approaches is that geomembranes are supposed to behave homogeneously, thus excluding the risk of local puncturing.

However, if one wants to consider geomembrane puncture, the problem's input factors—such as head pressure, drainage granular layer, and protection-type layer—are numerous. It is thus impractical to undertake experiments for every case study, and numerical modeling is probably more adapted. So far, few studies have been conducted to assess the mechanics of puncture in geosynthetics, and it was limited to nonwoven fabrics geotextile (Sun *et al.* 2011; Saberi *et al.* 2017) and geosynthetic cementitious composite materials (Jirawattanasomkul *et al.* 2019) using finite element method (FEM). To the best of our knowledge, no study has yet investigated the puncturing of a geomembrane and the related internal mechanisms that control its macroscopic mechanical behavior. Therefore, in this study, an original multiscale view of the geomembrane is proposed, allowing identification of the geomembrane's mechanical response by modeling its microstructure using Discrete Elements Method (DEM). Polyvinyl Chloride geomembranes (PVC) are examined in this research, as they are widely used in reservoirs and dams due to their high flexibility and high resistance to external stresses. The proposed multiscale approach has the ability to exhibit the elementary processes underlying the mechanical response of PVC geomembranes and to deepen the comprehension of the puncture failure mode.

2 AN OVERVIEW OF THE MICROSTRUCTURE OF PVC GEOMEMBRANES

PVC is polymerized from vinyl chloride. In such a process, small molecules called monomers (C_2H_3Cl) combine chemically to form a polymer, which is a very long chain-like molecule. In some places, the polymer arrange regularly in the form of crystallites, while in other places, no particular ordering is observed. The structure of PVC can therefore be idealized as crystallites tied together by a three dimensional network of tie molecules, where the average crystallites size is illustrated in Figure 1. Two forms of crystallinity might be exist. The first reveals that the crystals are comprised up of a set of polymer chains that are well-aligned in parallel, forming crystallized regions (see Figure 2a). The second type consists of molecular chains that fold itself into a long thin ribbon creating the lamella (see Figure 2b). The two types could coexist in the same crystallite.

Flexible PVC is produced by adding plasticizers or additives to the mix while manufacturing. Summers (1981) assumed that the plasticizers affect only the amorphous domain. Additionally, it has been determined that the plasticizer additions induce swelling in the amorphous regions, which results in an increase in the inter-crystallite distances. Macroscopically, flexible PVC is characterized by a yield-type stress-strain behavior under uniaxial tensile test. The material becomes increasingly more brittle and more rigid as the percentage of plasticizer decreases.
Figure 1. The micro-domain structure of PVC. (Right) Average crystallite size of PVC. Inspired from Summers (1981).
Figure 2. Two crystallinity-types are shown here. (a) The crystals is made up of a series of parallel polymer chains. (b) The lamella-shaped crystal is being formed by molecular chains that fold into a long thin ribbon.

3 PVC GEOMEMBRANE MODELING IN THE DEM FRAMEWORK

In this part, a three-dimensional model, that simulates the micro-morphology of the PVC structure, is presented. Each polymer fiber is modeled as of a set of interconnected cylinders (section 3.1). The following parts describe crystallite modeling and its spatial distribution (section 3.2), and then, the modeling of the amorphous zone (section 3.3).

3.1 *Polymer fiber modeling*

A polymer chain has been modeled as a set of connected cylinders that can only deform longitudinally. A Discrete Element Method (DEM) is well-suited for this discretization, due to its advantages in investigating inter-particle interactions. This DEM view is also important for tracking the mechanisms inside the geomembrane at the molecular level. It models a material as rigid particles, which displace independently from one to another, and interact only at contact point using physical contact laws. This process is simulated using a time-step algorithm based on an explicit time-difference scheme. Thus, the kinematics of each particle have been updated using Newton's equations at the end of each iteration.

The open source DEM platform YADE (Šmilauer & Chareyre 2010) is employed in this study. The deformable cylinder model developed by Bourrier *et al.* (2013) and extended by Effeindzourou *et al.* (2016) is used. A cylinder is made up of two gridNodes (i.e. spheres) joined by a connection known as the gridConnection. It can only deform longitudinally.

