GEOSYNTHETICS: LEADING THE WAY TO A RESILIENT PLANET

This volume contains the proceedings of the 12th International Conference on Geosynthetics (12 ICG), held in Roma, Italy, 17–21 September 2023. About 750 Authors – Academics, Researchers, Students, Practitioners, Contractors and Manufacturers – contributed to the peer-reviewed papers of this volume, which includes the Giroud lecture, the Bathurst lecture, the Rowe lecture, four keynote lectures and 296 technical papers. The content of these proceedings illustrates the sustainable use of geosynthetics in a variety of innovative as well as consolidated applications. After the sustainability implications in the correct use of geosynthetics, the ability to overcome the natural events effects, often related to the climate change, and to adequately afford the human activities (as the increase of pollution) forced to refer to a new keyword: Resiliency.

Hence the 12 ICG intends to become the base for the next step, therefore the conference theme is "Geosynthetics, Leading the Way to a Resilient Planet".

The conference topics, through general and parallel sessions, invited presentations and keynote lectures, address the most recent developments in geosynthetic engineering, and stimulate fruitful technical and scientific interaction among academicians, professionals, manufacturers, students.

The 12 ICG proceedings contain a wealth of information that could be useful for researchers, practitioners and all those working in the broad, innovative and dynamic field of geosynthetics.

Young member contest

Preface

This volume contains the contributions to the 12th International Conference on Geosynthetics – "Geosynthetics: leading the way to a resilient planet" – held in Roma (Italy) from September 17th to 21st, 2023.

Years after the successful EuroGeo 2, which was held in Bologna (Italy) in October 2000, the geosynthetics and geotechnical engineering community has reached full awareness over the last two decades, and the whole geosynthetics industry has focused on the sustainable use of geosynthetics in a variety of innovative as well as consolidated applications. After the sustainability implications in the correct use of geosynthetics, the ability to overcome the natural events effects, often related to the climate change, and to adequately afford the human activities (as the increase of pollution) forced to refer to a new keyword: Resiliency.

Hence the 12ICG intends to become the base for the next step therefore the conference theme is

GEOSYNTHETICS, LEADING THE WAY TO A RESILIENT PLANET

The conference topics will address, through general and parallel sessions, invited presentations and keynote lectures, the most recent developments in geosynthetic engineering, stimulating fruitful technical and scientific interaction among academicians, professionals, manufacturers and students.

We believe that the 12 ICG will provide an excellent opportunity to present recent experiences and developments to an audience of engineers, geologists and consultants, public and private contractors, local, national and international authorities, and to all those involved in research and practice related to geosynthetics.

The ICG conferences have always provided a unique and fruitful forum for the exchange of new ideas and discussion on key issues within the largest gathering of world's experts, academics and non-academics, working in the broad, innovative and dynamic area of geosynthetics.

About 750 Authors, coming from academic institutions, private companies and public bodies worldwide, contributed to the peer-reviewed papers included in this volume. The Scientific Committee was especially pleased with the general high quality of the papers.

A total of 296 manuscripts were finally accepted for publication in the Conference Proceedings. The papers were sorted into 19 topic categories, according to the subject areas typically addressed in ICG events:

- Sustainability with Geosynthetics
- Geosynthetics Properties and Testing
- Soil-Geosynthetic Interaction
- Durability and Long-Term Performance
- Reinforced Walls and Slopes
- Basal reinforced Embankments, GEC, piles and shallow foundations
- Seismic design with geosynthetics
- Unpaved and paved roads
- Railways and other Transportation Applications
- Landfills and remediation of contaminated sites
- Filtration and Drainage

- Hydraulic applications: canals, reservoirs and dams
- Innovative materials and technologies
- Design approaches and other applications
- Case Histories

The proceedings also include the Giroud lecture, the Bathurst lecture, the Rowe lecture and four outstanding keynote lectures presented by renowned experts on selected key topics.

A significant effort was made to provide the Authors with a rigorous and fair review of the papers. The Editors are therefore very grateful to the numerous assessors and reviewers, for their generous and valuable work.

We gratefully acknowledge the support of the Italian Geotechnical Society (AGI) and to the Italian Chapter of IGS (AGI-IGS), which organized the Conference. We would also like to express our appreciation to all the Sponsors that helped us in making this conference a success.

Many thanks to all Keynote Lecturers, Invited Speakers and Authors for their enthusiastic and proactive response to 12 ICG, and for their contribution to this Proceedings volume.

Finally, sincere thanks to Susanna Antonielli for her long-term dedication and tireless efforts towards the correct organization of this volume of proceedings and also to the success of the overall conference aspects.

We do hope you will find its content of valuable and long lasting use.

Geotextile filters: From idealization to real behaviour (Giroud lecture)

E.M. Palmeira
University of Brasília, Brasília, Brazil

ABSTRACT: Geotextiles have been used as filters in geotechnical and geoenvironmental works for decades. Despite their broad utilization, these filters still find obstacles to the expansion of their application in larger projects and under complex soil and flow conditions. However, environmental issues are increasingly pressing for a greater use of geotextile filters in substitution to natural granular materials. Even though many important studies in the literature have improved the understanding of soil-fluid-geotextile filter interaction, some issues still require thorough investigation aiming at a better understanding of the behaviour of geotextile filters and the development of better design methodologies. This paper discusses how geotextiles filters are expected to behave in the field and some contradictions between idealized and expected behaviour. Concerns regarding the use of geotextile filters under severe and critical conditions and how filter malfunction can be avoided or minimised are also addressed.

1 INTRODUCTION

Geotextiles have been used extensively as filters in geotechnical and geoenvironmental works for over five decades. The main reasons for the increasing use of these materials are the ease of transportation and installation, reduction or non-use of natural materials, consistency and repeatability of relevant properties and cost-effectiveness. More recently, an additional increasingly important benefit of the use of geotextile filters as substitutes for granular filters is the less environmental impacts caused by the former. Frischknecht *et al.* (2012) report that a geotextile filter can reduce important environmental impact parameters (greenhouse gas emissions, consumption of renewable and non-renewable energy, consumption of water etc.) by over 80% in comparison to sand filters. However, despite the huge success of geotextile filters, some issues remain regarding their actual behaviour in a geotechnical work and on how accurate current design and specification methods are. Failures of geotextile filters have been reported (Koerner & Koerner 2015) and, although representing a very small fraction of the use of such filters, the consequences of such failures can be very important.

For a significant fraction of designers and users, the substitution of a granular filter by a geotextile counterpart looks so natural and easy that important aspects for filter performance may be commonly overlooked. The general idea of a geotextile filter application is schematically shown in Figure 1a, where the geotextile will substitute the entire granular transition zone between the base soil and the coarser drainage layer. However, in most situation the expected conditions under which the geotextile filter will function are actually those shown in Figure 1b. Depending on the application, in the field the geotextile may be subjected to compression, tension, shear and impregnation by degradable or non-degradable solids. These conditions will influence the filter performance in a very complex way.

A huge number of examples of successful applications of geotextile filters can be found in the literature. Wilson-Fahmy *et al.* (1996) conducted a comprehensive study on the performance of geotextile filters of highway edge drains and some retaining walls and erosion

control systems. The sampling of specimens from the case histories investigated was not based on a random collection of sites, but on specific sites where there was suspicion of drainage system malfunction. Hence, a number of nonacceptable performance should be expected. Despite this biased selection, 77% of the filters presented acceptable performance. In another study involving the investigation of 91 case-histories, Koerner *et al.* (1994) concluded that if construction and maintenance related problems were eliminated, only 4 (4.4%) out of the 91 case-histories investigated would be considered nonacceptable situations, which is considered an excellent performance record. Lopes *et al.* (1991) and Morilha Jr. *et al.* (1994) also report the exhumation of geotextile filters over 10 years old from 6 highway drains suspected of malfunctioning in the state of Paraná, Brazil. No clogging nor degradation was observed in the geotextile filters and the apparent poor performance of the drains was a consequence of poor construction practice, improper location of the drain, drain outlet blocking or preferential flow of water through more permeable soil layers not intercepted by the drainage trenches. Lopes *et al.* (1991) and Morilha Jr. *et al.* (1994) also report the good performance of a geotextile filter in a road edge drain where partial clogging was observed in a conventional French drain. Despite these examples of successful performance of geotextile filters, some problems have been identified. An important analysis on unsatisfactory performance of such filters is presented by Koerner & Koerner (2015), where poor behaviour or failures have been caused by inadequate design, presence of atypical soils, unusual permeants and improper installation, corroborating what was found by the authors mentioned above. In addition, Koerner & Koerner stress that most of the conditions where geotextile filters failed are also known to be troublesome for sand filters.
Figure 1. Granular *vs.* geotextile filter. (a) Idealization; (b) Actual working condition of a nonwoven geotextile.

Geotextile filters must attend retention, permeability and anti-clogging criteria for proper performance. In addition, they have also to present suitable mechanical properties and resistance to degradation to withstand mechanical solicitations during installation and construction, as well to guarantee a satisfactory service life. The behaviour of geotextile filters has been investigated by many researchers under laboratory conditions, not rarely under conditions significantly more severe than those expected in the field. Very simple to quite complex testing techniques and methodologies can be found for the determination of important geotextile filter properties or to predict filter performance. However, unfortunately, all of them have limitations to model real filter in-service conditions. This is particularly so in situations where the filter will be in contact with problematic soils (internally unstable soils, for instance) or permeants (leachate, for instance). In addition, nonwoven geotextiles are highly compressible materials that in the great majority of the situations will work under confined conditions but may also function under tension. Besides, they can be impregnated by base soil particles during construction, which will influence its compressibility and clogging potential (Figure 1b). Thus, when the fluid reaches the filter the conditions of the latter may be quite different from those assumed in design and in current

standard laboratory tests. Conservative approaches have been the practice in these cases, although conservatism may not necessarily result in a problem free design since some uncertainties on how the filter will actually behave may remain.

The studies described above are just very few examples of the good performance of geotextile filters in general, but also raises important questions to be addressed to avoid unsatisfactory performance. Thus, it is of special concern the behaviour of filters under severe and critical conditions that may lead to filter (granular or geotextile) failure, being of utmost importance to identify such conditions in order to avoid or minimise the detrimental consequences of filter poor performance and/or to establish in advance appropriate monitoring and maintenance practices throughout the structure service life. So, this paper presents and discusses factors affecting the behaviour of geotextile filters, particularly under severe conditions of utilization, as well as how these factors can be considered in design.

2 PHYSICAL FACTORS INFLUENCING GEOTEXTILE FILTER BEHAVIOUR

2.1 *Geotextile impregnation by base soil particles*

The behaviour of nonwoven geotextile filters can be influenced by confinement and the presence of soil particles entrapped in its matrix. This particle entrapment can occur during placement and compaction of soil on the geotextile layer or due to the retention of particles brought to the filter by the action of seepage forces. The intensity of the impregnation can be quite significant (Lawson 1990, Qureshi *et al.* 1990, Palmeira *et al.* 1996, Palmeira & Gardoni 2000, Legge 2004), depending on the base soil and geotextile characteristics. These particles in the geotextile voids can reduce geotextile compressibility, geotextile permeability and the conditions for further internal clogging since their presence changes the available openings in the filter. Large soil particles can intrude the geotextile voids during spreading and base soil compaction, as shown in Figure 2 (Gardoni 2000, Palmeira & Gardoni 2000, Palmeira *et al.* 2010). Similar large, entrapped soil particles were observed by Niec *et al.* (2019) in geotextile specimens exhumed from a small dam in Poland. Impregnation of the geotextile can also occur in the laboratory in tests such as the gradient ratio test (*GRT*), particularly when vibration is used to compact a cohesionless fine grained base soil. The level of particle entrapment can be assessed by the impregnation level (λ) of the geotextile, defined as the ratio between the mass of entrapped soil particles and the mass of fibres of the geotextile (Palmeira *et al.* 1996). Impregnation of the filter by base soil particles may be relevant for base soils consisting of cohesionless fine grained materials and dispersive clays. Table 1 presents some ranges of variation of λ values obtained in laboratory and field studies. It should be noted that the value of λ and the geotextile void occupancy by soil particles depend on the density of the fibres of the geotextile.
Figure 2. Example of entrapped soil particles inside geotextile voids. (a) Cluster of particles in a geotextile specimen exhumed from a road drainage trench (Palmeira & Gardoni 2000), (b) Particle in an exhumed tailings dam filter (Palmeira *et al.* 2010), (c) Large entrapped soil particle in a geotextile exhumed from a road drainage trench (Gardoni 2000).

Significant reductions in the permeability coefficient of systems consisting of internally unstable soils and nonwoven geotextiles were observed by Qureshi *et al.* (1990) and the results suggest that these permeability reductions were caused by significant impregnation of the geotextile voids by base soil particles. Similar detrimental influence of soil impregnation in the soil-geotextile system permeability coefficient was observed by Lawson (1990), where the data available suggest values of impregnation level (λ) of the order of 8. Values of up to 15 were observed under laboratory conditions (Palmeira & Gardoni 2000). Table 1 also shows significant values of λ for geotextile specimens exhumed from field tests and real works.

A maximum value of λ considering a mass of soil particles (smaller than the geotextile voids) uniformly distributed inside the geotextile can be estimated by

$$\lambda_{\max} = \frac{\rho_s}{\rho_f}(1 - n_s)\left(\frac{n}{1-n}\right) \tag{1}$$

Table 1. Typical values of λ for nonwoven needle-punched geotextiles.

*M_A = geotextile mass per unit area, *FOS* = geotextile filtration opening size (O$_{95}$, O$_{90}$ or AOS, Apparent Opening Size, depending on the source), *GB* = glass beads, *NA* = not available, *PFA* = pulverised fuel ash mixture, λ = impregnation level, λ for tailings may be larger than for common soils depending on the particle density of the former, **Mechanism of impregnation: compaction (vibration etc., code C) and/or seepage (code S) under laboratory (code L) or field (code F) conditions,*** Some values were calculated based on data from tests reported by the sources, ****From Valcros Dam (Faure *et al.*, 1999) – geotextile porosity (n) assumed as 0.9 to estimate λ, *****Static and cyclic loadings.

where λ_{max} is the maximum value of λ, ρ_s is the density of the soil particles, ρ_f is the density of the geotextile fibres, n_s is the porosity of the mass of particles in the geotextile voids and n is the geotextile porosity not considering the presence of the entrapped particles.

For a mass of entrapped particles in a nonwoven polyester geotextile (ρ_f = 1380 kg/m³), with n = 0.92, n_s = 0.3 and ρ_s = 2650 kg/m³, equation 1 gives a value of λ_{max} of 15.5, which compares well with the maximum values of impregnation level for light geotextiles listed in Table 1. If all the geotextile voids are entirely occupied by a solid mass, which would be an extreme case of geotextile impregnation yielding to k_{GT} = 0, where k_{GT} is the geotextile permeability coefficient, equation 1 can still be used making n_s = 0.

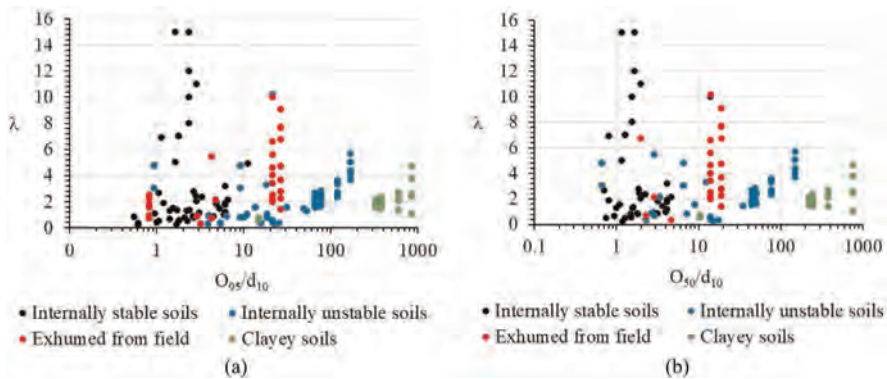
With more data obtained from the sources listed in Table 1 (Palmeira 2023) it is possible to plot the variation of λ with the ratios O_{95}/d_{10} and O_{50}/d_{10} shown in Figure 3 for different soil conditions, where O_{95} is the geotextile filtration opening size (*AOS* in some cases) and d_{10} is the base soil particles for which 10% in mass is smaller. It should be acknowledged that significant deviations between values of geotextile opening sizes (O_{95}, *AOS*, O_{90} etc.) can be obtained, depending on the test method used (Bhatia & Smith 1996, Blond e al. 2015, Fatema & Bhatia 2019). However, satisfactory comparisons have been obtained by some authors regarding results from bubble point and hydrodynamic sieving tests (Vermeersch & Mlynarek 1996, Palmeira & Trejos-Galvis 2017). The results in Figure 3 show a large scatter for λ, which is certainly associated with different geotextile properties, soils, hydraulic conditions and impregnation mechanisms, and highlights the complexity of the problem. Greater scatter and no clear trend of λ variation can be observed for O_{95}/d_{10} between 0.5 and 30 and O_{50}/d_{10} between 0.6 and 20, but a trend of λ increasing with O_{95}/d_{10} and O_{50}/d_{10} can be noted in the case of internally unstable soils for values of those ratios greater than 40 and 20, respectively. Similar levels of scatter are observed if different O_{95}/d ratios are considered (using d_{15} or d_{50}, for instance). It is interesting to note values of λ of up to 15 for internally stable soils, up to 10 for internally unstable soils and up to 10 for specimens exhumed from the field. For clayey soils, a maximum value of λ equal to 4.7 was observed. Large values of λ for clayey soils are likely to be associated with dispersive clays or clusters of clay particles. A statistical evaluation of the results in Figure 3 shows that λ is greater than 2.5 in approximately 66% of the cases. As an example, for a value of λ equal to 2.4, normal permeability tests on a confined impregnated nonwoven geotextile showed reductions in the geotextile permeability coefficient between 40.2% and 50.0%, depending on the vertical stress considered (Palmeira & Gardoni 2000).


Figure 3. λ versus geotextile pore size: (a) λ vs. O_{95}/d_{10}, (b) λ vs. O_{50}/d_{10}. Data from sources listed in Table 1 (Palmeira 2023).

Giroud (1996) investigated the influence of impregnation on geotextile hydraulic properties and developed an equation to estimate the coefficient of permeability of impregnated

nonwoven geotextiles. Palmeira and Gardoni (2000) rewrote that equation as a function of the geotextile impregnation level (λ) yielding to

$$k_{G\sigma}^* = \frac{\beta \rho_w g \left[n - \lambda \cdot \frac{\rho_f}{\rho_s} \cdot (1 - n) \right]^3}{\eta_w \left(\frac{4}{d_f} + \lambda \frac{\rho_f}{\rho_s} \frac{6}{d_s} \right)^2 (1 - n)^2} \tag{2}$$

where β is a dimensionless shape factor which depends on the path followed by the fluid, ρ_w is the density of the fluid, g is the acceleration of gravity, η_w is the dynamic viscosity of the fluid, n is the porosity of the geotextile without considering the presence of the soil particles in the voids, λ is the geotextile impregnation level, ρ_f is the density of the geotextile fibres, ρ_s is the density of the soil particles, d_f is the fibre diameter and d_s is the average diameter of the soil particles inside the geotextile (see Palmeira & Gardoni 2000 for predictions of d_s).

Satisfactory comparisons between predictions by equation 2 and measurements of geotextile permeability coefficient were obtained by Palmeira and Gardoni (2000) with β equal to 0.11 and 0.14 for virgin ($\lambda = 0$) and partially clogged nonwoven geotextiles, respectively. Thus, using equation 2, a predicted reduction factor due to geotextile impregnation can be expressed as

$$RF_\lambda = \frac{k_{GT0}}{k_\lambda} \tag{3}$$

where RF_λ is the reduction factor for geotextile impregnation, k_{GTo} is the coefficient of permeability of the virgin (clean) unconfined geotextile and k_λ is the coefficient of permeability of the impregnated unconfined geotextile.

As an example of the influence of the impregnation of the geotextile by soil particles on its permeability coefficient, Figure 4 presents the predicted variation of RF_λ with λ for a nonwoven, needle-punched, geotextile with a mass per unit area of 200 g/m^2, porosity of 0.92, uniformly impregnated throughout its thickness of 1.9 mm. This figure shows that under these conditions a value of λ of 5 would result in a RF_λ of 8.6, already quite close to the usual value of 10 suggested by some permeability criteria. Geotextile compression due to confinement increases the complexity of the problem. However, if the geotextile rests on coarse drainage material (gravel, rock or a geocomposite drainage core), sagging of the geotextile in the voids of the drainage material will cause a non-uniform compression of the filter, and geotextile tension, ground vibration and seepage may remove some of the entrapped base soil particles, reducing the value λ to some extent.
Figure 4.   Predicted reduction factor for geotextile permeability due to partial clogging.

Laboratory investigations have shown that uniform impregnation of the geotextile thickness by soil particles tends to occur for thin light nonwovens. The impregnation of thicker geotextiles tends to occur predominantly along a small fraction of the geotextile thickness at its face in contact with the base soil. In such cases, impregnation is likely to influence little geotextile compressibility. The results presented above show that some level of impregnation of a nonwoven geotextile filter soils should be considered in design.

2.2 Filters under confinement

Geotextile filters can be subjected to high compressive stresses in geotechnical works. By being compressible materials, confinement will influence filter performance, particularly in the case of nonwoven geotextiles. Figure 5 shows how significantly the pore dimensions of a nonwoven needle-punched geotextile can be affected by compressive stresses (Gardoni 2000, Gardoni & Palmeira 2002). Hence, compression will influence the retention capacity of the filter as well as conditions for potential clogging. These changes in the filter microstructure are difficult to predict and still not addressed by current filter criteria.
Figure 5. Effect of confining stress on a nonwoven geotextile (Gardoni 2000). (a) 2 kPa, (b) 1000 kPa.

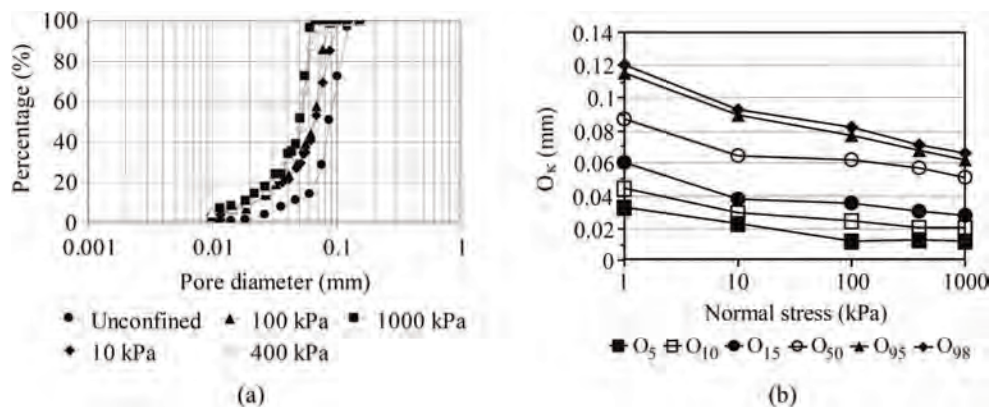
Results from Bubble Point Tests (*BBP*) on compressed nonwoven, needle-punched, geo-textiles have shown significant reductions in the geotextile pore sizes relevant for filter design. Figure 6a depicts pore size distribution curves for a nonwoven, needle-punched, geotextile (mass per unit area, M_A, of 200 g/m^2) in tests under vertical stresses ranging from 0 to 1000 kPa (Palmeira 2020). Figure 6b presents the influence of confinement on different geotextile pore diameters. These results show that the conditions of a buried geotextile filter will be significantly different from those simulated in laboratory tests commonly carried out to determine geotextile pore size dimensions.


Figure 6. Influence of confinement on geotextile pore diameter (Palmeira 2020). (a) Pore size distribution curves for different confining stresses, (b) Geotextile pore diameter *vs.* confining stress.

The capability of a geotextile filter to retain a moving soil particle depends on the number of confrontations (m) the particle will have to face to cross the geotextile. Compression of the geotextile will also influence the number of confrontations, as it reduces the geotextile thickness. Palmeira & Trejos Galvis (2018) backanalysed the value of m using the equation proposed by Giroud (1996) for five nonwoven, needle-punched, geotextiles (M_A in the range 200 to 1800 g/m^2) and obtained the results shown in Figure 7. A linear relationship between m and the geotextile thickness (t_{GT}) normalised by the geotextile fibre diameter (d_f) can be observed for the products tested. Thus, thinner or compressed thicker geotextiles will present a smaller number of confrontations. For the products tested in Figure 7, the recommended minimum value of m of 30 (Giroud 1996) would be achieved for a t_{GT}/d_f ratio of approximately 110. The number of confrontations decreases with confinement. However, so do the geotextile pore sizes.
Figure 7.   Number of confrontations vs. normalised geotextile thickness (Palmeira & Trajos Galvis 2018).

The geotextile retention capacity increases when the filter is subjected to the combined action of partial clogging and confinement, as shown in Figure 8. This figure presents the variation of geotextile filtration opening size (expressed as O_{95}) of a nonwoven needle-punched geotextile, obtained in *BBP* tests, normalised by the fibre diameter (d_f) with the confining vertical stress for different values of impregnation level (λ) (Palmeira & Trejos
Figure 8.   Geotextile filtration opening size *vs.* confining stress for different impregnation levels (Palmeira & Trejos-Galvis, 2017).

Galvis 2017). Reductions in O_{95} of up to 36% with respect to the result for the confined virgin specimen can be noted, depending on the impregnation level and vertical stress considered. In comparison with the unconfined ($\sigma_v = 0$) virgin ($\lambda = 0$) geotextile, the same geotextile with a value of λ of 6 under 1000 kPa showed a reduction in O_{95} of 67%. Hence, filter retention capacity is enhanced by confinement and partial clogging. It should be noted that the range of O_{95}/d_f values in Figure 8 covers the dimensions of particles of very fine sands and silts. This, to some extent, explains why cohesionless silts are usually viewed as problematic materials for geotextile filter performance.

2.3 *Filters under tension*

Geotextile filters can work under tension in some geotechnical structures, such as in drainage layers at the base of embankments on soft soils, in geotextile tubes, silt fences and as separators in roads on compressible grounds, for instance. The tensile strains developed can influence geotextile pore dimensions and filtration behaviour. Several studies can be found in the literature on the behaviour of geotextile filters under tension (Fourie & Kuchena 1995, Adel *et al.* 1996, Fourie & Addis 1997 and 1999, Moo-Young & Ochola 1999, Wu *et al.* 2008, Wu & Hong 2016, Palmeira *et al.* 2012, Chen *et al.* 2019, Palmeira *et al.* 2019, Tang *et al.* 2020a, b). Conflicting results have been obtained among different researchers, particularly in tests with woven geotextiles. These differences in results are likely to be due to different geotextiles properties and fabric structures as well as different experimental techniques being used.

Fourie and Addis (1997) investigated the effect of tensile loads on the filtration opening size of geotextiles. Tests with the geotextile specimens subjected to uniaxial and biaxial loads were carried out. The authors commented that the effect of an in-plane tensile load appeared to be more pronounced for the woven than the nonwoven geotextile. They also observed erratic variations of O_{95} of a nonwoven geotextile under tension and concluded that, despite increasing the geotextile retention capacity, the reduction in O_{95} may favour blinding or clogging of the geotextile filter. In another study on the influence of tension on geotextile filter behaviour, Fourie and Kuchena (1995) observed up to 80% reduction in flow rate in highly stressed woven and nonwoven geotextile specimens. The authors attribute this reduction to closure of pore spaces impeding flow of water through the geotextile. However, the dimensions of the tensioned geotextile sample strip from where the specimens used in the tests were collected did not satisfy plane strain conditions; hence, necking of the nonwoven specimens may have influenced the results. Necking of the specimen under tension must have also influenced the results obtained by Tang *et al.* (2020a) due to the size of the specimens tested.

The influence of uniaxial strain on geotextile pore size, flow rate capacity and compatibility (*GRT*) with soil was investigated by Wu *et al.* (2008). Increases in O_{95} were observed with increasing strain, with a slight rate of increase for the heavier nonwoven geotextile tested. The authors comment that uniaxial strain causes the straps to bulge in woven geotextiles in the direction normal to that of the load, enlarging the interstitial spaces. For all geotextiles tested, the tensile strains caused an increase in pore size, decrease in the gradient ratio, *GR*, (being more pronounced in the nonwoven geotextiles) and an increase in flow rate. Fourie and Addis (1999) observed that unequal orthogonal loads may distort the shape of the openings in a woven geotextile, effectively decreasing the pore spaces and that different mechanisms of expansion and flattening of geotextile strands under tension may influence differently the pore opening sizes in thinner and thicker geotextiles. Hong and Wu (2011) also observed the influence of geotextile straining on the results of filtration tests under sustained and pulsatory loads.

Chen *et al.* (2019) investigated the variation of nonwoven heat-bonded geotextile pore size distribution with tensile strain using the Discrete Element Method (*DEM*). The authors utilized image analysis to obtain the variations of geotextile pore size distribution.

They observed compression of some fibres in uniaxial loading depending on the direction considered. Overall, the geotextile opening size linearly increased with the tensile strain in both uniaxial and biaxial tensile tests, but with less intensity and magnitude when compared with the experimental results by Wu *et al.* (2008). The authors attribute these differences to simplifications made in the model such as the bonds between fibres in the same fibre web having been considered as unbreakable.

The effects of unequal tensile strains in warp and weft directions on the per cent open area (*POA*) and filtration opening size (O_{95}) of woven geotextiles were investigated by Tang *et al.* (2020b). The authors observed that *POA* and O_{95} showed marked increases with increasing unequal biaxial strain, similarly to what was observed by Palmeira *et al.* (2019) in tests on nonwoven geotextiles, and that tensile strains had a greater impact on smaller pores. An unequal biaxial strain may decrease or increase the geotextile *FOS* depending on the initial shape of the pores. Strain values, ratio between warp and weft strains and biaxial strains had a greater impact on geotextile *POA* than uniaxial strains.

Sagging of the geotextile filter between particles of the bedding material will also cause tensile strains in the geotextile filter. Palmeira *et al.* (2012) investigated this mechanism of geotextile deformation in tests with nonwoven, needle-punched, geotextiles resting on different bedding materials (steel spheres or gravel). Large strains were observed in the geotextile, particularly for the lighter ones, depending on the type and spacing between bedding material particles and vertical stress (Figure 9a). An adaptation of the method proposed by Giroud *et al.* (1990) to estimate geotextile strains in soil-geotextile layers overlying circular voids yielded to good comparisons between predicted and observed average geotextile strains in tests with spheres as bedding materials, as shown in Figure 9b. However, for the case of gravel as bedding material, the prediction should be multiplied by a factor of the order of 3 or more to improve accuracy. Thus, tensile strains due to geotextile sagging in the voids of coarse material can influence its retention capacity.
Figure 9. Tensile strains due to geotextile sagging in the bedding material voids (Palmeira *et al.* 2012). (a) Strain versus vertical stress, (b) Predicted vs. measured geotextile strain.

The variation of pore dimensions of nonwoven, needle-punched, geotextile filters due to tension and confinement was investigated by Palmeira *et al.* (2019). In their study, the authors used a bubble point test equipment capable of performing tests on previously in-plane tensioned geotextile specimens with or without the application of compressive stresses normal to the geotextile plane. It was observed that the values of O_{50}, O_{30} and O_{10} of the geotextile, particularly the latter, were less sensitive to the tensile strains than O_{95} and O_{98}. Contrary to what was observed in uniaxially tensioned geotextiles, the values of O_{98} and O_{95}

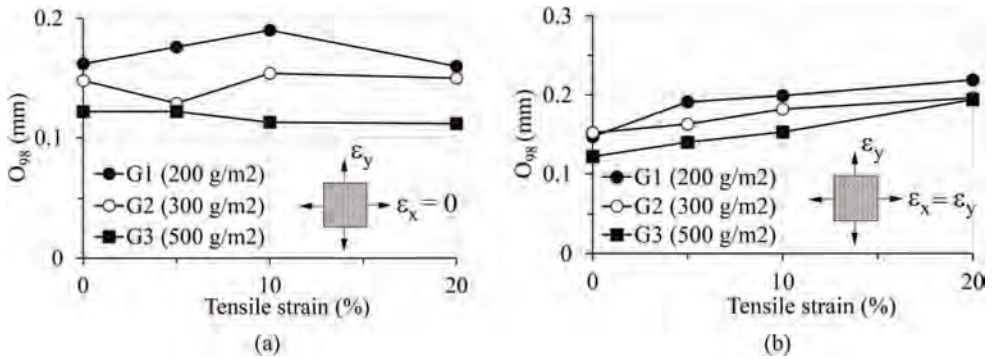
were rather insensitive to the tensile strain applied under plane strain conditions (Figure 10a), which is consistent with the observations by Fourie and Addis (1997) and Moo-Young and Ochola (1999). Confinement reduced the value of O_{98} independent on the tensile strain in the specimen, with the reduction of the influence of tensile strains due to confinement being more evident for the thicker geotextiles. The largest pore diameter increases were obtained in tests on specimens subjected to equal biaxial strains (Figure 10b). In this case, increases in O_{98} of up to 64% were noted in comparison with results from test on unstrained specimens, depending on the geotextile considered. However, again the pore dimensions of the tensioned geotextile were reduced by confinement.


Figure 10.   Pore dimension vs. tensile strain (modified from Palmeira, 2020). (a) Plane strain condition, (b) Equal biaxial strain condition.

Palmeira *et al.* (2019) proposed a solution to estimate an upper bound value for the filtration opening size of a tensioned nonwoven geotextile under equal biaxial tensile strains. The approach is based on Kirsh (1898) elastic solution for the increase in the diameter of a circular hole in a linear elastic, homogeneous and isotropic tensioned plate. This solution was adapted to consider large tensile strains. Figure 11 shows results of the ratio between geotextile filtration opening size (O_ε) for a given tensile strain (ε) and the filtration opening size under unstrained conditions (O_o) versus tensile strain (ε) obtained in bubble point tests. It also shows the predicted upper bound curves for different values of geotextile Poisson ratio
Figure 11.   Comparisons between measurements and upper bound values for filtration opening size (modifield from Palmeira 2020).

(*v*). The predicted upper bound for geotextile filtration opening size for a Poisson ratio of 0.3 was satisfactory regarding the experimental results. This approach may be useful for the prediction of a conservative upper bound for the geotextile filtration opening size under equal biaxial tensile strains, which would to some extent simulate the conditions expected for a geotextile separator in a road or for a geotextile sagging in the voids of a coarse underlying material.

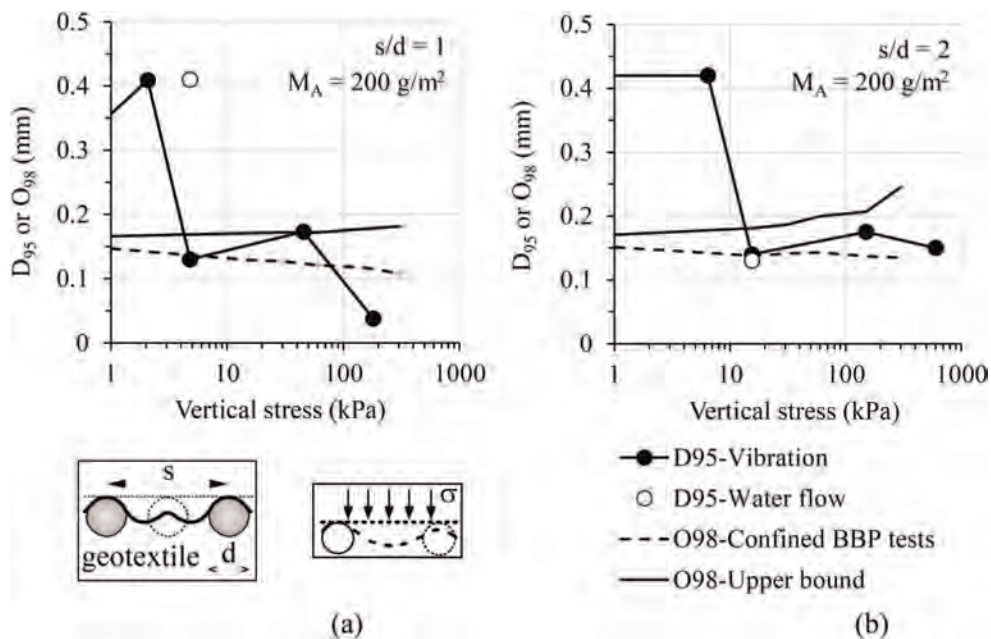
The upper bound for filtration opening sizes of tensioned nonwoven, needle-punched, geotextiles described above was compared to the diameter of particles that actually piped through geotextile filters in Gradient Ratio tests under confinement performed by Palmeira *et al.* geotextile (2012). In these tests, the bedding layer consisted of 18 mm diameter steel spheres with different values of spacing to diameter ratios (*s/d*, Figure 9). Vibration and water flow were the main mechanisms causing soil particle to pass through the geotextile filter in the tests. Figure 12 shows the variation of the maximum diameter (D_{95}) of the piped particles or geotextile filtration opening size (O_{98}, from *BBP* tests on confined and tensioned geotextiles, Palmeira *et al.* 2019) versus the vertical stress acting on the voids between bedding layer particles as calculated by the method proposed by Giroud *et al.* (1990). The upper bound (Palmeira *et al.* 2019) in Figure 12 was calculated using a geotextile Poisson ratio of 0.3. The results show piped soil particles considerably larger than the upper bound for low vertical stresses. This can be attributed to large particles being pushed through the geotextile voids or passing through needle holes in the geotextile due to the needle-punching process during geotextile manufacturing, base soil compaction or due to high seepage forces. For greater vertical stresses, the diameters of the largest piped particles were below the upper bound curve. The values of D_{95} oscillated around the curve of O_{98} vs. vertical stress in Figure 12a or were a little greater (Figure 12b). Bearing in mind the limited amount of experimental data available, the results in Figure 12 are encouraging with regard to the development of more realistic predictions of the retention capacity of nonwoven, needle-punched, geotextiles overlying coarse drainage materials.


Figure 12.   Diameter of the largest soil particle piping through a nonwoven geotextile overlying a granular drainage layer (modified from Palmeira 2020). (a) *s/d* = 1, (b) *s/d* = 2.

In summary, tension can influence geotextile filter performance in different ways, depending on the geotextile type and tensioning mechanism (uniaxial, biaxial, plane strain etc.). The situation is more complex in woven geotextiles, since opening size variation will depend on the type and characteristics of the geotextile fibres and on how they will behave under tension. The filtration opening size of nonwoven, needle-punched, geotextiles seem to be little affected by tension under plane strain conditions. Equal biaxial strain condition increases filtration opening sizes of woven and nonwoven geotextiles.

3 BEHAVIOUR OF GEOTEXTILE FILTERS UNDER SEVERE WORKING CONDITIONS

Geotextile filter failure under severe conditions can be the result of the following:

- Physical clogging (blinding, blocking or particle intrusion)
- Chemical clogging (precipitation of chemicals)
- Biological clogging (action of microorganisms)
- Biochemical clogging (combined action of chemical substances and microorganisms)

Commonly, a combination of two or more of the aforementioned mechanisms takes place under field conditions. However, under laboratory conditions, most researchers have tried to isolate or enhance a specific clogging mechanism to reduce the complexity of the problem. The following points discuss the behaviour of geotextile filters under severe working conditions.

3.1 *Geotextile filters in internally unstable soils*

A major concern of filter failure is on filters, either granular or synthetic, in contact with internally unstable soils. In an internally unstable soil, its smaller particles can be carried by the water through the voids of the soil skeleton formed by its larger particles in a process called suffusion. Gap-graded soils and soils with the gradation curve concave upwards with large values of coefficient of uniformity (C_u) are potentially internally unstable soils. According to Skempton and Brogan (1994), the critical content of fines below which the fine particles in a gap graded soil do not fill the voids in the coarse component ranges from 24% (dense packing) to 29% (loose packing). If the content of fines is greater than 35% the coarse particles are dispersed in a matrix of fine particles (Moraci *et al.* 2022). If the filter retains the soil particles carried by seepage forces, it may be blinded. On the other hand, if the filter allows the passage of a substantial amount of these particles internal clogging of the filter, clogging of drainage pipes or structural instability of the base soil due to excessive piping can occur. In addition, an internally unstable soil can clog itself, causing deviation of flow from the expected directions and pore pressure increases without necessarily being caused by filter malfunctioning. This may happen in the field in the case of heterogeneous soil masses and has not been simulated under laboratory conditions due to the complexity of dealing with heterogeneous materials.

The performance of geotextile filters in internally unstable soils has been evaluated by several researchers. Haliburton and Wood (1982) suggest that a percentage of open area (*POA*) of 23% of a woven geotextile would be required to attend the limit gradient ratio, *GR*, of 3 in gap-graded soils with 70% silt content. Fischer *et al.* (1994) report reductions between 68% and 94% in the geotextile permeability coefficient of the region comprising 25 mm of soil and geotextile in gradient ratio tests. Lee *et al.* (2002) present results of in-plane and cross-plane filtration tests on nonwoven geotextiles with reductions in geotextile permeability ranging from 27% to 67%, with a gradient ratio value of 1.5. Markiewicz *et al.* (2022) observed reductions in nonwoven geotextile filters permeability coefficient between 2.7 and 5.5 times in gradient ratio tests on geotextile-unstable soil systems. Khan *et al.* (2022) report

values of *GR* between 0.38 and 1.79, depending on the internally unstable soil gradation and that the dynamic loading applied to the soil-geotextile system enhanced the instability of specimens with high percentage of fines. For dynamic conditions, these authors also recommend the use of an indicative grain size d_{30} as an upper retention limit to stop washing out of coarse fraction of internally unstable soil through geotextiles. For internally unstable soils, a critical diameter of suffusion, d_c, is suggested as a lower retention limit to avoid blinding of soil-geotextile interfaces. The value of d_{85} of the soil in retention criteria for internally unstable soils does not guarantee the retention of particles below that value. If passage of the fine soil particles through the geotextile filter is allowed, the characteristic geotextile opening size should be greater than the value of d_c to avoid geotextile blinding (Khan *et al.* 2022). Instead of the commonly used piping limit of 2500 g/m^2 (Lafleur *et al.* 1989), Khan *et al.* (2022) suggest that the piping limit should be defined based on the gradation of the particles that constitute less than 30% (for uniformly graded soils) or 20% (for broadly graded soil) of the original soil gradation.

The discrete element method was employed by Tao (2018) to assess suffusion in soils and the formation of arches of smaller particles on voids between large particles was observed (Figure 13). Similar studies were carried out by Ryoo *et al.* (2022a, b). The intensity of suffusion will depend on the soil characteristics and the hydraulic gradient. It is interesting to note that Figure 13a is a numerical evidence of the potential of internally unstable soils to self-clog, as commented above, due to the retention of significant amounts of smaller particles in specific regions of the soil. Figure 13c shows impregnation of the geotextile filter in *DEM* simulations. The higher the hydraulic gradient the higher the intensity of suffusion. Regarding expected hydraulic gradients under field conditions, Giroud (1996), Moraci and Tondello (1996), and Moraci *et al.* (2010, 2022) present typical ranges of values in different geotechnical structures under one-way and reverse flow conditions.
Figure 13. Arching effect in internally unstable soils in DEM simulations: (a) Tao (2018), (b) Ryoo *et al.* (2022a), (c) Ryoo *et al.* (2022b).

Several studies can be found in the literature regarding the behaviour of geotextile filters in internally unstable soils showing a wide range of results. Table 2 summarises results from a rather large number of investigations present in the literature. Most soils have large values of coefficient of uniformity (C_u), coefficient of curvature (C_c) and some of them are gap-graded materials. The main results of the tests are expressed in Table 2 in terms of the ratio between the geotextile permeability coefficient (k_{GT}) after different types of filtration tests and that under virgin conditions (k_{GTo}), ratio between geotextile (k_{GT}) and soil coefficients of permeability (k_s) and/or the ratio between final (k_{sys}) and the initial (k_{sys-o}) permeability coefficients of the system (soil and geotextile). Some tests were carried out under confinement (vertical stresses up to 2000 kPa). Two studies tested undisturbed soil-geotextile systems in filtration tests and three tested geotextile specimens exhumed from field works. Values of k_{GT}/k_{GTo} in the range 0.000126 to 0.8 can be observed. Ratios k_{sys}/k_{sys-o}, which are also equal

to the ratios between final and initial flow rates, between 0.009 and greater than 1 can be noted as well as values of k_{GT}/k_s in the range 0.11 to 450. However, low values of k_{GT}/k_{GTo} or k_{sys}/k_{sys-o} do not necessarily mean drainage problems since the permeability coefficient of the partially clogged geotextile may still be considerably higher than that of the soil and the flow rate greater than that required.

Odabasi *et al.* (2022)	*NW*, *W*, M_A = 115–407 g/m², re-cycled materials, C_u = 2.63–72.1, σ_v = 0.	k_{sys}/k_{sys-o} = 0.06–19.2
		k_{sys}/k_s = 0.053–1
Santos & Palmeira (2023)	*NW*, *StS*, M_A = 200 g/m², C_u = 5.07–55.27, σ_v = 0 and 25 kPa.	k_{sys}/k_{sys-o} = 0.01–0.60

[*]C = clay, C_c = coefficient of curvature, C_u = soil coefficient of uniformity, ES = exhumed geotextile specimen, k_{GT} = geotextile permeability coefficient after test, k_{GTo} = permeability coefficient of the virgin geotextile, k_s = base soil permeability coefficient, k_{sys} = permeability coefficient of a soil-geotextile system, k_{sys-o} = initial k_{sys} value, M_A = mass per unit area, NW = nonwoven, PCA = permeability criterion ($k_{GT} > 10k_s$) attended, RS = residual soil, S = sands, St = silts, StS = silty sands, T = tailings, USS = undisturbed soil specimen, W = woven, σ_v = range of vertical stress on the soil-geotextile system.

The plotting of all the k_{sys}/k_{sys-o} data from the original references in Table 2 (Palmeira 2023) is shown in Figure 14 as a function of the nonwoven geotextile filtration opening size (FOS = O_{95}, O_{90} or AOS) normalised by d_{10} or d_{30} of the internally unstable cohesionless base soil. Scatter of the test results are due to different techniques employed to measure FOS, different hydraulic gradients and different equipment and experimental methodologies adopted in the tests. Figure 14a shows greater scatter in comparing k_{sys}/k_{sys-o} with FOS/d_{10}, whereas Figure 14b suggests values of k_{sys}/k_{sys-o} greater than 0.5 for values of FOS/d_{30} greater than 8. This may be because for large FOS/d_{30} values piping of the fine fraction of the base soil may prevail, whereas for smaller values of that ratio blinding and/or significant geotextile impregnation may cause greater k_{sys} reductions.
Figure 14.   *ksys/ksys-o* from filtration tests on internally unstable cohesionless soils-nonwoven geotextile systems. (a) *ksys/ksys-o vs. FOS/d₁₀*, (b) *ksys/ksys-o vs. FOS/d₃₀*.

A detailed analysis (Palmeira 2023) of the results in Table 2 also allows the calculation of what would be the appropriate flow rate reduction factor (RF_Q) for the soil-geotextile system. Figure 15 shows the frequency of RF_Q values for the tests in Table 2. It can be noted that in 42.9% of the cases the value of RF_Q should fall within the range 1 to 2, in 17.0% of the cases the appropriate reduction factor should be greater than 10 and in 2.7% of the cases between 100 and 200. So, the results in Table 2 and Figure 14 show that, in the absence of proper test results, a significantly higher RF_Q value should be adopted in preliminary analyses of problems involving internally unstable soils in comparison with values commonly used for internally stable soils.

It should be pointed out that the coefficient of permeability of an internally unstable soil is likely to vary during a filtration test. If this value is reduced during the test, a low ratio of
Figure 15.   Frequency distribution of required flow rate reduction factor.

k_{sys}/k_{sys-o} does not necessarily mean significant geotextile clogging or blinding. This can be exemplified considering the situation shown in Figure 16 in a filtration test, where the system is divided into two soil regions (A and B) after water flow stabilisation, where region B comprises the geotextile layer plus some thickness of soil above it where the fine soil particles dragged by the seepage forces have accumulated or from where they have been removed. From basic soil mechanics, the equivalent permeability coefficient of the system in the vertical direction is

$$\frac{k_{sys}}{k_{so}} = \frac{1 + L_s/t_c}{L_s/t_c + \frac{\alpha_s}{\alpha_c}} \alpha_s \qquad (4)$$

where k_{sys} is the equivalent permeability coefficient of the system, k_{so} is the soil permeability coefficient at the start of the test, L_s is the thickness of soil above region B, t_c is the thickness of region B (soil + geotextile), α_s is a parameter to account for the variation of soil permeability of region A during the test ($\alpha_s = k_{sL}/k_{so}$, where k_{sL} is the final soil permeability coefficient of region A) and α_c is a parameter to account for the variation of permeability of
Figure 16.   Schematic simplified condition in a filtration test.

region B ($\alpha_c = k_{st}/k_{so}$, where k_{st} is the final permeability coefficient of region B). If there is no change in the permeability coefficients (stable soils) during the test, $\alpha_c = \alpha_s = 1$. In a filtration test, a value of k_{sys}/k_{so} greater than one (α_c and/or $\alpha_s > 1$) is an indication of piping, rather than clogging. It can be assumed that in most test configurations ($L_s \gg t_{GT}$) the initial permeability coefficient of the system (k_{sys-o}) should be equal to k_{so}. Then, if L_s/t_c is large, the soil coefficient of permeability has a higher influence on the final value of k_{sys}. In addition, the variation of soil permeability coefficient due to suffusion is likely to be non-uniform along the specimen height (Figure 13a).

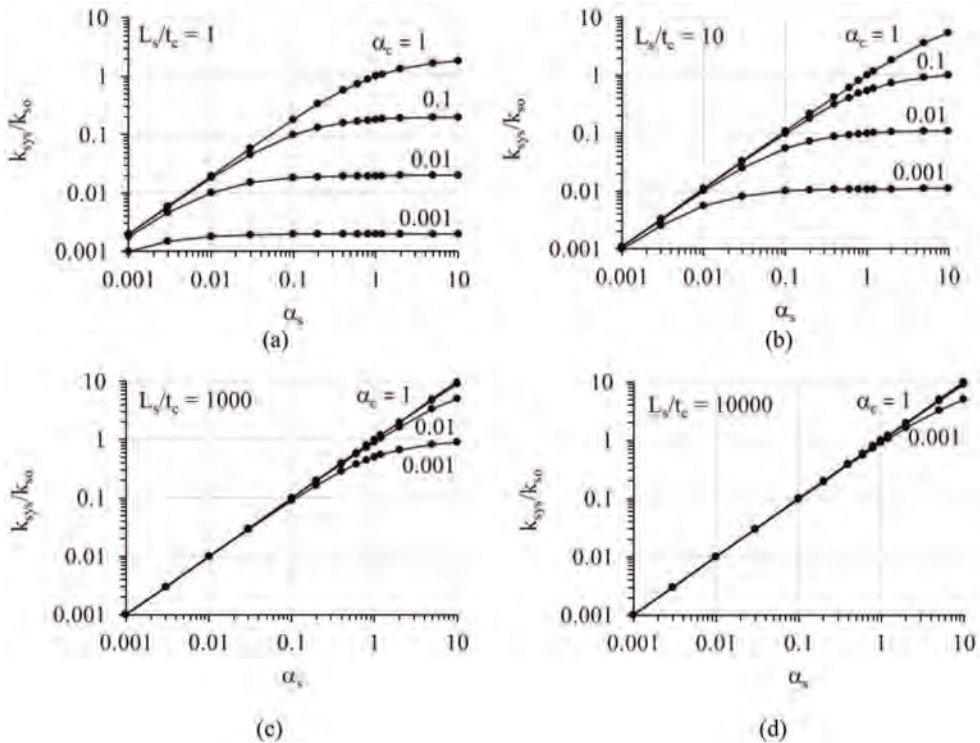
A wide variety of scenarios for the system in Figure 16 can be considered, depending on the values of L_s/t_c, α_s and α_c adopted in equation 4. It should be noted that α_s can be greater than one if the erosion of fine particles along the thickness L_s increases the permeability coefficient of that region. In the present case, α_c will be considered smaller than one, since it is assumed that the finer soil particles are retained by the geotextile. Under such conditions, Figure 17 shows the variation of k_{sys}/k_{so} with α_s for different values of L_s/t_c and α_c, assuming that at the start of the test the soil specimen is homogeneous, with a permeability coefficient equal to k_{so}. It can be observed that for $L_s/t_c = 1$, one order of magnitude reduction ($\alpha_s = \alpha_c = 0.1$) in the average permeability coefficients of the soil in regions A and B during the test, can yield to a k_{sys}/k_{so} (or k_{sys}/k_{sys-o}) value of 0.1 (Figure 17a), which is in the range of the lower values presented in Table 2. It can be argued that if the permeability in region B is reduced, the permeability in region A should increase. This is not necessarily true since localized blockings of soil pores in region A (Figure 13a) by the moving particles may still reduce the permeability coefficient in that region.


Figure 17.   Possible variations of k_{sys} during a filtration test on an internally unstable soil: (a) $L_s/t_c = 1$, (b) $L_s/t_c = 10$, (c) $L_s/t_c = 1000$, (d) $L_s/t_c = 10000$.

For larger ratios of L_s/t_c (Figure 17c and d) even large reductions in the permeability coefficient of region B ($\alpha_c = 0.001$, for instance) would result in k_{sys}/k_{so} close to 1 and the reduction in k_{sys} would be basically equal to the reduction in the soil permeability above the partially clogged zone. This type of behaviour will take place when the thickness of the soil mass affected by clogging is smaller compared to the thickness of the rest of the soil specimen. The results of filtration tests on internally unstable soils will depend on the intensity of suffusion that takes place during testing and how it influences the permeability coefficient along the soil thickness. Thus, under these conditions, thicker soil specimens should be used in this type of test (Giroud 1996) with the measurement of the permeability coefficient of the soil in different regions along the specimen height. The same comments apply to gradient ratio tests on unstable soils because the hydraulic gradient away from the geotextile specimen may also be affected by suffusion, influencing the value of GR obtained. Palmeira & Matheus (2000) recommend due care when deciding on the acceptance or not of a geotextile filter based only on the value of GR from tests on internally unstable soils. In such cases, the flow rate variation with time and the requirements from the project itself (minimum required flow rate, for instance) must also be considered for a final decision. In this sense, the advantage of working with the variation of k_{sys} with time is that it may anticipate the expected flow rate reduction. Long-term filtration tests are highly recommended under such conditions (Palmeira & Matheus 2000, Cazzuffi et al. 2015). Despite some simplifications, equation 4 shows that a very severe reduction in the permeability of the geotextile (or of a thin region adjacent to it) is necessary for a serious compromise of flow rate in typical field conditions.

Based on the comments above, it is clear that internally unstable soils are problematic soils either for granular and synthetic filters. Hence, it is of utmost importance to identify whether a soil is internally unstable or not beforehand. Different approaches for such evaluation are available (Kezdi 1979, de Graauw et al. 1984, Kenney & Lau 1985, Bhatia & Huang 1995, Indraratna et al. 2008, Moraci et al. 2012, for instance). Moraci et al. (2022) confirmed the greater reliability of the semi-empirical method proposed by Kenney and Lau (1985) in comparison with other criteria in assessing soil internal instability. Based on tests on 57 cohesionless soils (25 gap-graded and 32 broadly graded), Li & Fannin (2008) found that Kezdi (1979) criterion predicted better the internal instability or stability of the soil for values of the percentage of mass passing (F, as defined by Kenney and Lau 1985) greater than 15%, whereas Kenney and Lau (1985) predicted better for values of F smaller than 15%. Khan et al. (2022) also observed good predictions of soil internal instability by Kenney and Lau's and Kezdi's methods.

3.2 *Filters subjected to biological clogging mechanisms*

Geotextile filters can be used in environments which favour biological clogging. These are the cases of applications of such filters in landfills, for instance. Under such conditions, severe filter clogging can occur with repercussions on landfill slope stability and greater pollutant potential in case of failure of the underlying lining system. Granular filters and drainage systems can also clog due to bacteria activity (Fleming et al., 1999, Rowe et al. 2000a, McIsaac & Rowe 2007). Figure 18 shows images of landfill stone drainage layers, where in one of the cases (Figure 18a) that layer clogged after only 3 years in contact with leachate (Fleming et al., 1999). Rowe et al. (2000a) report reductions of 6 orders of magnitude in the hydraulic conductivity of 15 mm glass beads after 320 days of column tests with leachate as permeant.

The formation of bacteria films in the geotextile voids will certainly reduce its permeability. Figure 19 shows microscopic images of bacteria films in a nonwoven geotextile and the reduction in its permeability with time as the number of bacteria increases (Remigio 2006, Palmeira et al., 2008). In addition, the presence of solids in suspension in the leachate can further increase the clogging potential due to geotextile blinding or impregnation.

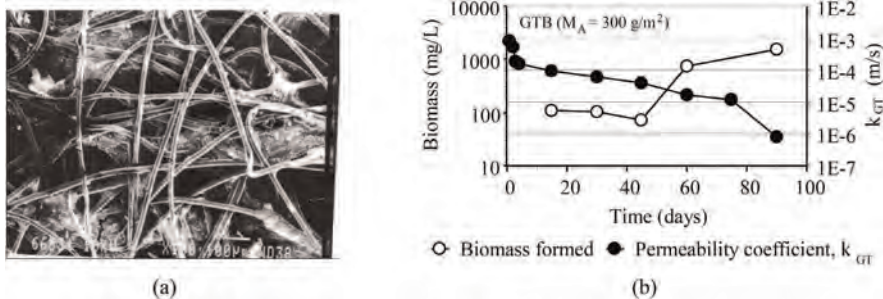
Mlynarek and Rollin (1995) found that for the filtration of wastewater, the intensity of the growth of biofilm depended on the geotextile opening size, with 17% reduction in the hydraulic capacity of a more open geotextile after 6 months of service under anaerobic conditions and 60% reduction under aerobic conditions.
Figure 18.   Examples of clogging of stone drainage blankets. (a) After 3 years in contact with leachate (Fleming *et al.* 1999), (b) Sever clogging of a gravel drainage layer (Fleming & Rowe 2004).


Figure 19.   Effects of bacteria film formation in a nonwoven geotextile after 90 days of leachate flow. (a) Bacteria films in the geotextile (Remigio 2006), (b) Mass of bacteria and geotextile permeability *vs.* time (Palmeira *et al.* 2008).

Laboratory column tests by different researchers have observed reductions in the geotextile coefficient of permeability to leachate between 10% and 100% (Koerner & Koerner 1991, Fourie *et al.* 1994, Kossendey *et al.* 1996, Colmanetti & Palmeira 2002, Silva *et al.* 2002, Goycoechea *et al.* 2020), being common reductions between 3 and 5 orders of magnitude (Cancelli & Cazzuffi 1987, Cazzuffi and Cossu 1993, Koerner & Koerner 1995, Palmeira *et al.* 2008, Liu & Liu 2020). Severe reductions in geotextile permeability can take place in a few hours under laboratory conditions when the leachate contains large amounts of solids in suspension (Cancelli & Cazzuffi 1987, Silva *et al.* 2002). However, large reductions in the geotextile permeability (due to its small thickness) may not necessarily compromise the drainage system performance (see section 3.1). Corcoran & Bhatia (1996) concluded that the reduction of one order of magnitude in the permittivity of a nonwoven geotextile filter of a drainage trench in Fresh Kills landfill should not affect the capacity of the filter to perform its function. Koerner & Koerner (1995) state that flow rate in leachate collection systems should not be altered until the filter coefficient of permeability becomes smaller than approximately 1×10^{-7} cm/s, which represents typically a 6 orders of magnitude reduction in typical values of permeability coefficients of nonwoven, needle-punched, geotextiles. Rowe *et al.* (2000a) assumed failure of a granular medium due to clogging when the reduction in its hydraulic conductivity was about 7–8 orders of magnitude for the

prediction of the time for clogging of a landfill leachate collection system. Based on field observations, drainage pipes wrapped (or socked) with a nonwoven geotextile showed intense clogging and should not be used in leachate collection systems (Koerner & Koerner, 1995). Better filter performance of nonwoven geotextiles than of woven geotextiles filters in drainage systems subjected to leachate flow have been reported (Fourie *et al.* 1994, Fleming and Rowe 2004, McIsaac & Rowe 2006, Goycoechea *et al.* 2020). Cancelli & Cazzuffi (1987) observed larger permeability reductions in heat bonded geotextiles than in nonwoven needle-punched geotextiles.

Biological clogging of geotextile filters is a complex mechanism and some conflicting results on its intensity and consequences can be found in the literature, where mild (Ionescu *et al.* 1982, Mlynarek and Rollin 1995) or severe (Koerner and Koerner 1991, 1995, Cazzuffi and Cossu 1993, Palmeira *et al.* 2008, Liu and Liu 2020, Silva and Lodi 2020) clogging was observed, depending on the type of filter and conditions to which the filter was subjected. Because severe clogging of the drainage systems of a landfill is very common, it has been argued whether a filter layer should actually be used between the waste mass and the drainage layer (usually coarse granular material). Giroud (1996) suggests that sand filters and geotextile filters should not be used in municipal solid waste landfills and wastewater treatment sludge landfills. However, significant intrusion of fines in the drainage layer at the waste-gravel interface has been observed when there is no filter (Figure 18) and that the presence of suitable filter between the waste and the drainage layer improves the performance of the drainage layer against clogging (Carey *et al.* 2000, Fleming & Rowe 2004, McIsaac & Rowe 2006). McIsaac & Rowe (2006) point out that the presence of the geotextile filter may prevent most of the fines from entering the underlying gravel layer. These authors also indicate that the use of a nonwoven geotextile inside the gravel can be a good approach since even if this layer is severely clogged the top gravel layer above the geotextile will allow the flow of leachate, avoiding leachate mounding. A drainage layer of a landfill where this solution was adopted was working very effectively for 11 years (McIsaac & Rowe 2006, Rowe *et al.* 2000b).

The development of encrustations can clog even an open material such as gravel, forming a block that has the consistency of a lean concrete (Brune *et al.* 1991, Turk 1995). Brune *et al.* (1991) observed very few mineral particles carried by the leachate in the incrustations, which were essentially composed of bacteria, their secretions and crusts of inorganic compounds. They also point out that there is much less biological growth in a landfill in its methane production phase (old waste, neutral pH) than in the early stages of landfill operation (fresh waste, acidic conditions). In addition, methane and sulphate-reducing bacteria increase the leachate pH, yielding to the precipitation of carbonates and sulphides from metal ions dissolved in the leachate (Brune *et al.* 1991, Rowe *et al.* 2000a). Biofilm formation and $CaCO_3$ precipitation were the primary clogging mechanisms observed by Liu & Liu (2020) in laboratory column tests on granular and geotextile filters subjected to leachate flow.

Management of the waste disposal processes and of the drainage systems in municipal solid waste landfills can inhibit or favour filter clogging. For instance, detrimental practices to the filter leachate collection system are the presence of a greater amount of organic matter, disposal of dewatered sludge and incinerated ash, which foster the generation of $CaCO_3$ (Liu and Liu 2020), and the disposal of construction debris, which favours an increase in the supply of calcium carbonate and iron, major components of encrustations in filters (Brune *et al.* 1991). Leachate recycling worsens the situation regarding filter clogging (Koerner & Koerner 1995). On the other hand, Legge (2004) reports on experiences gained in remediating biological clogging of geotextile filters by inducing sudden changes to the environment within which the organic material develops, such as the use of a "p-trap" on the drain outlet. This can suddenly change the conditions in the blanket drain from aerobic to anaerobic on a regular basis to control bacterial growth as required, with later removal of the "p-trap" from the outlet drainage pipe. Pretreatment by aeration of the waste for approximately 6 months prior to landfilling has been proposed to eliminate the acidic phase and hence the development of encrustations (Giroud 1996). Kossendey *et al.* (1996) also

recommend the pre-treatment of organic waste to keep the leachate carbon content as low as possible to reduce the potential of geotextile biological clogging.

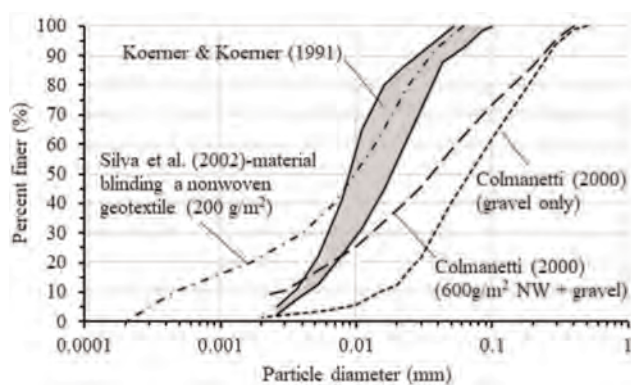
Leachate collection systems are prone to clogging due to solid particles retention, bacteria growth, iron oxide precipitation and salt precipitation. Iron oxide precipitation may be caused by the action of bacteria such as *Gallionella*, *Sphaerotilus*, *Leptothix*, *Thiobacillus ferooxydans* and *Sphaerotilus* (Mlynarek and Rollin 1995, Rollin and Lombard 1988). Crystals of salts can adhere to the geotextile fibres as water evaporates, eventually blocking the filter voids if the drying period is long enough. Studies by Koerner and Koerner (1991), Colmanetti (2000) and Colmanetti and Palmeira (2002) have shown that there is a great potential for filter clogging due to the presence of solids in suspension in the leachate. According to Koerner & Koerner (1995), although subjective, leachates with *TSS* (Total Suspended Solids) $\geq$ 2500 mg/l and/or $BOD_5 \geq$ 2500 mg/l should be viewed as harsh and of special concern. Figure 20 shows grain size distribution curves of solids in suspension in the leachate in tests performed by Koerner and Koerner (1991) and Colmanetti (2000). Results for the material blinding a nonwoven geotextile filter in large column tests performed by Silva *et al.* (2002) are also shown in that figure. It should be pointed out that a young leachate (160 days) was used in the tests reported by Colmanetti (2000), whereas in the case of Koerner and Koerner (1991) older leachates were tested. Most of the data from Koerner and Koerner (1991) fall in the silt size range (as well as the data from Silva *et al.* 2002, to some extent), whereas coarser material was observed by Colmanetti (2000). It should be noticed that in some of the cases shown in Figure 20, the leachate specimens tested by Colmanetti (2000) were collected after the effluent had passed through a 45 mm thick uniform gravel drainage layer (d_{50} = 12.5 mm, possibly very low filtration capacity) or by a drainage system consisting of a nonwoven geotextile (M_A = 600 g/m^2) overlying a 55 mm thick layer of the same gravel. Compared to the case where the leachate only passed through the gravel layer, it can be noted that the presence of the geotextile filter significantly reduced the diameters of the particles in suspension in the effluent. This type of diameter reduction in solids in suspension was also observed in the effluent from large field experimental domestic waste cells, as reported by Junqueira *et al.* (2006). The results in Figure 20 show a wide range of possible diameters and types of solids (degradable and nondegradable) in suspension in the leachate, depending on its age. Hence, a filter will have to face different conditions regarding clogging potential due to solids in suspension throughout its service life.


Figure 20.   Particle size distributions of solids in suspension in leachates.

The addition of antimicrobial agent during the manufacturing process of the geotextile has been suggested in order to reduce or avoid filter bioclogging (Fourie *et al.* 1994) aiming at inhibiting the attachment of bacteria to the fibre surface as well as reducing the adhesive

strength of the bioslime. However, Koerner & Koerner (1991) report that the remnants due to the use of biocide treated geotextiles in laboratory column tests were as troublesome as the viable bacteria in favouring subsequent geotextile clogging. Some studies have indicated that biological growth may be easily removed from the geotextile fibre surface (Koerner & Koerner 1991, Silva *et al.* 2002, Palmeira *et al.* 2008). However, that may not be the case for physical clogging due to the entrapment of non-degradable particles and incrustations. Colmanetti & Palmeira (2002) report physical clogging, rather than chemical or biological, as the clogging mechanism prevailing in large laboratory experiments on drainage systems for domestic wastes. The presence of fine-grained soils adjacent to leachate collection trenches can also partially clog the filter due to particles intrusion (Corcoran & Bhatia 1996).

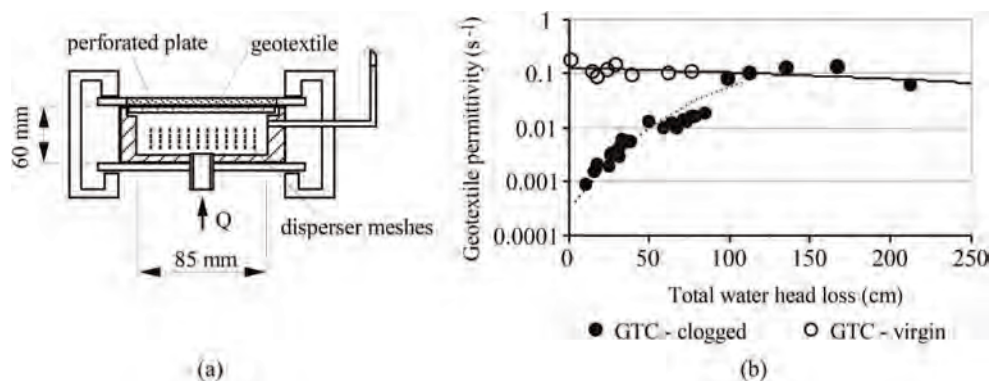
Techniques to unclog geotextiles have also been investigated by different researchers, namely backflush or reverse flow with different substances, with conflicting results. According to Koerner & Koerner (1991), backflush in column tests on geotextiles showed best performance when using water (50% improvement) followed by leachate (32% improvement) and by nitrogen gas (29% improvement). Vacuum (254 mmHg) extraction was the least effective (6% improvement) remediation measure, and only nominally improved flow rates. Silva *et al.* (2002) report that backflushing in large field column tests under a total water head of 0.18 m partially restored geotextile drainage capacity, but severe clogging followed after a few hours of leachate flow because the main clogging mechanism in this case was geotextile blinding by suspended solids in the leachate. Goycoechea *et al.* (2020) observed that filter unclogging with reverse flow in column tests was also unsuccessful because the flow rate increased little even when the applied hydraulic gradient was 5 times the initial value. Figure 21 shows results of geotextile permittivity versus total hydraulic head in column tests on a previously biologically clogged nonwoven needle-punched geotextile ($M_A = 600$ g/m^2) (Palmeira *et al.* 2008). In this case, it can be noted that just a total head loss approximately 1 m high, equivalent to a 1 m high mounding of leachate, was sufficient to wash out the bacteria films from the geotextile and restore the same trend of permittivity variation with head loss of the virgin geotextile. However, these tests were carried out on specimens where clogging was caused basically by the presence of biofilms in the geotextile voids (Figure 19a). Had non degradable particles or incrustations been present in the geotextile voids, certainly higher total head losses would be required to increase the drainage capacity of the geotextile. Thus, the efficiency of backflushing under low water pressures depends on the intensity and type of clogging mechanism developed. Under field conditions, special engineering facilities would be required to allow the use of the backflush technique, which would also face the difficulties associated with more complex clogging mechanisms and the typical dimensions of actual landfill cells.


Figure 21. Geotextile permittivity vs. total water head loss in backflush tests on a clogged geotextile specimen: (a) Apparatus, (b) Geotextile permittivity *vs.* total water head loss (Palmeira *et al.*, 2008).

Another issue that may be raised is the possible influence of the contact between leachate and geotextile filter on its mechanical properties. Researchers have reported no influence of the contact with leachate on the geotextile tensile properties (Ionescu *et al.* 1982, Cazzuffi & Cossu 1993, Corcoran & Bhatia 1996, Koerner & Koerner 1991), although Koerner & Koerner (1991) observed some strength reduction in a heat bonded geotextile due to weakening of thermally fused fibre junctions after 36 months duration column tests. Koerner and Koerner (1991) observed no influence of the polymer from which the geotextile was manufactured on its biological clogging behaviour.

Field and laboratory experiences seem to suggest that a more open product should be specified when using a geotextile filter in an environment that favours biological clogging, (Koerner & Koerner 1991, Cazzuffi & Cossu 1993, Mlynarek & Rollin 1995, Giroud 1996, Rollin 1996). Geotextile and/or soil filters to be used in leachate collection systems must be sufficiently open to pass the sediments, or particulates, along with micro-organisms contained in the leachate. In the case of woven geotextiles, Koerner & Koerner (1991) observed severe clogging in woven geotextiles with *POA* equal to 4% and limited clogging in a woven geotextile with *POA* equal to 10%. Giroud (1996) recommends that, if used, monofilament woven filters should have a *FOS* of 0.5 mm and $POA > 15\%$ (preferably, $> 30\%$) and the drainage medium should consist of an open graded material (gravel, minimum particle size of 10 mm, not limestone, and possibly geonet in slopes).

3.3 *Filters subjected to chemical and biochemical clogging mechanisms*

Chemical and biochemical clogging of filters are very complex and difficult mechanisms to simulate in the laboratory. A countless number of different scenarios are possible, depending on the chemicals and geotextiles characteristics and on in-service filter conditions. Thus, the results of laboratory research are still limited and focused on specific situations. Despite the complexity of the problem, important contributions can be found in the literature regarding chemical and biochemical clogging of geotextile filters under laboratory and field conditions.

High alkalinity ground water will precipitate calcium and magnesium (Koerner & Koerner 2005) and conditions such as those found in tailings dams or in natural soils may favour the precipitation of different elements. Chemical clogging of geotextiles in iron tailings can be influenced by multiple factors, such as concentration of ferrous iron ions, pH, hydraulic conditions, temperature, microorganisms, redox potential and oxygen partial pressure, and reductions in flow rates in column tests of up to 73% have been reported (Liu *et al.* 2021a). Woo (2005) reports calcium oxide (a major component of cement), dissolved from cement grouts used for ground reinforcement during tunnel construction, as being one of the main clogging materials in tunnel drainage systems, in addition to calcium carbonate and red sediments containing iron and soil particles (Kim *et al.* 2020a). According to Carey *et al.* (2000) the precipitation of chemicals, sulphates and iron oxides which can commonly cause clogging is much less prevalent under anaerobic and reduced conditions.

Veylon *et al.* (2016) present a thorough investigation on the performance of geotextile filters in trenches after 18 years in service. The formation of a calcite crust on the downstream face of the geotextile envelopes and of the reference drainage system (gravel without filter) (Figure 22) was the primary mechanism observed underlying the reduction in filter performance. The results of field instrumentation in the trenches revealed that the reference trench and the trench with the woven geotextile showed severe reductions in flow rate (93% for the reference trench and 94% for the trench with the woven geotextile filter). The measurements of flow rate in a trench with a nonwoven geotextile were compromised due to possible leakage of fluid to neighbouring trenches. The clogging rate, defined as a function of the reduction of flow capacity with time, varied from 16 to 21% for the trenches with geotextile filter and 73% for the reference trench. It was also observed that the presence of the geotextile filters reduced clogging of the slotted drainage pipes of the trenches. The authors

concluded that after 18 years in service the geotextiles performed well in terms of mechanical resistance and filtration performance.
Figure 22. Calcified interfaces between gravel and downstream calcite crust: (a) Reference trench (no filter), (b) Nonwoven geotextile filter, (c) Woven geotextile filter (modified from Veylon *et al.* 2016).

The clogging mechanism of geotextile filter envelopes of perforated corrugated pipes (socked pipes), 3 to 15 years old, in an arid region, was investigated by Guo *et al.* (2020). Three major slightly soluble salts (calcium carbonate, calcium sulphate and magnesium carbonate) are present in arid and semi-arid soils. Reductions in geotextile permeability of up to 99.5% were observed, although the permeability coefficients of the partially clogged geotextiles were still close or greater than those of the neighbouring soils ($k_{GT}/k_{soil} = 0.85$, or between 8.8 and 42.7). Silicon dioxide (SiO_2) and calcium carbonate ($CaCO_3$) were identified as common clogging substances in arid and semi-arid regions.

Increase in precipitation of salt crystals with increasing temperature and flow rate was observed by Guo *et al.* (2021) in immersion and permeability tests on geotextiles (Figure 23). The authors observed that the structure of the geotextiles tested did not promote or inhibit the chemical precipitation process under static (no flow) conditions. Guo *et al.* (2022) present a coupled model of chemical clogging and permeability coefficient of a geotextile filter considering the processes of geotextile fibre diameter increase after crystal precipitation and accumulation of crystal precipitates on the surface of the geotextile fibres.
Figure 23. Salt crystals attached to the fibres of a nonwoven geotextile (Guo *et al.* 2021).

The use of construction and demolition residues in geotechnical construction works has markedly increased in the last decades in response to environmental protection requirements and better sustainable construction practices, besides the significant volume that this type less harmful or inert residues can occupy in landfills. Therefore, researchers have investigated the clogging potential of geotextile filters in contact with such materials. The deposition of tufa precipitate (Figure 24) from the effluent of recycled concrete aggregate (*RCA*) in the voids of nonwoven geotextiles was investigated by Abbaspour & Tanyu (2021). The two major minerals

were identified as calcium carbonate ($CaCO_3$, mainly calcite, more dominant at the top face of geotextile specimens subjected to column tests) and calcium sulphate ($CaSO_4.2H_2O$, mainly gypsum, more frequently encountered on the bottom surface of the specimens). The authors observed a good performance of the filter but pointed out that a loss of filtration capacity of the system of the order of 50% to 80% after 25 years should be expected, which would require a reduction factor to account for chemical clogging between 2 to 3.5. Bilgen *et al.* (2020) also investigated the performance of geotextile filters in contact with *RCA* by means of column tests. In this case woven, monofilament, geotextiles were tested and average reductions in flow rates between 19 and 81%, reductions of *POA* between 37% and 65% and reductions in O_{95} between 25% and 51% were observed. Nevertheless, the authors report post-test geotextile permeability coefficients still between 5 and 200 times that of typical clean uniform sand layers. Britto (2020) reports no significant variations in the coefficient of permeability of systems consisting of sand and rubble dust from recycled construction and demolition wastes and nonwoven geotextiles in permeability tests under confinement. No significant changes in effluent rate were observed by Lee & Bourdeau (2006) in 2 weeks duration filtration tests on systems consisting of a nonwoven geotextile filter underneath rubbleized concrete aggregate agglomerated with asphalt emulsion and polymer modified prime chemicals exhumed from an old concrete pavement. Odabasi *et al.* (2022) also found satisfactory performance of geotextile-recycled materials combinations in long-term filtration tests. In this case, woven and nonwoven geotextiles were tested in contact with *RCA*, recycled asphalt pavement, foundry sand and recycled asphalt shingle. In 82% of the tests the performance of the geotextile filter was satisfactory. The authors discuss the limitations of current filter criteria to recycled material-geotextile systems. Thus, despite the still limited amount of data, the results so far seem to indicate satisfactory performance of geotextile filters in contact with construction wastes commonly used in geotechnical works.

The formation of ochre is a biochemical clogging process and can severely compromise the performance of filters, being common in lateritic soils of tropical regions. In Brazil, the first observation of this type of clogging mechanism in granular drainage systems occurred in the Rio Grande Dam, built between 1926 and 1937, close to the city of São Paulo (Kanji *et al.* 1981). Results of variable head permeability tests, 1.5-year duration, showed the formation of ochre and a 28-fold reduction in the permeability coefficient of the granular filter material over a period of 550 days. Other cases of clogging of granular filters caused by ochre formation can be found elsewhere (Terzaghi and Leps 1958, Spencer *et al.* 1963, Petersen 1966, Grass 1969, Infanti and Kanji 1974, Xu *et al.* 1976, Ferreira 1978, Guerra 1980, Lindquist and Bosegno 1981, Nogueira Junior 1988). Obviously, ochre formation can also clog geotextile filters, as shown in Figure 25 (Palmeira & Fannin 2002) and will occur only under suitable electrochemical conditions found at nonaerated-aerated soil-filter interfaces (Mendonca and Ehrlich 2006).
Figure 24.   Microscopic image of tufa precipitates on geotextile fibres (Abbaspour & Tanyu 2021).

The presence of a noticeable ochre-brown deposit on the geotextile as well as on the enclosed stone aggregate of the underdrainage system of two tailings dams in South Africa is reported by Scheurenberg (1982). The clogging mechanism was attributed to the precipitation of ferric hydroxides, such as goethite, and oxidation of ferrous compounds in solution at pH smaller than about 5. The author states that similar clogging mechanism would have occurred had graded sand drains, without a geotextile filter, been used.
Figure 25.   Clogging of a geotextile filter caused by ochre formation.

Puig *et al.* (1986) highlight the importance of the identification of the parent rock, presence and type of vegetation, pedologic analysis and chemical analysis of the water to assess the potential of ferric clogging of geotextile filters. Based on the case-histories analysed, the authors state that ferric clogging risk is extremely low (but not eliminated, depending on the influence of organic matter) in calcareous areas where water is free from any ferrous iron. On the other hand, non-calcareous areas rich in ferrous iron and organic matter favour the development of heterotrophic bacteria *Sphaerotilus* which may cause ferric clogging.

The influence of ochre formation on the performance of a geotextile filter will depend on the clogging intensity. Ochre formation in a geotextile filter envelope of a drainage layer had no influence on the hydraulic conductivity of the drainage system of Torcy-Vieux dam, in France (Testemale *et al.* 1999). In this case, it was observed that the partial clogging was caused by clay particles associated to some level of ochre formation, particularly up to a depth of 1.2 mm in the geotextile layer.

Fibre roughness, specific surface, distance between fibres, geotextile thickness and flow rate are important factors in iron ochre biofilm formation (Mendonca 2000, Mendonca *et al.* 2003). Mendonca *et al.* (2003) comment that more severe clogging of woven geotextiles than of nonwoven geotextiles should be expected due to the discrete localised openings of the former. Metcalf *et al.* (1995) observed more severe reductions in geotextile permeability caused by iron staining in woven slit-film (up to 95% reduction) and heat-bonded nonwoven (up to 85.5%) than in needle-punched nonwoven geotextiles (up to 76% reduction) separator geotextiles in permanent highways. Iron-oxide precipitates were also observed in exhumed geotextile (nonwoven, heat bonded and slit-film geotextiles) separators after 5 years in service in highways with a long history of poor pavement performance (Black and Holtz 1999). The observations suggested that precipitation was probably higher in slit-film geotextiles (14.5% to 95% permeability coefficient reduction) and that heat-bonded nonwovens were more susceptible to clogging ($\cong$ 85% permeability reduction) than needle-punched nonwoven geotextiles (33.7% to 76% permeability reduction). Iron-oxide precipitates on the woven geotextiles seemed to be deposited on the tapes, whereas they tended to be distributed throughout the structure of the nonwoven geotextiles. According to Koerner and Koerner (2015), a woven slit-film geotextile should not be used for critical filtration applications because of poor control over its opening sizes due to nonbonding of its intersecting fibres.

Mlynarek *et al.* (1990) observed ochre formation on only 5% of the geotextile surface of the upstream side of a geotextile filter in specimens exhumed from a small dam in Poland after 8 years in service. Roots of plants crossing the full thickness of the geotextile in four points were also observed. Permeability tests on the exhumed specimens revealed reductions of geotextile permeability between 11% (drainage system downstream face) and 50% (upstream face), but still with a geotextile permeability coefficient 10 times higher than that of the base soil.

Significant clogging (7.5 to 45.3-fold reductions in geotextile permeability) due to ochre formation (Figure 26) was observed in sand and geotextile filters by Mendonca and Ehrlich (2006) in long-term (up to 1,573 hours) column tests on soil-geotextile (or sand) filter-gravel systems. The significant clogging mechanisms observed (more intense in a light nonwoven tested) did not cause relevant reductions in the hydraulic conductivity of the soil-filter system. Reductions of up to 95.5% in the coefficient of permeability of nonwoven geotextile filters due to ochre formation have also been observed in bank protection works in canals, rivers and coast structures (van Zanten and Thabet 1982, Abromeit 2002). According to van Zanten and Thabet (1982), clogging was observed in most of the sites investigated in a research study in Dutch canals, river and coast structures, but the geotextile permeability remained larger than that of the subsoil.
Figure 26.   Examples of ochre formation in geotextile filters in column tests (Mendonca 2000): (a) Light nonwoven geotextile (200X magnification), (b) Woven geotextile (80X magnification).

Submersion of the filter has been commonly adopted to avoid conditions favouring ochre formation, for both granular and synthetic filters. The effect of submersion on ochre formation in a woven geotextile was investigated by Correia *et al.* (2017). The authors point out that despite submersion, dissolved oxygen can cause ochre formation due to diffusion, but even a small depth of submersion can reduce significantly ochre biofilm formation. In general, ochre was found deposited on the surface of the geotextile filaments (Figure 27, Correia 2014) and that the geotextile pores were not completely blocked. Results of tests performed by Correia *et al.* (2017) suggest that there is a maximum submersion depth threshold of the geotextile beyond which the influence of submersion becomes negligible, since the results of tests with geotextile submersion depths of 20 mm and 45 mm were equivalent.
Figure 27.   Image of ochre formation on the woven geotextile surface (Correia 2014).

Correia *et al.* (2022) performed column tests on a woven geotextile under three different submersion conditions and observed a marked reduction in Fe(II) and Fe(III) retention in the geotextile after percolation with D-glucose. The flow of D-glucose stimulated a pre-existing population of iron-reducing bacteria, which reduced Fe(III) to Fe(II) in anoxic pockets within the ochre biofilm, causing some loss of the ochre structural integrity.

The use of water jet to remove ochre formation in deep horizontal drains has been commonly used in periodical maintenance works. Ehrlich *et al.* (2021) report the influence of clogging of geotextile filters of deep horizontal drains on the movement of a talus-colluvium deposit in the state of Rio de Janeiro, Brazil. Maintenance works of the drains consisted of applying water jet to the drains once a year, before the raining season (Ehrlich 2023). However, for three years in a row maintenance was not done, causing dehydration of the ochre, making it impossible to remove by water jetting. This caused the movements of the slope to increase, requiring the installation of new deep horizontal drains.

3.4 *Mining tailings-geotextile filter interaction*

Geotextile filters have been extensively used in mining applications. The good performance of the filter in such applications is of utmost importance for the stability of mining structures such as tailings dams. This section discusses some aspects of applications and performance of geotextile filters in such works.

One of the complicating factors for filter performance in tailings dams is how the tailings are disposed. If the tailings or base soil adjacent to the filter is placed hydraulically, the mobility of its fine fraction may cause impregnation or blinding of the geotextile, which may compromise its performance (Legge 2004, Palmeira *et al.* 2010). In case of tailings disposed far from the filter, only fine particles and particles in suspension will reach the filter (larger particles will sediment along the way). Microscopic images of geotextile specimens exhumed from two tailings dams support this statement, as shown in Figure 28, where values of impregnation level (λ) ranging from 2 to 10 were obtained for geotextile specimens exhumed from tailings dams, as reported by Palmeira *et al.* (2010). These authors suggest that a testing technique simulating more accurately the type of deposition of the tailings in the field, such as the use of flumes, may provide more accurate information on filter performance than conventional filtration tests.
Figure 28. Intense impregnation of geotextile filters by fine tailings (Beirigo 2005).

Wind blow of the fine fraction of tailings can also cause impregnation of filters and drains. In such instances, Legge (2004) recommends the use of a sacrificial layer of geotextile (typically a light nonwoven product) as cover to the drain during construction to be removed immediately before the placement of tailings adjacent to the permanent filter. As commented earlier in this paper, the presence of the entrapped soil particles in the geotextile voids will

reduce its compressibility (Palmeira *et al.* 1996, Palmeira & Gardoni 2000). However, the partially clogged geotextile can still undergo significant compression, depending on the degree of impregnation and stress level. In addition, the presence of the particles in the geotextile voids reduces pore dimensions through which additional base soil particles may pipe (Palmeira & Trejos-Galvis, 2017), changing the conditions for filter clogging.

Despite the severe conditions of utilization, numerous examples of good performance of geotextile filters in tailings dams have been reported in the literature. The performance of different drainage systems incorporating geotextiles in some mine tailings dams in South Africa is presented by Bentel *et al.* (1982), who reported cost savings of up to 33% with solutions incorporating geotextiles and equally good performance as granular filters over 6 years of monitoring. The possibility of filter clogging due to ochre formation is considered of particular relevance by those authors. Similar good performance of geotextile (woven and nonwoven) filters in a tailings dam was observed by Haas (1982), as well as of a nonwoven geotextile in drainage blankets, chimney drain and foundation relief wells in tailings dams up to 74 m high in Brazil (Montez 1987). Similar good performance was observed by Mansen and Balbin (2008) with the use of a light geotextile filter and of a geocomposite for drainage in a 30 m high tailings dam in Peru.

Palmeira *et al.* (2010) report values of GR_{ASTM} (as per ASTM D5101) close to 1 in gradient ratio tests on a tailings-geotextile system for which clogging was observed in the filter of a vertical drainage system of a tailings dam (same tailings and geotextile as tested in the laboratory) after 6 years in service. These authors point out that the value of GR_{ASTM} alone may not be sufficient for the prediction of a good performance of the filter of vertical drainage systems similar to those employed in one of the dams studied and the values of gradient ratio obtained from ports closer to the geotextile specimen may be useful for a sounder decision on the filter to be used. This is particularly relevant in the case of internally unstable materials. Besides, tailings specimen preparation in the laboratory may not be realistic regarding the influence of tailings disposal in the field, as commented earlier. Values of *GR* between 0.7 and 1.2 were obtained in gradient ratio tests on tailings-nonwoven geotextile systems using cyclic flow by Fannin and Pishe (2001). In tests on a woven geotextile, values of *GR* between 0.1 and 2.0 were obtained, with intense piping through the more open woven geotextile tested.