In order to obtain fiber-like behavior, the interaction between two nodes of the cylinder is described as in an elasto-plastic beam, which supports only traction force. For this purpose, an internal cohesive contact law between the two gridNodes is used (Law2 ScGeom6D CohFrictPhys CohesionMoment in YADE). In this law, the rigidity of the gridConnection is defined as the elastic stiffness of a beam associated to the normal force:

$$K_n = \frac{E\,A}{L} \tag{1}$$

where E is the elastic modulus; A = the section area; and L = the length of the gridConnection.

Internal forces are calculated using the relative displacements of the two gridNodes. A failure condition is established by specifying normal elastic limits for the internal forces "the Adhesion value". For numerical reasons, a shear rigidity and a corresponding adhesion are also specified. The shear adhesion is set sufficiently large to guaranty that failure occurs only due to tensile force.

The external interactions between chains of polymers are described as interactions between two frictional spheres. The virtual sphere's translational and rotational velocities

are interpolated linearly between the cylinder's two nodes. Similarly, at the contact point, each cylinder in the cylinder–cylinder contact is associated with one virtual sphere.

The radius of the cylinder was determined from the average between the bond lengths of C-H and C-Cl. A bond length is defined as the distance between the centers of two covalently bonded atoms (i.e., shared electrons between atoms). It depends on each atom's electronegativity, which is the ability of an atom to attract a shared electron. The following empirical formula was proposed by Schomaker & Stevenson (1941) to calculate bond length:

$$d_{A-B} = r_A + r_b - 0.09|x_A - x_B| \tag{2}$$

where d_{A-B} is bond distance between two atoms A and B; r_A and r_B the covalent radii of A and B; and $(x_A - x_B)$ the electronegativity difference between A and B.

Accordingly, The C-Cl and C-H bond lengths are respectively 173.94 pm and 105.96 pm. Thus, the radius of the polymer chains is estimated as 140 pm.

3.2 Crystallites modeling

Geometrical shape of the crystallites was inspired from Summers (1981) as a parallelepiped with dimensions recalled in Figure 1. It was modeled in a shape of a wire mesh, using gridNodes connected by gridConnections, as shown in Figure 3. We designed a crystallite with eight vertical components as reported in Summers (1981).

In the modelled crystallites two different connections have to be modeled: strong links to account for covalent strength in the polymer chains, and weak links to account for Van der Waals forces between the well-aligned polymers within the crystallite. Therefore, two cohesion-types material have been used. In Figure 3, the first material (orange cylinders) represents the material of the cylinders composing the polymer chains, while the second (pink cylinders) describes the Van der Waals interactions between the polymer chains, which are 100 times weaker than the first material's cohesion.
Figure 3. A typical crystallite model.

One of the effects of the plasticizer, as mentioned in section 2, is to expand the space between the crystallites. Therefore, we proposed to use the distance between the crystals as a placeholder for the plasticizers existence. Numerically, in order to distribute the crystallite in space with a specific distance between them, a random pack of spheres, with diameter equals to this distance, was generated. The location of a sphere's barycenter stands in for the location of a crystallite's barycenter, as shown in Figure 4. To densify the pack, it undergoes a triaxial compression using the periodic boundary conditions (as seen in Figure 5). Eventually, within each sphere of control, a crystallite is inserted with a random orientation.
Figure 4.   A systematic illustration of crystallite-crystallite distance.
Figure 5.   Random walk algorithm procedure between two crystallites. This method entails creating the first cylinder from a randomly chosen node of the first crystal, with an orientation based on the crystal's normal vector having θ less than θmax. Then, to create the new cylinder, a random angle between the directions of the previous and new cylinders was determined. This process is repeated until it reached another random node along another crystallite's boundary.

3.3   *Modeling the amorphous region*

Using a cylinder-based random walk algorithm, the polymer molecules in the amorphous region are created. In such a way, the fiber is built by cylinders issued from one randomly chosen node along a crystallite boundary until it reaches another random node along another crystallite's boundary, (see Figure 6), or until it hits the sample boundaries, at which point it stops creating new cylinders. This algorithm is controlled by a random deviation angle $\theta_{\max}$ between the previous cylinder's direction and the next cylinder's direction.
Figure 6.   Distancing crystals procedure. A triaxial compression is applied by periodic boundary conditions to a pack of spheres with a diameter equal to the distance between the crystals. The final position of the sphere is used to indicate the barycenter of the crystallite.