Palmeira *et al.* (2005) obtained values of gradient ratios (GR_{ASTM}) varying between 1.1 and 1.3 in gradient ratio tests on tailings-nonwoven geotextile systems subjected to vertical stresses of up to 2000 kPa. Entrapped tailings particles in the geotextile reduced its compressibility. Despite partial clogging having been observed the geotextiles remained 5.5 to 420 times more permeable than the tailings. It was noted that considerably large particles (Figure 2b) were capable of intruding the geotextile voids due to vibration during specimen preparation, confinement and greater particle density in the case of ore tailings, which can facilitate the displacement of fibres and the intrusion of particles in the geotextile. Large particles in the geotextile voids were also observed by Niec *et al.* (2019) in specimens of a nonwoven geotextile filter exhumed from a small dam drainage system in Poland and by Palmeira *et al.* (2010) in a geotextile filter of a tailings dam. In similar gradient ratio tests on internally unstable tailings-geotextile systems, Palmeira *et al.* (2010) observed piping through two nonwoven geotextiles with values of *GR* close to 0.5, but rather constant with increasing vertical stress throughout the test. Even smaller *GR* values were obtained using the hydraulic heads measured at ports closer (3mm and 8 mm above the filter) to the geotextile layer. For the heavier geotextile tested (M_A = 627 g/m2), the authors argue that the presence of needle holes left after the needle-punching manufacturing process may be a reason for the low values of *GR*. Haliburton and Wood (1982) observed that for one of the needle-punched geotextiles subjected to *GR* tests flow occurred through the needle holes even when the other portions of the geotextiles were clogged with silt particles. However, under field conditions, such holes may not play an important role with respect to piping due to possible geotextile distortion during its installation and placement and compaction (when executed) of the cover material (Palmeira *et al.* 1996).

The use of nonwoven geotextiles in association with thin granular filter layers may be effective in reducing clogging of geotextile filters in mining applications, besides additional benefits (Legge 2004). The use of thin sand layers between the tailings and the geotextile filter in gradient ratio tests was investigated by Liu *et al.* (2021b). Values of *GR* between 0.38 and 0.53 were obtained even with the sand layer above the geotextile. However, much less quantities of tailings particles piped through the filters than the commonly used limit of 2500 g/m^2 proposed by Lafleur *et al.* (1989). The presence of the sand layer prevented the formation of a mass of fine particles at the soil-geotextile boundary, lowering the clogging potential of the geotextile and increasing the drainage capability of the system, especially under high hydraulic gradients. Nevertheless, it should be pointed out that too thin sand layers with uniform thicknesses are difficult to execute in the field.

4 MODELLING FILTER PERFORMANCE

Because of the complex nature of geotextile filter behaviour, different approaches for modelling geotextile filter performance have been proposed by several authors using simple or sophisticated solutions. Early proposals for the investigation of geotextile retention capacity employed geometrical models for nonwoven geotextile filters simulated as an array of cylinders (Laflaive & Puig 1974, Fayoux & Evon 1982, Giroud 1996, for instance). Methods based on probabilistic analyses have also been developed to estimate the nonwoven geotextile pore size distribution (Gourc 1982, Faure 1988, Lombardi 1989, Faure *et al.* 1990, Sória & Viviani 1993, Elsharief & Lovell 1996, Urashima & Vidal 1998, Simmonds *et al.* 2007, Rawal 2010 and 2012, for instance). More recent research has employed more sophisticated approaches such as the use of the discrete element method (*DEM*), fractal geometry theory and elementary cellular automata neural networks (Liu *et al.* 2011, Ozelim *et al.* 2016, Chen *et al.* 2019, Ibrahim & Meguid 2022, Ryoo *et al.* 2022b).

To some extent, both geometrical and probabilistic models may predict satisfactorily the geotextile pore size if appropriate parameters intrinsic to these methods are properly chosen or backanalysed. For instance, Giroud (1996) proposed the following equation to estimate geotextile filtration opening size based on a geometrical model

$$\frac{O_F}{d_f} = \frac{\delta}{\sqrt{1-n}} - 1 + \frac{\xi n}{(1-n)t_{GT}/d_f} \tag{5}$$

Where O_F is the geotextile filtration opening size, d_f is the geotextile fibre diameter, n is the geotextile porosity, t_{GT} is the geotextile thickness and δ and ξ are empirical parameters.

Palmeira & Trejos-Galvis (2018) extended the application of equation 5 to different values of the geotextile pore sizes (O_κ) corresponding to a given percentage (κ), where κ is the percentage of remaining pores that are smaller than O_κ. With appropriate values of δ and ξ, a satisfactory comparison between O_κ/d_f predicted by equation 5 and measured values using bubble point tests was obtained, as shown in Figure 29a, in tests on five nonwoven geotextiles under different vertical confining stresses (up to 1000 kPa). However, the values of δ and ξ in this case are likely to be product specific. The method proposed by Faure *et al.* (1990) was also calibrated to predict O_κ for the same geotextiles in Figure 29a. This method is based on the probability of a soil particle passing through a nonwoven geotextile assumed as a random stacking of elementary films with a given thickness. The calibration of the elementary film thickness yielded the comparison between predicted and measured O_κ/d_f values shown in Figure 29b, where a satisfactory level of agreement can also be noted. The calibrated Faure *et al.* (1990) method was also capable of predicting well the geotextile pore size distribution curve, as shown in Figure 30. However, the predictions of the pore size distribution curves using the geometrical approach (equation 5) were not as accurate as those of the probabilistic method (Palmeira & Trejos-Galvis 2018). Thus, probability seems a

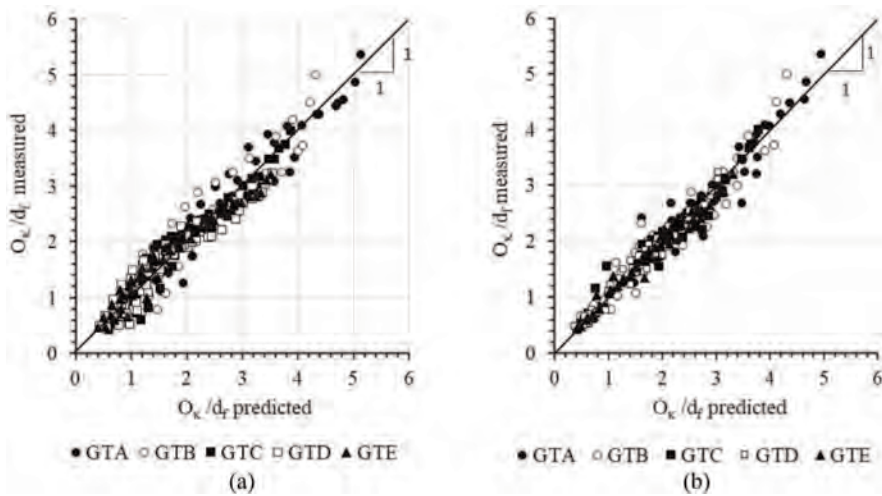
powerful tool for the prediction of nonwoven geotextile pore dimensions, although some improvements are necessary for a broader application to any nonwoven product.


Figure 29. Comparisons between predicted and measured pore sizes: (a) Predictions by equation 5, (b) Predictions by Faure *et al.* (1990) (modified from Palmeira & Trejos-Galvis 2018).
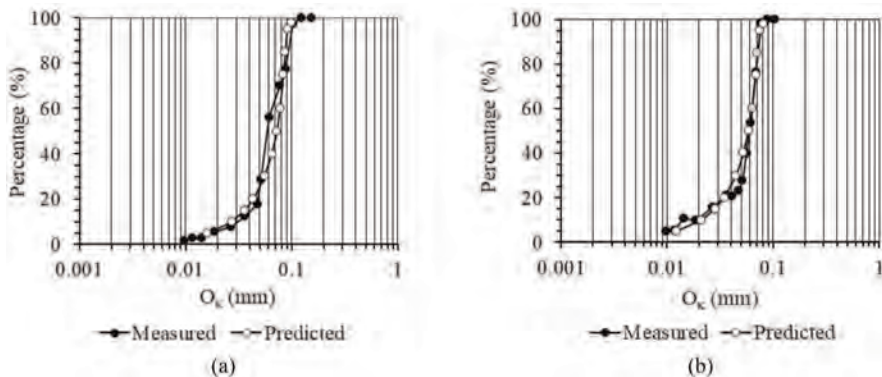

Figure 30. Measured and predicted pore sizes distribution curves by Faure *et al.* (1990): (a) For zero vertical confining stress, (b) For a vertical stress of 100 kPa. (Palmeira & Trejos-Galvis 2018).

Rawal (2010) developed a model for the prediction of nonwoven geotextile pore size distribution combining stochastic and stereological or geometrical probability approaches, which incorporates the influence of geotextile fibre orientation. The model predicted variations in O_{95} of a light (75 g/m^2) nonwoven geotextile of up to 26% for the range of values of the fibre directional parameter used in the method. An approach to model the compression induced morphological behaviour of nonwoven geotextiles was introduced by Rawall (2012). A mechanistic model of pore size distribution was proposed for geotextiles under compression also considering the out-of-plane orientation of the geotextile fibres. Predicted and measured pore diameters of a thermally bonded nonwoven product were compared, but under much lower vertical stresses (< 2.1 kPa) than those expected in geotechnical works. The trend of the predictions was satisfactory, but deviations between predicted and measured O_{95} ranging from 20% to 48% were observed. Regarding geotextile fibre orientation, using X-ray computed

34

tomography, Ishikawa (2018) observed that most of the fibres tend to be oriented parallel to the plane of a nonwoven web in the case of parallel-laid webs. The needle-punching manufacturing process can locally orient some fibres perpendicular to the web plane. Compression will further increase the percentage of fibres parallel to the plane of the geotextile.

The discrete element method was employed by Chen *et al.* (2019) to evaluate the variation of the apparent opening size of a heat bonded nonwoven geotextile with tensile strain under uniaxial and biaxial tensile loadings. The results obtained suggest that the change in the orientation angle of the fibres was smaller during biaxial tensile tests than during uniaxial tensile tests. The authors also observed that the deformation pattern of the modelled geotextile during the biaxial tensile test was almost axisymmetric. The rates of opening size increase with tensile strain under uniaxial and biaxial loading were similar to those obtained by Palmeira *et al.* (2019) in bubble point tests on nonwoven, needle-punched, geotextiles subjected to tension, but significantly smaller than those obtained by Wu *et al.* (2008) in tests on a heat bonded geotextile.

5 INNOVATION AND ADVANCES IN GEOTEXTILE FILTERS

The need for better performance of geotextile filters facing severe conditions as those described in this paper has led to the development of new geotextile products. Combinations of existing products with alternative drainage materials have also been the subject of research and applications by several authors (Palmeira 2016, Palmeira *et al.* 2021a, b, Touze 2021). For instance, Narejo *et al.* (2013) report the good performance of a hybrid layered monolithic filter consisting of a nonwoven needle-punched and a woven monofilament for the filtration of fine particles of coal combustion residuals. A better performance of a filter consisting of the combination of a thin layer of one nonwoven needle-punched geotextile and a thicker layer of a second nonwoven needle-punched geotextile in comparison with a conventional monolayer geotextile is reported by Sabiri *et al.* (2017). Ryoo *et al.* (2022b) describe and analyse the use of woven and nonwoven conical filters by means of laboratory and computational modelling (*DEM* simulations), where higher simulated system permeabilities with the new product were obtained in comparison with conventional geotextile counterparts. The use of alternative geocomposites for drainage and the potential use of biodegradable geotextiles in temporary filter applications are discussed in Junqueira *et al.* (2006), Silva & Palmeira (2013) and Prambauer *et al.* (2019). In addition, the development of new and advanced geotextile filters has also increased.

In addition to the ingenious combinations of existing geotextile products with alternative materials, materials science and advances in manufacturing processes have produced innovations in geotextiles with repercussions on their applications in geotechnical and geoenvironmental engineering. One example of such developments is the use of wicking geotextiles, which are products capable of draining water out from unsaturated soils. Wang *et al.* (2017) describe the development and application of a type of wicking woven geotextile made of special hydrophilic and hygroscopic fibres with multi-channel cross sections (Figure 31). The geotextiles contain micro-channels with diameters varying between 5.7 and 47.8 microns, high shape factor and hight wicking fibre specific surface area. In an experiment with this geotextile in a base course on a fine-grained subgrade, the authors observed that the geotextile did remove water out of the cross section of the model road, especially after a simulated rainfall of 38 mm/h intensity for 40 min. The wicking geotextile effectively wicked water out from the base soil even when this layer was prepared at a moisture content close to the optimum moisture content. Guo *et al.* (2019) observed that in average the wicking geotextile reduced the water content of the overlying soil in a region approximately 200 mm thick above the geotextile layer in column tests. Guo *et al.* (2022) tested a modified wicking geotextile with additional wicking fibre yarns artificially knitted into the geotextile. The results obtained in laboratory tests showed that the wicking geotextile drained both free

and capillary water, reducing the average gravimetric water content of the soil. The wicking geotextiles were also able to wick water from both the overlying and the underlying soils, and the results suggest that the influence range of reducing the moisture content of the underlying soil due to a siphon effect was of at least 100 mm. Other successful applications of wicking geotextiles under unsaturated conditions are reported by Azevedo & Zornberg (2013), Zhang *et al.* (2014), Guo *et al.* (2017), Lin *et al.* (2017) and Zornberg *et al.* (2017), Lin *et al.* (2021). Zaman *et al.* (2022) observed greater wettability of a wicking woven geotextile in comparison with a non-wicking one and to a nonwoven geotextile, indicating that water penetrates faster in wicking geotextiles. Wettability of nonwoven geotextiles can be increased during manufacturing with the addition of a surfactant solution to the geotextile fibres surface to make them hydrophilic. Bouazza (2014) shows significant increases in the wettability of two nonwoven geotextiles along their in-plane direction after this type of treatment.
Figure 31.   Shape of a wicking geotextile fibre.

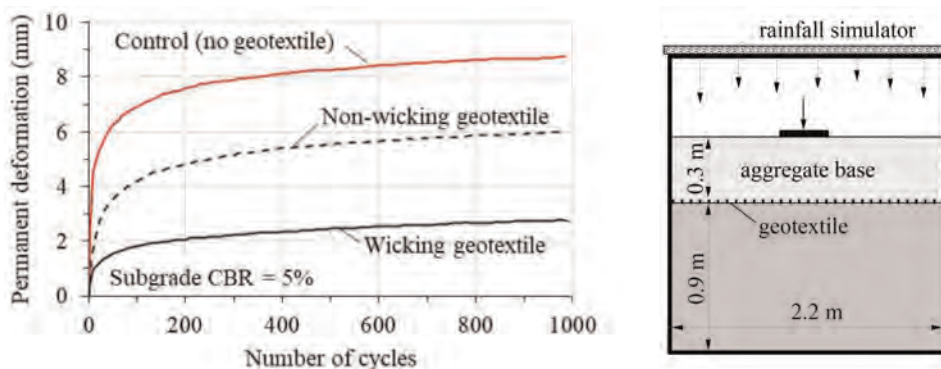
Guo *et al.* (2021) carried out an experimental study on the performance of pavement bases under three conditions: without geotextile on the subgrade, with a non-wicking geotextile on the subgrade and with a wicking geotextile on the subgrade. The pavement consisted of a granular layer (0.3 m thick) on a subgrade (0.9 m thick, *CBR* of 4% or 5%) which was constructed in a large testing box and subjected to cyclic loading by a circular rigid plate. The pavement was subjected to series of simulated rain fall and surface loading. Overall, the authors observed that the water content in the wicking geotextile section decreased at a significantly faster rate than in the control and non-wicking geotextile sections. The permanent surface deformation of the section with the wicking geotextile was considerably smaller than those of the other sections, as shown in Figure 32.


Figure 32.   Permanent deformation at the pavement surface at 7 days after the first rainfall simulation (modified from Guo *et al.* 2021).

Filtration tests on nonwoven geotextiles treated by negative ions were carried out by Lee and Jeon (2008) aiming at evaluating the influence of the treatment on the reduction of clogging. The principle was that the negatively charged fine clay particles would be repelled

by the negatively charged geotextile fibres. The level of geotextile clogging calculated based on the mass of soil particles entrapped in the geotextile was reduced by 33.8% and the discharge rate increased 16% for the geotextile with higher electric charge in comparison with the control one (no electric charge). The highest clogging level was observed in the control geotextile.

Significant improvements in the performance of geotextiles are expected in the coming years due to the promising results of recent research on the use of geotextiles with fibres coated with graphene and nanoparticles (Kelsey 2015, 2016, Kim *et al.* 2020, Senadheera *et al.* 2022), as well as due to other forms of incorporating advanced materials in the manufacture of geotextiles. Regarding the filtration function, the incorporation of graphene is expected to improve filter performance and endurance by increasing mechanical strength, antimicrobial performance (filter biological clogging prevention) and hydrophilic behaviour, for instance (Kelsey 2015). Strength increase will reduce or avoid the possibility of mechanical damages in geotextile filters. Antimicrobial action may reduce biological clogging of geotextile filters in landfills, for instance. Graphene enhanced geotextiles are already being manufactured in Australia and in the United States (Kelsey 2016). It is also likely that in the future geotextile filters may benefit from the advances in the research on smart textiles, particularly as a response to the COVID-19 pandemics. For example, the use of new antimicrobial agents to be incorporated into advanced masks used as personal protective equipment for healthcare professionals has been investigated (Ivanoska-Dacikj & Stachewicz 2020), whose application in the manufacture of geotextile filters could be considered.

6   CONCLUSIONS

This paper discussed factors that may influence the actual behaviour of geotextile filters. By being cost-effective and easy to install, some important issues are frequently overlooked in geotextile filter applications. Based on the experience gained and lessons learned over the years, the main conclusions regarding the behaviour of geotextile filters are as follows.

Most (if not all) problematic situations for geotextile filters are also problematic for natural filters. These are the cases where biological and/or chemical clogging can take place as well as for filters in contact with internally unstable soils. Under complex field conditions such as those of filters in tailings dams, filters in contact with internally unstable base soils or subjected to the flow of liquids with solids in suspension, it is very difficult, if possible, to specify a problem-free filter material, be it natural or synthetic. Despite such uncertainties, some general recommendations can reduce or avoid poor filter performance.

Partial clogging of the filter before its operation can take place due to spreading and compaction of the base soil on the geotextile layer. Impregnation of the filter will reduce its permeability, increase its retention capacity and change the condition for further clogging during filter operation. Thus, appropriate reduction factors should be used to account for nonwoven geotextile impregnation by soil particles. Investigations on the behaviour of internally unstable soil-geotextile systems have shown that significantly greater reductions factors than the usual value of 10 may be necessary to account for the flow rate reduction caused by geotextile impregnation and/or blinding. Some contributions in the literature discussed in this paper may provide useful tools to predict geotextile performance under such conditions.

In case of drainage systems of landfills, waste management and selection may reduce the risk of drainage system malfunction. Practices such as leachate recirculation, disposal of construction debris, large amounts of organic matter, dewatered sludge and incinerated ash should be avoided. In addition, drainage pipes wrapped (or socked) with nonwoven geotextiles should not be used in leachate collection systems. More open geotextile filters (say $FOS > 0.13$ mm for nonwoven geotextiles and $FOS > 0.5$ mm and $POA > 15\%$ for woven geotextiles) and coarser ($d > 15$ mm) granular drainage materials have performed best. It is

recommended that leachate collection and removal systems should be kept under anaerobic conditions or under unsaturated conditions as long as possible to extend their service lives. Under similar severe conditions, nonwoven needle punched geotextiles seem less prone to clogging than heat bonded ones and woven geotextiles.

Due care should be taken with filters in arid and semi-arid regions due to the possible clogging action of silicon dioxide and calcium carbonate. The same applies to possible salt precipitation in engineering works in marine environment. Submersion of the drainage system can avoid or reduce the risk of filter clogging due to ochre formation.

In mining applications, tailings deposition may influence filter performance, particularly for vertical drainage systems. The possibility of ochre formation in the filter should also be foreseen depending on the composition of the tailings. The combination of a thin sand layer and a geotextile filter may be an appropriate solution when geotextile blinding is a possibility.

Laboratory testing should try to simulate as accurately as possible the hydraulic and physical conditions expected in the field. This includes the use of appropriate surcharges to simulate the overburden stresses on the buried geotextile filter as well as the deposition and compaction of the base soil on the geotextile filter. The simulation of the tailings deposition process is highly recommended in tests on tailings-geotextile systems. In tests with internally unstable soils, the measurement of the variation of soil permeability coefficient at different positions along the specimen heigh may provide useful information on system behaviour. Soil specimens in these tests should be high enough (say 100 mm or more) to accurately reproduce the internal instability mechanism taking place along the specimen height during testing. Measurements of hydraulic heads close to the geotextile filter may also provide useful information on geotextile clogging mechanism in gradient ratio tests.

Besides some conventional and simpler solutions to predict geotextile filter behaviour, recent more sophisticated theoretical solutions have been employed such and the use of discrete element modelling, neural networks, complex probabilistic analyses etc. that will certainly contribute to a better understanding and prediction of the behaviour of geotextile filters.

Despite the filter performance issues raised in this paper, geotextile filters are undoubtfully a great success. Failures often receive great exposition (and they should be exposed!). However, one should bear in mind that they have represented a tiny fraction of geotextile filter applications, many of them occurring due to the lack of appropriate design considerations and construction practices. A great advantage of a synthetic filter over a natural one is that the technological developments that may be incorporated into the former and the development of new products based on material science studies can reduce the possibility of failures and improve design. The future will certainly bring new products that will be more efficient, less expensive and will provide more environmentally friendly engineering solutions.

Research and practice on geosynthetic MSE walls: Past, present and future
(Bathurst lecture)

Y. Miyata
National Defense Academy, Yokosuka, Japan

ABSTRACT: Although technology on geosynthetic mechanically stabilized earth (MSE) walls can help solve classical geotechnical earth retaining wall problems, it also contributes to achieving new required performance for these infrastructures. To further develop this technology, it is essential to analyze the history of its progress. This study summarizes the state-of-the-art on the mechanical and soil interaction properties of geosynthetics, physical modeling and in-situ measurements, analytical and numerical modeling, and reliability analyses by reviewing approximately 700 papers published in well-known international journals in this field and some notable conference paper contributions. The latest analytical methods, such as risk-based life cycle cost and CO_2 emission assessments and damage/failure predictions, are introduced to evaluate the resilience and sustainability performance of geosynthetic MSE walls. Finally, prospects of a seismic isolation technique with new types of geosynthetics and life cycle management with a long-life sensor for geosynthetic MSE walls are discussed.

1 INTRODUCTION

Traditionally, classical infrastructure design only considered basic performance aspects, such as structural safety and economic efficiency. In modern design, more advanced performance aspects such as resilience and sustainability are also considered (Lounis & Mcallister 2016). New infrastructure technologies are needed to meet these advanced performance requirements.

Geosynthetic mechanically stabilized earth (MSE) walls mainly consist of geomaterials, geosynthetics, and facing materials. The performance of these structures can be controlled by varying the reinforcement conditions. Research on geosynthetic MSE walls began in the 1970s (Holtz 2017). The good performance of these wall systems has been demonstrated in both research and practice. For example, seismic damage investigation of actual structures has reported the high performance of geosynthetic MSE walls (Koseki 2012; Kuwano *et al.* 2017; Ling *et al.* 2001; Tatsuoka *et al.* 1996; White & Holtz 1997). Nevertheless, classical geosynthetic MSE wall design methods have much room for improvement (ex. Bathurst *et al.* 2005b, 2014). If a design method able to reasonably determine the reinforcement conditions by considering the required performances can be developed, technology on geosynthetic MSE walls will be able to contribute to the success of various civil engineering projects more than ever before. The keywords considered in this study are the "past," "present," and "future" of research and practice on geosynthetic MSE walls. For the "past," research trends in geosynthetic MSE walls over the past 40 years are reported based on a review of approximately 700 technical papers. Changing research topics and approaches over time are visualized. For the "present," the latest analytical methods, such as risk-based life cycle cost and CO_2 emission assessments and damage/failure predictions, are presented to evaluate the performances of geosynthetic MSE walls. Finally, for the "future," prospects

of a seismic isolation technique with new types of geosynthetics and information and communication technology (ICT)-based life cycle management with fiber optics for geosynthetics are discussed.

2 REVIEW OF RESEARCH ON GEOSYNTHETIC MSE WALLS OVER THE LAST 40 YEARS

2.1 *Aim of the review*

Research on geosynthetic MSE walls can be divided into four categories: research on the mechanical and soil interaction properties of geosynthetics, research to clarify their mechanical behavior through physical model tests and in-situ measurements, research on analytical and numerical modeling to predict the mechanical behavior of geosynthetic MSE walls and research on reliability analyses for evaluating their performance. The relationships among these four research areas are shown in Figure 1. They can be connected by correlations, understandings, suggestions, and/or validation processes. It is important to clarify the detailed progress in these research areas and their interrelationships for the future development of technology on geosynthetic MSE walls.

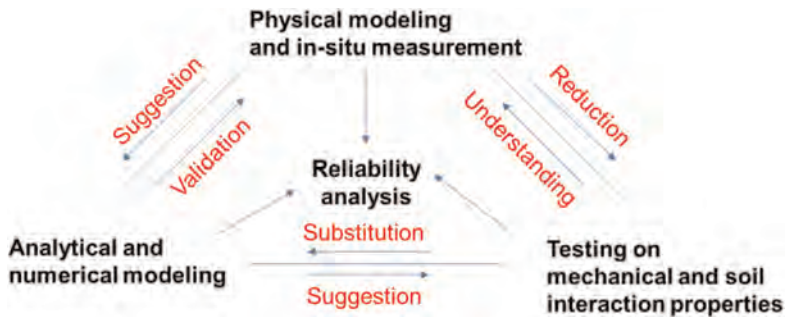
The information required to identify research trends in geosynthetic MSE walls includes journal articles, technical reports, test standards, and design specifications. Journal articles can be obtained even if time has passed since their publication, and their contents can be easily verified. More importantly, they are peer-reviewed and, therefore, judged to be reliable for information. For these reasons, the author focused on journal papers in this study. Nevertheless, there are a number of valuable conference papers cited in this review.


Figure 1.   Research areas in technology on geosynthetic MSE walls and relationships.

In many state-of-the-art papers on geosynthetic MSE walls, technological progress was explained by relating to important papers with significant contributions to progress in research and practice (ex. Bathurst & Alfaro 1997; Otani *et al.* 1997; Palmeira 2009; Rowe & Ho 1993; Rowe & Li 2003; Bathurst & Kaliakin 2005). Giroud (1994) published a two-volume book of article lists on geosynthetic engineering such as books, journals, conference papers, theses, and reports and publications from selected authors. Many of these studies have made significant contributions not only to solving practical problems but also to setting research directions in the early stages of research on geosynthetic MSE walls. Insofar as the present study, the author believes that the degree of progress is closely related to the number of published papers; thus, progress is demonstrated using statistical data on the number of papers on geosynthetic MSE walls. The advantage of this research method is that it allows us to visualize the research direction with objective indicators. It is a survey approach that can only be implemented once research results have been sufficiently accumulated. This section discusses the overall research trends in geosynthetic MSE walls and chronological changes in research topics and methods.

2.2 Review methodology

Technology on geosynthetic MSE walls is an interdisciplinary field, with relevant papers published in various fields. This study only considered journal papers published in the field of geotechnical engineering. Based on this policy, three categories of journals were examined: 1) journals covering all areas of geotechnical engineering, 2) journals specializing in geomaterials testing, and 3) journals specializing in geosynthetic engineering. Specifically, for Category 1, the following journals were reviewed: Geotechnique (GT, Institution of Civil Engineers (ICE)), Journal of Geotechnical and Geoenvironmental Engineering (JGE, American Society of Civil Engineers), Soils and Foundations (S&F, Japanese Geotechnical Society), and Canadian Geotechnical Journal (CGJ, Canadian Geotechnical Society). These journals were first published in the 1960s and are well-suited for examining long-term research trends in geosynthetics. Category 2 included the Geotechnical Testing Journal (GTJ, American Society for Testing and Materials (ASTM) International). This journal publishes papers that include testing and experimental methods for geosynthetics. Two journals were included in Category 3: Geotextiles and Geomembranes (G&G, Elsevier) and Geosynthetics International (GI, ICE). These are the official journals of the International Geosynthetics Society (IGS) and were first published in 1983 and 1994, respectively. They contain many papers on geosynthetic MSE walls.

The papers were collected from each journal's website. Keywords were entered into the search engine of each journal's website to generate a list of candidate papers. After downloading the papers, their contents were reviewed, and those meeting the objectives of this review were included in the database. Table 1 shows statistics of journal papers collected. A total of 701 papers were collected. The largest contributor was G&G, followed by GI.

2.3 Considerations

The number of papers on the mechanical and soil interaction properties of geosynthetics, analytical and numerical modeling, physical modeling and in-situ measurements, and relia-

Table 1. Statistics of journal papers collected on the technology of geosynthetic MSE walls.

Journal	GT	JGE	S&F	CGJ	GTJ	G&G	GI	Total
Total	24	100	56	33	20	285	183	701

GT: Geotechnique, JGE: Journal of Geotechnical and Geoenvironmental Engineering, S&F: Soils and Foundations, CGJ: Canadian Geotechnical Journal, GTJ: Geotechnical Testing Journal, G&G: Geotextiles and Geomembranes and GI: Geosynthetics International.

bility analyses of geosynthetic MSE walls are shown in Figures 2–5. The vertical axis represents the cumulative number of publications, and the slope of the curve represents the number of publications per year. Changes in the number of publications over time should be understood in the context of academic, practical, and social trends. Table 2 provides a chronological table of events that can be considered relevant to geosynthetic MSE walls. All the curves in the four research areas can be approximated by a group of straight lines whose slopes change twice from small to large, regardless of the type of research. It can be assumed that a period with a small slope represents the accumulation phase, and one with a large slope represents the development phase. In this case, it can be understood that these phases have repeated themselves twice, and MSE wall technology is now in the second development phase. Interestingly, the timing of the first accumulation and development phases is almost the same in the three research areas of mechanical and soil interaction properties, physical
Figure 2. Total number of papers on the mechanical and soil interaction properties of geosynthetics as published in selected leading journals.
Figure 3. Total number of papers on physical modeling and in-situ measurement of geosynthetic MSE walls as published in selected leading journals.

modeling and in-situ measurements, and analytical and numerical modeling. As shown in Table 2, during the first accumulation period, the IGS was established, and technical committees on geosynthetics were formed in the ASTM and International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE). In addition to establishing academic societies and technical committees, an international conference on geosynthetics and the international symposium on soil reinforcement were regularly organized (Ochiai 2007). Thus, a development phase was achieved owing to the dissemination of technical information and the exchange of research ideas.

During this first development phase, several earthquakes caused significant societal losses. The high reliability of technology on geosynthetic MSE walls was demonstrated in damage investigations of these earthquakes (Koseki 2012; Kuwano *et al*. 2014; Tatsuoka *et al*. 1996;
Figure 4.   Total number of papers on analytical and numerical modeling of geosynthetic MSE walls as published in selected leading journals.
Figure 5.   Total number of papers on reliability analyses of geosynthetic MSE walls as published in selected leading journals.

White & Holtz 1997). These works have contributed to the widespread use of MSE wall technology. In research on mechanical and soil interactions, physical modeling and in-situ observations, and analytical and numerical modeling, the earliest transition from the second accumulation phase to the development phase was in research on analytical and numerical modeling. During this period, computers began to be used in all aspects of practice. This trend probably stimulated further research on analytical and numerical modeling. Research on reliability analyses began in the 2000s.

The third edition of the International Organization for Standardization (ISO) 2394 on the general principles for the reliability of structures was published in 1998. It stated that the target performance of a structure should be expressed in terms of probabilities. This trend is

considered to have strongly influenced the research field of geosynthetic MSE walls, especially research on reliability analyses. To identify the area with the largest number of publications in each period, i.e., the most-active research area in geosynthetic MSE walls, the ratios of the number of papers in the four areas mentioned above to the total number of papers for each year were calculated. The chronological changes were visualized as shown in Figure 6. In the early 1980s, research on physical modeling and in-situ measurements represented the largest proportion of publications. Approximately five years later, the proportion of papers on the mechanical and soil interaction properties of geosynthetics took the lead.

After that, the proportions of papers on mechanical modeling and interactions shifted to favor papers concerning analytical and numerical modeling. Currently, the proportion of papers in these three areas is approximately 30%, and the proportion concerning reliability
Figure 6.   Changes in four research areas on geosynthetic MSE walls over time.

analyses is 10%; this has remained constant for the last 10 years. These changes indicate that research on geosynthetic MSE walls has progressed in the following order: understanding of the macroscopic behavior of the walls, elucidation of the elemental properties, development of analysis methods, and evaluations of reliability.

Changes have also occurred in research topics related to the mechanical and soil interaction properties of geosynthetics. This area of research can be divided into four categories: tensile, creep, pullout resistance, and interface shear resistance. Figure 7 depicts the time-series changes in the proportions of papers as classified by year of publication. In the early 1980s, even if the total number of papers was small, most papers focused on pullout tests.

In the mid-1980s, the proportion of papers on mechanical properties, such as tensile and creep, increased. Subsequently, the proportion of papers on mechanical properties shifted to papers on soil interactions. Presently, the ratio of papers on mechanical properties to those on soil interactions is reversed from the ratio in the mid-1980s.
Figure 7.   Changes in research topics on mechanical and soil interactions of geosynthetics over time.

The changes in the research topics in physical modeling, in-situ measurements, and analytical and numerical modeling can also be discussed. Studies in these areas can be categorized into those on static deformation properties, static stability, and behaviors under extreme loads, such as earthquakes and rainfall, and others, which include case histories and environmental performance.

The proportions of papers are classified by year of publication, and the time-series changes are visualized in Figure 8. In the mid-1990s, the good performance of geosynthetic MSE walls was revealed through post-disaster investigations of large earthquakes occurring during this period. Since then, the proportion of studies on the dynamic behavior of geosynthetic MSE walls through physical modeling and numerical analysis has increased. More recently, the number of papers on hydraulic effects has increased in consideration of the effects of climate change. Notably, the percentage of papers on static deformation has remained almost unchanged over the past 40 years. It can be considered that the basic reinforcement mechanism, in which the soil deformation is constrained by reinforcing materials, has already been elucidated. Nevertheless, this trend indicates that unresolved issues remain, such as those concerning long-term behavior.
Figure 8. Changes in research topics on the mechanical behavior of geosynthetic MSE walls over time.

3 ADVANCED ANALYSIS METHODS FOR RESILIENCE AND SUSTAINABILITY OF GEOSYNTHETIC MSE WALLS

3.1 Background

In classical structural design, emphasis has traditionally been placed on indicators related to structural safety and economic efficiency. Structural safety has been evaluated based on a factor of safety, and economic efficiency has been evaluated based on the initial cost, i.e., the construction cost. In recent years, structural designs have required advanced performance with respect to resilience and sustainability (Lounis & Mcallister 2016). Resilience generally refers to the ability to respond to changes. In the design of a structure, it is often assessed as the ability of a structure to maintain a minimum level of functionality and recover quickly after damage from natural disasters or external events. In contrast, sustainability is more

holistic and generally refers to a system or process being able to continue to function without losing its functionality in environmental, social, economic, etc., terms. In the design of a structure, sustainability is often evaluated in terms of the degree of global environmental impact. It has been suggested that both performances need to be evaluated throughout the life cycle of a structure (Bocchini *et al.* 2014). Damians *et al.* (2018) demonstrated a methodology to evaluate the sustainability of earth retaining wall structures considering the three pillars that contribute to sustainability (economics, societal/functional/resilience and environmental) and showed that MSE walls were more sustainable than candidate conventional gravity and cantilever wall types performing the same function.

When evaluating the resilience and sustainability of a structure over its lifetime, it is necessary to assume potential scenarios of events occurring to the structures during their service lives. As these events include damage caused by natural disasters, the evaluation includes a high degree of uncertainty. Therefore, the assessment should be risk-based, i.e., the uncertainties in the events should be assessed probabilistically (Lounis & Mcallister 2016). As the chair of the technical committee of the IGS Japan Chapter, the author has been working on this task from the beginning and has been advocating the advantages of geosynthetic MSE walls in the Japanese social infrastructure development community (Miyata *et al.* 2010, 2013). This section presents the extended analysis results of this activity as an advanced analysis method in current practice.

Another important perspective when evaluating the life cycle resilience and sustainability of structures is the prediction of the damage or failure modes of structures. The latest Japanese design standard on geostructures requires consideration of the effects of the damage or failure of geostructures on adjacent roads and houses (MLIT 2015).

Numerical analyses are expected to be introduced to predict the damage to or failure modes of such structures. Figure 9 shows the applicable ranges of the finite element method (FEM) finite difference method (FDM) and particle method as continuum analyses, and the discrete element method (DEM) to assess the limit state of a structure. Although this classification is tentative, because research on each method is currently being conducted to expand their range of applications, it is understood that the discrete element method and particle method can be applied to reproduce structural behavior up to and after collapse. However, these analysis methods have not been sufficiently developed for geosynthetic MSE walls. To overcome this problem, the authors' group has been developing a particle method for geosynthetic MSE walls (Nonoyama *et al.* 2022). The main contents of this latest analysis method in current practice are introduced in section 3.4.

Analysis method / Performance level		Deformation	Damage	Failure
Continuum approach	FEM, FDM			
	Particle Method			
Discontinuous approach	DEM			

Figure 9. Applicability of numerical analysis to limit state estimations of structures. (FEM = finite element method, FDM = finite difference method, DEM = discrete element method).

3.2 *Risk-based life cycle cost analysis*

In ISO (2015) 2394: General principles for the reliability of structures, the risk *R* is defined as follows:

$$R = \sum P_i \, C_i \qquad (1)$$
Figure 10. Relationship between the performance level of the structure, initial cost, seismic risk, and total cost.

In the above, P_i is the probability associated with event i (probability of failure) and C_i is the magnitude of the damage if the event i occurs.

In this section, the discussion is limited to earthquake risks. Figure 10 shows the relationship between the performance level of the structure, initial cost, seismic risk, and total cost. The total cost is a simple sum of the initial cost and seismic risk. The higher the performance level of the structure, the higher the initial cost. In addition, the higher the performance of the structure, the lower the seismic risk, because the probability of failure is lower. Therefore, the total cost is a downward convex curve as shown in the bottom plot of the figure. A probability-based risk analysis can help to reasonably set the target performance level for a structure while considering the balance between the initial cost and risk. This section explains a risk-based life cycle cost analysis method for geostructures. The analysis results are shown for geosynthetic MSE walls, L-shaped retaining walls, and non-reinforced embankments under simple conditions (Miyata *et al.* 2010). The life cycle cost (LCC) considers the seismic risk and maintenance costs and can generally be calculated as follows:

$$LCC = C + M + R \qquad (2)$$

Here, C is the initial construction cost, M is the maintenance cost, and R is the seismic risk. The current Japanese design method for geosynthetic MSE walls assumes multiple failure modes as shown in Figure 11 (PWRC 2013), as do popular design specifications elsewhere in the world. Based on this, the probability of occurrence of each failure mode $P(E_i)$ is calculated using the reliability analysis method. Finally, the
Figure 11.   Failure modes considered in the current design (PWRC 2013).

seismic failure probability P_f of the geosynthetic MSE wall is calculated as follows:

$$P_{\mathrm{f}} = 1 - \prod_{i=1}^{Life} \{1 - P(E_i)\} \tag{3}$$

In the above, Π is an operator denoting the product probability. Total cost caused by seismic failure event C_f can be calculated as follows:

$$C_{\mathrm{f}} = C_{\mathrm{s}} + C_{\mathrm{c}} + C_{\mathrm{j}} + C_{\mathrm{d}} + C_{\mathrm{p}} \tag{4}$$

Here, C_s is the cost of demolition and removal, C_c is the cost of reconstruction, C_j is the cost of lost time owing to road damage, C_d is the cost of lost travel owing to detours during reconstruction, and C_p is the cost of human losses owing to damage.

The LCC calculations were performed for geosynthetic MSE walls, L-shaped retaining walls, and non-reinforced embankments constructed for local roads. In the series of analyses, the following conditions were assumed.

(1) Geomaterial properties: Unit weight: $\gamma = 19.0$ kN/m^3, Cohesion: c = 0 kN/m^2, Angle of internal friction: $\phi = 30°$.
(2) Safety factors and seismic action: Required safety factor: $F_s = 1.2$ for permanent actions, $F_s = 1.0$ for seismic action; Design horizontal seismic intensity $k_h = 0.20$.
(3) Service condition: Service life = 50 years, average daily traffic condition = 10000 vehicles.
(4) Collapse area: 30 m in the direction of road expansion, regardless of the seismic conditions.
(5) Structure dimension: Width = 30 m, H = 4.0, 6.0, 8.0, and 10.0 m, respectively.
(6) Uncertainty of design parameters: Coefficients of variation were 10% for the geomaterials, 5% for the tensile strength of the geogrid, and 50% for the seismic intensity. Figure 12 shows the typical cross-sections that were analyzed.

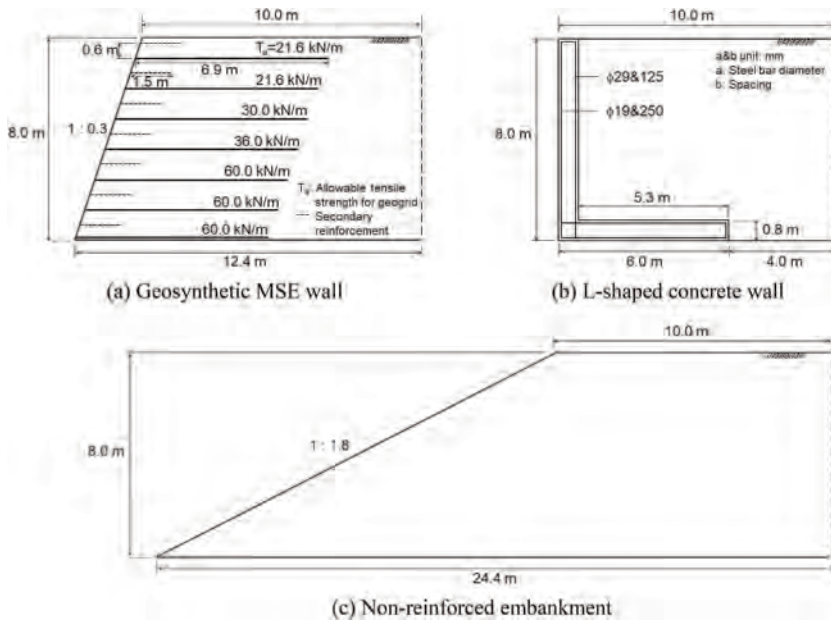
Figure 13 shows the calculated LCCs of the soil structures. The geosynthetic MSE wall has the lowest LCC, followed by the non-reinforced embankment and L-shaped retaining wall. One reason for the high LCC of the L-shaped retaining wall is that it requires a greater number of days for rehabilitation after being damaged by a disaster. The non-reinforced embankment incurs the lowest initial construction cost. When compared with the risk-based LCC, the order of the embankment and geosynthetic MSE wall is reversed. When selecting the type of structure for road construction, the risk of failure should be properly considered.


Figure 12. Typical cross-sections of geosynthetic MSE wall, L-shaped concrete wall, and non-reinforced embankment.
Figure 13. Life cycle cost analysis results for geosynthetic MSE wall, L-shaped concrete retaining wall, and non-reinforced embankment.

3.3 *Risk-based CO_2 emission analysis*

This section briefly explains an analysis method for CO_2 emissions and the advantages of geosynthetic MSE walls with greening. Similar analyses were performed by Heerten (2012) and Damians *et al.* (2017). They performed rigorous environmental analyses and showed the advantages of geosynthetic MSE walls. One improvement in this study is that the CO_2 emissions are considered in a risk-based analysis. This study presents the CO_2 emissions by the CO_2 equivalent weight [kg-CO_2] based on ISO (2006) 14040 and Miyata *et al.* (2013).

The life cycle CO_2 (LCCO$_2$) is assumed, as shown in Equation (5).

$$LCCO_2 = I_c + S_c + R_c \qquad (5)$$
Figure 14.   Life cycle CO_2 analysis results for geosynthetic MSE wall, L-shaped concrete retaining wall, and non-reinforced embankment.

(a) During construction　　　　　　　　(b) Greened wall facing

Figure 15.   Greening technique combining geogrid and geotextile for geosynthetic MSE wall (courtesy of Dr. Hironaka).

In the above, I_c denotes the initial construction emissions, S_c is the absorption by the greening of the facing, and R_c is the risk of disaster recovery. R_c can be evaluated by multiplying the failure probability of the structures and CO_2 emissions during disaster recovery. A CO_2 emission analysis was performed for geosynthetic MSE walls with and without greening, L-shaped retaining walls, and non-reinforced embankments. Figure 14 shows the analysis results. One feature of the geosynthetic MSE walls is that the type of facing can be selected according to the construction conditions. Figure 15 depicts a greened geosynthetic MSE wall during construction and while in public service.

In the case of geosynthetic MSE walls, the greening of the facing can be accomplished using geogrids, geotextiles, steel mesh wall materials, and greening sheets, even if the construction conditions are complex. The analysis results show that the structure with the largest LCCO$_2$ emission among the four cases is the L-shaped retaining wall. In contrast, the lowest LCCO$_2$ emission is the geosynthetic MSE wall with greening. Surprisingly, assuming a service life of 50 years, the CO$_2$ emissions become negative. Thus, the geosynthetic MSE walls could be recognized as a structure type that contributes to carbon neutrality, i.e., sustainability.

3.4 *Damage/failure analysis*

This section discusses the damage/failure analysis and advantages of geosynthetic MSE walls based on the analysis results (Nonoyama *et al*. 2022). To analyze the damage and failure conditions of a geosynthetic MSE wall using the particle method, the soil is represented by an elastoplastic model, the soil-geosynthetics-soil hybrid element is represented by an elastoplastic model based on a two-mixture theory, and the facing panel is represented by an elastic model. In the mixture model for reinforced soil, the rate dependence of the geosynthetics and the constraining effect of the soil reinforcement are introduced. A strain-based yield criterion is introduced for the reinforced soil elements. In this modeling, when the calculated horizontal strain of a reinforced soil element reaches the limit value in one cal-
Figure 16.   Analyzed cross-section of the full-scale testing of geosynthetic MSE wall (Bathurst *et al*. 1993).

culation step, the incremental displacements are calculated in the next step by reducing the element stiffness to practically zero. In the present study, the horizontal limit strain is set at 2.0% based on Allen *et al*. (2003) and Bathurst and Allen (2023). To validate the proposed model, a full-scale loading experiment on a geosynthetic MSE wall with a height of 3.0 m as conducted by Bathurst *et al*. (1993) was analyzed. In this experiment, the geosynthetic MSE wall was damaged by airbag surcharge loading on the top surface. An overview of the full-scale model is shown in Figure 16. The fill material was sandy soil with gravel with a unit volume weight $\gamma = 18.0$ kN/m^3, water content w = 2%, cohesion c = 0 kPa, and angle of internal friction $\phi = 53°$. The reinforcement material was a biaxial geogrid with a tensile strength T$_{ult}$ = 12.0 kN/m and thickness t =1 mm.

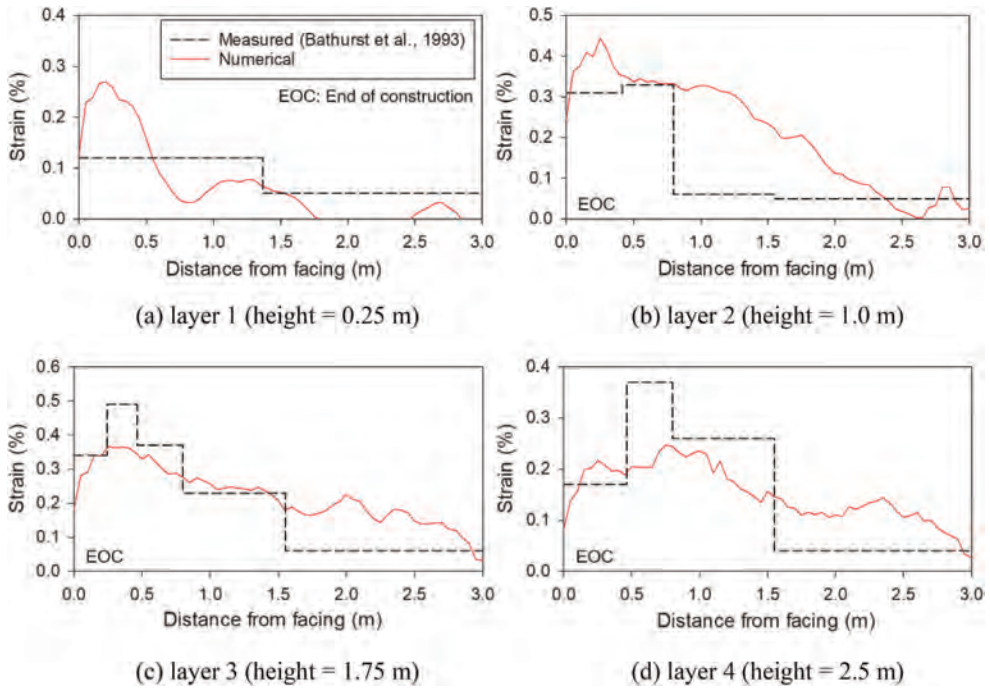
Figure 17 compares the analytical and measured strain distributions along the geogrids at the end of construction. Good agreements are obtained for the location and magnitude of the peak strain. Figure 18 compares the measured and calculated displacements of the facing panels during surcharge loading pressures of 12, 30, 50, and 70 kPa. In both phases, the


Figure 17.   Measured and numerical strain distribution along the geogrid reinforcement layers (Nonoyama *et al*. 2022).
Figure 18.   Measured and numerical horizontal panel deformations (Nonoyama *et al*. 2022).

calculated values generally agree well with the measured values. Thus, the proposed particle method can be applied in damage analyses of geosynthetic MSE walls.

To validate the proposed failure analysis method, a scenario-based numerical analysis was performed. A scenario was assumed in which the foundation directly below the wall of a geosynthetic MSE wall slides horizontally, eventually resulting in the functional loss of the foundation and facing panels. This assumption was based on full-scale testing considering the foundation failure (Miyata *et al.* 2015).

In a series of analyses, a horizontal displacement rate of 1.0 cm/sec was applied to the
Figure 19.   Numerical analysis of failure behavior of geosynthetic MSE wall (Nonoyama *et al.* 2022).

foundation with an initial surcharge of 60 kPa applied to the top of the backfill. After the horizontal displacement of the foundation reached 4 cm, the foundation and facing elements were removed from the analysis.

Figure 19 shows the displacement field of the fill material after the foundation and wall material lose their functionality. It would be difficult to fully simulate the entire failure process of geosynthetic MSE walls using particle methods. In previous post-disaster reports on geosynthetic MSE walls (ex. Kuwano *et al.* 2014), almost no cases occur where the geosynthetic MSE wall completely collapsed. As shown in Figure 19, many geosynthetic MSE walls reach equilibrium conditions at the large-deformation stage following structural failure. Therefore, the particle method can qualitatively simulate the failure behavior of geosynthetic MSE walls.

4   ADVANCED SOLUTIONS FOR THE NEXT DECADE

4.1   *Background*

Geotechnical challenges are becoming increasingly complex, requiring the further development of geosynthetic MSE wall technology. One requiring improvement is the earthquake-resistance technique. This is because earthquake damage is becoming increasingly severe. As shown in Table 2, a severe earthquake leads to massive economic losses and human suffering, and a great deal of effort is required to recover from the damage. In the field of structural engineering, seismic isolation and vibration control technology have been actively developed to reduce seismic actions on structures and increase their resistance to earthquakes

(Ikeda *et al.* 2019; Spencer Jr & Nagarajaiah 2003). In the geosynthetic MSE wall field, new systems such as integral bridges and their combinations with soil improvement and anchoring are being considered for improved seismic performance (e.g., Tatsuoka *et al.* 2009). For vibration control, the application of expanded polystyrene (EPS) has been studied (Koseki 2022). Notably, Bathurst *et al.* (2007) and Zarnani & Bathurst (2008) conducted a pioneering study on the use of compressible EPS geofoam as seismic buffers to attenuate dynamic loads against rigid retaining wall structures. However, few studies have been conducted on seismic isolation control for geosynthetic MSE walls. This study considers the potential of seismic isolation using geosynthetics having three-dimensional structures which are beginning to be used as vibration-reducing materials on construction sites.

Life cycle management methods also require improvement. To rationally perform life cycle management, it is necessary to periodically diagnose conditions and rationally determine the necessity of measured performance. In geosynthetic MSE wall life cycle management, the first question is which data to measure? Allen *et al.* (2003) showed that the reinforcement strain is an important indicator of the integrity of a geosynthetic MSE wall. They proposed that prediction models developed based on a statistical approach using measured strain data from various geosynthetic MSE walls are useful not only for design but also for evaluating structural integrity.

Another question is how to collect the field data quickly, inexpensively, and securely. The authors' research group developed a prototype sensor system for geosynthetic MSE walls and confirmed the effectiveness of ICT-based management (Miyata *et al.* 2012). However, issues have remained regarding providing reinforcement strain monitoring applicable throughout the actual service life of a geosynthetic MSE wall. In the next section, the applicability of ICT management and an attachment-type fiber optic sensor for geosynthetic MSE wall life cycle management are discussed.

4.2 *Seismic isolation technique*

Figure 20 shows a geosynthetic MSE wall with a seismic isolation layer. This type of structural system is expected to demonstrate high seismic performance owing to the inherent reinforcement and seismic isolation effects of the geosynthetic MSE wall. The seismic isolation layer must have frictional resistance properties to provide sufficient sliding resistance to horizontal earth pressures from the retained backfill during (operational) static loading and a function to reduce the vibration transmitted to the geosynthetic MSE wall during earthquakes. The author focused on applying geosynthetics, as these are beginning to be used as construction vibration reduction materials (Ogawa *et al.* 2022). An example of
Figure 20.   Concept of geosynthetic MSE wall with seismic isolation layer.
Figure 21.   Geosynthetics made from polyolefin elastomer with three-dimensional structure.
Figure 22.   Laboratory model test apparatus to investigate isolation efficiency of geopad geosynthetic samples.

geosynthetic is shown in Figure 21. This product is made of polyolefin elastomer and has a three-dimensional structure. This product is referred to as a geopad in this paper. Figure 22 shows a schematic of the laboratory tests conducted to investigate the seismic isolation characteristics of this product. The apparatus consists of a vertical stress loading apparatus, a vibration machine, and specimen mounting apparatus. In the experiment, the specimen was sandwiched between two steel plates. The upper plate was subjected to sinusoidal vibration and the acceleration transmitted to the lower plate was measured. The experimental results were summarized by calculating the isolation efficiency E from the acceleration measured on the upper steel plate a_{in} and that measured on the lower steel plate a_{out}.

$$E = a_{out}/a_{in} \tag{5}$$

Experiments were conducted using a natural rubber sheet, commonly used for construction vibration countermeasures, a single geopad layer, and double geopad layers. Vibrations were applied at five different frequencies ranging from 5 to 80 Hz.

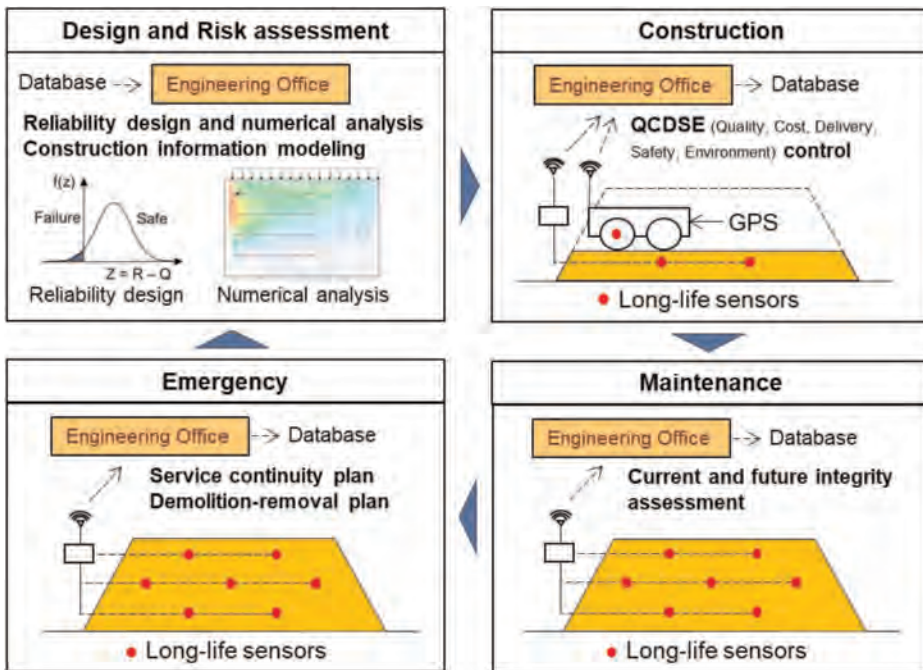
The experimental results are shown in Figure 23. In the case of the natural rubber sheet, the vibration transmission is 185% at 5 Hz and 45% to 52% at 10 to 40 Hz. The double geopad layers improve the isolation effect, transmitting only 20% to 30% of the vibration of the natural rubber. These experimental results demonstrate the applicability of the geopad
Figure 23.   Relationship between the frequency of shaking and isolation efficiency (modified from Hironaka *et al.* 2023).


Figure 24.   Concept of information and communication technology (ICT)-based life cycle management of geosynthetic MSE wall.

used herein to improve the seismic isolation effect of geosynthetic MSE walls. As a next step, we plan to verify the seismic isolation effect of the geopad based on shaking table experiments on geosynthetic MSE walls. After that, we plan to establish a method for analyzing the seismic isolation effect and evaluating the material properties of the geopad.

4.3 *Information and Communication Technology (ICT)-based life cycle management*

Figure 24 schematically depicts the roles of the ICT-based geosynthetic MSE wall life cycle management for the stages of "Design and Risk Assessment," "Construction," "Maintenance," and "Emergency." The structural data is always sent to the engineering office so that all the data can be used to make decisions for any life cycle stage of a structure.

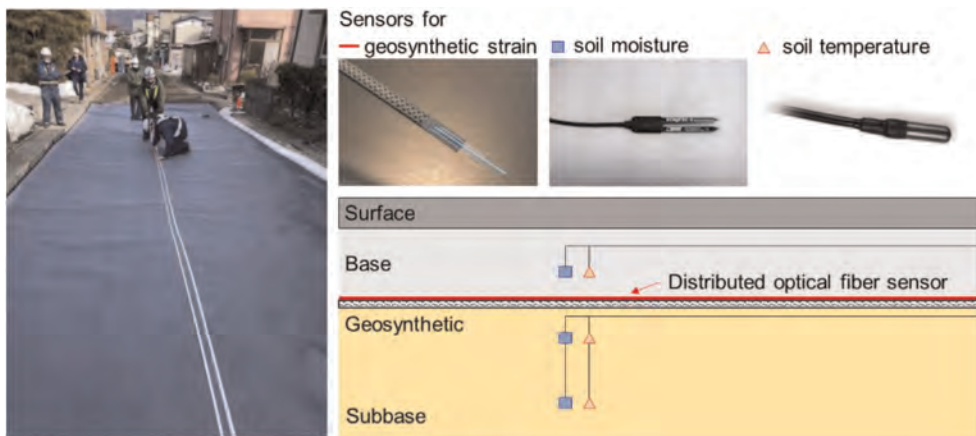
The technical reliability of geosynthetic MSE walls will be further enhanced once such a system is developed, and a management approach is put into practice. Two key issues must be addressed for the practical application of this management. One concern is the need for long-life sensors for monitoring the internal conditions of geosynthetic MSE walls throughout the life of the structure. Geosynthetic strain measurements have been shown to be effective in assessing the structural integrity of geosynthetic MSE walls (Allen *et al.* 2003). Corresponding long-term measurements should be developed. Hatami *et al.* (2009) proposed a strain-sensitive conductive geosynthetic based on nanotechnology. Fiber optic sensing is another candidate approach for long-term measurements. It has recently been applied in the


Figure 25.   Fiber optics applied to a field construction site with geosynthetic reinforced soil (courtesy of Dr. Nagatani and Dr. Hironaka).

measurement of civil engineering structures (Soga & Luo 2018). In the geosynthetic MSE wall technical field, pioneering work has been performed by Yashima *et al.* (2009). In recent years, the progress in optical fiber sensors has been remarkable. The latest sensor system makes it possible to acquire structural data with higher accuracy and speed than ever before. The author and researchers at civil and geosynthetics engineering companies have jointly initiated a study to confirm the applicability of using distributed fiber optic sensors examined by Kishida *et al.* (2022) for geosynthetic MSE walls. As a first step in the research, strain measurements were conducted at an actual site. Figure 25 shows the site situation. The measurement data will be presented at another time, but the author can report that the results show the effectiveness of the measurement system. It is expected that many engineers/researchers will study new long-life sensing for geosynthetic MSE walls.

Another issue is the need to further develop reliability analyses to utilize data from long-life sensors in practice. Allen and Bathurst (2015) developed reinforcement tensile load prediction models for MSE walls under operational conditions based on a statistical approach. Bathurst and Allen (2019, 2023) calibrated the load and resistance factors for geosynthetic MSE walls. Miyata *et al.* (2018, 2019) and Bathurst *et al.* (2020) demonstrated

how this general approach can be applied to PET strap walls. Reliability analysis is very powerful for improving design methods by using in-situ data. Reliability analysis can be used for other phases of the MSE wall life cycle. In the construction process, reliability analyses using design estimates and observed data can be used to evaluate deviations between design assumptions and actual as-built conditions. In addition, probabilistic reliability indices can be used as a basis for considering measures such as halting construction and changing the design before a serious accident occurs.

During the maintenance period, monitoring systems can assist to predict the future internal conditions of a structure using reliability analysis applied to observed data, allowing the user to consider changes to the inspection schedule and measures to be taken. Deep learning will undoubtedly be effective for future predictions. In emergency situations where damage is caused by large actions such as earthquakes and rainfall, data on the internal condition of the structure before and after such actions can be compared and checked for anomalies on a reliability basis. Even if demolition or removal is deemed necessary, a reliability analysis using the observed data can be a useful tool for safety evaluations during planning and execution. Finally, reliability theory can be used in the risk assessment phase. The massive amounts of data collected by ICT management will contribute to more realistic risk estimations.

5 SUMMARY

The paper describes the overall research trends in geosynthetic MSE walls over the past 40 years, the latest analysis methods based on the author's research, and an outlook on the future of this technology. In the research summary section, the author visualized the evolution of the number of papers and the content of the research on geosynthetic MSE walls by reviewing approximately 700 journal papers published on geosynthetic MSE walls. These changes were discussed together with events in the academic, practical, and social trends. The importance of preparing a place for the exchange of technical information and presentation of research was reaffirmed. The advanced analysis section, how to calculate life cycle costs and carbon dioxide emissions on a risk-based basis was introduced and it was shown that the benefits of geosynthetic MSE walls become clearer when considered on a life cycle basis. In addition, it was shown that the particle method could solve the entire process of a geosynthetic MSE wall from deformation to failure. New performance requirements such as resilience and sustainability can be adequately evaluated by using these advanced engineering tools for geosynthetic MSE walls. Finally, the author discussed a seismic isolation technique and more rational life cycle management as future applications for geosynthetic MSE walls. For the former, the isolation efficiency of geosynthetics with three-dimensional structures was discussed based on the results of recently conducted laboratory tests. For the latter, the new potential of management methods using the latest ICT such as fiber optic sensors was discussed. As civil engineering structures become increasingly complex, the design and maintenance of infrastructure must become more rational, economical, and environmentally friendly. Technology on geosynthetic MSE walls has great potential to meet these demands and should be further developed, taking into account developments in other technology fields.

Selection of long-term shear strength parameters for strain softening geosynthetic interfaces (Rowe lecture)

R. Thiel

Thiel Engineering, Oregon House, CA, USA

ABSTRACT: The behavior of strain-softening geosynthetic interfaces that can lead to progressive failures in lined containment facilities has been a source of confusion in slope stability evaluations for over 30 years. The paper presents fifteen mechanisms that can potentially induce displacements along strain-softening interfaces, along with measures that can be considered to reduce strain-softening displacement. New quantifications of shear strength variability that can be caused by manufacturing, installation, and construction practices are introduced. Guidance and recommendations are given that are applicable to numerical continuum as well as limit-equilibrium approaches to assist in selecting appropriate geosynthetic shear strength parameters for containment facilities that have strain-softening interfaces. While most of the paper focuses on deep-seated critical interfaces for high normal stress bottom liners, low normal stress veneer covers are also addressed.

1 INTRODUCTION

1.1 *General*

Slope instability of large waste or mining containment facilities presents one of the most potentially immediate and consequential impacts to the greatest spectrum of stakeholders. Often a sizable portion of the critical slip surfaces for these facilities follows a strain-softening geosynthetic interface. The present paper identifies numerous factors that can be considered when selecting appropriate long-term shear strength parameters along these interfaces.

This specific topic has been an active, and occasionally intense, subject of technical papers in the geosynthetic industry for at least 35 years. Indeed, there have been several references with nearly the same title as the present paper over the past 20 years (e.g. Eid 2011; Gilbert 2001; Sabatini et al. 2001; Stark & Choi 2004; Stark 2022; Thiel 2001). Even so, confusion still exists among design practitioners regarding the appropriate testing, interpretation, and selection of long-term shear strength parameters for geosynthetic interfaces. Undoubtedly there will be future papers with a similar title, especially as more knowledge and experience becomes available related to the effects of ageing, durability, and latent weak zones within strain-softening geosynthetic interfaces.

Due to length restrictions, the present paper is shortened from a longer companion paper version that will be published in *Geosynthetics International* under the same title. Where appropriate, the reader is directed to consult the longer version for more information. For example, definitions of several geotechnical terms as used in this paper that are in common usage by practitioners in the containment industry are provided in the *Geosynthetics International* companion paper appendices.

1.2 *Concept of strain softening and progressive failure*

Probably the greatest amount of confusion and controversy regarding the selection of appropriate shear strengths for geosynthetic interfaces occurs because many of these interfaces are characterized as 'strain-softening'. A quasi-synonymous term that is sometimes used in the literature is 'brittle.' However the connotation of brittle might imply a narrower amount of strain deformation to achieve peak and residual strength conditions than might occur, and so the term 'strain softening' is adopted in the present paper. Whatever term is preferred, the shear strength of many geosynthetic interfaces reaches their peak value with a relatively small amount of relative shear deformation, often less than 2-20 mm, and then degrades relatively rapidly with continued deformation to lower values, as illustrated in Figure 1. These lower values are variously referred to as 'post-peak' shear strength, 'large-displacement' shear strength (commonly cited as occurring at approximately 75 mm of relative displacement), ultimately reaching a constant minimum value of what is called 'residual' shear strength.

In classical geotechnical engineering, strain-softening soils have been, and continue to be some of the most difficult to evaluate for slope stability analyses. Thus, it is not surprising that confusion exists in the geosynthetics profession, considering that this complex type of shear strength interface is the norm in geosynthetics engineering.
Figure 1.   Schematic of shear-stress versus displacement at geosynthetic interface illustrating strain-softening behavior.

In simplest terms, the problem with strain-softening interfaces is that even though a correctly performed limit equilibrium stability analysis based on peak strength indicates a generally accepted factor of safety (*FS*) greater than 1.5, the slope may still fail. The reason for this is a phenomenon called 'progressive failure.'

Strain-softening soils, or geosynthetic interfaces, promote the phenomenon of progressive failure, and make it impossible to count on mobilizing peak strength simultaneously at all locations along the failure surface (Duncan & Wright 2005). Perhaps the best, and first description of progressive failure was made by Skempton (1964), and it bears repeating here, as it is directly applicable to our subject. Note that the current author has substituted the words [geosynthetic interface] where the original quote used the word 'clay':

> *"Irrespective of the physical explanation of the drop in strength after passing the peak, the existence of this decrease in strength must be accepted as a fact which has been well established. Thus, if for any reason a [geosynthetic interface] is forced to*

pass the peak at some particular point, the strength at that point will decrease. This action will throw additional stress onto the [geosynthetic interface] at some other point, causing the peak to be passed at that point also. In this way progressive failure can be initiated and, in the limit, the strength along the entire length of a slip surface will fall to the residual value. Obviously, in any given case, a slip may occur before the residual strength is attained throughout the [geosynthetic interface], but once a progressive failure has started the average strength of the [geosynthetic interface] will decrease inexorably towards the limiting residual value."

The next paragraph in Skempton's 1964 paper explains that zones of weakness and zones that have already failed past peak strength can act as stress concentrators and can then cause shear deformations to take place at an average stress that is far less than the ideal strength of the material. The current author is not aware of attempts, and has not himself attempted, to quantify the magnitude of stress concentrations within the plane of a strain-softening shear interface containing abrupt boundaries with weak zones. This concept is explored in later sections of this paper as a potential contributing factor to progressive failure, and a subject that merits further research.

1.3   *Strain-softening potential of typical geosynthetic interfaces*

The magnitude of strain softening, R_{ss}, is defined by Gilbert and Byrne (1996) as the ratio of residual to peak shear strength:

$$R_{ss} = \frac{\tau_r}{\tau_p} \tag{1}$$

Given that much of the geosynthetics literature and testing results are based on LD rather than the true residual, this term can receive a modified subscript as R_{ss-LD} when it is known that the basis is LD. A value of $R_{ss} = 100\%$ would mean that the geosynthetic interface would not lose any of its shear strength after exceeding the peak strength and would not be considered strain-softening. A value of $R_{ss} = 60\%$ would mean that the geosynthetic interface would lose 40% of its shear strength after exceeding the peak strength, a significant loss of strength that would define that interface as highly strain-softening.

   Koerner and Narejo (2005) provide peak and LD shear strength data on 48 different geosynthetic interfaces that was collected from the Geosynthetic Accreditation Institute's database of proficiency test results from 3,260 large-scale direct shear tests performed by many laboratories in general accordance with ASTM D5321. A synopsis of those results is provided in the *Geosynthetics International* companion paper appendices.

   The author commonly specifies aggressive texturing which results in $R_{ss-LD} \approx 40\text{-}60\%$ for these interfaces (e.g. see Figure 2). While aggressive texturing will provide the highest available peak shear strength, is that peak strength reliable given the high magnitude of strain-softening potential? This is a significant aspect of the subject of this paper considering that an average overall $R_{ss} \leq 67\%$ could potentially cause an *FS* value of 1.5 that is based on peak strength to fall below 1.0.

1.4   *Limit equilibrium and numerical continuum analysis approaches*

For deep-seated failures that have strain-softening interfaces, limit equilibrium analyses that assume peak strengths can give non-realistic and non-conservative results, and also give no indication of the distribution or magnitude of mobilized shear stresses or displacements. However, the vast majority of the slope stability analyses performed in the geo-environmental containment industry are done by professionals using computer software programs based on limit-equilibrium models, such 'Spencer's method', or the 'Janbu method', or any of several
Figure 2. Shear-displacement graph for interface of aggressively textured HDPE geomembrane against geo-composite drainage layer having non-woven geotextile surfaces. Note that the magnitude of strain softening increases with normal stress, with $R_{ss\text{-}LD}$ ranging from 61% at 96 kPa to 41% at 766 kPa.

other limit-equilibrium models that have been accepted and used for slope stability for many decades. Many users of these common and popular slope stability computer programs either do not realize that all of these models employ an assumption that soil blocks function as rigid bodies, or they do not understand the implications of this assumption. Because this assumption is a distinct limitation of these models, using them can lead to the following misleading or incomplete results when the critical interface is strain-softening and when peak strengths are assumed:

- The outputs of these models present a non-realistic, non-conservative uniform variation of shear stress mobilization that is proportional to normal stress, and an equally non-realistic uniform factor of safety along the entire sliding surface.
- The real-world non-uniform mobilization of stresses and strains, which are a significant driver for the inducement of displacements that lead to progressive failure in strain-softening materials, cannot be predicted by these popular programs.
- If peak strength is preserved everywhere, with no exceedance of peak strength at any point along the sliding surface, then the average factor of safety represented by limit equilibrium methods may be correct. Likewise, if residual strength exists everywhere along the sliding surface and is used in the model, then the average factor of safety represented by limit equilibrium methods may be correct.
- The results of these popular programs are non-conservative when using peak strength for strain-softening shear interfaces that would experience a drop-off in shear strength with a small amount of displacement, unless special precautions are taken to model the appropriate locations within the cross-sections being analyzed, using degraded shear strengths that are less than the peak shear strengths (e.g. residual shear strength).

Numerical analyses that employ continuum mechanics models (e.g. finite element or finite difference computer programs) are able to approximately predict the complex patterns of

73

displacements and non-uniform mobilization of stresses along the critical interfaces. However, the greater amount of time, effort, and expense required to perform numerical analyses makes them unattractive for everyday use. Although the use of continuum analyses is generally increasing, the vast majority of slope stability analyses in engineering practice continue to be performed using limit-equilibrium programs.

The limitations of limit equilibrium methods may not be as severe in the evaluation of relatively thin soil (veneer) layers on sloped lining systems, but even in these cases the potential for degradation of geosynthetic interface shear strength is significant and should be considered.

1.5 *Goals of the present paper*

The present paper has three goals: (1) provide a contextual history of our understanding of progressive failure along strain-softening geosynthetic interfaces for lined containment, (2) describe mechanisms that could lead to progressive exceedance of peak strength along strain-softening interfaces, and (3) describe measures that can be used to allow for or mitigate strain softening mechanisms.

Due to space limitations for the present paper, the significant discussion of the history and literature related to the issue of strain softening and progressive failure along geosynthetic interfaces in lined containment facilities is provided in the *Geosynthetics International* companion paper appendices, which includes a rather lengthy list of references, and which serves as a resource for anyone interested in conducting their own research or evaluation of this topic. In conjunction with the extensive reference material, the *Geosynthetics International* companion paper appendices also present a historic review of bottom liner slope stability failures that involved geosynthetic or geosynthetic-like interfaces.

1.6 *Organization of the present paper*

The present paper is organized as follows:

1. Introduction and background.
2. Review of mechanisms that can potentially induce displacements along strain-softening geosynthetic interfaces.
3. Review of measures that can be implemented to reduce or mitigate displacements that can lead to progressive failure along critical strain-softening interfaces.
4. Discussion of risk and other considerations when considering peak strength.
5. Conclusions and recommendations.

2 MECHANISMS AFFECTING DISPLACEMENT ALONG STRAIN SOFTENING INTERFACES

This section of the paper presents a list of 15 Mechanisms that can potentially induce displacements along strain-softening interfaces, and thus contribute to a progressive failure mechanism. This is the most extensive such list that has been published to date. All 15 of the potential Mechanisms discussed in this section are relevant to bottom liner (high normal stress) situations, while 9 of these mechanisms are also deemed to be potentially relevant to veneer (low normal stress) situations. Some of the Mechanisms suggested by the author may be considered speculative, unproven, or theoretical. Several of the Mechanisms that affect displacements as discussed in this paper are interrelated and may seem redundant from a purely technical point of view. Even so, it is worthwhile discussing them separately to develop an awareness of the range of influences and their nuances that might affect the exceedance of peak strength, and hence the propagation of displacements, at the interfaces.

The Mechanisms that could lead to progressive displacements are grouped into five categories based on the nature of their causes.

- Category 1 includes five Mechanisms that are related to static stress and strain mobilization due to planned geometry, gravity, and constitutive material properties such as density, stiffnesses, compressibility, and Poisson's ratio. For a given geometry and material properties, the strain-softening effects from this set of Mechanisms are unavoidable and can best be estimated using numerical analyses.
  o Mechanism #1: Non-uniform mobilization of shear stresses.
  o Mechanism #2: Waste settlement, stiffness, compressibility, creep, and degradation.
  o Mechanism #3: Static lateral spreading of the waste.
  o Mechanism #4: Foundation settlement.
  o Mechanism #5: Strain/deformation incompatibility between overlying waste/ore material and the liner system interface.

- Category 2 includes four Mechanisms that are related to the aggravation of stresses and strains caused by construction and operational activities.
  o Mechanism #6: Waste placement activities.
  o Mechanism #7: Slope overfilling/oversteepening.
  o Mechanism #8: Toe excavation.
  o Mechanism #9: Construction-induced shear strength degradation.

- Category 3 includes three Mechanisms that are related to different types of short- or long-term transient influences that are not due to construction and operational forces, and that could affect mobilized shear stresses.
  o Mechanism #10: Pore pressures.
  o Mechanism #11: Seismic loading.
  o Mechanism #12: Increased operating temperature.

- Category 4 includes one Mechanism related to the factor of time.
  o Mechanism #13: Long-term ageing and creep of geosynthetics.

- Category 5 includes two Mechanisms related to variability.
  o Mechanism #14: Variability of material manufacturing.
  o Mechanism #15: Variability of installation practices.

2.1 *Mechanism #1. Non-uniform mobilization of shear stresses*

This Mechanism, which was previously described in Section 1.4, is reiterated here for the sake of completeness. Byrne (1994) was the first landmark paper to clearly demonstrate, using numerical analyses, that the non-uniform mobilization of shear stresses is a significant cause of the initiation and progression of failures in strain-softening materials for bottom liner systems. The reason for this is that with deformable materials some areas will be stressed much higher than the average, which could cause those areas to exceed their peak strength. Such a situation can be further exacerbated if those areas have weak spots (e.g., localized delamination) or other conditions (e.g., pore pressures, downdrag) that increase the shear demand on adjacent areas, as discussed later as contributory mechanisms. In the present paper we list this Mechanism first in our list of reasons why peak strength could be exceeded, as we highlighted more than 20 years ago in Thiel (2001). Acknowledgment of this fact established our acknowledgment that waste and soil materials do not act like rigid bodies, and that limit equilibrium analyses are only approximate tools that do not accurately represent physical reality.

We also list this as the #1 Mechanism because (a) this mechanism will co-exist with all other mechanisms that may exist, and (b) this mechanism is generally not intuitive and often needs to be explained and emphasized to practitioners. It could be true that many, perhaps

even the majority of designers who perform limit equilibrium slope analyses, have not studied the implications of the numerical analyses presented in the literature cited herein. In the evaluation of slopes that involve strain-softening interfaces, which includes most lined containment facilities, limit equilibrium analyses on bottom liners should be overseen by trained geotechnical professionals who have studied these principles and can exercise appropriate engineering judgement.

While the principle of the static non-uniform distribution of shear stresses is general to all geotechnical structures, its effect is generally less pronounced for veneer liner systems due to the quasi planar load distribution Considerations of non-uniform distribution of shear stresses in veneer systems is typically ascribed to other mechanisms such as differential settlement below the liner, localized pore pressures, construction activities, or variabilities in materials or installation as described below.

2.2 *Mechanism #2. Waste settlement, stiffness, compressibility, creep, and degradation*

Localized strength degradation of liner interfaces due to waste settlement that results in significant displacements adjacent to the lining system is probably the most commonly cited reason for the promotion of progressive failure (Gilbert & Byrne 1996; Kavazanjian et al., 2006; Long et al. 1995; Richardson & Thiel 2001; Sabatini et al. 2002; Stark 2022; Stark & Poeppel 1994; Thiel 2001).

Slope stability studies based on continuum numerical approaches described in the literature references (e.g. Byrne 1994) generally model waste settlement that is due only to the elastic compression of the waste. The development of relative displacements occurs more readily and to a greater extent on sideslopes as compared to the flatter base of a deep-seated critical surface. Reddy et al. (1996) and Gilbert et al. (1996) both mention that waste stiffness is a major factor affecting mobilized shear stresses and displacement distribution. More compressible, less stiff waste results in more accumulation of strain along the base, especially towards the toe, due to the transfer of stresses from the waste above the sideslope to the waste on the base that acts as a buttress.

Note on the concept of liner-system integrity related to downdrag. Downdrag of the waste along a liner system due to settlement also affects another aspect of liner-system performance, which is generally termed 'integrity.' This concept regards the issue of strains in the liner system that might ultimately cause a tensile failure in the liner, particularly at the crests of slopes at intermediate benches, and the top anchor trench where strains are the greatest. The issue of 'integrity' is not to be confused with the issue of slope stability, though they are related to each other by the causal mechanism of waste settlement and by the nature of the interface shear strengths. The numerical analyses that are used to evaluate both issues are quite similar. Thus, discussion of the integrity issue is relevant to the subject of the present paper. The subject of liner integrity being compromised due to waste settlement was apparently first discussed by VonPein and Lewis (1991), with the first numerical solutions being proposed by Long et al. (1995). Yazdani et al. (1995) measured smooth HDPE geomembrane strains on a 2.1 m high 3(H):1(V) slope in a California landfill to confirm design assumptions and confirmed that the maximum strains occurred near the top of the slope. Villard et al. (1999) measured strains and displacements on a slope in a full-scale field experiment and correlated their results with a numerical analysis that showed, interestingly but not surprisingly, that the maximum strains in tension and compression occurred where there was the least relative displacement (at the toe and crest of the slope), with the minimum strain (zero) occurring where there was the maximum relative displacement in the middle of the slope. Another numerical simulation of a failure of integrity was presented by Jones and Dixon (2005), a work that was carried forward by the same group in the UK as published in a series of papers related to doctoral work presented in Fowmes (2007). The subject of integrity has received much additional attention in the past decade as well, including

publications by Thiel et al. (2014), Yu and Rowe (2018), and Gao et al. (2022). The focus of these studies has been the impact of waste settlement on strains in the geomembrane, rather than relative displacements along the geomembrane. The assumptions in these cited papers from this past decade did not model the strain-softening characteristics of the interfaces but assumed the most conservative case, from the point of view of the criterion of integrity failure, namely that of peak strengths being maintained, to illustrate the worst-case strains at the top of the slope. The important lessons learned from these papers, relative to the subject matter of the present paper, are:

- The length of a sideslope, sideslope inclination, waste loading and settlement, and relative interface shear strengths above and below a geomembrane all influence the maximum geomembrane strain (Yu & Rowe 2018). Similar conclusions were drawn by Gao et al. (2022), and those same factors would also be relevant to the amount of potential displacement on strain-softening interfaces.
- Sideslope flattening provides the most significant mitigation against downdrag and sideslope displacement problems. VonPein and Lewis (1991) state that "there does not appear to be any problems where the slopes are 3(H):1(V) or flatter", based on their experience and field observations. Yu and Rowe (2018) state that numerical analyses, for the conditions they evaluated, indicate that without geosynthetic reinforcement, slopes steeper than 3(H):1(V) display long-term problematic strains, while the 3(H):1(V) slopes had acceptable strains. Similar conclusions were later expressed by Gao et al. (2022). The penalty for flatter slopes, of course, is reduced airspace for waste or mining ore.
- Increasing the number of intermediate benches on a sideslope is very beneficial in that it reduces the maximum liner strains (Breitenbach & Athanassopoulos 2013; Gao et al. 2022; Thiel et al. 2014; Yu & Rowe 2018), and is also a means of improving the overall slope stability in the case of weak and strain-softening interfaces, as will be discussed later in Section 3.5.
- Gao et al. (2022), who employed the most sophisticated constitutive model for the waste fill, were able to show that mechanical creep and biodegradation can be significant factors in the development of tensile strains in a liner system and can lead to a continuing increase in maximum tensile strains (and displacements) after capping of the landfill.
- The benefit of introducing a stiff, strong geosynthetic reinforcing layer (e.g., a geogrid or high-strength geotextile) to reduce strains in the sideslope geomembrane was emphasized as a possible solution by Long et al. (1995), Thiel et al. (2014), and Yu and Rowe (2018).

This Mechanism is not considered applicable for veneer systems. Related mechanisms that would be applicable to veneer systems would include foundation settlement and construction activities, as discussed below.

2.3   *Mechanism #3. Static lateral spreading of waste*

The issue of static out-of-slope lateral spreading of waste causing displacements along a bottom liner appears to have been raised first by VonPein and Lewis (1991), who suggested that "it is probably reasonable to assume that the toe of a large canyon landfill will move 60 cm or more during filling." Stark et al. (2000) presents inclinometer data taken at the bottom of a 16.5 m high waste fill into the underlying native clay, installed adjacent to, and immediately after, the 1996 Rumpke landfill slope failure, which showed significant out-of-slope movements of the waste that extended into the native clay. They suggest that this phenomenon could have caused excessive shear displacements in the weak base layer that contributed to the progressive failure mechanism of strain softening in the native clay that resulted in the Rumpke slope failure. The reason for static lateral spreading is described by Duplancic (1990), who presents landfill inclinometer data similar to that of Stark et al. (2000), and states that: "Fills on slopes commonly experience lateral deformation due to the

lateral force component imposed by the slope." This mechanism is generally not considered applicable for veneer systems.

2.4 *Mechanism #4. Foundation settlement*

Gilbert and Byrne (1996) refer to foundation settlement as another mechanism that could cause localized deformations that lead to the exceedance of peak strength of strain-softening geosynthetic interfaces. This factor might be especially prevalent in the case of piggyback liner systems installed atop old waste. USEPA (2004) describes potential magnitudes and effects of waste settlement on cover systems. In general, total settlement below veneer systems would be expected to have negligible impact on displacements, while differential settlements will locally increase shear stresses in a manner that would promote progressive displacements on the critical interface.

2.5 *Mechanism #5. Strain/deformation incompatibility between overlying waste/ ore material and the liner system interface*

A situation where the critical failure surface is along the base of a bottom liner system, and then daylights up through the waste, illustrates the concept of 'strain incompatibility' between a strain-softening interface and the overlying waste. This has been emphasized by Stark et al. (2000) as being a mechanism that can promote progressive failure. It is a dynamic of 'incompatibility' which occurs because as the waste/ore mobilizes shear stresses in order to resist collapse, the degree of strain needed to mobilize peak stresses on the strain-softening interface is quite low as compared to the degree of strain needed to mobilize significant shear stresses in the waste/ore material. The result is an unbalanced development of shear stresses mobilized between these two materials, which results in the exceedance of peak strength in the strain-softening geosynthetic interface, which can then lead to progressive failure. This mechanism was identified by Stark et al. (2000) as a contributing factor in the Rumpke failure. This mechanism is generally not considered significant for veneer systems.

2.6 *Mechanism #6. Waste placement activities*

Stark and Choi (2004) mentioned waste placement activities as a contributory factor in promoting progressive failure, referencing Yazdani et al. (1995) as a source. As discussed in Mechanism #2 above, the field measurements presented by Yazdani et al. (1995) represent the strain that would accumulate from waste settlement, and the data collected in that study would be more germane to the issue of downdrag as related to 'integrity' as discussed above. However, one could also imagine that the effects of waste or mine ore operational placement activities could be similar to those of construction activities, as described in Mechanism #9 (Section 2.9), where the presence of heavy equipment in proximity to the liner interface could potentially induce additional temporary dynamic forces that might cause some localized displacement, especially where there are weak spots that would act as stress concentrators that could contribute to progressive failure. In the context of veneer systems, this mechanism would be related to construction activities as described for Mechanism #9.

2.7 *Mechanism #7. Slope overfilling/oversteepening*

Normal waste filling and its concomitant settlement have already been mentioned as being the most commonly recognized mechanism causing liner displacement (Mechanism #2). Stark et al. (2000) mention *over*-filling as an exacerbating factor when the filling exceeds the approved design/operations plan. This often happens when a new cell is not ready in time and the existing capacity of the landfill is overextended. Overfilling then creates additional shear stress and deformations that are often beyond the design limitations. This mechanism

is really an extension of the mechanisms of non-uniform mobilization of shear stresses (Mechanism #1) and waste or mine ore settlement (Mechanism #2) but is listed as a separate mechanism that is a result of operational decisions that can promote progressive failure. This mechanism was identified by Stark et al. (2000) as a contributing factor in the Rumpke failure.

2.8 *Mechanism #8. Toe excavation*

Though the removal of a small amount of toe buttressing may seem innocuous, it can actually be quite devastating due to the initiation of non-uniform mobilization of shear stresses and the static lateral spreading of waste. The plots of the numerical analyses performed by Byrne (1994, Figure 10 of that paper) for mobilized friction angle, and by Filz et al. (2001, Figure 6 of that paper) of the mobilized shear stresses clearly indicate that the real-world phenomenon of non-uniform mobilization of shear stresses (Mechanism #1) concentrates shear stresses at the toe of the fill on the base. Stark et al. (2000) point to the excavation at the toe of the Rumpke landfill as being not only a contributing factor to the failure, but also a factor that allowed the runout of the translational landslide to extend further than it otherwise might have.

What is particularly pernicious about a toe excavation is that it reduces buttressing, thus inviting progressive lateral displacements, and could be the triggering mechanism for a failure. Given that real-world mobilization of shear stresses favors increased stresses at the toe, as demonstrated by Byrne (1994), a small displacement that exceeds the peak strength at the toe makes that zone weaker, which means it can carry less of the lateral load. That in turn puts more of the load on zones adjacent to the critical plane, which may in turn cause another part of that plane to become overstressed and exceed its peak strength (which is the classical description of progressive failure). This mechanism is also applicable to veneer situations. The full-scale field study by Villard et al. (1999) showed how removal of the toe at the base of a veneer fill significantly increased the geosynthetic strains. Stark et al. (2012) describes the value of a toe buttress when constructing veneer layers.

2.9 *Mechanism #9. Construction-induced shear strength degradation*

Concern over the effects of deformations and displacements on the long-term operational peak strength of interfaces that occur during construction has been previously expressed by Gilbert and Byrne (1996), Thiel (2001), Sabatini et al. (2002), and Stark and Choi (2004). None of these sources, however, specifically addressed exactly how construction activities could impact liner system interfaces. The present paper provides updates regarding this issue.