$\theta_{\max}$ controls the density of the amorphous phase, as well as the number of entanglements. This is illustrated in Figure 7, where the density and entanglements of the amorphous phase

rise when θ_{max} equals 0.1π rad, whereas for a small number, the fibers are more straight, which decreases the density.

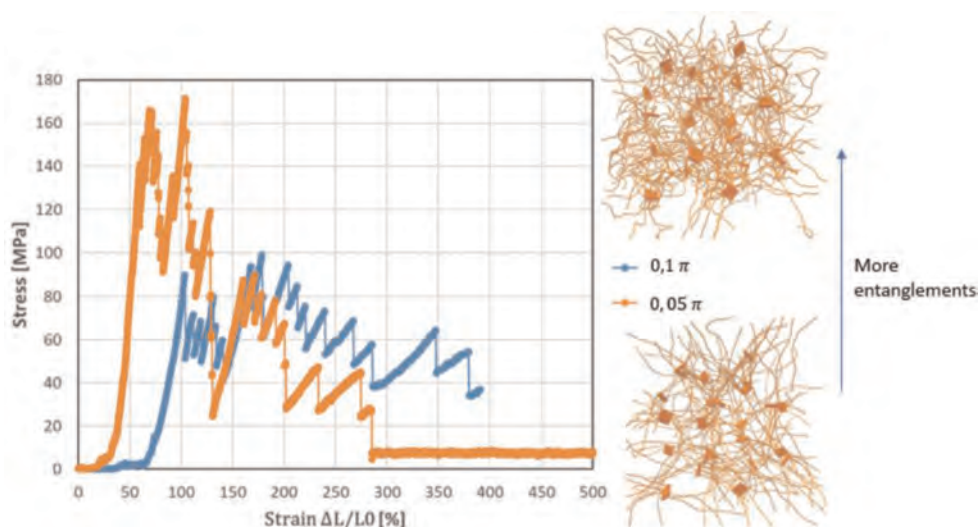
Preliminary uniaxial tension simulations were performed to illustrate the capabilities of our PVC geomembrane model. Figure 7 shows that the model is able to qualitatively describe stress-strain behavior. The stress increases until polymer breakage starts, which generate successive drops in the stress strain curve. For the sake of a proper comparison to understand the effect of the value of the maximum deviation angle θ_{max}, two uniaxial tension simulations were ideally performed with two different values of θ_{max} (0.1π and 0.05π rad). The initial part of the curve (Figure 7) shows how strain increases while there is no significant increase of the stress. This obviously relates to the effect of fiber untwisting (chain rotation) in the direction of tension. As θ_{max} increases, this impact gets larger. Expressly, this refers to the fact that when θ_{max} increases, the random walk algorithm causes the chains to lengthen, increasing the amount of deformation produced by chain untwisting when a load is applied, without notably increasing internal stress. Once the chains are almost aligned in the direction of loading, the stress starts to increase. Here, it can be seen that the curve is less steep as θ_{max} is bigger, this is caused by the effect of the entanglements contribution to the system rigidity, which significantly weakens the behavior.


Figure 7. Preliminary results of the stress strain behavior under Traction Test of two different configurations of PVC geomembrane microstructure with two different values of θ_{max}.

Of course, these results remain only a proof of concept as they were computed on a limited number of crystallites. More crystallites are needed to reach the size of a representative elementary volume (REV), and further calibration is required to better account for flexible PVC behavior until failure.

4 CONCLUSIONS

This work proves the potential capability to rationally model the microstructure of PVC geomembranes. A micro-mechanical model has been created by implementing polymer dimensions, crystallites shape and size, and the complex amorphous regions using discrete elements "Cylinders". Several factors, such as polymer density, fiber rigidity, and Van der

Waals interactions, have also been considered. Additionally, this approach makes it possible to depict indirectly the effect of the plasticizer by increasing the volume in the amorphous phase.

According to the preliminary results under traction test, it is possible to determine the stress-strain behavior under tensile stress and to display internal deformation during the load application. As a result, our method has demonstrated the capability of obtaining macroscopic behavior from the microstructure modeling.

Of course, many parameters, as well as the dimension of the REV remains to be calibrated. But this approach will be an important step toward understanding PVC geomembrane perforation failure and will pave the way for additional micromechanical inspection.