The construction of geosynthetic-lined containment facilities commonly involves a relatively thin layer of soil to be spread over one or more geosynthetic layers; this applies to both bottom liner and final veneer liner systems. A key point here is that the *localized* shear stresses caused by a soil-spreading operation using a dozer are significantly higher than the *average* shear stresses that are assumed to be distributed over the entire slope length. This is due to forces needed to overcome the friction at the base of the soil pile being spread, the weight of the dozer, and any acceleration/deceleration of the dozer.

We would note that this consideration is completely different from the usual consideration of the stability of equipment operation on slopes that is most commonly cited from sources such as Koerner and Soong (1998), Qian et al. (2001), Druschel and Underwood (1993), McKelvey (1994), and USEPA (2004). These references only consider an entire slope reach, and equipment stresses are assumed to be distributed over the entire slope length, often with the objective of calculating the anchorage strength required to secure the geosynthetics, thereby preserving slope stability during this type of construction. If the veneer stability of the entire slope length is at issue, then the references cited in this paragraph can be used, and the calculation is straightforward.

A much more pernicious situation, which is dangerous from the point of view of progressive failure, is if the peak shear strength of any of the interfaces is exceeded by the construction-induced *localized* shear stresses. In this case the shear resistance of these interfaces will be degraded little by little as they experience relative displacements during construction. Such localized relative displacements, and the resulting localized shear strength degradation, may or may not be apparent as construction proceeds. Obvious failures that the author has seen in this regard include a case history presented in Thiel and Narejo (2005), and another confidential case history used as an example in Thiel and Giroud (2023). Localized track spinning, which would cause relative displacements of a geotextile to a textured geomembrane on the order of one to twenty centimeters, would be deleterious to the integrity of the interface's peak shear strength at all locations where that occurred. These types of small but impactful slippages could occur over and over without attracting the attention of the dozer operator or the construction observer. The cumulative effect of such localized shear strength degradation events over the course of construction of an entire slope can thus be seen as detrimental to the slope's static and dynamic stability in the long term, especially in light of a progressive failure.

There are five references that suggest methods to quantify the elevated localized shear stresses below the dozer tracks could cause localized exceedance of shear strength: Paruvakat and Richardson (1999), Kerkes (1999), Jones et al. (2000), Thiel and Narejo (2005), and Thiel and Giroud (2023). Each of these references either adds to or improves upon the work presented in the other references, and taken as a whole, they provide useful approaches to quantification of the problem, as well as suggestions for construction specifications and construction quality assurance (CQA) that can mitigate the problem.

To the author's knowledge, the effect of interface deformation at low normal stresses on the subsequent shear strength at higher normal stresses has only been documented in one study, that of Esterhuizen et al. (2001). They showed that for a particular smooth geomembrane/clay interface, deformations at low normal stresses would reduce the peak strength of the interface at higher normal stresses. They present results showing that the peak shear strength at 345 kPa normal stress was reduced by approximately 13% due to pre-shearing at 35 kPa normal stress. They provided an interesting "work-softening" model to describe this behavior in a manner that can be used in a finite-element analysis. Although their model fits the data very well, it is only applicable to the specific clay and geomembrane used for their study.

Limited testing was performed for the present paper in order to provide some insight into this issue for a textured geomembrane/geocomposite interface, where the geocomposite surface was a nonwoven geotextile that was heat-bonded to a geonet. Two cases were checked: one for high normal stress (bottom liner) situations and one for long-term low-normal stress (veneer) situations. For the high-normal stress situation, this particular interface was pre-sheared at a low normal stress of 24 kPa, representative of dozer loading, and then final-sheared at a higher normal stress of 192 kPa. The results, presented in Figure 3, indicated that the peak strength at the high normal stress was reduced by approximately 13% due to pre-shearing at the dozer construction stress, as compared to shearing a virgin sample at the high normal stress. For the low-normal stress situation, this particular interface was pre-sheared at a construction normal stress of 24 kPa to represent the dozer loading, and then final-sheared at a lower normal stress of 10 kPa, representative of the typical long-term loading of a cover system. The results, presented in Figure 4, indicated that the dozer-induced pre-shearing resulted in LD shear strength under the design normal stress of 10 kPa to be approximately 42% lower than the peak strength that would typically be obtained by shearing a virgin sample.

Note related to the expansion/contraction of exposed geosynthetics. Stark and Poeppel (1994), Stark and Choi (2004), and Zamara et al. (2014) mention thermal expansion/contraction of exposed geosynthetics as being a possible cause that peak strength could be reduced at strain-softening interfaces. The present author has commissioned testing on two
Figure 3. Test results showing effect of pre-shearing at low normal stress on peak strength at high normal stress for an interface of a textured HDPE geomembrane against the nonwoven geotextile surface of a drainage geocomposite.
Figure 4. Test results showing effects of pre-shearing at dozer construction normal stress on peak strength at low veneer normal stress for an interface of a textured HDPE geomembrane against the non-woven geotextile surface of a drainage geocomposite.

separate projects that used different types of textured geomembranes that had been dragged over non-woven geotextile based GCLs during deployment to determine if the dragging caused any degradation of shear strength as compared to virgin materials tested at 400 kPa normal stress. The result was that no perceptible differences were noted. The author is not aware of any other such zero-normal-load shear-degradation studies that have been conducted. This cause for possible peak strength degradation is included here as a subset of potential construction-induced strength degradation, a possibility that remains to be verified by further testing.

2.10 Mechanism #10. Pore pressures

Apart from gravity, pore pressures (most pervasively those caused by liquid, but also possibly caused by gas) are the single most prevalent factor contributing to slope stability failures. The reason for this is that pore pressures reduce the effective normal stress that gives interfaces their shear strength, but the applied shear stress is often unaffected by pore pressures. Examples of significant excess pore pressure buildups in bottom liner systems that have been observed are failure or malfunction of pumps, power, or controls; leachate collection systems that experience collapsed pipes (observed by author via in-pipe cameras and exhumations); and leachate collection systems that clog due to poor design (Koerner et al. 1994) and/or long-term inorganic precipitation where biological clogging is typically a catalyst (Rowe & VanGulck 2004). Localized waste saturation can create conditions for the development of significant pore-gas pressures which have been measured in excess of 200 kPa that are suspected of causing a stability failure in a high-food-waste-content MSW landfill (Ma et al. 2019). In final cover systems the overloading of the drainage layer on top of the barrier layer is the most common cause of the many veneer-cover failures caused by inadequate transmissivity, susceptibility to being overloaded with water during construction, and inadequate or blocked outlets. Even if pore pressure buildups are just temporary, such as during a control system failure in a storm event, progressive failure can be triggered.

Pore pressures on the underside of the liner system could manifest as a result of saturated high-plasticity clays in the subgrade that do not have adequate time to dissipate relative to the rate of loading for bottom liner systems, or landfill gas pressures for final cover systems.

2.11 Mechanism #11. Seismic loading

Seismic loading increases the potential for displacements to occur along the critical failure plane which, in conjunction with the non-uniform mobilization of shear stresses, can locally (or globally) cause displacements that reduce the strength of the critical interface below its peak strength, thus leading to progressive failure. In this regard the design practitioner should assess the potential for this type of deformation.

When performing calculations to determine if seismic deformations due to the design earthquake will be within acceptable limits (as defined by standard practice or the regulations), LD or residual values for the strengths should be assumed along the entire critical interface for purposes of those calculations, even if peak strengths have been determined to be acceptable for purposes of the static stability (Kavazanjian 1999, 2023). The design should then be checked to meet other project-specific standards or regulatory requirements separately for static FS, and for the maximum estimated displacement due to the design earthquake.

2.12 Mechanism #12. Variations in operating temperature

Hanson et al. (2015) performed laboratory testing to determine the effects of temperature on the shear strength of the interface between a textured HDPE geomembrane (asperity height of 0.45 mm) and a needle-punched GCL having a woven geotextile interface with the geomembrane. Tests were performed for low-normal load (cover system) applications at an average normal stress of 15 kPa, and high-normal load (bottom liner) applications at an average normal stress of 150 kPa. The temperatures for the low-normal load load testing were 2, 20, and 40°C. The temperatures for the high-normal load testing were 20 and 40°C. Their research suggests that the design values of shear strengths for interfaces between textured geomembranes and a non-woven geotextile-based product could potentially be prorated downwards by as much as 15-20% for cover systems, and 10-15% for bottom liner systems, to account for the effects of temperature.

Karademir and Frost (2021) performed an extensive interface shear program to evaluate the effects of temperature on interface shear strength between several different types of geomembranes (smooth PVC and HDPE, as well as three different types of textured HDPE) and needle-punched nonwoven (NPNW) polypropylene (PP) geotextiles. Tests were performed at normal stresses of 10, 100, and 400 kPa, and at temperatures of 21, 26. 30. 35. 40, and 50°C. In all cases their results indicated that the interface shear strength increased with temperature. The increases in strength going from 21 to 50°C ranged from 14-23% for peak strength and from 14-18% for large displacement strength for the various interfaces tested. They concluded that for the range of normal stresses and materials tested that interface shear behavior determined at room temperature yields interface friction values that are conservative.

Given the differing conclusions between the two studies mentioned above, the present author does not recommend adjustments to interface shear strength due to temperature effects, and that the standard factor of safety of 1.5 would be appropriate to account for variations in this regard.

2.13   *Mechanism #13. Long-term ageing and creep of the geosynthetics*

Several authors have pointed to long-term ageing and creep as being potentially significant contributors to a mechanism of progressive failure along strain-softening interfaces for both high- and low-normal-load situations (e.g., Byrne 1994; Breitenbach 1997; Gilbert & Byrne 1996; Jones & Dixon 2003; Skempton 1964; Sabatini et al. 2002; Thiel 2001; Zanzinger & Alexiew 2002; Zanzinger & Saathoff 2012).

Trauger et al. (1997) performed long-term internal shear testing of soaked reinforced GCL specimens at both low (24 kPa) and high (97-389 kPa) normal stresses with applied shear stresses equivalent to 26.6° and 19.3° friction, respectively, for up to 10,000 hours without shear failure. Zanzinger & Alexiew (2002) performed long-term internal shear testing on GCL specimens at low normal stresses with applied shear stress ratios of up to 90% of the short-term internal shear strength on reinforced GCLs for up to 5,000 hours without shear failure. These studies indicate good long-term durability for GCL reinforcement exclusive of ageing of the geotextile fibers.

Marr and Christopher (2003) considered long-term ageing and creep of the internal reinforced needle-punched fibers of GCLs. This is important because if the internal shear strength of the GCL exceeds its peak then the remaining residual strength will be that of hydrated bentonite, which can be as low as 4° friction. Most designs provide another interface that is weaker than the peak internal strength of the GCL to 'ensure' that the peak internal GCL strength never fails (this is known as the 'fuse' concept, where the 'critical interface' is defined as the one that has the lowest peak strength, even if it does not have the lowest residual strength). Marr and Christopher (2003) cautioned that long-term creep could challenge this design concept, and recommended that the following reduction factors (R_f) be applied to the *difference between* the peak and residual internal shear strength of the project-specific GCL: R_{f-cr} = 3 to account for long-term creep; and R_{f-age} = 1.1 (100-year life) or 2.0 (300-year life) to account for ageing. The two values of R_f would be multiplied by each other to yield a total R_f ranging from 3.3 to 6.0. The resulting value would be *added back* to the residual value of the GCL internal shear strength to obtain the maximum allowable long-term internal design strength, $\delta_{GCL-all}$, of the project-specific GCL. Marr and Christopher (2003) further suggested that to prevent failure from occurring inside the GCL, another interface should be provided in a layer above the GCL that has a short-term peak interface strength less than $\delta_{GCL-all}$. This latter goal cannot always be achieved within the constraints of the available materials and design goals, and the present author suggests that the same design intent could also be met by verifying, through analyses, that the long-term mobilized shear stress of the design is less than $\delta_{GCL-all}$. Note that this type of calculation can only be quasi-reliable when numerical analyses are used, since limit equilibrium methods do not provide an accurate picture of the true mobilization of stresses or strains of deformable

bodies. The present author believes that this approach is conservatively biased because the high peak internal shear strength at high normal stresses for needle-punched reinforced GCLs, even under fully hydrated conditions, is much greater than the sum of the bentonite shear strength and geotextile tensile strength, due to some mechanism that is not fully understood at this time (Thiel & Maubeuge 2002). The R_f values suggested by Marr and Christopher (2003), therefore, might not need to be applied to the entire difference between the peak and residual internal shear strength of the GCL. More research is needed in this regard.

Abdelaal and Solanki (2022) performed laboratory testing to investigate, among other things, the effect of geotextile ageing on the interface shear behavior, using a 2 mm thick blown-film textured HDPE geomembrane having an average asperity height of 0.45 mm. Three different single-layer non-woven needle-punched staple fiber geotextiles with mass per unit areas of 200, 580, and 1500 g/m^2 were tested at normal stresses of 250, 700 and 1000 kPa. The results showed that for the interfaces that involved geotextiles that were aged prior to the shear box experiments for up to 2 years at 85°C, all the highly aged single-layered geotextiles showed an increase in the peak interface friction angles as their ageing increased. For these single-layered geotextiles, the results suggest that assessing the interface friction angles using unaged geotextiles for a stability analysis is a conservative practice as long as the geotextile remains intact in the field. This is a welcome finding in light of the previous ambiguity that dogged the question of long-term ageing relative to shear strength, at least for interfaces involving nonwoven geotextiles set against textured HDPE geomembranes.

2.14   Mechanism #14. Variability of material manufacturing

Consideration of material variability is endemic to geotechnical engineering in which the accurate characterization of soil properties is often a statistical endeavor. One of the often-touted benefits of geosynthetics is their relative uniformity, compared to soils, due to their being manufactured under controlled conditions. While there is merit to this perception, casual acceptance of this as a fact has led to abuse in the adoption of geosynthetics via the assumption that single tests, especially those related to shear strength, can be taken as representative for entire projects. Even worse is when published values of shear strength are blindly accepted as a design basis with no further qualification.

The idea that facilities constructed without the benefit of project-specific testing can be less reliable than those verified with testing is generally well accepted and espoused in the literature (e.g., Dixon et al. 2006; McCartney et al. 2004; Richardson et al. 1998; Sabatini et al. 2002; Thiel 2001). Construction conformance (verification) testing of shear strength is standard practice for lined containment facilities where slope stability is important.

Often it can be time consuming and costly to conduct numerous interface shear performance tests during construction. For that reason, index tests are often performed, where it is presumed that attainment of certain minimum index values will infer that the shear strengths that had been verified by performance tests will be achieved. Example index tests that might be relevant to shear strength for soils could include grain size distribution, Atterberg limits, clay fraction, moisture, and density. Example index tests that might be relevant to shear strength for geosynthetics include asperity height for geomembranes, and peel strength for GCLs and geocomposites. Although precise correlations between the results for these various index tests and shear strength might not be available, engineering judgement indicates that replication of benchmark values that have been previously demonstrated to be satisfactory should result in acceptable performance.

However, even when conformance testing of materials supplied to a job site is performed, weak locations can exist that are not representative of the average strength may become host to impactful stress concentrations. This fact, when combined with the fact of non-uniform mobilization of shear stresses (Mechanism #1 above), could result in a localized progressive exceedance of peak strength that could contribute to a stability failure. Examples of

geosynthetic manufacturing variability that have been observed to create weak zones are non-uniform texturization of HDPE geomembranes (e.g. 'tiger striping'), variation of peel strength across the roll width of GCLs, and variations of peel strength of GCLs from beginning to end of needle-board changes during the manufacturing run. Perhaps one of the most highly variable interfaces that currently exists for geosynthetic shear interfaces is the heat bonding of a geotextile to a geonet that is commonly performed to create a geocomposite drainage layer. While the relationship between peel strength and (internal) interface shear strength of the geotextile/geonet products is not well understood, an attempt to study this and demonstrate such a relationship exists was published by Thiel and Narejo (2005) as a result of an investigation of a field failure of this interface. Standard testing for geocomposite peel strength, which is an index of shear strength, is almost always performed in the USA according to ASTM D7005, Standard Test Method for Determining the Bond Strength (Ply Adhesion) of Geocomposites. This test only requires reporting of the results based on the average of five 100 mm wide specimens across the panel width. Because there is a natural laboratory bias towards cutting specimens from the sample that do not fall apart, zero-strength specimens are almost never taken, even though they commonly exist due to manufacturing limitations. Thiel and Gatrell (2019) tested the variability of the peel strength of samples in which contiguous 100 mm wide specimens were cut in a checkerboard pattern across the panel width. Figure 5 presents the results for a sample that yielded 38 specimens, which resulted in an average peel strength of 290 N/m with a standard deviation (assuming normal distribution of data) of 230 N/m, not counting the unbonded edges of the panel. It is noteworthy that even though the average value was soundly above the target specification of 175 N/m and 'passed' the conformance testing requirements, 12 of the 38 specimens (32%) were below the target specification. Of these 12, 7 of the values (18.4%) were less than one-fourth (25%) of the target specification, which is very low (< 44 N/m). The test results presented in Figure 5 may represent the lower end of quality that can be achieved for geocomposite bonding, but such results have been qualitatively reported to the author by others and experienced by Thiel and Narejo (2005).
Figure 5.   Results of contiguous peel tests across geocomposite panel width (from Thiel & Gatrell 2019).

The study concluded that the current practice of taking only five specimens across the panel width is inadequate to verify the variability of bonding across geocomposite drainage products that are created by heat bonding. In addition, even with contiguous

specimen testing across the panel width the question remains as to which value would be representative for design purposes, considering the strain-softening nature of the interface.

2.15 *Mechanism # 15: Variability in the installation of geosynthetic interfaces*

The present paper introduces the idea that variability in installation practices is a potentially significant contributor to the introduction of repetitive weak zones in geosynthetic installations, as related to the seaming of geosynthetics. Examples of this apply both to high- and low-normal-load situations and include:

- Smooth edges on otherwise textured geomembranes that are intentionally manufactured to improve seam quality. The width of the smooth edges is commonly 0.15 m on both sides of a 6.86 m wide panel. Considering that seam overlaps are commonly 0.1 m, this leaves 0.2 m of smooth surface for every 6.76 m, or about 3.0% of the area.
- Geocomposite drainage layers comprised of geonets with geotextiles heat-bonded to one or both sides typically have the geotextiles unbonded along each edge to allow for seaming. The width of the unbonded edges is commonly 0.3 m on both sides of a 4.42 m wide panel. Considering that seam overlaps are commonly 0.1 m, this leaves 0.5 m of unbonded surface for every 4.32 m, or about 11.6% of the area.
- GCLs are commonly overlapped with an approximately 0.08 m wide ribbon of free bentonite applied within the overlaps. The width of the overlap is commonly 0.15 m on both sides of a 4.42 m wide panel. This leaves 0.08 m of potentially hydrated loose bentonite for every 4.27 m, or about 1.9% of the area.

The shear strengths of each of the seam zones for each of these materials will generally be substantially weaker than those of the non-seam zones, depending on which type of materials are placed against these interfaces. It is possible that some designers have taken some of these considerations of installation variability into account and have prorated the design shear strength accordingly. However, even simple proration of shear strengths may not be a completely adequate response to this issue with strain-softening materials in bottom liner situations because of the potential consequences of shear stress concentrations that would likely occur at the edges of these weak inclusions.

The relative significance of this issue depends upon not only the pervasiveness of the weak zones and the degree of their weakness, but also the configuration of the site-specific lining system. Consider the example of a liner system that was used in a design example presented by Qian and Koerner (2010), shown in Figure 6.

Figure 6.   Detail of liner system that was used in a design example presented by Qian and Koerner (2010).

The detail shows that there are two layers of geomembrane, two layers of geocomposite, and one layer of GCL, all in close proximity to one another (<15 mm). The shear strengths of each of the seam zones for this cross-section could be evaluated as follows:

- The smooth edges of both geomembranes would have one side against the geotextile surface of a geocomposite. Stark and Richardson (2000) report secant peak and residual smooth geomembrane/geotextile shear strengths as being 9° and 5°, respectively, with peak strength mobilization occurring at 2 mm of displacement, for a normal stress of 400 kPa. This compares to peak and residual secant strengths of 30° and 15°, respectively, for textured interfaces, with peak strength mobilization occurring at approximately 6 mm of displacement.
- Regarding the geocomposite panel edges with the unbonded geotextile, limited testing was performed for purposes of the present paper in order to provide information regarding the interface strength between a loose geotextile and a geonet with the shear taking place *parallel to the geonet rails*. Whereas testing the shear strength of this interface in either the machine- or transverse-panel-direction of the geonet will deliver apparently high friction values, the shear strength parallel to the geonet rails is very low, as can be experienced by simply walking around construction sites and stepping on the edge of an unbonded geocomposite. The test results indicated peak and large-displacement geonet/geotextile shear strengths of 12.5° and 9.7°, respectively, over a normal stress range of 50-200 kPa, with peak strength mobilization occurring at approximately 5 mm of displacement.
- Since in this case the GCL is designed to be installed in the dry secondary layer, bentonite hydration in the seam is ignored in this exercise.

Consider the installation of this liner system on a 3(H):1(V) sideslope. Typically, the geosynthetic materials would be deployed with their machine-direction going downhill in the direction of the slope. Since the unbonded geonet edge strength was measured parallel to the geonet ribs, this is the orientation that should be considered. Figure 7 is a photograph of the sample testing in the laboratory showing a 25° angle of the geonet ribs relative to the machine direction of the geonet. (This value will be specific to the product being tested.) To account for this orientation when considering the shear stresses and potential for progressive failure on a 3(H):1(V) (18.4°) slope, it can be calculated that the angle of the sideslope at a 25° skew is 16.7°. Adding up the tributary areas of the weak seam zones for the two layers of
Figure 7. Photograph of test setup with geotextile on top of geonet for shear parallel to the geonet ribs. (Courtesy of SGI Testing, Atlanta, GA).

geomembranes and the two layers of geocomposites yields a result of $2 \times (3\% + 11.6\%) = 29.2\%$ of the area having a shear strength of less than $10°$ friction at the critical inclination of $16.7°$. This indicates a very significant proportion of weak areas could exist that have a shear strength substantially less than the critical slope inclination, and which would be significantly less than either the peak or residual strength of a textured geomembrane/geotextile interface.

The conclusion we reach from this discussion of Mechanism #15 is that the seaming mechanics required for each of the different types of geosynthetics can introduce regularly spaced weak areas in the liner system that provide sites for the initiation and promotion of progressive failure. The detrimental effects of these weak zones may also be exacerbated by shear stress concentrations that induced by the sudden changes in shear strength at their edges. A related weak-zone issue can also be created during installation by leaving excess geosynthetic scraps and rubsheet materials below geomembranes rather than collecting these materials and throwing them away, a practice which should be addressed by vigilant specifications and CQA.

2.16 *Note regarding the combined material and installation variability of drainage geocomposites*

This discussion of the material and installation shear strength variability that is potentially introduced by the use of drainage geocomposites should be cause for designers and owners to exercise a high level of scrutiny when using those materials where slope stability is important. Consider the large variability of material with regard to geocomposite peel strength described in Section 2.14, where test data indicated that 18.4% of the 'bonded' area was less than one-quarter of the specified valued of 175 N/m peel (i.e. < 44 kN/m). A reasonable and prudent assumption is that areas with bonding of less than 44 N/m (0.25 pounds per inch) will become fully unbonded during construction and in-service conditions. For a net installed panel width of 4.32 m this would represent 16.2% of the total installed area for that side of the geocomposite having a low shear strength (< $10°$ friction) in the direction parallel to the geonet rails. (Although the other side had similar bonding problems, the geonet rails on the other side run in a different direction and so only one side would be counted.) To this could be added the unbonded edge zones that represent 11.6% of the installed area, as described in Section 2.15, now producing a total unbonded area on the order of 27.8% of the total planimetric area that could have a low shear strength (< $10°$ friction) in the direction parallel to the geonet rails. If two layers of geocomposite are used in a liner system, such as the one depicted in Figure 6, then a value potentially greater than 50% of the lined area in service could have this low degree of shear strength in the direction of the geonet rails due to the poor bonding, depending on how much overlap of the poorly bonded zones occurred between the two geocomposite layers from a planimetric perspective. The debilitating nature of the high frequency of both known and random poorly bonded areas in a geocomposite can play an outsized role in reducing the dependable shear strength. It is highly recommended then, to give special attention to specifications for the bonding between geotextiles and geonets when using drainage geocomposites. Where slope stability is critical, specifications for these materials should be written that require minimal widths of unbonded edge zones, and higher average peel strengths to compensate for the very high standard deviations in manufacturing that seem endemic to these manufactured products. In addition, increased conformance (verification) testing frequency of peel strength would be advised, requiring that more specimens be tested across the panel width, and perhaps even contiguous specimens for CQA, as illustrated in Figure 5. The examples of materials and variability in installation presented herein are for specific products and situations that have been encountered by the author. The frequency, magnitude, and distribution of defects could therefore be quite different for other products in other regions, and for different installation practices. While the author regularly specifies these products with confidence, it is always done with these considerations.

3 THIRTEEN MEASURES THAT CAN BE ADOPTED TO REDUCE OR MITIGATE DISPLACEMENTS THAT CAN LEAD TO PROGRESSIVE FAILURE

There are measures that can be adopted to reduce the tendency for shear displacement along a critical strain-softening interface, thus improving the liner's reliability against failure. The development of relative displacements occurs more readily and to a greater extent on side-slopes as compared to at the base of deep-seated critical surfaces. The target zones for application of the measures described below would have to be evaluated on a case-by-case basis. For example, while it may be advantageous to pursue bolstering of the peak strength of a liner system along the base, to attempt to do so along a steep sideslope could prove detrimental due to the threat of high-strain integrity (i.e. ripping) failures on the sideslope.

This section presents a list of thirteen Measures that can reduce or mitigate the tendency for displacements that might lead to progressive failure in the presence of strain-softening interfaces in high normal load bottom liners, of which ten also apply to veneer situations. These Measures have been grouped into five categories depending upon the treatment mechanism, and can generally be targeted to benefit the base, sideslope, or both areas of a given design.

- Category 1 includes five Measures that are related to geometric modifications that would increase the factor of safety and reduce the magnitude of relative displacements that could occur.
  - Measure #1: Fill slope flattening and avoidance of over-filling.
  - Measure #2: Sideslope flattening.
  - Measure #3: Longer base design.
  - Measure #4: Buttressing of the toe and avoidance of excavation at the toe.
  - Measure #5: Geometric interruptions in the subgrade.

- Category 2 includes five Measures that are related to the attempt to preserve peak strength to the extent possible. Preserving peak strength can be useful for one or more phases of the project, which include construction, operations, and final build-out stability. These measures could target the base liner, or the sideslope liner, or both.
  - Measure #6: Increase peak strength.
  - Measure #7: Reduce weak spots resulting from variabilities in materials and installation practices.
  - Measure #8: Minimize any significant interface damage resulting from construction or waste filling.
  - Measure #9: Mitigate foundation settlement.
  - Measure #10: Implement high strength reinforcement along sideslopes.

- Category 3 includes one Measure that is related to avoiding the transient destabilizing influence of pore pressures.
  - Measure #11: Mitigate potential against high pore pressures.

- Category 4 includes one Measure that is related to the assumption that residual strength will develop along the geosynthetic interfaces.
  - Measure #12: Increase the residual strength of the interface with the lowest peak.

- Category 5 includes one Measure related to adaptive management:
  - Measure #13: Long-term instrumentation and monitoring.

3.1 *Measure #1: Fill slope flattening and avoidance of over-filling*

Fill slope flattening is a common geotechnical measure taken to improve slope stability and reduce the risk of failure. Since the only reason slope stability is an issue is the presence of a

slope, reducing the severity of the slope quite naturally reduces the risk of instability. The penalty for fill slope flattening, of course, is less capacity for waste or mining ore. This Measure has a significant beneficial influence on veneer stability.

3.2 Measure #2: Sideslope flattening (discussion for bottom liner situations only; see Measure #1 for veneer situations)

Although flattening of the lined sideslope at the back of the waste or mining ore mass might have a greater chance of preserving peak strength on the sideslope, this Measure does not necessarily improve slope stability, and may even worsen it for bottom liners. A relatively steep sideslope for bottom liners can be a more stable configuration than a flatter sideslope because a steeper sideslope typically allows more base area to develop forces that resist sliding. A proof of this is provided in the *Geosynthetics International* companion paper appendices.

3.3 Measure #3: Longer base

Having a greater ratio of base length to sideslope length is a proven means of improving slope stability (Reddy et al. 1996; Stark 2022). This fact is also demonstrated in the example proof described above in Measure #2, which is published in the *Geosynthetics International* companion paper appendices. Even so, a very long base is not a panacea against displacements along a liner with low-stiffness waste materials that can experience significant static lateral spreading. This measure is not applicable to veneer systems.

3.4 Measure #4: Construct toe buttress and avoid excavation at the toe

Constructing a buttress at the toe of a slope is a common geotechnical solution employed to improve the stability of slopes in general. This technique is commonly used in canyon landfills and in valley-fill mining leach pads. The size and resistance of a toe buttress can be designed to allow the containment facility to safely mobilize residual shear strength conditions along the lined interface. A toe buttress is essentially a dam that provides resistance to prevent the waste or mining ore body from sliding down the canyon or valley, or from spreading laterally. Providing a buttress at the toe greatly reduces the likelihood that the toe of the fill will displace, which is important, because numerical analyses have shown that this can be the location that triggers a progressive failure. The obverse of a toe berm is excavation at the toe, which can be especially debilitating and is suspected of having played a role in the Rumpke failure (Stark et al. 2000).

USEPA (2004) shows examples of toe buttresses for veneer situations that not only support the toe but also allow general slope flattening. A variation of a toe buttress is a tapered thickness cover soil (Koerner & Soong 1998). Designing shorter slope lengths between benches on a veneer slope is another way to increase the effect of intrinsic toe buttressing by limiting the finite slope length of any given slope reach. For practical engineering purposes, when the ratio of the slope length to veneer soil thickness exceeds 10-20, the slope will act like an 'infinite slope', and the benefits of toe resistance to slope instability then provide diminishing returns as the slope length increases.

3.5 Measure #5: Geometric interruptions in subgrade

Among the most effective and reliable methods of improving the stability of a containment facility that has strain-softening liner interfaces is to create non-planar interruptions along the critical slip interface that will force the critical failure surface to intermittently pass through stronger materials that are above and/or below the geosynthetic interfaces. This Measure generally applies to bottom liner systems rather than veneer systems. The best

overall description of this approach is provided by Breitenbach and Athanassopoulos (2013), who describe three types of geometrical subgrade interruptions that improve stability:

1. Stability Berms. Also referred to as "speed bumps", stability berms can be constructed in the subgrade before the liner is placed. They cause the critical slip plane to either pass along a non-planar surface, or to pass through higher strength materials. Depending upon the details of the geometry it is likely that both phenomena will occur, and overall stability will be improved as compared to having a planar surface lined with geosynthetics. Breitenbach and Athanassopoulos (2013) provide an example sensitivity analysis which considers the effects of the number, width, height, spacing, and subgrade shear strength of stability berms upon the slope stability factor of safety.
2. Stability Trenches. The geometrical inverse of a berm is a trench, and in this regard a stability trench can provide an effect similar to the that of a stability berm. Trenches can be excavated into the subgrade, lined, and backfilled with the waste, mining ore, or other materials in order to cause the critical slip plane to either pass along a non-planar surface, or to pass through higher strength materials. Breitenbach and Athanassopoulos (2013) note that trenches can create more complications when implemented with gravity drainage systems on the liner than would be the case with stability berms.
3. Stability Benches. The use of benches on slopes to improve stability and reduce downdrag liner strains, a practice that functions similarly to the way stability berms function on the base, has also been emphasized by Thiel et al. (2014), Yu and Rowe (2018), and Gao et al. (2022).

While the implementation of these various techniques to interrupt the subgrade geometry all involve extra earthworks, drainage, and lining complexities, they are viable means of increasing the stability factors of safety, even as some displacement does occur along the strain-softening geosynthetic interfaces.

3.6 *Measure #6: Increase peak strength*

If the design basis is to preserve peak strength along a portion of the liner system (e.g., along the base) then specifying materials that increase the peak interface strength will enhance that goal. Examples of methods to accomplish this include more aggressive texturing of geomembranes, and the incorporation of high-friction (granular) soil layers between geosynthetics. Where GCLs are used, enhanced needle punching should be employed to ensure that the internal shear strength of the GCL is not the weak link, and to ensure its strength by a confidence-inducing margin, as discussed in Section 2.13.

3.7 *Measure #7: Reduce weak spots due to variabilities in materials and installation practices*

This Measure can be considered a direct countermeasure to Mechanism Nos. 14 (material variability) and 15 (installation variability). Tools for the practical implementation of a reduction in the negative effects caused by the variability of material and installation interface strengths are: (a) an understanding of the limitations of manufacturing and installation, (b) strict specifications regarding what is required as related to material manufacturing and installation, and (c) diligent CQA to verify that what is specified is actually provided. There are limits as to what can be provided through manufacturing and installation, which is why it is important for the designer to be very familiar with those limitations.

Section 2.16 directly addressed specific issues related to the variability of geocomposites, which typically present a greater degree of variability in terms of both manufacturing and installation than do other geosynthetic materials, at least in the USA. Possible approaches to address these variabilities include:

- The geocomposite drainage layer could potentially be replaced with a granular drainage layer which has a very dependable internal and interface shear strength. The emphasis of concern would then switch to the potential for damage during construction resulting from the placement of a thin granular layer.
- Geocomposites are typically manufactured with a certain unbonded distance near the edge to allow for seaming by overlap and zip-tying of the geonet cores. The manufacturer could be requested to manufacture the material with the minimum amount of unbonded distance from the edge. If the design does not depend on the transverse-direction transmissivity, then the material could perhaps be manufactured without unbonded edges.
- To compensate for the weak spots caused by the high standard deviation of peel strength associated with geocomposite drainage materials, a higher average peel strength may need to be specified. For products created by heat-bonding, this will usually require a thicker geonet core because of the reduction in transmissivity that goes with obtaining a higher peel strength. It is also good to be aware that a high average peel strength requirement can make it very difficult to peel the geotextile back at the ends of the panels where butt seams need to be performed.

Regardless of the approach taken, a high level of project-specific preparation of the specifications, conformance testing, and CQA construction enforcement is required to reduce the incidence and degree of variability, which the author has found to be a successful approach.

3.8 Measure #8: Minimize any significant interface damage due to construction or waste filling

As discussed in Section 2.9, the main cause of construction damage to the geosynthetic interface is excessive shear stresses and displacements induced by construction equipment. The most common issue in this regard is the shear forces induced by dozer tracks when drivers attempt to push too large of a soil pile upslope, or often worse, downslope. Other conditions of excessive shear stress can occur when construction equipment applies braking forces when moving in a downslope direction. Solutions to these issues require clearly defined enforceable constraints in the specifications that require review by the responsible engineer for all proposed equipment operations on thin (veneer) soil layers being placed on lined slopes. Approaches to the required calculations are presented in Paruvakat and Richardson (1999), Kerkes (1999), Jones et al. (2000), Thiel and Giroud (2023), and Thiel and Giroud (2024).

3.9 Measure #9: Mitigate foundation settlement

To the extent that foundation settlement might introduce additional undesirable relative displacements along the liner system, foundation improvements such as dynamic compaction, preloading, or bridging weak zones to the extent feasible with geosynthetic reinforcement, can help mitigate this issue.

3.10 Measure #10: High strength reinforcement along sideslopes

Insertion of a stiff reinforcement layer within a sideslope liner system to carry a large portion of the tangential stresses, and thus reduce displacements and strains along all the other interfaces, is a well-known design approach. This concept is especially relevant for thin layer cover systems in general, especially during construction (e.g. Druschel & Underwood 1993; Koerner & Soong 1998; McKelvey 1994; USEPA 2004), but is also applicable to bottom liner systems (Long et al. 1995; Thiel et al. 2014).

3.11 Measure #11: Mitigate the potential for high pore pressures

Control of, and proper accounting for pore pressures is a fundamental geotechnical design requirement that is not unique to lined containment facilities. What can be particularly problematic for lined containment facilities, though, is the fact that excessive pore pressures generated at the lined interface can cause a localized exceedance of the peak shear strength, which in strain-softening materials can promote a progressive failure mechanism. Such situations can arise due to equipment malfunctions, power failures, failures of backup systems, leachate mounding within the waste mass above fouled or crushed leachate/liquid collection systems, long-term reductions in drainage infrastructure capacities, and the low permeability of high-organic waste leading to waste saturation and localized high gas pressures. Redundancy and robust reduction factors in drainage infrastructure can improve reliability.

Design of bottom liner leachate or solution collection systems should account for long-term clogging mechanisms appropriate for the site-specific hydraulic and chemical loading, drainage layer and pipe layout design, and filtration. A good review of these mechanisms and design approaches to address site-specific issues is presented by Rowe and Yu (2010), and an interesting design case history is presented by Yu and Rowe (2016).

Proper design of reliable lateral drainage layers above and/or below the barrier layers of veneer lining systems, and providing robust drainage outlets, cannot be over emphasized due to the sensitivity of veneer stability to relatively small increases in pore pressures. When designing a lateral drainage layer above a veneer liner system in order to control pore pressures that would be caused by meteoric water infiltration from above, it is advisable to use the unit-gradient technique as recommended by Thiel and Stewart (1993) along with conservative long-term hydraulic conductivity estimates of the cover soil to estimate the amount of water coming into the drainage layer. NRC (2011) suggests that regardless of climate, cover profile, or placement condition, the saturated hydraulic conductivity of most cover soils will increase over time until it is in the range of approximately 8×10^{-8} to 6×10^{-6} m/s. The typical lateral drainage factor of safety related to pore pressure relief should be greater than 2 after applying appropriate reduction factors (Giroud et al. 2000). When designing a lateral drainage layer below a veneer liner system in order to control gas pressures it is recommended to follow the methods outlined by Thiel (1998). A special need for caution is noted here since veneer slopes are especially vulnerable to failure during an intermediate stage of the construction process when the drainage layer may be exposed to direct precipitation before topsoil placement is completed, making it vulnerable to washout (a type of stability failure).

3.12 Measure No.12: Increase the residual strength of the interface with the lowest peak

The critical interface within a liner system is the one that has the lowest peak strength. Once the peak strength of that interface is exceeded, stability will depend upon the residual strength of that particular interface. It is common for designs to introduce a weak interface, sometimes referred to as a 'fuse layer', so that the location of slippage can be controlled above the critical containment geosynthetics in such a way as to avoid damaging the containment integrity of the liner system. This concept was mentioned in Section 2.13 with regard to protecting the internal shear strength of the GCL, as recommended by Marr and Christopher (2003). Within limits, certain geosynthetic materials can potentially be selected for the 'fuse layer' that will have higher residual shear strengths than other options. While this is an excellent goal to pursue, it may be difficult to achieve with reliability and precision, especially considering manufacturing variability. Brown et al. (1999) describes a case history for a California steep sideslope canyon landfill where selection of the geosynthetic interfaces was carefully tested and specified in an attempt to 'dial in' an optimal combination of (a) protection of the critical containment geosynthetics against an integrity failure via the

selection of a reliable 'fuse layer', and (b) maintaining as high a degree of a residual strength as possible along the 'fuse layer.'

3.13 *Measure No.13: Adaptive management; Long-term instrumentation and monitoring*

Considering that intensive use of geosynthetics has only occurred since the 1980s, we could say that we really don't have enough data on the long-term performance of geosynthetics used in liner systems to make accurate estimates of performance regarding ageing and creep of geosynthetics, considering that structures such as landfills may need to remain stable for hundreds of years (i.e., until they become inert). This situation mandates either incorporating extra conservatism in design decisions, or long-term monitoring.

A design that includes reliable methods of monitoring the system performance, and adapting fill plan operations to the results of instrumented feedback, could be a component of risk management that supports a slope stability design basis. The ideal is that real-time monitoring can aid in addressing uncertainties in the analysis by allowing for a comparison between the system's actual performance and its predicted performance, thus allowing for corrective measures if needed.

An excellent review of the approaches, value, and technology for instrumentation and monitoring of slope stability is provided by Marr (2013). Advances in communication and data management technology over the past 30 years have made real-time monitoring and data evaluation a practical reality that is within reach of projects of all sizes. Instrumentation can be used to monitor performance during all phases of a project, including construction, operations, and post-closure. Instrumentation that could be considered include various types of inclinometers and extensometers to keep track of settlement and lateral movements along a vertical profile; survey monuments to keep track of settlement and lateral movements on the surface; piezometers and pressure transducers to keep track of fluid pressures at specified point locations; pressure cells to keep track of actual normal pressures at various locations; temperature sensors installed during construction or in boreholes, pipes, wells, or sumps; different types of strain or deformation gauges to measure elongation, contraction, or relative movement (i.e. slippage) at an interface; load cells to measure total or effective normal stress; and accelerometers to measure dynamic forces from equipment, blasting, or earthquakes. See Marr (2013) for further discussion.

The measurement of strains or deformations along a liner system are possible in concept (e.g. Daniel & Scranton 1996; Fowmes 2007; Villard et al. 1999; Yazdani et al. 1995; Zamara et al. 2014), but the long-term viability of instrumentation of this type, especially at significant distances or depths, has not been fully proven along liner system interfaces. Though a handful of field-scale instrumented studies have been performed, and the results of numerical analyses have compared favorably with limited observed failures, the validation of numerical models via a comparison with the results of field measurements is needed (Fowmes 2007; Kavazanjian et al. 2018). The reporting of full-scale case studies of such monitoring would be a great contribution to the profession.

In concert with any monitoring plan there should be a response-action plan. For example, if cracks are observed near slope crests, or lateral spreading of the waste toe is observed, or tension-thinning of a geomembrane at a slope crest is observed, etc., what should be done? A typical hierarchy of responses could include, for example, immediate increased/expanded monitoring of movements with survey points and inclinometers, engagement of qualified geotechnical professionals to assess the situation, cessation of any continued slope loading or toe excavation, aggressive removal of any sources of pore pressures (liquid or gas), consideration of toe buttressing with earthworks, and consideration of crest unloading. One of the greatest lessons learned in past failures as related to the designer's limitation of liability is to provide operational plans to owners as part of their scope of work. Important elements of

such plans, as related to the subject of the current paper, would be fill sequencing plans, periodic inspections and monitoring, and basic response-action plans.

4 DISCUSSION OF RISK AND OTHER CONSIDERATIONS IN THE USE OF PEAK STRENGTH

Duncan (1996) writes that the only fully reliable design in the presence of a strain-softening interface is the use of residual strengths. Admittedly, there are situations where designers believe that the geometry, high peak shear strengths, control of pore pressures, and lack of a significant seismic threat should allow peak strengths to be used. As described by Baecher (2023) geotechnical uncertainties are generally epistemic in nature, meaning that selected parameters and approaches are often subjectively based on our experience, and invoke what is called 'engineering judgement'. Designers should be sufficiently experienced and qualified to make such judgements and should provide well documented justification for their decisions. Such determinations should also include consideration of the level of risk and the consequences of failure. A discussion of risk, reliability, and consequences as relates to this paper is provided in the *Geosynthetics International* companion paper appendices.

4.1 *Designs for bottom liners based on peak strength*

Recognizing that all designs will have higher reliability when using LD or residual shear strengths, there are possible project-specific scenarios in which the use of appropriately modified peak strengths is viable. In such cases the following considerations might be taken into account for bottom liner systems:

1. The first element that should be considered is the geometry and the presence of slopes. Industry field experience, and numerical analyses, have confirmed that slope inclinations approaching and exceeding 3(H):1(V) have a high susceptibility to experiencing displacements caused by the non-uniform mobilization of shear stresses and settlement of the overlying fill, and the resulting stress and strain distributions on the slopes can also affect the flatter areas. Influential in this regard will be the relative stiffness of the contained waste or mining ore, and its long-term compressibility and settlement. Estimations of the propensity for displacements to cause exceedance of peak strength can be approximated using examples of numerical analyses previously published in the literature. Otherwise, project-specific numerical analyses can be performed.
2. If pore pressures or seismic factors have significant potential to cause liner displacements, then residual strengths should be used.
3. In all cases where 'peak' strengths are considered they should be appropriately modified or adjusted to account for construction impacts, spatial variabilities due materials manufacturing and installation, ageing, and any other factors deemed relevant.
4. The designer should consider preparing an operational plan that illustrates safe parameters for the fill sequencing, maximum fill limits, and perimeter buttressing.
5. An adaptive approach to management can be implemented through the use of instrumentation and monitoring. Such a program is only useful in conjunction with a reliable response action plan, and when early warning signs are not ignored.
6. Designing around an appropriately adjusted peak strength for the early phases of a project life may be feasible. Settlement strain values during this period will be less than the long-term post-closure values. Thus, while the stability analysis of the final geometry of a filled facility can be based on rule-based approaches such as those recommended by Stark and Choi (2004), it may be legitimate to count on peak strength, with caution, during certain early operations of facilities when a well-engineered filling plan is provided and followed.

4.2 *Designs for veneer liner systems based on peak strength*

Stark and Choi (2004) present recommendations that landfill cover systems (which represent a major category of veneer liner systems) can be designed using the peak strength of the weakest interface with a factor of safety greater than 1.5. Stark and Choi (2004) mention three situations in which residual shear strength with a factor of safety greater than 1.0 should be considered: (1) if the slope angle of the final cover system is greater than the peak strength of the weakest interface, (2) if large construction-induced displacements are expected, and (3) if seismically induced displacements can be expected. Stark and Choi (2004) do not describe how the peak strength would be measured and evaluated. A standard design practice is to obtain manufactured samples for laboratory shear strength testing in order to determine the peak interface strengths. Those results are then commonly used in the slope stability analyses without further modification. For the reasons described previously, the present paper recommends that the measured peak strength of any veneer system interface should be modified on a project-specific basis from the test results normally obtained in the laboratory. While thoughtful specifications and a high-level of CQA can help mitigate the need for some conservatism, there are other factors that require engineering judgement related to peak shear strength adjustments from laboratory-measured values.

Based on the above discussion, the present paper recommends that, while the use of 'peak' strength can be appropriate for veneer lining systems, the peak strength be selected such that it accounts for conditions that include variabilities in materials and installation practices, construction damage, seismic displacements, foundation settlement, potential effects of long-term ageing and creep, and the potential for any of these factors to cause stress concentrations at the boundaries of a change shear strength (e.g. going from an unbonded to a bonded condition of a geotextile lamination to a geonet.) Having considered these possible adjustments, the design factor of safety is typically recommended to be greater than 1.5 to account for geotechnical variabilities, unknowns, and simplifying assumptions, as is standard in the geotechnical profession.

5 CONCLUSIONS AND RECOMMENDATIONS

The present paper has identified that:

1. Limit equilibrium stability analyses are based on the fictitious assumption that the soil or waste blocks above a liner system function as rigid bodies. This could result in an unrealistic uniform variation of shear stress mobilization and FS along the critical surface that could be highly non-conservative for strain-softening interfaces if the design is based on peak strengths.
2. Limit equilibrium stability analyses provide no feedback on the amount of displacement that may occur. Thus, the available shear strength of strain-softening materials in the field is unknown.
3. Limit equilibrium analyses are the most common type of slope stability analyses used in general.
4. Most geosynthetic interfaces are strain-softening.
5. Numerical continuum modeling can roughly predict the non-uniform distribution of mobilized shear stress and displacements along the critical surface, considering strain-softening behavior.
6. Only a handful of numerical modeling studies of geosynthetic lined containment facilities have been published. The use of numerical analyses in practice is relatively limited due to the time they require and the expense of performing them, although their use is becoming slightly more prevalent as time goes on.
7. The number of bottom liner failures that have occurred in the containment industry over the past 35 years that can be attributed to progressive failure along strain-softening

geosynthetic interfaces is relatively small. They have definitely occurred though, and when they have, they have been large, costly, and consequential. The failures that have occurred represent conditions and circumstances ranging from base liners to sideslopes, and from smooth interfaces to textured.

8. For containment facilities containing strain-softening interfaces there are potentially: 15 Mechanisms that could promote displacement that could lead to progressive failure initiation and propagation in bottom liner systems, and 9 such Mechanisms in veneer systems; and 13 Measures that can be taken to reduce or mitigate the development of displacements in bottom liner systems, and 10 such Measures in veneer systems.

9. For bottom liner systems the likelihood that significant interface displacements will be experienced is project-specific, and dependent upon the complex interaction of all of the considerations discussed in the present paper. A responsible evaluation can be made based on a combination of numerical analyses, engineering judgement that is based on a review of case histories and inductive reasoning, sensitivity studies, reliability analyses, and heedfulness of the Mechanisms and Measures described in Sections 2 and 3.

10. Bottom liner systems with sideslopes approaching and steeper than 3(H):1(V) have a high probability of experiencing significant interface displacements that will lead to strain softening. Inclusion of a sacrificial slip layer above the critical containment liner element on slopes, with the assumption of residual strength along this interface, is a common design remedy that could be considered to protect the liner's integrity.

11. It may be legitimate to count on appropriately adjusted peak strength, with caution, during early operations of bottom liner facilities as long as well-engineered construction and filling plans are prepared with good construction monitoring.

12. The state of our understanding of the specific causation and propagation of progressive failure along strain-softening geosynthetic interfaces is, overall, in a semi-quantitative and semi-empirical phase. It is simply not easy to accurately deduce the mobilized stresses and displacements, and the available shear strength, in the field at all points along a strain-softening bottom-liner interface. Detailed numerical continuum analyses can be of great help in this regard. And even with such analyses, there are numerous stress concentration possibilities (localized variabilities in materials, installation, or construction damage) that have not been captured by, or incorporated into, such models to date. Also, many of the factors that potentially affect displacement along interfaces are not fully understood. Though a handful of field-scale instrumented studies have been performed, and the results of numerical analyses have compared favorably with the limited observed failures, we still await validation of numerical models as compared with field measurements (Fowmes 2007; Kavazanjian et al. 2018).

13. Most slope stability designs are driven by rules that were formulated by a combination of inductively obtained conclusions from past failures, along with approximate engineering models for slope stability. Forensic studies have attempted to apply numerical analyses in a deductive manner with the goal of determining the root cause of slippages, but there are significant nuances to these dynamics that have yet to be completely modeled.

14. Over-reliance on a small number of laboratory shear and conformance testing results, and ignorance of variabilities in the installation process, remain a large area of concern.

15. The factor of pore pressures has been mentioned in the literature as one of the contributors to many of the documented (and undocumented) bottom liner and veneer system failures in the containment industry. Some of the cases reported pore pressures due to head buildup above the liner, and some due to saturated non-consolidated clays or gas pressures below the liner.

16. If the use of peak strength values is relevant to the slope stability design, the basis of the definition of peak strength should be documented. It may not be appropriate to adopt the peak strength results measured from a factory sample that is tested in the laboratory. Modifications to the peak strength should be considered based on the several factors described in this paper.

17. It is the responsibility of the design engineer to communicate relative degrees of risk concerning slope stability to owners so that owners can make informed decisions.
18. Simple reliability analyses are helpful because they can highlight where small variations in assumptions can have a significant impact on the probability of failure.
19. If a designer follows the rule-based analysis of Stark and Choi (2004) for bottom liner systems, the design will intrinsically be substantially safe.

Based on these findings the following recommendations are suggested:

1. Designers should be concerned about activities that may affect strain-softening interfaces after they issue a design for construction. This would include the construction, operational, and post-closure phases. They should also consider the possibility of changes in project ownership. Designers should convey their expectations clearly in the project documentation, which would include the construction specifications, construction inspection requirements, facility operations, and post-closure monitoring expectations.
2. Project-specific testing is recommended in order to determine the peak and LD (or residual) shear strengths that are representative of the actual materials being used for construction and representative of field conditions (e.g. spraying all interfaces being tested with water during the shear test assembly process to mimic the condensation that occurs in the field, in addition to being flooded during testing).
3. In the evaluation of slopes that involve strain-softening interfaces, which includes most lined containment facilities, limit equilibrium analyses of deep-seated failure surfaces (e.g., bottom liners) should be overseen by trained and experienced geotechnical professionals who have studied the principles described in the present paper and can exercise appropriate engineering judgement.
4. When peak strengths are being assumed in stability analyses of bottom liner or veneer lining systems, consideration should be given to modification of the peak strengths to account for variabilities in materials and installation processes, construction damage, seismic displacements, foundation settlement, potential effects of long-term ageing and creep, and the potential for any of these factors to cause stress concentrations at the boundaries of a change in shear strength, such as can be found in the transition from an unbonded to a bonded condition of a geotextile lamination to a geonet. Following these adjustments, the design factor of safety should be greater than 1.5 to account for geotechnical variabilities, unknowns, and simplifying assumptions, as is standard in the geotechnical profession.
5. It is recommended to give special attention to specifications for the bonding between geotextiles and geonets when using drainage geocomposites. Where slope stability is critical, specifications for these materials should be written that require minimal widths of unbonded edge zones, and higher average peel strengths to compensate for the very high standard deviations in manufacturing that seem endemic to these manufactured products. In addition, increased conformance (verification) testing frequency of these parameters would be advised, requiring that more specimens be tested across the panel width than typically suggested by ASTM D7005.
6. Sensitivity and probabilistic studies can provide insight into determining which elements of the design are the most critical so that design efforts can be focused. An evaluation of the failure risk, especially as regards potential consequences, should be considered as part of this type of evaluation.
7. A degree of uncertainty can be addressed by implementing a long-term program of instrumentation and monitoring, combined with a response action plan.
8. When considering the use of peak strengths, the consequences of failure should be weighed against the uncertainties in the design.
9. Where designers wish to minimize uncertainties and follow a safe defensible standard practice for bottom liner static stability without the use of sophisticated numerical analyses, the rule-based recommendations of Stark and Choi (2004) are probably the

most pragmatic and straightforward. This is the case because they address regulatory concerns (FS > 1.5), as well as the work of Gilbert and Byrne (1996), which seeks to achieve FS > 1.0 under residual strength conditions. The Stark and Choi (2004) rules can be summarized as follows:

- For landfill bottom liners, assign residual shear strengths to the sideslopes, peak shear strengths to the base of the liner system, and satisfy a factor of safety greater than 1.5.
- Assign residual strengths to the sideslopes and base of the liner system, and satisfy a factor of safety greater than unity.

10. When performing calculations to determine if seismic deformations due to the design earthquake will be within acceptable limits (as defined by standard practice or the regulations), LD or residual strengths should be assumed along the entire critical interface for purposes of those calculations, even if peak strengths have been determined to be acceptable all parts or all of the critical interface for purposes of the static stability. The design should then be checked to meet other project-specific standards or regulatory requirements separately for static FS, and for the maximum estimated displacement due to the design earthquake.

11. Designers should attempt to position the critical slip plane above the primary geo-membrane to the extent feasible for a given project.

12. The stability of veneer liner systems can be based on peak strength, but consideration should be given to modify the peak strength to take into account the factors described in Section 4.

13. Recommendations for future studies include: (1) the effects of regularly or irregularly spaced weak zones in the plane of geosynthetic strain-softening interfaces, such as those created by commonly found manufacturing weaknesses or installation seaming practices, and how those might initiate interface displacements that could contribute to progressive failure; (2) the potential for weak zones to act as stress concentrators within the plane of the interface, and thus enhance the tendency for progressive interface displacement initiation and propagation; and (3) the long-term ageing, durability, and creep performance of geosynthetic interface shear strength.

The road to resilience: Advanced soil-geosynthetic interface characterization and its role in reinforcing soil structures for sustainability

G. Cardile
Department of Civil Engineering, Energy, Environment and Materials (DICEAM),
Mediterranea University of Reggio Calabria, Calabria, Italy

ABSTRACT: Geotechnical Engineering, as a scientific discipline, plays a crucial role in advancing sustainable development and enhancing resilience to natural hazards. The concepts of resilience and sustainability are closely linked: resilience pertains to the ability of a system to withstand and recover from disturbances (such as seismic events, landslides, and floods), while sustainability focuses on the long-term well-being of society and the environment. The augmentation of resilience cannot be limited to a single action but instead demands an ongoing process of adaptation and enhancement as conditions change and new insights emerge. The design and implementation of geotechnical projects must address immediate societal needs and consider the long-term environmental impacts and potential for future disasters. For these reasons, assessing the resilience and sustainability of geotechnical systems requires considering both technical performances and environmental-social-economic factors.

Geosynthetics within civil and environmental engineering structures can enhance safety and serviceability, minimising ecological impact. Specifically, geosynthetics used as reinforcement have gained wide recognition as an efficient approach to enhance the resilience of earthworks. Their effectiveness is particularly notable in their ability to withstand deformation and failure under various loading scenarios. However, a comprehensive understanding of the mechanical behaviour of the geosynthetic-soil interface and the mechanisms of load transfer is crucial for designing and constructing geosynthetic-reinforced structures (GRS), as they govern their performance. In this paper, the author will conduct a comprehensive analysis of experimental data to delve into the intricacies of the geosynthetic-soil interface by examining the effects of different pullout-loading conditions on design parameters and highlighting recent advancements in the field.

1 INTRODUCTION: BUILDING STRONGER, GREENER STRUCTURES

According to the World Commission on Environment and Development, "sustainable development is a development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (1987). Integrating sustainability criteria into the decision-making process of Civil Engineering design is becoming a prevalent practice. Characterising sustainability involves fulfilling the demands of the interdependent "three pillars", the three domains: environmental, economic, and social/functional. Sustainable design requires striking a proper balance among these conflicting objectives (Basu et al. 2015; Basu & Puppala 2015). The interplay between these domains renders the comprehension of sustainability complex, as changes in the requirement and solutions of one domain have a ripple effect on the requirement and solutions of the other ones. The concept

of time is integral to sustainability, and addressing sustainability issues necessitates examining fluctuating resources and needs over a temporal framework. Therefore, a crucial aspect of sustainable design is an approach that considers a structure or project's entire life cycle, from "cradle to grave", "cradle to operation", or "cradle to gate" (ISO 14040, 2006a; ISO 14044, 2006b).

The construction sector and its associated industries contribute significantly to the exploitation of the Earth's natural resources, both renewable and non-renewable, resulting in a detrimental environmental impact. Specifically, this industry accounts for the depletion of two-fifths of the world's raw stone, gravel, sand, and one-fourth of virgin wood. Additionally, it consumes 40% of the total energy utilisation and 16% of the global water supply annually (Dixit et al. 2010). In Geotechnical Engineering, geostructures are frequently integral components of crucial infrastructures, and therefore sustainability considerations must encompass both the reliability and robustness of engineering design. A geostructural plan prioritising the environment or economy in Civil Engineering may result in a structurally insufficient structure and lacking reliability. Despite being cost-conscious, this design may be prone to failure under unforeseen external threats and not support sustainability goals, particularly in critical infrastructure structures. The absence of resilience to unaccounted external forces is frequently unacceptable in this field.

Incorporating innovative approaches and utilising innovative materials in civil and environmental engineering may offer a viable solution that meets the desired outcome. Geosynthetics are probably the most crucial development in Civil Engineering practice in the 20th Century (Giroud 2005). Unlike disposable plastics, geosynthetics, despite being polymeric materials, allow high sustainability due to their long service life in the engineering applications that utilise them. Geosynthetics provide technological solutions that can aid in addressing the issue of global warming and climate change by reducing emissions compared to conventional geotechnical structures. Geosynthetics have a lower environmental impact than traditional materials because they require fewer natural resources for production and entail a lower carbon footprint throughout the life cycle (Wallbaum et al. 2014). Using these materials aligns with the United Nations' 2030 Agenda for sustainable development, addressing issues such as clean water and sanitation, responsible consumption and production, and climate action. Today, geosynthetics represent a sustainable and mature technological solution in civil engineering, a flexible and adaptable solution to the specific needs of different applications. Moreover, geosynthetics can be combined with other materials to optimise the performance of geotechnical structures. Furthermore, stringent environmental regulations have imposed limitations or banned the utilisation and exploitation of certain conventional construction materials, thereby driving the development and adoption of innovative and eco-friendly materials as geosynthetics in the construction industry (Palmeira 2016).

Engineering applications, such as reinforced earth-retaining structures, bridge abutments, embankments, and steep slopes, can utilise geosynthetic materials as soil-reinforcing components. These materials can also play a role in safeguarding against landslides by constructing passive structural barriers. Moreover, they can function as basal reinforcement beneath embankments on soft foundation soils, even in the presence of piles, providing benefits to the soft soil through geosynthetic-encased columns. Furthermore, geosynthetics can be used to avoid sinkholes, build waterways and flood protection structures, reinforce landfill barriers, reduce seismic pressure on retaining walls, improve foundation soil, stabilise roadway and railway foundations, and prevent pavement cracking (Brandl 2011; Correia & Zornberg 2016; Koffler et al. 2008; Kwon et al. 2005; Palmeira et al. 2008; Perkins & Ismeik 1997a; Perkins & Ismeik 1997b; Touze-Foltz et al. 2016; Wu et al. 2015; Yang & Al-Quadi 2007; Zornberg & Kavazanjian Jr 2001).

Using geosynthetics in retaining walls and reinforced slopes reduces environmental impact as determined by various metrics. Adopting a Geosynthetic-Reinforced Soil (GRS) wall leads to a substantial decrease in environmental impact, with cuts ranging from 63% to 87%

(the values considering a functional unit of 1 m of slope retention with a 3 meters high wall), as a result of replacing traditional concrete and steel reinforcement materials (Frischknecht et al. 2011). Specifically, for the same functional unit, the climate change impact associated with using geosynthetics is approximately 1 ton CO_2-eq per meter lower than conventional methods, which represents 84% of the overall climate change impact generated by the construction and disposal of a traditional system throughout its 100-year design life.

Damians et al. (2018) utilised the Value Integrated Model for Sustainable Evaluations (MIVES) methodology to demonstrate that GRS retaining wall solutions were consistently the preferred choice for sustainability across the environmental, economic, and social/functional categories to conventional gravity and cantilever wall solutions. Furthermore, GRS wall solutions were the most commonly selected optimal option when considering the aggregate of all three pillars.

Using geosynthetics in geotechnical systems has decreased the depletion of raw materials such as stone, gravel, and sand, thereby preserving natural resources. It has been aided by the fact that the cost of materials and installation is reduced compared to utilising their natural counterparts (Christopher 2014). One illustration of the efficacy of geosynthetics pertains to road construction projects executed over soil with limited bearing capacity. Research indicates that by incorporating geosynthetics, the depletion of raw aggregate materials can be reduced by as much as 40%, thereby reducing costs.

Geosynthetics can provide a cost-effective solution for many engineering applications, reducing the overall cost of construction and maintenance. Compared to traditional reinforced concrete technologies, the short-term economic savings from geo-reinforcements in a retaining wall can range from 25% to 50% (Christopher 2014). Additionally, it is often possible to reduce construction costs significantly by utilising the granular soil available on the construction site or a portion of it, thus eliminating or reducing transportation costs from quarries. Furthermore, using geosynthetics in the road and railway embankments allows for steeper batters and consequent savings in expropriation fees. Geosynthetics solutions also ensure considerable cost savings over the structure service life, measurable through the lower maintenance required and superior performance, especially during seismic events (Fang et al. 2003; Huang & Wang 2005; Huang 2000; Koseki et al. 2006; Koseki et al. 2000; Koseki et al. 2009; Kuwano et al. 2014; Ling & Leshchinsky 2005; Ling et al. 2001; Sandri 1997; Tatsuoka et al. 1995 1997; Wartman et al. 2006; White & Holtz 1994).

2 ENHANCING RESILIENCE IN GRS WALL: AN APPROACH THROUGH ADVANCED SOIL-GEOSYNTHETIC INTERFACE CHARACTERISATION

Resilience refers to the ability of GRS walls to withstand and recover from extreme events, minimising damage and disruption to the surrounding community. These structures exhibit exemplary behaviour compared to traditional walls after a high magnitude of seismic events because they efficiently dissipate energy from the activation of internal plastic mechanisms and permit significant deformations, increasing their ductility (Masini et al. 2015). A complete collapse in seismic conditions is infrequent in reinforced retaining walls or steep slopes, except for dynamic liquefaction of the foundation soils or excessive settlements caused by seismic motion. Typically, the observed damage consists of the development of permanent deformations (with displacements affecting the entire structure or a portion of it) and, in some cases, the collapse of a part of the facing system.

Climate change has increased natural disasters, such as typhoons, landslides, and floods, significantly impacting human health, food production, and global economic and political stability. To address this, reducing greenhouse gas emissions, particularly carbon dioxide, is a pressing and imperative task. Geosynthetics can also play a role in adapting to the effects of climate change. Adaptation measures, such as GRS passive structural barriers for

landslide risk mitigation and embankments for flood protection, can increase the resilience of infrastructural and geotechnical structures to natural disasters.

In conclusion, the concepts of resilience and sustainability are closely interlinked. Resilience refers to the capacity of a system to endure and bounce back from disruptions, whereas sustainability concentrates on the long-term prosperity of society and the planet.

As is well known, a GRS wall structure is constructed by alternately layering compacted soil and polymeric reinforcements (mainly geogrids or geotextiles). These reinforcements can either be wrapped around the structure facing or securely connected to it, utilizing cast-in-place concrete or precast concrete blocks or panels. The differentiation between GRS retaining walls and GRS steep slopes is a convention stemming from differing traditional design and analysis methods. In both instances, designers must consider ultimate limit states regarding external stability, such as base sliding, overturning, bearing resistance, and overall stability. These can be assessed using standard geotechnical engineering practices for these structures. Additionally, internal stability limit states, including failure of the reinforcements due to insufficient structural tensile strength or insufficient interaction resistance at the soil-geosynthetic interface (i.e. pullout failure), as well as the failure of the facing due to inadequate strength of the facing or low strength of the reinforcement connections, must also be evaluated. Finally, compound stability limit states involving significant slip mechanisms that affect both the reinforced block and the back retained soil must also be considered. Serviceability limit states, which occur when in-service deformation exceeds prescribed limits, can be attributed to both external factors, such as foundation settlements, or internal factors, such as reinforced mass deformations due to creep strain of polymeric reinforcements, creep of fine-grained fill soil, presence of a layer of wet fill, or polymer degradation. Analysing possible internal instability mechanisms is crucial for determining the appropriate tensile strength and stiffness of reinforcements, their spacing and anchorage length, and the structural characteristics of facing and connections in GRS structures.

The continual advancement of knowledge regarding the mechanical behaviour of geosynthetic materials and the intricacies of soil-geosynthetic interaction has supported using these environmentally conscious design solutions. Through research, innovation has emerged to provide resilient solutions for developing and protecting the territory following social and environmental sustainability.

Currently, the design of reinforced soil structures is deemed sufficiently advanced and reliable. The design parameters for both the backfill soil and the mechanical properties of the reinforcement are determined using a conservative approach due to multiple factors, including the cautious choice regarding the shear strength angle of the highly compacted soil used for the reinforced block (Cardile & Pisano 2020). Additionally, specific design choices prompted by seismic recommendations, such as using the creep reduction factor on material tensile resistance in combination with seismic loads, may result in an overly conservative approach (Kongkitkul et al. 2007; Tatsuoka et al. 2004).

Conversely, advanced characterisation of the soil-geosynthetic interface parameters under pullout conditions is one aspect that requires additional attention and further investigation. Specifically, there is a need for greater understanding and implementation of more rigorous design practices, particularly regarding the serviceability performance of these structures under cyclic/seismic loading and long-term conditions. Acquiring a thorough comprehension of the mechanical behaviour of the interface and the mechanisms of load transfer is essential for designing and constructing GRS structures, as it greatly influences their performance.

Experimentation has been, and continues to be, the starting point and driving force behind technological and design advancements in this field. Recent research results about determining short- and long-term design parameters of geosynthetics and geosynthetics-soil interface will develop this Keynote Lecture. Design parameters have been investigated using a Representative Elementary Volume and large-scale (prototype) test apparatuses, which reproduce monotonic, sustained, and cyclic load conditions. The results obtained will be discussed regarding the interaction mechanisms activated along the geosynthetic specimen

under pullout conditions. The author will also examine the factors affecting the results of pullout tests and explore the theoretical approaches for analysing soil-geosynthetic interface behaviour. Finally, the potential for incorporating these research findings into engineering design practices will be regarded.

2.1 *Investigating the tensile performance of geogrids under cyclic loading and sustained loading scenarios*

Before continuing in the following paragraphs to examine the pullout behaviour of the soil-geogrid interface under various load conditions and its effects on design parameters, it is crucial to comprehend the in-air tensile behaviour of the geosynthetic reinforcing material under sustained or cyclic loads.

According to studies conducted by Hirakawa et al. (2003), Kongkitkul et al. (2004), Tatsuoka (2008), and Chantachot et al. (2018), creep effects do not result in material degradation, unlike the impact of chemical, physical, mechanical, environmental, and biological factors that can cause a degradation of the material structure. The tensile rupture strengths recorded in monotonic tensile tests with one or more pre-rupture sustained load stages (constant loading over time, e.g. sustained load for 30 days) were comparable to the tensile rupture strengths observed at the same temperature and for the same geogrid during standard constant strain rate (CSR) tensile tests. This finding suggests that creep does not result in material degradation. However, it is essential to note that the above considerations are valid in the absence of soil confinement and other deteriorating agents (such as chemical, physical, mechanical, and biological factors).These factors must be taken into account when developing constitutive models for geosynthetics.

Cardile et al. (2017b) developed a multistage (MS) test procedure for evaluating the influence of cyclic tensile load applied on geosynthetic mechanical behaviour; the test comprised three distinct phases (Figure 1):

- First phase: a pre-stress stage at CSR equal to $\varepsilon'=0.2\%$ per minute, reaching a fixed tensile monotonic load P_i chosen as T_{max} (maximum tensile strength per unit width) percentage;
- Second phase: a cyclic stage using a sinusoidal function, with a fixed, controlled tensile loading amplitude A (chosen as T_{max} percentage) and frequency f, for 1000 cycles;
- Third phase: a post-cyclic stage at CSR equal to $\varepsilon'=0.2\%$ per minute until specimen rupture occurs; it is helpful to verify the influence of the applied cyclic loading on geogrid tensile strength.
Figure 1.   Multistage test procedure (Cardile et al. 2017b).

The residual strain, denoted as ε_r, represents the strain accumulation in a specimen after each cycle of tensile cyclic loading when the load returns to the pre-stress value (P_i). The graph in Figure 2a, which pertains to a frequency of 0.1 Hz, displays the residual strain ε_r as a function of the number of cycles (N) on a logarithmic scale, grouping the results of all tests by A/T_{max} classes, where the P_i/T_{max} ratio varies. It can be seen that the ε_r increases with both the number of cycles and the normalised loading amplitude (A), and its trend deviates increasingly from linearity. Furthermore, for the lower A/T_{max} classes, the dependence of ε_r on the normalised pre-stress load P_i is negligible during early loading cycles. However, as the number of cycles increases, this dependence becomes more apparent, especially at higher loading amplitudes.

As Cardile et al. (2017b) show, for a fixed number of cycles, the residual strain ε_r increases with decreasing frequency across the various A/T_{max} classes examined (Figure 2b). The difference in strain accumulation at different frequencies can be linked to the variation in loading time, with longer loading times leading to a higher strain component due to creep. The relationship between ε_r and N at a frequency of 0.01 Hz is concave downward, and its slope decreases with the increasing number of cycles. Conversely, the relationship at a frequency of 1 Hz is concave upward until N reaches 100, after which it decreases. This trend can be attributed to the gradual disappearance of residual strain increments with increasing cycles, reaching a stable state.

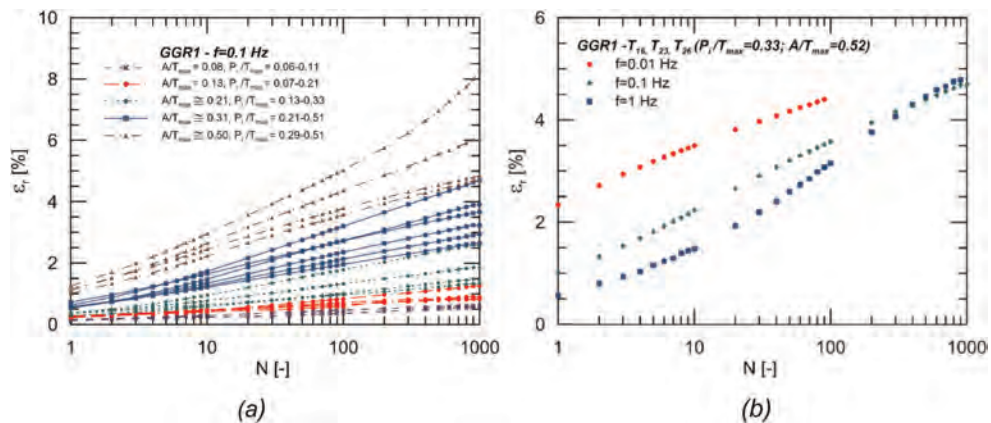
The comparison between the tensile load-strain relations for the monotonic CSR test and those for the MS tests was also conducted to assess the impact of cyclic loading on maximum tensile strength. Figure 3 presents the maximum tensile strength per unit width Tmax (MS) obtained from all multistage tests, normalised to Tmax, for varying normalised loading amplitude (A) and different ranges of normalised pre-stress load P_i. A slight increase in strength with increasing loading amplitude (A) can be observed, which could be attributed to the increased strain rate during the cyclic stages at the same frequency. However, these differences are negligible and within the bounds of material production variability, always positive and less than 6%. Furthermore, the results show that pre-stress load levels do not significantly affect the outcomes. Hence, the results support the conclusion that cyclic loading histories do not reduce geosynthetic tensile strength.


Figure 2. Trends in residual strain with the number of loading cycles for tests conducted at a frequency of 0.1 Hz (a) and tests with P_i/T_{max} equal to 0.33 and A/T_{max} equal to 0.52 at various frequencies (b) (Cardile et al. 2017b).

2.2 *Examining the soil-geosynthetics interaction*

It is crucial to understand that, within the Geosynthetic Reinforced Soil (GRS) structures, the forces mobilised along the reinforcement can be transmitted in varying directions from soil to geogrid or vice versa. The existence of distinct force transfer mechanisms arises from identifying two zones, referred to as the Pushout and Pullout zones, as described by Derksen et al. (2021). The Pushout area (within the active soil area) is characterised by the soil displacement being more significant than the geogrid displacement; in this area, the force transferred to the geogrid is induced by the lateral spreading of the soil. This results in the transfer of interaction stress into the reinforcement through its longitudinal and transverse members, which is directed towards the wall's front face. In contrast, the Pullout zone (within the resistant soil area) is defined by the geogrid displacement being more significant than the soil displacement. In this scenario, the geogrid mobilises elementary interaction mechanisms through the resistance provided by the soil (Cardile & Pisano 2020), and the transfer of shear stresses into the reinforcement occurs towards the interior of the wall.

Improving soil-reinforcement interaction enhances the load transfer from the soil to the reinforcement, from the reinforcement to the soil and its neighbouring layers (Cardile et al. 2016a; Morsy et al. 2020).

To summarise, in each reinforced layer, the tensile force acting on the geogrid starts with a value near the facing, which is contingent upon the stiffness of the facing and its connection type with the geosynthetic, and then gradually increases (in the active area) towards the interior of the wall until reaching a maximum value. This maximum tensile load works as a pullout load for the geosynthetic portion anchored to the resistant zone. At this stage, the tensile forces acting on the geosynthetic commence decreasing until they can reach zero value when relative displacement between the soil and reinforcement nullifies.

Measurements on full-scale tests of geosynthetic-reinforced retaining walls have revealed that the trend of tensile forces along the geosynthetic specimens under serviceability conditions remains unchanged as the load approaches failure conditions. In contrast, the magnitude of these forces in each longitudinal bar increases as long as it might fail. In the reinforced soil mass, failure might occur due to the formation of a critical sliding surface, which coincides with the locus of points of maximum tensile load mobilised in each layer. Therefore, it is essential to ensure that this maximum tensile load is compatible with the design pullout resistance (P_{Rd}) and the design resistance of connections (if present), in addition to not exceeding the design tensile strength (R_{td}).

Comprehending parameters associated with soil-reinforcement interaction and their variations over time concerning applied loads is indispensable for designing geosynthetic reinforced soil structures. The reinforcement length and, as a result, the size of the reinforced soil mass depend on the coefficient of friction chosen to represent the interaction between soil and geosynthetic materials.

Three distinct elementary interaction mechanisms can be mobilised at the soil-geosynthetic interface, contingent upon the failure mechanism and the reinforcement structure (continuous or open mesh-type). These mechanisms include (i) the skin friction between soil and the solid surface of the reinforcement (applicable to both geotextiles and geogrids), (ii) the passive resistance mobilised against elements placed transversely to the direction of tensile load application, and (iii) the skin friction arising due to soil shearing over soil through the apertures of the geogrid (Jewell et al. 1985). These mechanisms have been extensively studied and documented in the literature by various authors: theoretical and experimental studies have been carried out to enhance the comprehension of soil-geosynthetic interaction in geosynthetic-reinforced soil structures (Cardile et al. 2017a; Cardile & Pisano 2020; Cazzuffi 1983; Derksen et al. 2022; Derksen et al. 2021; Jacobs et al. 2014; Moraci & Gioffrè 2006; Moraci et al. 2014; Palmeira 2009; Wang et al. 2014; Zhou et al. 2012). These studies have demonstrated that various interaction mechanisms mobilise when specific failure mechanisms occur, such as sliding a reinforced soil section along a

soil-geosynthetic interface or the pullout of reinforcement from the passive zone. These mechanisms can be replicated in laboratory settings through large-scale test apparatuses.

To study the pullout failure mechanisms gathering the interaction mechanism in the anchorage zone at the soil-geosynthetic interface is possible to use a pullout test apparatus and related tests procedure (ASTM D6706-01 2013). The equipment used in this test typically includes a large and rigid steel box, a system for applying vertical loads, a device for applying horizontal forces, a clamp system, and various measurement, control, and data acquisition instruments.

The behaviour of the soil-geosynthetic interface is influenced by many factors, such as the stress state acting on the interface, the type, geometry, and stiffness of the geosynthetics, the soil grain size distribution, the soil plasticity, the soil density and water content, the specimen size, the drainage and loading conditions, the test displacement rate and magnitude, and other parameters.

Several factors have been identified to affect the outcome of pullout tests, including the impact of the vertical load application system, the boundary conditions at the front wall, the efficiency of methods used to reduce friction between the side walls and soil, the size of the box and the width of the geosynthetic specimen, the type of clamping device used, and the displacement rate during the test. Based on the results of pullout testing studies, specific measures can be implemented to minimise the impact of factors such as boundary conditions and friction on test outcomes (Moraci & Recalcati 2006; Moraci et al. 2017). Specifically, a flexible membrane should be utilised to exert vertical confining pressure on the specimen to ensure proper evaluation of soil-geosynthetic interaction. At the same time, materials with low friction characteristics (such as Teflon) should be applied to the lateral surfaces of the pullout apparatus. Additionally, sleeves of a minimum length of 200-300 mm should be employed on the front walls of the pullout apparatus. An internal clamping system should restrain the specimen throughout the test duration. The pullout apparatus should be enough size to accommodate a representative geosynthetic specimen (have a width that matches the device's width as closely as possible). They should allow for the containment of a soil sample of at least 600 mm in height.

The procedure for conducting a pullout test involves (i) preparing the internal walls of the pullout box, (ii) filling the lower half of the box with soil and compacting it, (iii) placing the geosynthetic specimen and installing test instrumentation on it, (iv) filling the upper half of the box and compacting the soil, (v) placing the vertical load application system, (vi) closing the pullout box by using a steel plate, (vii) connecting the clamp system to the horizontal force application device, (viii) connecting the test instrumentation, and (ix) starting the test.

The experimental data summarised in the following paragraphs refer to tests carried out on specimens of High-Density PolyEthylene (HDPE) uniaxial extruded geogrids embedded in granular soils compacted within the pullout box until soil dry unit weight value (γ_d) be at least 95% of the maximum value ($\gamma_{d,max}$). Compaction was carried out manually with a rammer; loose soil was spread in layers of such thickness as to reach, after compaction, a final value of 150 mm. In any case, the type of soil aggregate and geosynthetic used in the research ensure that the damage induced during test preparation is nil. The graphs and results presented herein may pertain to different interfaces as they are derived from prior research studies. Their primary purpose is to facilitate a qualitative comprehension of the load transfer mechanism at the interface and its mechanical response under shear conditions.

2.2.1 *Characterising pullout behavior in monotonic loading conditions*

The peak shear resistance, which soil-geogrid interfaces oppose to the tensile loads that reinforced earth structures may be subject to during their service life, can be mathematically expressed through the equation:

$$P_R = 2 \cdot L_R \cdot \sigma'_n \cdot f_b \cdot \tan \phi' \tag{1}$$

where P_R is the maximum shear resistance per unit width; L_R is the length of reinforcement in the anchorage zone; σ'_n is the effective stress acting orthogonally to the plane of reinforcement; ϕ' is the soil shear strength angle; f_b is the soil-geosynthetic interaction coefficient under shear conditions.

The values of the soil-geosynthetic interaction coefficient, f_b, can be determined through back-analysis using the results of pullout tests. However, the choice of the mobilised soil shear strength angle to use in the expressions (1) for f_b is a crucial but challenging task, as a variety of factors, such as 3D effects, dilatancy phenomena, and the extensibility of the reinforcement, influence it. One potential approach to address this uncertainty is to utilise an alternative parameter to describe the interface, specifically, the peak apparent coefficient of friction at the soil-geosynthetic interface, $\mu^P_{S/GSY}$, as determined by the equation provided:

$$\mu^P_{S/GSY} = f_b \cdot \tan \phi' = \frac{P_R}{2 \cdot L_R \cdot \sigma'_n} \tag{2}$$

This design parameter eliminates the need for assumptions regarding the values of the mobilised soil shear strength angle, resulting in a more accurate interface characterisation. The parameters in equation (2) can be easily obtained through large-scale pullout tests.

Ezzein & Bathurst (2014) developed a novel integration of technologies which enables the quantification of the continuous displacement field of reinforcements during pullout tests (Figure 4). The apparatus comprises a transparent bottom made of Plexiglas that allows for the visual examination of geosynthetics embedded in a synthetic soil substrate, which is constituted by a non-crystalline form of silicon dioxide quartz sand. The soil becomes translucent upon saturation with a blend of oils, namely Puretol 7 and Krystol 40.

Figure 4 clearly shows that the transfer of pullout load along an extensible geosynthetic specimen embedded in compacted soil can significantly elongate the reinforcement. Focusing on soil-geogrid interfaces, at the start of pullout loading (at time $t_i > t_0$), the head of the geogrid moves by an amount equal to δ_i and at the same time, only a tiny portion of the interface (referred to as the active length, L_A) experiences shear stresses (Figure 5), which are a function of skin friction and bearing resistance. Simultaneously, tensile strains occur in the reinforcement, with each portion between two transverse bars, S, experiencing an elongation ΔS_i, which becomes smaller for the parts farther from the geogrid's head ($\Delta S_{i1} > \Delta S_{i3} > \Delta S_{i3}$).
Figure 3. Normalised maximum tensile strength across varying normalised loading amplitudes for distinct ranges of normalised pre-stress loads at a frequency of 0.1 Hz (Cardile et al. 2017b).
Figure 4. The longitudinal displacement field of a geogrid specimen across the width of the geogrid specimen during a pullout test, captured by Digital Image Correlation (DIC) technique and transparent granular soil (Ezzein & Bathurst 2014).
Figure 5. Pullout load transfer mechanism: (a) P=0; (b) P>0 (Cardile et al. 2016a).

The form of the distribution and the local magnitude of mobilised shear stresses at the interface are complex and depend on: (i) loading and boundary conditions; (ii) physical properties and mechanical characteristics of the soil; and (iii) structural, geometric, and mechanical characteristics of the geosynthetic. The active length (L_A) is the portion of the geogrid specimen that experiences the mobilisation of the interaction mechanisms (skin friction and bearing resistance) to withstand the applied load. The evaluation of the active length is crucial to understanding the behaviour of soil-geosynthetic interfaces during the two phases of the pullout process, which are (i) the load transfer phase and (ii) the pullout phase.

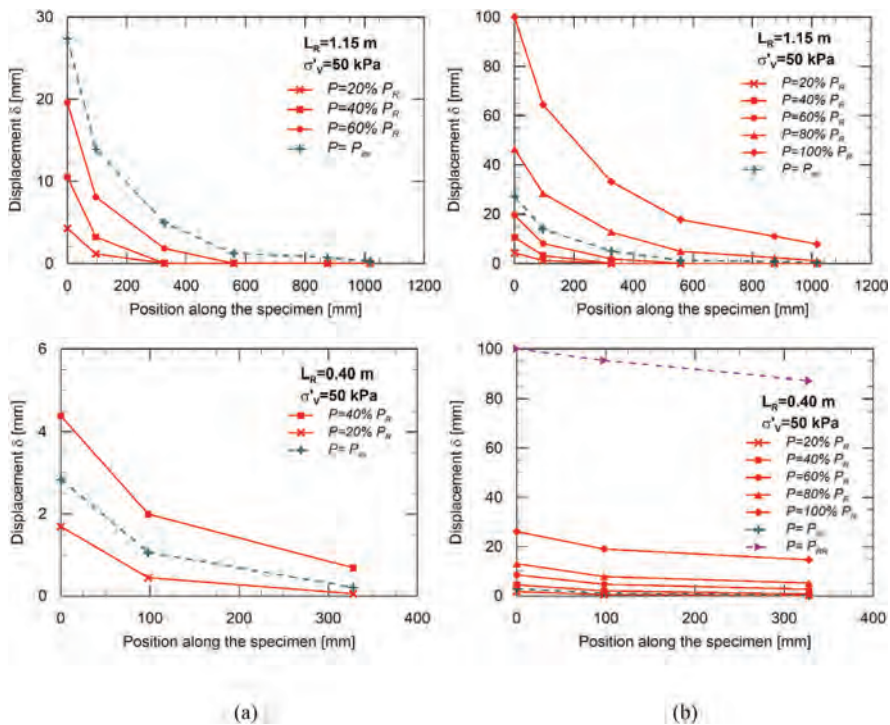
The pullout load transfer mechanism can be better understood by examining results obtained from pullout tests. Figure 6 illustrates the distribution of transverse rib displacements along a geogrid specimen for varying applied pullout forces, specifically under monotonic loading conditions. The upper and lower graphs depict long (L_R = 1.15 m) and short (L_R = 0.40 m) reinforcements. The graphs on the left show the tensile load transfer phase (Figure 6a), in which the active length increases with increasing applied pullout force until a limit value (known as the triggering force, P_{ini}) is reached, causing the movement of the last transverse rib. The pullout phase is shown in the graphs on the right (Figure 6b), which begins when the rear end of the geogrid starts to move, with the active length coinciding with the entire length of the specimen plus its elongation. In this study, the short reinforcement resulted in the pullout failure phenomenon, characterised by two adjacent curves parallel to each other when considering different pullout load levels (bottom graph of Figure 6b). The pullout failure is characterised by a reached stage in which the geogrid


Figure 6. Distributions of the nodal displacements along the geogrid specimen for a fixed vertical effective stress (50 kPa) and different values of the applied pullout force. The upper graphs refer to long reinforcements, while the lower graphs refer to short reinforcements, showing both (a) the tensile load transfer phase and (b) the pullout phase (Cardile et al. 2016a).
Figure 7.   Equivalent, uniform shear-stress distribution (Cardile et al. 2016a).

translates inside the soil without deforming and, therefore, cannot further increase pullout resistance.

The nonlinear shear stress distribution at the interface leads to a nonlinear transverse rib displacement distribution in extendable reinforcements. This non-linearity increases as the reinforcement tensile stiffness decreases. Conversely, for rigid reinforcements (inextensible), the shear stress at the interface could be assumed to be constant along the specimen (in the case of specimens having a uniform surface). Geogrids with the same tensile stiffness generally exhibit a marked extensibility effect in long reinforcement specimens, which leads to a progressive mobilisation of the interface interaction mechanisms that determine pullout resistance (Figure 6a). On the other hand, generally, short reinforcement specimens exhibit lower longitudinal strains (lower extensibility effects) and almost immediate development of the interface interaction mechanisms along the specimen (Figure 6b).

Analysing the discrete displacement field of different pullout tests, Cardile et al. (2016a) defined the average longitudinal strain, ε_A, which considers that load and elongation act on a varying portion of the reinforcement during pullout tests. Specifically, the ratio of the recorded total elongation of the specimen, ΔL, to the difference between the related active length, L_A, and ΔL, represents ε_A. As previously stated, the distribution of shear stress along the length of the reinforcement is not linear (Moraci & Recalcati 2006; Moraci & Cardile 2012; Perkins & Cuelho 1999; Wang et al. 2014), but it can be approximated by an equivalent, uniform, average shear-stress distribution, τ_{AL} (Figure 7). This shear-stress value can be found by taking the applied pullout load (P) ratio to twice the active length ($2L_A$).

The ratio between the average shear stress value and the effective vertical stress, σ'_v, is represented by the apparent coefficient of friction, $\mu^{AL}_{S/GSY}$, at the soil-geosynthetic interface, calculated using the active length. Figure 8 presents a comparison of the coefficient of friction calculated with the total anchorage length ($\mu_{S/GSY}$, represented by dashed lines) and with the active length (represented by lines with symbols) under a fixed effective vertical stress and varying specimen lengths embedded in compacted granular soil, subject to monotonic loading.

During the load transfer phase of a pullout test, the ratio of $\mu^{AL}_{S/GSY}$ remains independent of the reinforcement length. This fact is indicated by the three coinciding lines with different symbols. The value of this ratio depends solely on the applied confining vertical stress for a given geogrid and soil. When the geogrid's inactive segment remains immobile relative to the adjacent soil, it does not make a substantial contribution to the mechanical interaction and does not play a role in reinforcing the soil during that specific period. Derksen et al. (2021) refer to this stationary region as the "interlocking zone", which denotes a region of force
Figure 8. Apparent coefficient of friction at the soil-geosynthetic interface for a fixed vertical effective stress (50 kPa) and different specimen lengths (Cardile et al. 2016a).

balance at the interface where interlocking mechanisms dominate the interaction between soil and reinforcement. This phenomenon arises due to the absence of any appreciable relative displacement between the soil and the reinforcement.

The large x-shaped markers in Figure 8 indicate the onset of the pullout phase: as the length of the reinforced specimen increases, the displacement value at which the entire geogrid becomes activated increases. As the tensile load transfer phase progresses, the active length of the reinforcement increases rapidly, leading to a decrease in the $\mu^{AL}_{S/GSY}$ as the displacement of the first confined section increases. The trend of $\mu^{AL}_{S/GSY}$ reflects that of average longitudinal stress (τ_{AL}), as the latter is equal to the normalised value of $\mu^{AL}_{S/GSY}$ with respect to the effective vertical stress σ'_v acting upon the system. However, once the pullout phase begins, the active length becomes almost constant ($L_R+\Delta L$) while the pullout load continues to increase, resulting in a change in the trend of the average shear stress, which now increases with displacement. In this phase, the interaction mechanisms at the soil-geosynthetics interface are mobilised almost simultaneously along a short specimen. In contrast, they are mobilised progressively in a long specimen, resulting in more pronounced extensibility effects and a lower peak of average shear stress, which is mobilised at higher displacement than shorter reinforcements (progressive failure). Once the longitudinal strain stops increasing, pullout failure occurs.

Summarising the results obtained for a geosynthetic-soil interface at different vertical effective stresses and using various reinforcement specimen lengths, presented in Figure 9, it is possible to observe a clear correlation between the dilatancy of the soil and the apparent coefficient of friction at the interface. As the effective vertical stress on the interface increases, there is a significant decrease in the peak apparent coefficient of friction. Notably, the tensile strength mobilised at a given average longitudinal strain (mobilised on the active length) of the same geosynthetic material exhibits a significant variation depending on the boundary conditions.

The apparent pullout stiffness (defined as the ratio between the applied pullout load and the related average longitudinal strain) is generally higher than the tensile stiffness allowable for geosynthetic material solely stressed in air through a tensile force applied at the same test rate and for the same strain level (Figure 10a) (Cardile et al. 2016a). This phenomenon is mainly observable in specimens with high anchoring lengths (even more so for higher

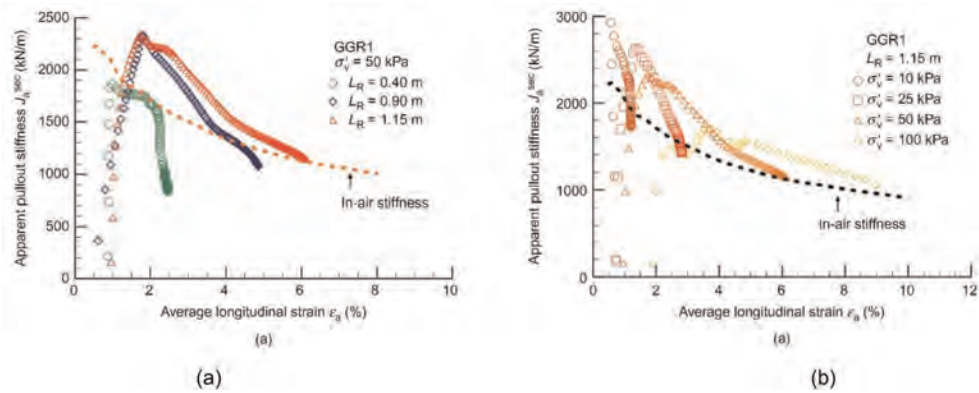

Figure 10. Apparent pullout stiffness plotted against average longitudinal strain obtained by pullout tests: (a) HDPE geogrid of different specimen lengths and under the same effective vertical pressure (50 kPa); (b) influence of effective vertical pressure on the apparent pullout stiffness for geogrid of specimens length L_R=1.15 m (Cardile et al. 2016a).

confinement stresses), where progressive failure mechanisms play a crucial role in gradually and increasingly slower load transmission along the specimen (Figure 10b). The confinement effect, the related different load transfer mechanisms, and the viscoelastic nature of the polymer thus contribute to an increase in the mobilised average stiffness in pullout

118

conditions. Furthermore, confined stiffness curves show a well-defined stiffness peak, which could be attributed to the mechanical behaviour of the compacted granular soil in contact and the related dilation effects at the interface.

2.2.2 *Characterising pullout behaviour in sustained loading conditions*

Throughout both the construction and service life of a Geosynthetic Reinforced Soil (GRS) wall, it is critical for the various reinforcements in the anchorage zone to sustain the tensile load resulting from lateral earth pressure acting within their influence area. Lateral earth pressures are primarily generated during construction, as successive layers are added, and lateral strains are induced. It is worth noting that the lateral stress state within a horizontal plane along a reinforcement layer is not uniform and undergoes changes during loading. Furthermore, the lateral earth pressure varies in tandem with changes in the strain experienced by the reinforcements (Morsy & Zornberg 2021). This tensile load initiates soil-geosynthetic interactions, which generate pullout resistance and activate a portion of the anchorage length of the geogrid. Once equilibrium is attained, a deformed configuration of the geogrid is temporarily reached. However, it is subject to change over time due to the viscoelastic properties of the reinforcement and, eventually, changes in loading and boundary conditions. Specifically, the strains in the active portion of the geosynthetic due to the tension, which remain constant during a given balance configuration, lead to a decrease in mobilised resistance (relaxation phenomenon) due to the geosynthetic's viscoelastic properties. This decrease in resistance means that to handle the tension again, previously unused portions of the geogrid must be activated, and the interaction mechanisms (skin friction and bearing resistance) must move forward, meaning the reinforcement is further deformed to regain the lowered tensile resistance, reaching a new temporary balance configuration. This process continues until the pullout limit state is reached, at which point the reinforcement can no longer deform, and further resistance cannot be mobilised.

In light of the above, the interface parameters obtained from conventional soil-geosynthetic interaction tests may not be sufficiently conservative concerning the serviceability of the structure during its design working life. As this aspect has not yet been explored in the scientific literature, to investigate how the behaviour of the soil-geosynthetic interface evolves, Cardile et al. (2021) have designed and constructed a large-scale prototype apparatus (Figure 11) that can exert a constant pullout load over a prolonged period. This research represents a significant advancement in the field as it allows for the simulation and monitoring of the temporal variation of the strain state along the specimen by reproducing the geosynthetic pullout mechanism typically observed in the anchorage zone of geosynthetic-reinforced soil (GRS) structures.

The long-term pullout apparatus utilises a fully mechanical system comprising weights, gear wheels, and pulleys, configured to yield a theoretical transmission ratio of 10:1 (with a maximum potential force of 70 kN). The apparatus comprises a large, sturdy steel box measuring 625x400x1700 mm designed to minimise scale effects. The box walls are constructed with a suitable thickness and coated with Teflon films to reduce friction. Furthermore, the apparatus features metal sleeves, 200 mm in length, which are positioned in the crack of the front wall to mitigate the effects of its stiffness on the results. It also includes an internal clamping system for the geosynthetic and a pneumatic system for applying vertical loads. Additionally, there is a reserve tank to ensure continuity of air supply in case of power interruption, a mechanical system for applying horizontal loads, and six rotary variable displacement transducers (RVDT) to measure geosynthetic displacements. A data acquisition system is also included to monitor the apparatus and testing process.

The HDPE geogrid was characterised through various tests, including wide-width tensile tests and conventional tensile creep tests following UNI EN ISO 13431 (2002) guidelines. The tests were conducted under controlled temperature and humidity conditions (T = 20 ± 2 °C at 65 ± 5% RH). The specimens were loaded smoothly, with the full tensile creep load
Figure 11.   Large-scale prototype apparatus for long-term pullout tests.

applied within 60 seconds, using the same two levels of load used in subsequent confined long-term tests.

Two long-term pullout tests were parallel conducted on twin apparatus under controlled temperature and humidity conditions by applying an effective vertical stress of 50 kPa to both soil-geogrid specimens (330 mm in width and 1200 mm in length, with 19 longitudinal ribs and five transverse bars in total). The used soil was classified as SW and A1-b according to the USCS (ASTM D2487 2017) and UNI EN ISO 14688-1 (2018) classification systems, respectively. The sustained pullout loads applied were set to be 50% and 70% of the peak pullout resistance obtained from the standard pullout test on the same interface at a constant displacement rate of 1 mm per minute and carried out at the same vertical effective stress. During the initial loading phase, the tensile load was applied at a controlled rate of approximately 0.7 kN/m per minute to prevent excessive stiffening of the geogrid specimen. This procedure avoided an accelerated load transfer along the reinforcement, causing displacements of the reinforcement higher than those anticipated during the construction phase of an actual GRS structure.

Figure 12 presents the results of strains values calculated along the portion of the geogrid closest to the clamp, designated as $\varepsilon_{\text{H-B1,conf}}$ (i.e. the segment subjected to the highest stress, extending from the initial confined section, H, to the first transverse bar, B_1), normalised to the cumulative strain at the first hour (coefficient b) as a function of time in a logarithmic scale (Cardile et al. 2021). The $\varepsilon_{\text{H-B1,conf}}$/b strains were compared with those obtained by tensile creep tests carried out in-air at the same load level. The objective of the comparison is to examine the distinctive slopes of the curves, which is crucial in determining the performance of soil-reinforcement interfaces over their design working life. This comparison is feasible due to the assumption that the geogrid experiences a near-constant tensile loading in the short portion from the initial confined section to the first transverse bar (H-B1). Stationary creep condition is evident throughout the test for the confined geogrid specimen subjected to a sustained pullout load.

Upon conducting data analysis, it is apparent that initially, the two curves exhibit similar gradients for the first 20 hours. However, after reaching the 20th hour, it can be seen that the strains in $\varepsilon_{\text{H-B1,conf}}$ display a lower gradient for the test duration. This change in trend reflects the progression of the pullout interaction mechanisms along the geogrid. The active
Figure 12.   Comparison between $\varepsilon_{\text{H-B1,conf}}$ strains normalised to corresponding cumulative strain at the first hour (b coefficient) (Cardile et al. 2021).

length of the geogrid segment that can resist the applied load gradually increases over time, reducing the deformation rise of the most stressed geogrid part (H-B1). If the observed trend persists, attaining a potential tensile creep rupture under pullout conditions would significantly surpass the time recorded in traditional in-air tensile creep tests. It implies that the creep reduction factor extrapolated from accelerated laboratory tests (as per ISO/TR 20432 2007) to the design working life and used to decrease the geosynthetic tensile strength in current design practices may be overly conservative.

It can be observed that the strains of the most stressed specimen portion (H-B1) resulting from the application of a sustained tensile load (i.e., the creep strains) are lower in the confined test scenario (as illustrated in Figure 12) due to the soil confinement effect and its related load transfer mechanisms. Therefore, a prediction of structure deformation under serviceability conditions based only on isochronous curves obtained from in-air creep tests may be conservative.

BS 8006 (2010) recommends considering both the ultimate limit state and the serviceability limit state when determining the design tensile strength of a polymeric reinforcement. Therefore, the geosynthetic tensile strength must be calculated considering the lesser between the short-term tensile strength (reduced by the reduction factor for creep) and the tensile strength concerning creep strain. The latter is the tensile load which induces a prescribed limiting value of post-construction strain in the reinforcement. This value can be estimated from isochronous load-strain curves for the end of construction and the end of the design life. The prescribed post-construction strain value varies based on the type of structure. To conform to the serviceability limit state, it must not exceed 0.5% for bridge abutments and retaining walls with permanent structural loading and 1% for retaining walls with only transient live loadings.

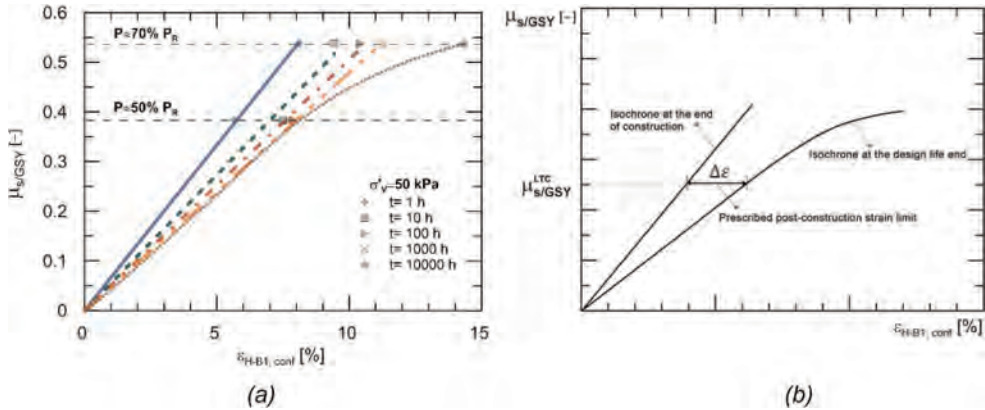
It is important to note that the aforementioned isochronous curves, obtained from in-air creep tests, do not account for the interaction with the soil. As a result, it is necessary to analyse the extent to which the peak apparent coefficient of friction mobilised at the interface should be reduced to consider the creep and relaxation phenomena that impact the deformation of the geosynthetic over time. Cardile et al. (2021) plotted the isochronous curves by


Figure 13. Isochronous interaction curves under long-term pullout conditions. (a) Test results (Cardile et al. 2021); (b) Long-term apparent coefficient of friction assessed at a prescribed limiting value of post-construction strain in reinforcement using isochronous curves.

computing the $\mu_{S/GSY}$ values by experimentally investigating two sustained load levels (P = 50% P_R and 70% P_R). For each value of the $\mu_{S/GSY}$, they calculated the $\varepsilon_{H\text{-}B1,conf}$ strains mobilised at set times (1 hour, 10 hours, 100 hours, 1000 hours, and 10000 hours). Then, curve fitting was applied to the pairs of $\mu_{S/GSY}$-$\varepsilon_{H\text{-}B1,conf}$ values to obtain the isochronous trend shown in Figure 13. It can be seen that this trend is nearly linear, assuming no local rupture phenomena or tertiary creep occurs (except for the isochrone at 10000 hours close to the higher load levels).

The study by Cardile et al. (2021) shows that for a given $\mu_{S/GSY}$ value (i.e. sustained applied load P), the cumulative strains in the anchorage zone decrease over time, moving from one time in logarithmic scale to the next (except for the isochrone at 10000 hours at higher load levels). As expected, the graph shows that with increasing sustained applied load, the increasing mobilisation of the $\mu_{S/GSY}$ value necessary to maintain the stability of the structure over time results in an increase of reinforcement strains in the anchorage zone. It is valid for each reinforcement layer, as the effective vertical stress varies. In conclusion, it is crucial to determine if the strain reached during the design working life complies with the serviceability standards of the structure.

The construction of the isochronous interaction curves under long-term pullout conditions (Figure 13a), created for various vertical effective stresses, can aid in the design to choose a peak apparent coefficient of friction that considers the long-term mechanical behaviour of the soil-geosynthetics interface. If design methods focusing on the ultimate limit state are used, the design parameter $\mu_{S/GSY}$ may be selected through the $\mu_{S/GSY}$-$\varepsilon_{H\text{-}B1,conf}$ isochronous curves to also indirectly consider the serviceability limit state. It will suffice to search for the ordinate at which the horizontal distance between the two reference isochronous curves (at the end of construction and the end of design life) corresponds to the strain limit set for the designed structure (Figure 13b).

Post-construction allowable strain limit may vary based on the type and functionality of the structure. The correlation between $\varepsilon_{H\text{-}B1,conf}$ and the actual deformation of the structure (e.g. horizontal deformation of GRS wall facing) for each reinforcement layer performed through numerical analyses and full-scale wall measurements would be permitted to calibrate this threshold strain value. To effectively transform the design proposal into a comprehensive design scheme, it is essential to determine the isochrones, which will be

calculated at the design working life of the structure for different vertical effective stress levels. Therefore, future research in this field will focus on conducting accelerated long-term pullout tests using higher temperatures to speed up the analysis of the confined creep behaviour.

2.2.3 *Characterising pullout behavior in cyclic loading conditions*

Previous experimental studies have demonstrated that geosynthetic reinforcing materials (generally geogrids) exhibit no degradation under various loading conditions. The wide-width tensile strength (obtained by using standard monotonic procedure tests) remains unchanged even after the application of cyclic loading (Cardile et al. 2016b, 2017b) or constant loading sustained over time (Chantachot et al. 2018; Hirakawa et al. 2003; Kongkitkul et al. 2004; Tatsuoka 2008).

It should be noted, however, that this may not hold for the geosynthetic-soil interface. The pullout behaviour of geogrids under cyclic tensile loads is a complex phenomenon influenced by various factors. These include the frequency, amplitude, and number of cycles of the cyclic loading history and the static tensile load level already acting on the geosynthetic at the initiation of the cyclic load. Understanding how these factors interact is essential for adequately designing and applying geosynthetic systems subjected to cyclic loads. To determine the effect of cyclic loading on interface design parameters when the reinforcement is embedded in the soil, Cardile et al. (2019) conducted pullout tests using a multistage (MS) test procedure (Moraci & Cardile 2009).

The test procedure for evaluating the geosynthetic-soil interface behaviour comprises three distinct phases:

– First phase: The pullout test is conducted under controlled displacement using a constant rate of displacement (CRD) of 1 mm per min until a specified tensile load, P_i, is reached.
– Second phase: During this phase, load-controlled cyclic loading is applied using a sinusoidal function with a specified amplitude, A, and frequency, f, for a fixed number of cycles, N.
– Third phase: The test is once again conducted under controlled displacement, specifically at the same velocity used in the first phase of the multistage test (v=1 mm per min), until either the geogrid fails in tension or the pullout conditions are reached.

The MS pullout tests involved varying the applied vertical effective stress (10, 25, 50, and 100 kPa) and the cyclic load amplitude (30% and 45% of the peak pullout resistance obtained from static pullout tests at a constant rate of displacement of 1mm per minute). A total of 1000 cycles were applied. The cyclic loading frequency was 1 Hz, and the initial tensile loading level was set at 35% of the peak pullout resistance. Specifically, $P_i \approx 35\% \ P_R$ was adopted for the first step as it could be considered an upper bound value for those representatives of GRS structures' design.

The comparison between the curves obtained from monotonic tests and those obtained from MS tests has revealed that for geogrids installed in well-compacted granular soils, the applied cyclic loading history can lead to a reduction in post-cyclic pullout resistance. For the specific test conditions, a decrease (ranging from 10% to 33%) in the post-cyclic peak apparent coefficient of friction concerning the values obtained in monotonic pullout tests has been observed (Figure 14).

Specifically, this reduction increases with decreasing effective vertical stress (becoming negligible at higher stress values) and increases with increasing cyclic load amplitude. These effects should be considered when designing GRS structures in seismic areas or subjected to cyclic vehicular loads. It is advisable to appropriately reduce the interface parameters generally obtained through constant rate of displacement pullout tests, as the reduction of interface parameters affects the shallower reinforcement levels, which are more susceptible to the pullout limit state.
Figure 14. Comparison between apparent peak coefficients of friction evaluated under post-cyclic conditions and those obtained using CRD pullout tests for varying effective vertical stress (Cardile et al. 2019).

To more clearly explain the reduction of the interface design parameters in post-cyclic conditions, the results of two of the tests conducted (static and MS tests for σ'_v = 50 kPa, A ≈ 30% P_R and P_i=35% P_R) on the same interface are presented in a dual graph, plotting the displacement of the first confined section of the specimen, δ, against the confined average strain, ε, mobilised by a specific pullout load, P (Figure 15a).

Data points 1 and 5, which correspond to the beginning and end of the cyclic phase, reveal that compared to static result (CRD test), the application of the cyclic load results in more significant strain (ε) of the geogrid (due to viscous effects associated with the application of loading over time) as well as increased displacement of the first confined geogrid's section (δ). It implies that after the cyclic phase, the displacements of internal points along the specimen are greater than those mobilised in the corresponding reference static test at the same load level P_i (refer to the top of Figure 15b). As a result, as the pullout process progresses, the pullout load is transferred to a rapidly increasing portion of the geosynthetic, leading to a reduction in the "reserve" of pullout resistance available for the post-cyclic phase.

During the third phase of the test, the interface attempts to mobilise the same pullout resistance as it would have without the cyclic stage (the polymeric material itself does not degrade under cyclic loading, and it could still mobilise the ultimate tensile strength T_F, (Cardile et al. 2017b)), exhibiting a hardening behaviour. However, this is not possible due to the degradation of the interface. If the cyclic pullout load had not progressed the interaction mechanisms along the specimen, the post-cyclic δ-ε curve would have followed the "ideal" trend of the monotonic curve (path 5-7). In reality, the curve is more bent due to the effects of the cyclic load (path 5-8). Therefore, when the first confined section reaches the maximum displacement allowed by the pullout device (100mm, bottom of Figure 15b), the configuration of the displacements of the internal points of the geogrid (6b curve) deviates from the ideal trend (6a curve). The geogrid begins to deform less and reaches the pullout limit state sooner.

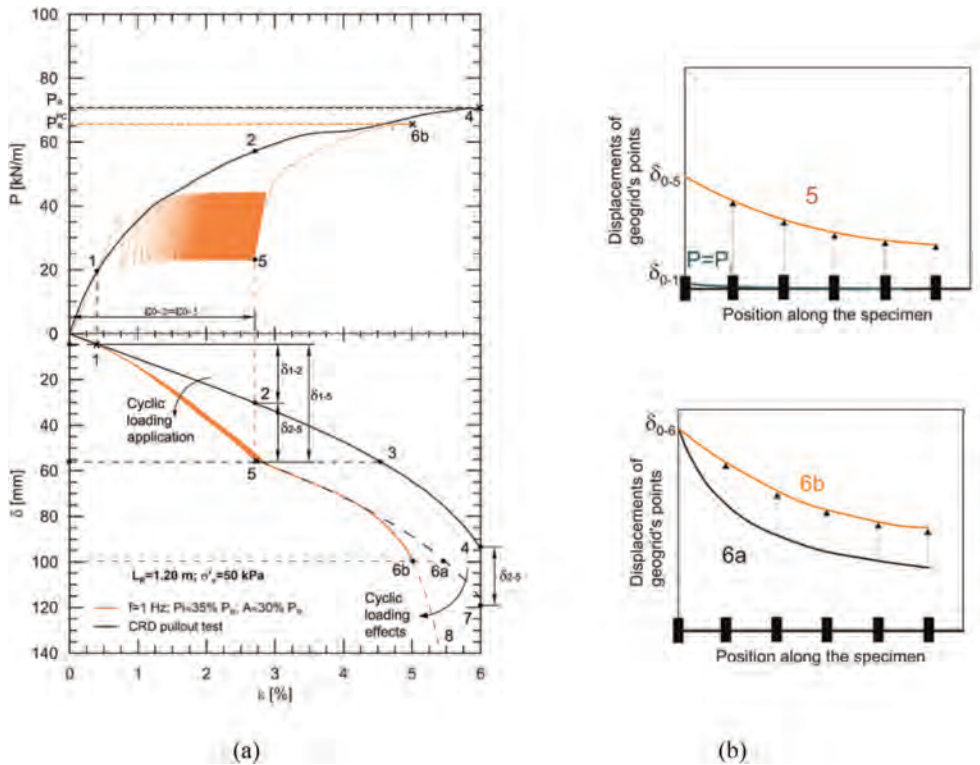
124


Figure 15. Comparison between P-ε and δ-ε trends obtained in CRD and multistage conditions (a) and qualitative distribution of the geogrid's points displacements in various phases of the test (b) (Cardile et al. 2019).

This outcome can affect the mobilisation of the maximum pullout resistance, namely the peak apparent coefficient of friction at the soil-geosynthetic interface. Reaching the geogrid average strain corresponding to the peak pullout resistance obtained under static conditions is still theoretically possible if the first confined section can undergo further displacement. However, this is only possible if the pullout limit state has not been reached (when the 6b-8 curve reaches a vertical asymptote, Figure 15a), as the geogrid can no longer deform and thus cannot increase the mobilised resistance.

2.3 Analytical modeling of the interface: A simplified approach

As previously discussed, the primary mechanisms influencing the pullout resistance of geogrids embedded in compacted soil are the skin friction between the soil and the solid surface of the reinforcement and the bearing resistance generated against the transverse members. Accordingly, the peak pullout resistance (P_R) of soil-geogrid interfaces is usually modelled as the sum of these two components:

$$P_R = P_{RS} + P_{RB} \tag{3}$$

where P_{RS} is the skin friction component of the peak pullout resistance, and P_{RB} is the bearing resistance component.

The pullout-loading force applied to the soil-geosynthetic system triggers the mobilisation of passive soil resistance in front of the transversal rib-bearing surface, leading to a rise in stress and a rotation of the principal stresses (Palmeira 2004). The pullout displacement of the geogrid creates a decrease in stress behind each transversal rib, producing a disturbed soil volume. If the subsequent bearing member is situated too close, perturbed soil volume may negatively impact the maximum bearing resistance developed along this geogrid member. For a fixed equivalent bearing member thickness (B_{eq}), the reduction in strength due to the interference phenomenon increases as the spacing (S) between consecutive transversal ribs decreases.

In recent years, various researchers have employed micro-image analysis systems to examine the pullout behaviour at the interface (Bathurst and Ezzein 2015a, b; Ezzein and Bathurst 2014; Zhou et al. 2012). This novel combination of technologies enables the measurement of the entire displacement field of the reinforcement and target particles seeded in the surrounding soil during pullout tests. Zhou et al. (2012) used micro-image analysis to capture the interaction mechanisms between compacted sand and the transverse ribs of the HDPE geogrid (by positioning the geogrid close to the glass side wall) and particle image velocimetry (PIV) technology for analysis, allowing it to be captured. Figure 16 displays particle motion around a transverse rib at various stages above and below the interface. Sand particles ahead of the transverse rib rotate during pullout, with particles above the longitudinal axis of the geogrid rotating clockwise and particles below the longitudinal axis rotating counterclockwise. Particles on the top right side of the transverse rib fall into the voids created by the movement of the geogrid in the softened region. The micro-image analysis confirms that the soil in front of the transverse rib is subjected to a passive state of stress, while behind it, an active state is reached, resulting in a loose soil region.

Furthermore, interference is affected by the thickness of the bearing member, referred to as Beq, and its relationship with the soil particle diameter (B_{eq}/D_{50}). The minimum ratio S/B_{eq}, beyond which interference affects pullout behaviour, decreases as the B_{eq}/D_{50} ratio increases (Sukmak et al. 2015). To provide a deeper understanding, a decrease in D_{50} generally reduces soil shear strength, impacting the softened region and shaping the failure plane that develops in front of the transverse ribs.

Cardile et al. (2017a) modified the theoretical method Moraci & Gioffrè (2006) devised to determine the maximum pullout resistance of geogrids extruded into compacted granular soil. This upgraded method is based on the results of several extensive pullout tests,
Figure 16. Particles motion around transverse rib (modified from Zhou et al. 2012).

including those performed by Calvarano et al. (2012), Cazzuffi et al. (2011) and Cazzuffi et al. (2014). The method is suitable for soil-geogrid interfaces where the scale effect is negligible and considers the nonlinear behaviour of compacted granular soils arising from dilatancy and the progressive mode of soil-geogrid interaction development resulting from the deformability of the reinforcement. The method is significant in the design and optimisation of geosynthetics, particularly in their geometry, shape, and stiffness. It also considers the interference mechanism in closely spaced bearing members, specifically when S/Beq is less than 50.

According to Cardile et al. (2017a), the pullout resistance can be evaluated using the following equation:

$$P_R = 2 \cdot C_{\alpha S} \cdot \alpha_S \cdot L_R \cdot \sigma_n^{'} \cdot \tan \delta + C_{\alpha b} \cdot n_t \cdot n_{tb} \cdot A_b \cdot \sigma_b^{'} \qquad (4)$$

where $C_{\alpha S}$ is a reduction coefficient to take into account the geogrid's area in which skin friction develops; δ is the mobilised friction angle between soil and the geogrid, which depends on soil dilatancy and reinforcement extensibility; $n_t = (L_R/S)$ is the number of geogrid's bearing members; n_{tb} is the number of nodes in a transverse element; A_b is the area of each rib element, which includes the single node and the bar portion between two nodes where the bearing resistance can be mobilised; and $C_{\alpha b}$ is a reduction coefficient taking into account the interference mechanism.

In their initial stage, Cardile et al. (2017a) conducted a study in which they sought to eliminate the impact of interfaces that had a non-negligible scale effect. They determined the value of $\sigma_b^{'EXP}$ using equation (4) to accomplish this objective by using the peak pullout resistance obtained through experimentation on those interfaces where the interference effect was negligible (i.e. $S/B_{eq} > 50$). This methodology allowed them to set $C_{\alpha b}=1$.

To facilitate a comparison between the experimental $\sigma_b^{'EXP}$ values obtained for various soil types, Figure 17 presents the results that have been normalised relative to the ($\sigma_n^{'} \tan \varphi'$) value. The data indicates that, beyond a threshold of $B_{eq}/D_{50} > 10$, the normalised bearing resistance is independent of the average grain size, regardless of the normal effective stress. Upon discovering this threshold, all the tested interfaces with a B_{eq}/D_{50} ratio greater than 10
Figure 17.   Scale effect: results of pullout tests in terms of $\sigma_b^{'}/(\sigma_n^{'} \tan \varphi')$ ratio, carried out on different soils using uniaxial geogrids in which interference effect is negligible (Cardile et al. 2017a).

were analysed to determine the $C_{\alpha b}$ coefficient through the application of the following equation:

$$C_{\alpha b} = \frac{P_R^{Exp} - P_{RS}^{Theor}}{P_{RB}^{Theor}} = \frac{P_R^{Exp} - 2\alpha_S L_R \sigma_n' \tan \delta}{n_t \cdot n_{tb} \cdot A_b \cdot \sigma_b'} \tag{5}$$

where the peak pullout resistance P_R^{Exp} is obtained experimentally and σ_b' is evaluated using the equation proposed by Matsui et al. (1996).

P_{RS}^{Theor} component was evaluated using an average shear strength angle, calculated as the mean between the peak and constant volume values. This methodology facilitated the integration of both reinforcement extensibility and the nonlinear failure envelope of soil into the analysis of the mobilisation of interaction mechanisms. On the other hand, the P_{RB}^{Theor} component was evaluated by utilising the peak soil shear strength angles that corresponded to the various normal effective stresses.

Figure 18 shows the interference reduction factors $C_{\alpha b}$, which were determined through linear regression analysis for varying S/B_{eq} ratios. For S/B_{eq} values greater than 50, the interference effect can be considered negligible, leading to a $C_{\alpha b}$ factor equal to one. As a result, the $C_{\alpha b}$ interference reduction factor can be calculated using the following equation:

$$C_{\alpha b} = \begin{cases} \alpha \cdot \dfrac{S}{B_{eq}} & \dfrac{S}{B_{eq}} \leq 50 \\ 1 & \dfrac{S}{B_{eq}} > 50 \end{cases} \tag{6}$$

In equation (6), the constant coefficient α is equal to 0,02. In summary, the peak pullout resistance can be determined by combining Equations (4) and (6).
Figure 18. Variation of the reduction factor for the bearing resistance with varying the normalised spacing between transversal members (Cardile et al. 2017a).

Figure 19 compares experimental and theoretical values of the peak pullout resistance computed for selected interfaces. This comparison was conducted as part of the research undertaken by Cardile et al. (2017a) and was executed at different normal effective stress levels. The results of this comparison provide clear evidence of the efficacy and usefulness of the analytical method proposed.
Figure 19.   Comparison between experimental and theoretical values of peak pullout resistance for a biaxial geogrid embedded in a compacted uniform medium sand (Cardile et al. 2017a).

3   CONCLUSIONS

The results summarised in the keynote, obtained through several experimental investigations conducted over the last 15 years, highlight the complexity of the interaction mechanisms that mobilise at the interface between geogrid and soil during the service life of a GRS wall. The evidence obtained under different load conditions (static, sustained, and cyclic) has allowed a detailed understanding of the complex load transfer mechanism under pullout conditions, identifying some critical aspects that are not yet fully codified in the design of such structures.

In particular, the research has highlighted the importance of viscous phenomena characterising the tensile-deformation behaviour of the polymeric geosynthetic reinforcement installed in the GRS structures. The mode and rate at which the tensile load is transferred along the reinforcement affect the mechanical behaviour of the geogrid and its interaction with the surrounding soil.

The complexity of load transfer mechanisms, dependent on the geometry, structure, and stiffness of the reinforcement and the geotechnical characteristics of the soil in contact, is amplified by the progressive failure phenomena characteristic of the pullout of long extensible reinforcements embedded in compacted soils.

It has been highlighted that the current codified design practice does not sufficiently consider the actual effects of the long-term behaviour of the geosynthetic-soil interface under pullout conditions. The first tests conducted through a prototype long-term pullout apparatus have allowed us to verify that the confinement offered by the compacted soil interferes with load transfer mechanisms, modifying the effects of tensile creep and improving the mechanical behaviour over time of the HDPE polymer material constituting the

geosynthetic. For these reasons, it could reach creep failure under confined conditions over a longer time than that modelled through current standard procedures performed in the absence of confinement. On the other hand, the effects of a constant pullout load over time cause a slow advancement of elementary interaction mechanisms along the anchored part of the reinforcement, causing deformed configurations of the structure that may not satisfy the serviceability for which it was designed. It is, therefore, necessary to consider these effects by adopting a design parameter at the interface calibrated through long-term pullout tests.

The experiments conducted through a new multistage pullout testing method, which alternates monotonic loading phases with a stage in which a sinusoidal pullout load of a given amplitude and frequency is applied, have allowed verification that contrary to current design practice, it would be advisable to reduce (especially at the lowest vertical confinement stresses) the interface parameters due to the degradation of the pullout resistance caused precisely by the cyclic loading phase. This more cautious approach should be adopted, especially in those areas most susceptible to seismic risk.

An in-depth analysis of the numerous experimental data produced on several soil-geosynthetic interfaces has also allowed the development of a simple theoretical model that predicts the pullout resistance mobilised under peak conditions, taking into account interference phenomena, soil dilation, and reinforcement extensibility.

ABSTRACT: There is a growing realization that the current model of development is unsustainable. In other words, we are living beyond our means. Climate change is the defining crisis of our time, and it is happening even more quickly than we feared. Rising temperatures are fueling environmental degradation, natural disasters, weather extremes, food and water insecurity, economic disruption, conflict, and terrorism. Sea levels are rising, the Arctic is melting, coral reefs are dying, oceans are acidifying, and forests are burning. The goal of sustainable development is to enable all people throughout the world to satisfy their basic needs and enjoy a better quality of life, without compromising the quality of life of future generations. This paper will provide a perspective from the UK on how geosynthetics are supporting the global cause of limiting climate change. Examples of sustainable geosynthetic solutions are given from a team of UK researchers and practitioners.

1   INTRODUCTION

This paper is the written version of the keynote lecture delivered to the 12th International Conference on Geosynthetics in Rome, Italy in September 2023. It presents a brief summary of the UK government policy on sustainable development in the context of the United Nations Sustainability Development Goals. It aims to show how geosynthetics can support sustainable development with focus on six of the Sustainability Development Goals. The paper considers ways of measuring the sustainability of civil engineering projects with a focus on Life Cycle Analysis and embodied carbon assessment. Examples are presented of sustainable development using geosynthetics and these include accelerated embankment consolidation, reinforced bund construction with contaminated cohesive fill, temporary working platform construction, pavement construction, instrumented and "smart" geosynthetics and

finally active geosynthetics. These examples, whilst not all from the UK, present a brief insight into sustainable development using geosynthetics from a UK perspective.

2 UNITED NATIONS SUSTAINABILITY GOALS

The United Nations has set out 17 Sustainable Development Goals (SDGs) as part of the 2030 Agenda for Sustainable Development (United Nations 2016), and these are depicted in Figure 1. These high-level goals are designed to influence national decisions, and focus the scale and priorities for funding, with each country facing specific range and combination of challenges. The SDGs are:

- Goal 1 – No Poverty: End poverty in all its forms, everywhere.
- Goal 2 – Zero Hunger: End hunger, achieve food security and improved nutrition, and promote sustainable agriculture.
- Goal 3 – Good Health and Well-being: Ensure healthy lives and promote well-being for all at all ages.
- Goal 4 – Quality Education: Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all.
- Goal 5 – Gender Equality: Achieve gender equality and empower all women and girls.
- Goal 6 – Clean Water and Sanitation: Ensure availability and sustainable management of water and sanitation for all.
- Goal 7 – Affordable and Clean Energy: Ensure access to affordable, reliable, sustainable, and modern energy for all.
- Goal 8 – Decent Work and Economic Growth: Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all.
- Goal 9 – Industry, Innovation, and Infrastructure: Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation.
- Goal 10 – Reduced Inequalities: Reduce inequality within and among countries.
- Goal 11 – Sustainable Cities and Communities: Make cities and human settlements inclusive, safe, resilient, and sustainable.
- Goal 12 – Responsible Consumption and Production: Ensure sustainable consumption and production patterns.
- Goal 13 – Climate Action: Take urgent action to combat climate change and its impacts.
- Goal 14 – Life Below Water: Conserve and sustainably use the oceans, seas, and marine resources for sustainable development.

Figure 1. UN sustainability goals launched in January 2016 (United Nations 2016).

- Goal 15 – Life On Land: Protect, restore, and promote sustainable use of terrestrial eco-systems, sustainably manage forests, combat desertification, and halt and reverse land degradation and biodiversity loss.
- Goal 16 – Peace, Justice, and Strong Institutions: Promote peaceful and inclusive societies for sustainable development, provide access to justice for all, and build effective, accountable, and inclusive institutions at all levels.
- Goal 17 – Partnerships for the Goals: Strengthen the means of implementation and revitalize the global partnership for sustainable development.

These goals provide a comprehensive and ambitious agenda for sustainable development, addressing a wide range of economic, social, and environmental challenges facing the world today. Kraus (2022) argues that the SDGs need to be considered within the context of remaining within the "planetary boundaries concept" developed by Stockholm University (Rockström et al., (2009). The authors state that crossing the nine defined planetary boundaries increases the risk of generating large-scale abrupt irreversible environmental changes. Kraus (2022) argues that there is a fundamental tension between the minimum resources required for human development and the planetary boundaries and presents the "doughnut" model developed by Raworth (2012).

Figure 2. The "doughnut" model proposed by Raworth (2012).

The Doughnut consists of two concentric rings: an inner social foundation, to ensure that no one is left falling short on life's essentials, and an outer ecological ceiling, to ensure that humanity does not collectively overshoot the planetary boundaries that protect Earth's life-supporting systems. Between the two boundaries lies an area – shaped like a doughnut – which represents an environmentally safe and socially just space for humanity to live in. It is also the space in which inclusive and sustainable economic development takes place.

Kraus (2022) discusses the interaction of geosynthetics with the planetary boundaries and gives examples of the positive effects geosynthetics can have on the climate change boundary. It could be argued that geosynthetics can also have a positive impact on all other planetary boundaries particularly with the reduction of greenhouse gases (GHGs), air pollution and chemical pollution.

3 UK GOVERNMENT POLICY

The UK government's policy on sustainable development is guided by the SDGs and is based on a holistic approach that takes into account economic, social, and environmental considerations. The UK government has committed to achieving these goals by 2030 and has set out a plan for doing so in its 25 Year Environment Plan, published in 2018 (Defra 2018). It's approach to sustainable development involves balancing economic growth with social and environmental considerations, which aims to create a prosperous and sustainable economy that benefits everyone, while protecting and enhancing the natural environment. The 25 Year Environment Plan outlines a range of policies and initiatives aimed at achieving this goal by reducing GHG emissions, protecting and restoring natural habitats, promoting sustainable consumption and tackling equality and poverty.

The UK government has set a legally binding target of net zero greenhouse gas emissions by 2050 which was supported by all main political parties. The Climate Change Act 2008 committed the UK to an 80% reduction in carbon emissions relative to the levels in 1990, to be achieved by 2050, then in June 2019, secondary legislation was passed that extended that target reduction to "at least 100%". The UK government has introduced a range of measures to achieve the target, including investing in renewable energy, encouraging energy efficiency, and promoting low-carbon transport. There is a focus on zero carbon operation of infrastructure but no mention of savings during the construction phase. However, the UK construction industry has developed a strategy articulated in the report Construction 2025 (HM Government 2013), which identifies low carbon and sustainable construction as a strategic priority of the industry, with an ambition to reduce GHG emission by 50% by 2025. There is an expectation that GHG emission will be a criterion used to select construction solutions and all major projects will have to have GHG evaluation as part of their environmental assessment. To date, there is no independent assessment of the likelihood that the construction industry will meet the 2025 target.

In the UK, the pre-eminent professional body for construction is the Institution of Civil Engineers (ICE). This body is leading debate and knowledge transfer to help deliver a reduction in carbon emissions produced by construction and infrastructure activities (e.g. Skinner 2020). Infrastructure is responsible for more than half of the UK's carbon emissions, which justifies the significance given by the ICE to this challenge. In recent years, the ICE has produced a range of opinion pieces and information to enable the engineering community to make a meaningful contribution to meeting the UK's net zero target. For example, Skinner (2020) selected achieving net zero carbon as the focus for her prestigious and high-profile Presidential Address, and as the primary theme for her year in office. The ICE has established a Decarbonisation Community Advisory Board to facilitate collaboration, share knowledge and best practice, and hence deliver low-carbon solutions across the construction sector. Solutions incorporating geosynthetics are contributing to the achievement of this goal, but more can still be done.

4   USING GEOSYNTHETICS TO SUPPORT SUSTAINABLE DEVELOPMENT

Geosynthetics are synthetic materials used in civil engineering and construction projects to enhance the performance of soil, rock, and other materials. They can be used to support sustainable development in a number of ways including:

4.1   Goal 2 – zero hunger

Geosynthetics can be used to stabilize soil and prevent erosion, which helps to protect ecosys-tems, reduce water pollution, and maintain soil fertility. Heibaum (2010) describes how surface erosion can be reduced by the use of geosynthetics, and Touze (2021) presents example of how geosynthetics can improve crop protection by drainage of agricultural land, promoting germination and plant growth through using ground cover and control of growing conditions, pests and insects. Touze (2021) gives example of the use of geosynthetics in fish farming thus reducing the pressure on wild fish stock, and also using geosynthetics to support the management of agricultural waste through manure storage and sludge man-agement, and the production of energy from waste through anaerobic digestion. Geosynthetic solutions can also be used to create, shelter and regulate the internal envir-onment in agricultural buildings which has a positive effect on livestock yields and geosyn-thetics also contribute to the capture, storage and distribution of water, see below.

4.2   Goal 6 – clean water and sanitation

Geosynthetics can be used in the construction of dams, canals, and other water management structures, helping to conserve water resources, prevent flooding, and mitigate the effects of drought. Koerner et al. (2008) described a geosynthetics freshwater cycle for capture, transportation, storage and distribution of freshwater, and Touze (2021) presents examples of the use of geosynthetics in three main elements of this cycle, namely dams, canals and pipes. In addition, Touze (2021) gives examples of how geosynthetics can be used to preserve water quality.

4.3   Goal 7 – affordable and clean energy

Geosynthetics can be used to support the development of renewable energy sources such as wind and solar power, by providing stable foundations for infrastructure and reducing the environmental impact of construction.

4.4   Goal 9 – industry, innovation and infrastructure

Geosynthetics can be used to build roads, bridges, and other infrastructure more efficiently, reducing the use of resources and minimizing the environmental impact of construction. In paved and unpaved roadways, geotextiles and other materials are used as a separating layer or to improve soil performance and capabilities. In these cases, the geosynthetics are covered with asphalt, concrete, or on-site soils. Geogrids are used to reduce construction footprint by steepening slopes and allowing the use of site-won soils limiting the importation of virgin aggregate.

4.5   Goals 14 and 15 – life below water and life on land

Geosynthetics can provide useful support to pollution control and thus improving the quality of life on land and below water. Minimising the impact of waste on the environment is a key aspect of geosynthetics use worldwide and this comprises using barrier systems to limit contaminant migration from landfill bodies, prevent water infiltration into waste

bodies and prevention of uncontrolled gas migration to atmosphere. New geosynthetic permeable re-active filters selectively protect the underground from the contaminant while allowing the carrier medium to pass through. contaminated water percolates through the filter, the transport of the pollutants is stopped, but the water can follow its natural flow path into the underground unimpeded and thus continue to serve as a potential habitat, water reservoir, nutrient reservoir. These goals are also supported by the use of geosynthetics in mining applications where the operation of heap leach pads, tailings storage facilities and mine waste storage facilities benefit from geosynthetic containment.

In addition to these specific applications, geosynthetics can support sustainable development by improving the efficiency, safety, and durability of civil engineering and construction projects. By enabling the construction of more sustainable and resilient infrastructure, geosynthetics can help to support the long-term economic, social, and environmental well-being of communities and regions around the world.

5 ASSESSING SUSTAINABILITY OF GEOSYNTHETICS

5.1 *Carbon footprint*

Carbon footprint is a measure of the total amount of greenhouse gases (primarily carbon dioxide) caused directly and indirectly by a person, organisation, event or product. It is measured in tonnes of carbon dioxide equivalent (tCO2e). A carbon footprint can cover emissions over the whole life of a product, service or a construction solution and embodied carbon (EC) is an indicator of cumulative carbon emissions used in the solution adopted. Dixon et al. 2017 show an example subdivision of a hypothetical material and processes contributing to the EC of an end product, such as a geosynthetic, see Figure 3.

It should be noted that sometimes Embodied Energy is reported in place of Embodied Carbon. Conversion between the two measures needs knowledge of the CO2 emitted during generation of the energy used (Defra 2013). This is country specific and hence is a challenging calculation to undertake as information on mixes of energy sources is sparse and this currently makes international comparisons difficult. Comparison of calculated carbon
Figure 3. Example of contributions to the EC of a geosynthetic product (after Dixon et al. 2017).

footprints for alternative solutions can be used to inform selection of the most 'sustainable' option. A site-by site approach can consider project specifics such as available materials on-site and nearby, supply logistics, site layout, method of construction etc.

Assessing the carbon footprint can support sustainable development in several ways. Firstly, measuring or calculating a carbon footprint can help raise awareness of the impact of human activities on the environment and climate change. By understanding the amount of carbon emissions associated with various activities, individuals, businesses, and governments can take action to reduce their carbon footprint through selection of solutions with least emissions and hence minimize the impact of their actions on the environment. Secondly, the carbon footprint can be used as a basis for setting targets to reduce greenhouse gas emissions. By setting targets to reduce carbon footprint, businesses and governments can take action to reduce their environmental impact and work towards achieving sustainable development. Once targets have been set, ongoing measurement of the carbon footprint can be used to quantify the progress towards meeting them. Businesses and governments can assess the effectiveness of their sustainability initiatives by tracking changes in carbon emissions over time, and then adjust their strategies as needed to achieve their goals. Measuring carbon footprint can also encourage innovation by promoting the development of new technologies and practices that reduce greenhouse gas emissions.

5.2 *Life cycle analysis*

Life Cycle Assessment (LCA) is a tool for measuring the environmental impact of products or systems over their lifetime. It can consider extraction of raw materials, through production, use, recycling and disposal of waste, and provides a systematic and comprehensive approach to evaluating the environmental impacts of products and processes. LCA is often used to compare the impact of two competing products or systems, with the analysis process informed by ISO14040 (ISO 2006a) and ISO14044 (ISO 2006b) or other approved tools. LCA boundaries are clearly defined boundary conditions and are required to describe which parts of the material production, manufacture and deployment are taken into account in calculating the carbon footprint. Typically used LCA are shown in Figure 4 mapped against the stage of product manufacture and application.

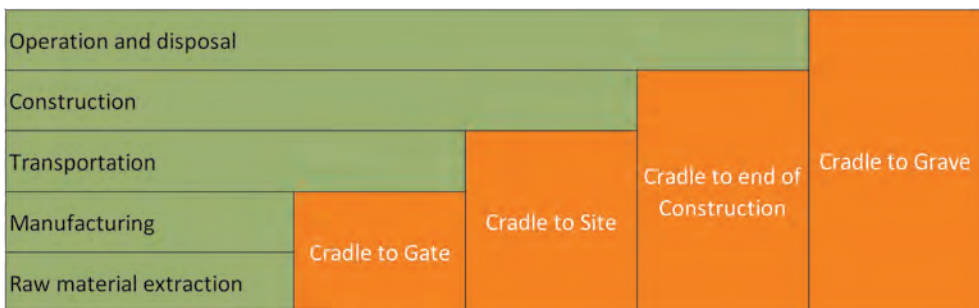
There is a growing trend for product manufacturers (e.g. concrete, steel, geosynthetic) to develop in-house carbon calculators for quantifying LCA of products and designs that can be used for comparisons between alternative solutions. While this is a welcome development, in some cases these are perceived as being marketing tools and there is a danger that they will be considered unreliable, in part due to a lack of transparency of the method and material EC values employed. There is need for a geosynthetics industry standard approach endorsed


Figure 4. Life Cycle Analysis boundaries for typical stages of geosynthetic product manufacture and application.

by geosynthetic manufacturers and suppliers, recognised and trusted by construction organisations and clients.

A number of geosynthetic manufacturers have started to provide independently verified Environmental Production Declarations (EPDs). Construction products are assessed using a single set of Product Category Rules (PCR) ensuring consistent reporting for similar products. EPDs for construction products in Europe use EN 15804 (2019), as their PCR, to ensure that the information is provided using the same LCA rules and boundary conditions, with the same environmental indicators, and in a way that means the information for different products can be brought together to provide the environmental impacts for adopted solutions.

5.3 *LCA for geosynthetic solutions*

There is a growing body of literature detailing studies of the sustainability credentials for geosynthetic based solutions. While all use EC as a measure, a subset also considers a wider range of criteria for a broader evaluation of sustainability including: cumulative energy demand; photochemical ozone formation; particulate formation; acidification, eutrophication, land competition; and water use. The large majority use EC for the geosynthetic products taken either from the ICE database (Hammond & Jones 2011) and earlier versions of the EcoInvent Centre (2016) databases. Whilst the number of case studies using product specific EC values is growing, a direct comparison between case studies is not possible because the type of study varies, with some using project level information and others defining functional units of a given application/solution, and in addition different ranges of LCA boundaries are employed, however, general trends can be identified.

The UK Waste & Resources Action Programme (WRAP) published a report in 2010 (WRAP, 2010) which delivered an accessible report with a very clear unambiguous conclusion that construction solutions incorporating geosynthetics led to significant cost and CO_2 savings. The European Association of Geosynthetic Manufacturers (EAGM) commissioned a study of the environmental performance of solutions using commonly applied construction materials versus geosynthetics. The findings of the in-depth analysis are reported by Stucki et al. (2011). The study provided comprehensive qualitative and quantitative information on the environmental performance of commonly applied construction materials (i.e. concrete) versus geosynthetics. The key finding from this study is that geosynthetic based solutions are consistently assessed as more 'sustainable' using a range of environmental performance measures.

Since these two early studies, many authors have presented the results of a variety of projects such as: assessment of geosynthetic solutions in steep slope and road applications (Heerten, 2012), analysis of EC for a landfill capping project (Raja et al. 2014), environmental assessment of earth retaining wall structures (Damians et al. 2016), non-reinforcement applications of geotextiles (Dixon et al. 2016; Koerner et al. 2019; Whitty et al. 2020).

Some geosynthetics manufacturers have recently introduced a range of geosynthetics produced from 100% recycled polymers, and whilst consideration should be given to the impact of recycled polymer use has on the end product properties, material produced from recycled polyester for example, it stated to require 59% less energy in its manufacturing compared to virgin polyester (Huesker 2023).

These 'new' recycled products have already been applied in asphalt and soil reinforcement applications and are subject to the same manufacturing quality assurance and certification standards as virgin polymer counterparts. The use of recycled material within geosynthetic additionally supports the sustainability benefits of a circular economy preventing the disposal to landfill in the first instance and its reuse again at end of its current life/form as a geosynthetic.

6 EXAMPLE OF SUSTAINABLE SOLUTIONS USING GEOSYNTHETICS

Polymer based geosynthetics represent high embodied energy materials (Raja et al. 2015) and their sustainability benefits come from their careful use within wider geosystems rather than the materials themselves. The following examples present case histories which demonstrate the environmental benefits of using a range of geosynthetics and promote the United Nations' SDGs.

6.1 Example 1: Accelerated embankment consolidation

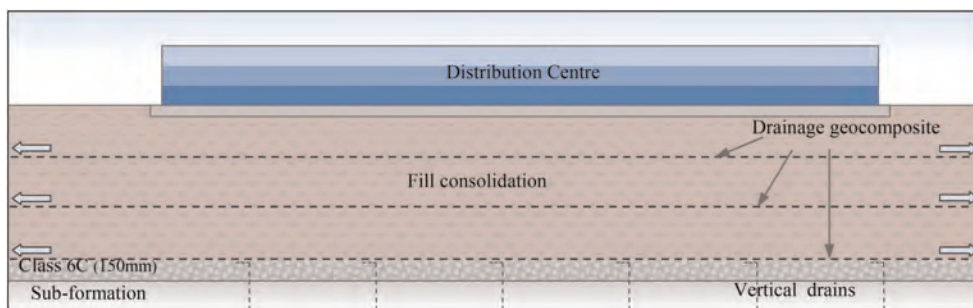
A large distribution centre needed considerable areas of earthworks and ground improvement to enable the rapid construction of a new logistics and business park to provide 770,000 m² of logistics floor space. A large proportion of this development was constructed on weak soil and it was first necessary to drain the sub-formation using prefabricated vertical drains with a horizontal geocomposite drainage blanket. The enabling works involved a 9 m change in site elevation levels and the embankment fill and sub-formation required consolidation before foundations for the new sheds could be constructed. Additional horizontal geocomposite drainage layers were placed at 3 m vertical intervals to accelerate the rate of consolidation by up to 70%.


Figure 5.   9 m of ground level rise ready to receive logistic sheds showing starter and consolidation geocomposite drain layers.

Each of the geocomposite drainage layers replaced an equivalent performance 150 mm stone drainage saving on stone transportation and carbon production impact. 31 deliveries of geocomposite replaced 8,000 aggregate deliveries. Total savings using the geocomposite resulted in 2,998 tonnes of embedded carbon, cradle to end of construction savings for 400,000 m² of treated area.

6.2 Example 2: Reinforced bund with geosynthetics using contaminated cohesive fill

This example describes the construction of a visual and acoustic bund to separate a new housing development from a neighboring metal recycling facility, located in Coventry, East Midlands, UK. The bund required to be 9.5 m high and 450 m long with a 2 m fence on top. The design solution included the use of 80,000 m³ of hydrocarbon and heavy metal contaminated fill, that otherwise would have gone into landfill. The dimensions of the base footprint were reduced by designing the bund was a geogrid reinforced soil slope with a 70 deg face angle on the external face and a 26 deg slope on the internal face.

The contaminated fill was provided from local construction sector and imported under license and treated on site prior to being used in the bund construction. The imported

Figure 6. Placement of starter layer geocomposite prior to raising of formation level (ABG Geosynthetics Ltd).

material was managed in accordance with the Development Industry Code of Practice (CL: AIRE 2011) and an environmental permit that promoted the sustainable use of waste soils. Site specific hazard and environmental risk assessments ensured that reusable soils did not pose a threat to the environment of future users of the site.

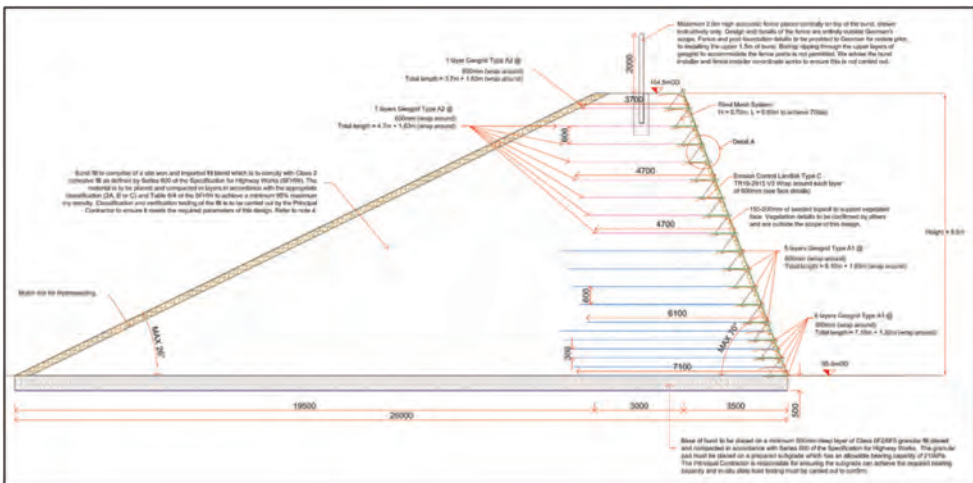
The imported fill was a dry cohesive/stoney cohesive Class 2A/2C soil, in accordance with Standards for Highways (2017), and the design was carried out in accordance with BS 8006 (2010) and BS EN 1997-1 (2004).


Figure 7. Cross-section Visual and Acoustic Bund – Reinforced Soil Bund (Geosynthetics Ltd).

While the sustainability benefits of re-using a fill that would otherwise go to landfill are self-evident, a calculation of the total CO_2 emissions associated with the materials used for the bund was performed using the UK National highways carbon tool, taking into consideration the principles of PAS 2080 (2016) to quantify, promote and deliver a low carbon solution for the project. The analysis was carried out for the Product and Construction process stages, to compare the CO_2 footprint of the reinforced bund using geosynthetics versus a conventional unreinforced solution using selected granular material Cass 6I/6J (Standards for Highways (2017) for the bund.

Table 1. Reinforced soil bund, carbon calculations for materials.

OPTION 1: Reinforced Soil Bund Materials	Total CO2e (Tonnes)	3,315.65								
Classification under National Highways Carbon Tool	Description	Item (National Highways)	Type (National Highways)	Unit	Quantity	Carbon Factor Value	Carbon Factor Unit	Conversion Factor	tCO2e
Bulk Materials: Civil Structures	Fill material for bund Class 2A/2C (contaminated fill from local construction sites, imported and treated on site)	Fill, Aggregate and sand	Recycled Resources, no heat treatment	Tonnes	142,299.79	0.0061	tCO2e/t	1.00	867.360
Earthworks	Mulch mix for Hydroseeding (for 1:2 slope. Note: slope 70deg protected with Landlok)	Imported soil	General soil/topsoil	Tonnes	23.00	0.024	tCO2e/t	1.00	0.552
Earthworks	Stratagrid SGU for slope reinforcement	Geosynthetics	PP/PET/PE	m2	56,050.00	2.36	tCO2e/t	0.001	132.278
Earthworks	Landlok TRM for Erosion control	Geosynthetics	PP/PET/PE	m2	11,899.40	2.42	tCO2e/t	0.001	28.797
Civil Structures	Steel mesh A252 and Hooks H10: formwork face 70deg slope	Steelwork (Rivel mesh face)	General Steel	Tonnes	41.30	1.55	tCO2e/t	1.00	64.015
	Materials CO2e (Tonnes)								**1,093.00**

Calculations were carried out for the selected reinforced soil bund solution and a traditional bund bult from granular fill and are presented in the tables below.

From the calculations in Tables 1 and 2 it can be seen that the total carbon for this option was 3,315 tCO2e. This is considerably lower than the value calculated for the second option of 7,843 tCO2e, see Tables 3 and 4. This comprises a 58% reduction in the carbon footprint of the bund.

Using geogrids for the reinforced soil bund allowed the use of contaminated cohesive fill that would otherwise be transported and disposed into a landfill. The reinforced solution provided significant benefits such as less excavation, less disposal of unsuitable material, less vehicle movements, less land required for the construction of the bund and costs reduction.

6.3 Example 3: Temporary working platforms on HS2

Temporary working platforms are increasingly becoming an important element of construction. They support heavy construction site equipment such piling rigs and cranes, where ground conditions do not carry enough bearing capacity to withstand heavy loadings.

Figure 8. Installation of the working platform at HS2 Stoneleigh Park (Tensar International Ltd).

Geogrids are now routinely installed in temporary working platforms, as they offer contractors cost, time and carbon savings compared to alternative non-stabilised solutions.

This case study presents a classic example where a temporary working platform utilising stabilising geogrids was constructed at the mega project High Speed Rail 2 (HS2) in the UK. A working platform was required for the Stoneleigh Park Overbridge, Warwickshire, for piling operations, which needed to address the issues of high rig track pressures over a variable subgrade. Using reinforcing geogrids in the working platform design means that significant aggregate thickness reductions can be achieved. This contributes to reduced construction time platform installation, and significant savings on carbon emissions.

Utilizing publicly available design and value calculation methodology (www.TensarPlus. com) design solution and quantification of cost and environmental benefits, compared with non-stabilised alternative, was estimated as follow:

- £250,000 (65%) estimated reduction in construction cost;
- 15 days (75%) estimated reduction in construction time; and
- 100,000 CO2e (75%) estimated saving in carbon emissions.

The above represents a typical saving on a relatively small size platform (this example was around 5,000 m^2).

6.4 *Example 4: Pavements Construction, Essex UK*

Geogrids are also often utilized in surfaced or non-surfaced (temporary or permanent) pavement designs. They allow for reduction in aggregate thicknesses required in the design solution, maintaining the same performance as the alternative non-geogrid solutions. In addition to that, pavement utilizing stabilisng geogrids allow for increased lifespan of the construction, contributing to reduction of maintenance costs for the asset owners.

To facilitate the construction of a new road at North Heybridge, a mechanically stabilised layer incorporating geogrid was used to act as a capping over low strength soils (Figure 9). This was required to achieve a Foundation Class 1 as required by the project specification from the Design Manual for Roads and Bridges CD 225 – Design for new pavement foundations (Standards for Highways 2020).

A cost-effective solution was required when low strength subgrade soils were encountered across the site. The pavement design needed to achieve a prescribed CD225 foundation class to allow the client to adopt the carriageway. Project granular fill costs were high as it was being imported from outside of the local area, and so a geogrid based solution was adopted to meet the CD225 foundation requirements as well as dealing with construction trafficking close to the low strength subgrade. The stabilised capping layer reduced granular fill quantities, as well as project excavation operations and also offered a more sustainable solution by reducing the carbon footprint of construction and transportation activities.

Figure 9.   Installation of the pavement capping layer at North Heybridge (Tensar International Ltd).

Design solution and quantification of cost and environmental benefits, compared with non-stabilised alternative, was calculated as:

- £177,000 (54%) estimated reduction in construction cost;
- 12 days (50%) estimated reduction in construction time; and
- 80,000 CO2e (57%) estimated saving in carbon emissions.

6.5   *Example 5: Instrumentation and "Smart" geosynthetics*

As previously discussed, the sustainability benefits can come from the careful use of geo-syntheyics within wider geosystems, and so over-specifying the quantity or grade of geosynthetic, through either poor design, or excessive conservatism will have a detrimental impact to the sustainability of the project. Conversely under-specification can lead to catastrophic failures and reputational damage to not only those involved, but the geosynthetics industry as a whole. It remains imperative that we fully understand the mechanisms of interaction between the geosynthetics and the surrounding environment and are able to validate our designs against measured performance. Whilst there is ever increasing complexity of numerical assessment of geosynthetic performance, validation against measured in situ performance remains scarce. Instrumentation allows us to measure performance but is inherently challenging due i) the often-aggressive environment ii) technical installation of appropriate sensors iii) selection and installation of sensors that do not, by their presence, alter the behaviour of the geosynthetics.

To date, much of the instrumentation applied to geosynthetics has focussed on physical strain measurement. Zamara et al. (2022) summarised the types of instrumentation available, in this case for geogrids, but also applicable across a wide variety of geosynthetics and they were broadly categorised as foil type strain gauges, fibre optic instrumentation, strain meters and conductive coatings or elements.

Fibre optics have attracted significant attention as a method of installing a chemically inert corrosion resistant sensor. Zamara et al. (2012) reported successful instrumentation of geomembranes across a fixed 500 mm gauge length using fibre bragg gratings which allow strain measurement as an average value between main point of attachment whilst Chen *et al.* (2015) report use of distributed optical fibre sensors that allow strain measurement independent of the node fixities. More recently, promising results were shown in the work by Xu et al. (2022) where fibre optics were integrated into geogrids for ground movement detection systems.

Sensor development is evolving with material and manufacturing techniques. Hatami et al. (2014) considers a tensoresistive PVC coating whilst Bi et al. (2023) highlight the use of Flexible conductive materials which are widely used in other forms of structural health monitoring and can be adapted to allow strain measurement in conductive geosynthetics. Whilst challenges remain of how such coatings or materials would be applied in the geosynthetic manufacture and installation processes, they offer more opportunities to the industry to adopt these techniques.

Increasing we are seeing the use of Smart Geosynthetics where sensors are incorporated into or onto geosynthetics and couple with sensing technologies and advances in data processing and visualization allowing for more efficient design, operation and maintenance of construction and infrastructure assets.

Radar detectable geosynthetics are an early example of this technology where radar detectable strips are incorporated in a geosynthetic. In 2001, Terram produced a thermally bonded non-woven polypropylene incorporating a 50 mm wide aluminium foil. The addition of the stripe of electrically conductive material, which is an extremely good reflector of radar energy, was the key to both improving the accuracy of depth prediction of GPR surveys, and providing additional diagnostic tools to assess changes in the condition of ballast over time and deterioration in formation and development of soft spots.

Figure 10. Non-woven polypropylene incorporating a 50 mm wide aluminium foil (Terram Ltd).

These early radar geotextiles did not prove to provide long term effectiveness as a measuring system principally due to the degradation of the reflective strip. More recent developments have incorporated more durable reflective strips and enhanced reflectivity.

Figure 11. Radar detectable geosynthetic.

The increased durability of the sensing strip coupled with enhancement in the Ground Penetrating Radar technology (GPR) and its visualization are allowing for better classification and condition of the penetrated ground and allow more informed decisions as to the existing condition and health of the infrastructure for planned interventions and maintenance and provide potentially an early warning system of sub-formation geohazards, depending on the frequency of GPR readings. Radar Detectable Geosynthetics are a relatively low-tech example of smart geosynthetics.

A more sophisticated form of smart geosynthetics is Optical Fibre Integrated Geosynthetics (OFIG) which combine geosynthetics with fibre optic technology. The optical fibre can take a number of forms such as Fibre Bragg gratings, Simulated Brillouin Scattering, Raman Scattering and Distributed Fibre Optic Sensing (DFOS). DFOS enables
Figure 12. Section indicating RDG in track ballast renewal.
Figure 13. Ground penetrating Radar plot with clear chevron of reflective strip.

Figure 14. Improved visualization technology with GDPR.

measurement of temperature, strain, and acoustic energy distributions along the entire length of a fibre optic sensing cable (Kerchavarzi et al. 2016; Xu et al. 2022).

The incorporation of DFOS cables into the ground could provide significantly improved information on the location and magnitude of subsurface ground movement and subsidence (Möller et al. 2022) and have reported that the quality of fibre optic sensing data is highly reliant on the mechanical coupling between fibre optic cables and their surrounding soil.

A recent fibre optic-instrumented geogrid (Sensorgird) was developed in collaboration between Huesker, the Centre for Smart Infrastructure and Construction at the University of Cambridge and Epsimon Ltd. This fibre optic-instrumented geogrid was recently deployed to monitor potential ground movement beneath a 100 m long, 10 m wide stretch of the mainline alignment on the HS2 site at Tilehouse Lane Cutting, where the cutting though chalk had highlighted a number of solution features, the condition of the infill material varies, and voids are occasionally present. Engineered mitigation has been constructed for the highest risk features, but this approach is not sustainable for the whole of the affected area.

The cutting is being utilised during construction for the transportation of the Colne Valley viaduct concrete segments units. The units are to be transported through the cutting on self-propelled mobile transporters. The fibre optic-instrumented geogrid installation is centred

around a new over bridge over the cutting where the clearance envelope around the over-bridge is limited and the presence of potentially unmapped chalk solution features in the chalk cutting developing while transporting the viaduct units posed an unacceptable ground risk which could significantly impact the delivery of the project.

To mitigate the residual risk, a geogrid-reinforced mattress is constructed over the area. This will span any potential voids that migrate to the formation depicted either side of cement stablised layer indicated orange in Figure 15, with the fibre optic-instrumented geogrid being installed beneath this to enable identification of movements occurring beneath the reinforced mattress, (Xu et al. 2022).
Figure 15.   Cross section though construction haul road/mainline at Tilehouse Lane Cutting.

Prior to its use in the mainline a field trail was initiated on site as 'proof of concept' of the fibre optic-instrumented geogrid with the following intended trail outcomes:

- Realistic field-scale data (scalability);
- Real-world test of fibre/grid arrangement (sensitivity);
- Assessment of fibre resilience to damage in a construction environment (durability);
- Comparison with traditionally measured deformations (usability);
- Test dataset to assess post processing requirements (near real-time?);
- Opportunity to explore temporal visualisation (early warning of surface movement);
- Explore requirements for field installation & check robustness (splicing, protection, etc); and
- Confirm any changes to fibre or general set-up in advance of Tilehouse Lane Cutting works.

Controlled field tests were first performed on two simulated sinkholes using 3x3m pits in which water-filled bags were placed and covered with stabilised chalk and granular soils. By deflating the bags in varying sequences, the captured strain signature profiles from the instrumented geogrid were compared with displacement measurements from conventional instrumentation, to assess the geogrid's sensitivity to millimetre-scale settlements.

Separate onsite durability tests were conducted adjacent to the trial pit area to simulate the construction process that it would encounter on site in Tilehouse Lane Cutting which included placement and levelling of a stabilised chalk fill over the fibre optic-instrumented
Figure 16: Installation of fibre optic-instrumented geogrid and supporting geogrid at Tilehouse Lane Cutting (Huesker Ltd.)

geogrid, and compaction of that fill with eight passes of a 20-tone vibratory roller. For all treatments, the optical power measured along the fibre optic cables integrated in the fibre optic-instrumented geogrid was measured and some unacceptable losses of signal were observed which were likely due to excessive bending in the fibres generated by sharp aggregates.

Figure 17. Visualization dashboard displaying strains in monitored section at Tilehouse lane cutting.

The fibre optic cables used in these two trials were 2.5 mm in diameter and consisted of single-mode optical fibre with a 0.9 mm Hytrel coating embedded in an elastic 2.5 mm polyurethane outer sheath. They were knitted into a geogrid by substituting it for yarns of similar size. They were subsequently substituted with a more robust cable following on from on-site installation trials.

The data acquired from the fibre optic cables is automatically processed and displayed in real-time on a web-based visualisation dashboard. This enables the project engineers to detect any incipient ground movement below the road surface in the monitored section, enabling them to take timely preventative action if necessary.

Smart geosynthetics that incorporate simple and sophisticated sensors which potentially allow for the non-intrusive, continuous, remote monitoring of critical infrastructure network can highlight their deterioration to allow for the potential for planned interventions and maintenance. This is preferable to the reactivate/emergency interventions moreover they are able to provide early warning of geohazards whether these geohazards occur naturally due to the local geology or a legacy of underground mineral extraction.

6.6 *Example 6: Active geocomposites*

Active geocomposites can be installed as large-area contaminant filters respectively barriers for soil and groundwater protection as well as for remediation of contaminated sites. These newly developed geosynthetic contaminant barriers allow protection of the clean subsoil and groundwater by filtration of pollutants from seepage or runoff (i.e., persistent organic pollutants, including per- and polyfluoroalkyl substances (PFAS), heavy metals, oil, and petrochemicals). The current standard, in which subsoil and groundwater protection is ensured by sealing, is overcome by the contaminant filters. As a result, the subsoil retains its natural function as a water reservoir, nutrient store, and habitat. Geosynthetic contaminant filters are also used for site remediation. In sediment or soil capping applications they avoid or reduce earthworks with transportation and landfilling of contaminated soil/sediments.

In many places, anthropogenic processes generate substances with negative effects on the environment and/or human health. These substances move with carrier media (water, gas) or on carrier substances (particles, dust). Volatile substances move with the air, dissolved substances disperse with water, and bound substances move with particles to which they adhere. They can enter the body through inhalation, fluid ingestion, or through our food. Medical research is increasingly revealing the effects of the uptake of these substances in our bodies. A very recent example is the persistent pollutant group of PFAS. As a result, interrupting the pathways of pollutant effects has long been a high priority in environmental engineering.

The use of geosynthetic contaminant filters (GCF) protects the subsurface by collecting only the environmentally relevant contaminant, but not the carrier medium. The concept offers innovative groundwater protection without removing the water from the natural cycle. This also has the advantage that the soil below the GCF continues to be available, for example, as a water reservoir during heavy rain events and, if necessary, as a planting area.

The term geosynthetic contaminant filter refers to a new product group in the field of geosynthetics. It includes products consisting of at least two layers of geotextiles sandwiching an amendment material (Figure 18). Due to its novelty, the term has not yet been standardized. In some cases, therefore, different terms are used, such as sorption mats or geotextile contaminant barrier. However, all terms refer to the same product group.

The geotextile components consist of woven and/or nonwoven. They are joined together by mechanical bonding techniques, such as needle-punching or stitching. GCF have a coefficient of permeability $k \geq 1 \times 10^{-5}$ m/s. This is important to ensure that the contaminated water (in other applications also suitable for contaminated gas) can flow through the filter. This free flow ensures that the natural water flow remains unaffected. The geotextile components take on various application-specific functions. For example, they not
Figure 18.   Detailed view on geosynthetic contaminant filter (Huesker Ltd).

only serve as a carrier for the amendments, but also perform other important tasks in the field of pollutant filtration (acc. to ISO 10318-1):

- Reinforcement: use of the stress-strain behaviour of a geosynthetic material to improve the mechanical properties of soil or other construction materials;
- Separation: prevention from intermixing of adjacent dissimilar soils and/or fill materials by the use of a geosynthetic material; and
- Filtration: restraining of uncontrolled passage of soil or other particles subjected to hydrodynamic forces, while allowing the passage of fluids into or across a geosynthetic material.

The durability of the materials is also important. The pollutants must be chemically isolated until they decompose naturally. This process can sometimes take several decades, so the geotextiles must also have a similar life expectancy. Oxidation tests can be used to simulate the ageing of the geotextile components to make statements about their service life *in situ*. A life expectancy of 100 years can be considered normal for quality manufactured geotextiles which have been correctly installed and exposed to natural conditions with soil pH values of $4 \leq pH \leq 9$ and soil temperatures of $\leq 25 \,°C$.

Amendments are materials that remove and bind environmentally relevant substances/contaminants from a liquid or gaseous carrier medium. Since not every amendment is suitable for every pollutant, the most suitable type must be selected for the specific application. For this selection, the pollutant must be sufficiently known. Relevant pollutants can initially be divided, for example, into water-soluble and non-water-soluble substances.

An example of a non-water-soluble, i.e. non-polar, group of substances is hydrocarbons. For these pollutants, active substances can be used that absorb non-polar substances and at the same time are resistant to contamination by the oil itself. Special absorbent polymers fulfil these properties. They bind hydrocarbons in their inner structure and thus separate them from the runoff. The absorbent material can bind many times more oil than their own weight.

Water-soluble pollutants can be further divided into organic and inorganic substances. Organic pollutants include compounds such as polycyclic aromatic hydrocarbons, polychlorinated biphenyls or PFAS. A prominent active ingredient for the removal of these substances from water is activated carbon. Due to its mesoporous structure, activated carbon has a very large surface area. For example, 10 g of activated carbon, made from coconut shells, has a surface area the size of a soccer field. This surface area is important because the

Table 5. German preliminary max. permissible concentrations for corresponding recovery classes (BMUV 2022).

PFAS congeners	RC 1 Unrestricted open replacement (μg/l)	RC 2 Restricted open replacement in areas with elevated PFAS concentration (μg/l)	RC 3 Restricted emplacement in technical structures with defined safety measures (μg/l)
Perfluorobutanoic acid, PFBA	≤ 10.0	≤ 20.0	≤ 50.0
Perfluorohexanoic acid, PFHxA	≤ 6.0	≤ 12.0	≤ 30.0
Perfluorooctanoic acid, PFOA	≤ 0.1	≤ 0.2	≤ 1.0
Perfluorononanoic acid, PFNA	≤ 0.06	≤ 0.12	≤ 0.6
Perfluorobutane sulfonic acid, PFBS	≤ 6.0	≤ 12.0	≤ 30.0
Perfluorohexane sulfonic acid, PFHxS	≤ 0.1	≤ 0.2	≤ 1.0
Perfluorooctane sulfonic acid, PFOS	≤ 0.1	≤ 0.2	≤ 1.0

pollutants adhere to it due to Van der Waals forces, and so the larger the surface area, the more pollutants will find a place on the adsorber.

Inorganic pollutants are typically salt-like, molecular compounds and include metals such as copper, zinc or lead. Some of these substances pose a risk to the environment and human health even at low concentrations, as they accumulate in the tissue of living organisms. For the removal of these contaminants, which are sometimes referred to as "heavy metals", amendments with the functions of adsorption, precipitation or ion exchange are suitable. The adsorption takes place schematically in the same way as with the activated carbon. In the case of precipitation, the pH value is adjusted by the sorbent in such a way that the metals dissolve from the water and can be separated. In ion exchange, an environmentally harmless substance, such as calcium, dissolves from the amendment and gives its place to an environmentally harmful substance. In this way, a strong bond is formed between the amendment and the pollutant.

A recently developed GCF for PFAS removal was tested in both laboratory and field trials as proof of concept and are described herein (Niewerth et al. 2022). Guidelines for PFAS Assessment of the German Federal Ministry for the Environment (BMU 2022) provisional maximum permissible concentrations for PFAS are defined in the 2:1 liquid/solid-eluate. These values result in a recovery classes (RC), which in turn decides on the containment measure to be taken.

The division into the three classes results from the consideration that the concentration in the technical structure will be transported into the subsoil over time. The aim of the GCF underneath the technical structure is to filter the leachate before it percolates into the uncontaminated subsurface. The PFAS concentration must reach a concentration of RC 1 below the GCF, see Figure 19.

In addition to groundwater protection, the advantage of this approach is the successive decontamination of the soil. The infiltration of rainwater into the structure is used specifically to dissolve PFAS compounds. The leachate loads itself with the environmentally relevant components and transports them to the permeable filter. To eliminate the concern of
Figure 19. Schematic of technical structure with GCF at the base of the structure and leachate concentration.

pollutants entering the subsurface, the effective removal of the contaminants and a long-term binding of PFAS to the filter must be proven and ensured. Extensive testing with PFAS-contaminated soil from a former US airbase in Germany was performed to meet these requirements.

A series of tests were carried out in close cooperation between Huesker Synthetic GmbH and CDM Smith. Large-scale lysimeter tests were established, see Figure 20. Three different rain events were simulated in different 1 m³ HDPE-containers. Their effect on PFAS mobilization was investigated and the effectiveness of the GCF was tested.

As a control, all rain scenarios were also carried out in a container without the active component. In the test setup, the active geocomposite was laid out in the bottom of a container that was open at the top. A contaminated silty sand with a thickness of 0.7 m was placed on top. The leachate produced during the respective rainfall simulations was collected and analyzed at different times. The water quantities follow the definitions for moderate, heavy, and extremely heavy rain events according to the German Weather Service (Deutscher Wetterdienst, DWD):

- Rain Event 1: moderate rain with 10 L/m² in 60 minutes;
- Rain Event 2: heavy rain with 30 L/m² in 60 minutes; and
- Rain Event 3: extremely heavy rain with 50 L/m² in 60 minutes.

No PFAS were detected in the leachate after filtration by the GCF in these tests for all three simulated rain events.

7 CONCLUSIONS

The landmark Paris Agreement adopted by 196 parties at the UN Climate Change Conference (COP21) in Paris in 2015, entered into force on 4 November 2016. Its overarching goal was to limit the increase in the global average temperature to 1.5°C above pre-industrial levels. This is because the UN's Intergovernmental Panel on Climate Change warns that crossing this 1.5°C threshold risks severe impact such as more frequent and severe droughts, heatwaves and rainfall. A recent report issued by the World Meteorological Organization (WMO 2023) concluded that there is a 66% likelihood that the annual average global temperature between 2023 and 2027 will be more than the 1.5°C target for at least one year. The report states that this does not mean that the world will permanently exceed the 1.5°C level, but it is a warning that the 1.5°C level will be breached on a temporary basis with increasing frequency. It is clear, therefore, that the shift towards sustainable development needs to accelerate.

Geosynthetics can play an important role in supporting the world's goal of limiting the effect of global warming. This paper has presented example of where geosynthetics can reduce the carbon footprint of civil engineering projects in several ways. Firstly, they can reduce the need for importing virgin aggregate to be used for drainage, working platform and pavement applications. The thickness of aggregate can be reduced, and eliminated in some cases, minimising the need to use primary aggregate and the carbon emissions associates with its excavation, haulage and placement. Secondly, geosynthetics can enable the use of poor quality site-won soil, and in the example shown even use contaminated soils in the engineered solution to prevent the off-site disposal at landfill. This paper has also highlighted new developments which will provide further environmental benefits to using geosynthetics. Instrumenting geosynthetics is becoming increasingly possible with fibre optics, radar detectable materials and distributed fibre optic sensing techniques allowing continuous, non-intrusive remote monitoring of critical infrastructure. Finally, active geosynthetics are an exciting development that can provide protection to clean subsoil and groundwater by filtration of pollution from seepage or runoff.

The examples given in this paper are not an exhaustive list of how geosynthetics can support sustainable development. The International Geosynthetics Society (IGS) in its Sustainability Statement states that it believes that geosynthetics and associated technologies make a significant contribution to the achievement of sustainable development. The IGS website has an excellent section on sustainability (IGS 2023) and the authors encourage readers to seek further examples of the sustainable development benefits of geosynthetics from this source.

Insight towards the stability of complex geosynthetic reinforced soil structures

B.A. Leshchinsky
Oregon State University, USA

ABSTRACT: Typical design of geosynthetic-reinforced soil structures is based on the arbitrary classification of a wall and slope, which require different checks of internal and compound stability. However, both limit state conditions may be evaluated consistently through Limit Equilibrium (LE) analyses, particularly when the solutions are used to solve for tensile loads within reinforcements, such as that proposed by Leshchinsky et al. (2017). Herein various expanded examples using the top-down LE method and associated tension maps are explored to demonstrate the nuance and complexity of internal and compound stability, even for seemingly simple geosynthetic reinforced soil structures. Further, a special limit state design condition is explored – called "hybrid" stability conditions, where specific applications such as a footing placed on reinforced soil, may encounter a variety of failure mechanisms that related to external stability, compound stability and internal stability. Nuances of these complex, but increasingly relevant case are discussed, and potential limit state analyses are proposed. Lastly, future directions are briefly described.

1 INTRODUCTION

Geosynthetics have been widely used as an economical means of soil reinforcement in earth retention and slope construction for decades. The design of geosynthetic reinforced soil structures (e.g. AASHTO 2020) treats reinforced walls and slopes (differentiated by a 20° or 30° batter, depending on the internal stability method) with different design criteria – namely earth pressure-based and slope stability-based design, respectively. Despite the different basis for evaluating reinforcement loading, at strength limit state conditions, both reinforced walls and slopes are subject to design focused on internal stability, external stability, and compound stability. Internal stability is traditionally focused on pullout and rupture strength of reinforcements. External stability often focuses on sliding, overturning and bearing failure of the reinforced mass. Compound stability is traditionally a "final" check to ensure that failure through or around the reinforced mass is unlikely. While walls are often designed based on earth pressure theory, a more consistent alternative would be evaluation through limit equilibrium methods, i.e. the methods used to design reinforced slopes. The different techniques used for design of reinforced slopes commonly apply (or adapt) concepts of the limit equilibrium method (or limit analysis method) to determine critical failure mechanisms and associated reinforcement loading (Duncan & Wright 1991; Leshchinsky & Reinschmidt 1985; Leshchinsky & Boedeker 1989). However, in many some instances, use of internal and compound stability checks may be inconsistent with one another, lead to paradoxical results, and most importantly, cannot encompass the breadth of design constraints often required for each structure (Leshchinsky et al. 2017). This is particularly true for complex, but realistic, design scenarios, such as supporting footing loads, building walls on slopes, tiered structures, etc. Further, there exists scenarios, such as reinforced walls or slopes supporting surcharge

loading, that lie outside of traditional internal, external and compound stability checks, i.e. "hybrid" stability checks. Herein, the importance of mechanics-based design procedures as a means of exploring internal, external, compound and hybrid stability of geosynthetic reinforced soil structures is explored.

1.1 *Limit state methods*

Limit state analyses, such as that proposed by Leshchinsky et al. (2017) inherently assume that the *design* strength of the soil in consideration is mobilized and consequently, the degree of mobilization signifies the margin of stability or factor of safety, *Fs*. Coupled with this assumption is the expectation that reinforcements are implicitly only installed in slopes that otherwise would be inherently unstable. Therefore, at an actual limit state, the *design* strength of the soil is fully mobilized (i.e. *Fs*=1.0) and the stability of any trial slip surface hinges upon the mobilized tensile resistance of the reinforcement. At that state, design should ensure that the long-term strength of the reinforcement (e.g. factored rupture strength) will be available throughout the reinforcement (e.g., Leshchinsky et al. 2017; Liu 2016). It is assumed that reinforcements will not rupture and that they are compatible with the soil as it deforms, mobilizing tensile strength (e.g., Liu 2016). These assumptions are reasonable as geosynthetic reinforcements are generally ductile and capable of developing substantial strains that are much larger than those needed for nonplastic backfill to mobilize its strength (i.e., to form an 'active' mass). Consequently, these limit state concepts and limit equilibrium or limit analysis methods in particular are suitable for design of geosynthetic reinforced slopes and walls. Note that while LE and LA are employed to analyze the limit state in this study, one may use alternative approaches, such numerical methods that can deal with limit state, such as finite element (FE) and finite difference (FD) analyses (Ambauen et al. 2015; Leshchinsky & Han 2004; Leshchinsky & Vulova 2001; Mohamed et al. 2014). These methods are also valuable for exploring stability problems where there are feedbacks between potential failure modes, such as bearing capacity and/or slope stability (e.g. Leshchinsky 2015; Leshchinsky & Xie 2017; Yang et al. 2019, 2021). For example, when reinforced structures are required to support a surcharge load (Xie et al. 2019), the stability of such a system is inherently external, internal, and compound, consequently termed a "hybrid" stability problem herein. While continuum mechanics-based numerical methods are insightful to all of these possible controls on reinforced structure stability, implementation of these approaches in ordinary design may add unnecessary complexity, and more simplistic but representative solutions are valuable. In this study, exploration of more holistic internal and compound stability checks based on limit equilibrium are explored. Further, the role of hybrid stability problems is described with a particular focus on surcharge loading of reinforced walls and slopes. In all cases, mechanics-based design enables consistent and explainable design.

2 INTERNAL AND COMPOUND STABILITY

For geosynthetic reinforced soil structures, internal stability design is focused on reinforcement strength, pullout and connection strength (Xie et al. 2016). Previous literature has described pullout resistance between geosynthetics to be dependent on soil particle size, apertures (if applicable), soil type, and interface friction (Jewell 1990; Lee 2000). When sufficient interlocking behavior between geogrid and soil is realized, pullout may be inhibited, where shear strains may propagate in the soil adjacent to the reinforcement instead of at the soil-geogrid interface, demonstrated experimentally and numerically (Ambauen et al. 2015; Boyle 1995; Bathurst & Ezzein 2016; Hatami & Bathurst 2005; Yoo & Kim 2008) for geosynthetic reinforced soil structures. Connection strength is an important design consideration, particularly for walls with block or panel facings. Connection loads may be

amplified when vertical spacing between reinforcements is large or there is significant differential settlement; however, with proper construction practices (i.e. compaction) and sufficiently small vertical reinforcement spacing, connection issues may be mitigated (Soong & Koerner 1997). Internal stability design for rupture strength is based on evaluation of a single (or multiple) potential slip surfaces contained within the reinforced mass. Such a limit state analysis typically assumes that a slip surface is fully formed, consequently allowing calculation of required reinforcement loads under a given set of assumptions (e.g. mobilization of soil strength, modifications for reinforcement extensibility, etc.). However, these traditional approaches largely ignore the potential influences of multiple shear surfaces, internal and compound, and potential feedbacks between reinforcement mobilization, pullout and connection loads (Leshchinsky et al. 2017). Typically, these requisite reinforcement loads must account for potential durability, installation damage, and creep reduction factors in addition to a margin of safety (Leshchinsky et al. 2020).

2.1 *Limit state design framework for geosynthetic-reinforced soil structures*

The limit state approach used here was first explored by Han and Leshchinsky (2006) using planar slip surfaces. It was further modified to deal with rigorous log spiral limit equilibrium framework for simple geotechnical problems (Leshchinsky et al. 2014). This modification showed that in many cases, curved slip surfaces are more critical. Additional work by Leshchinsky et al. 2016 generalized the framework to deal with internal/compound stability of nearly any practical geotechnical problem utilizing Bishop's method. For example, typical geotechnical problem is different properties of reinforced and retained soils, complex wall geometry or complex reinforcement layout, permeating water, and impact of facing. Such generalization made the general framework as a subset of geotechnical slope stability analysis with particular emphasize on the resulted load distribution along each layer. This 2016 report also provides experimental and numerical assessment of the framework. Finally, Leshchinsky et al. (2017) presents the method in a complete and concise fashion.

As per the prior work of Leshchinsky et al. (2017), the use of the top-down Limit Equilibrium method is used to explore the complexities and nuances of internal and compound stability of geosynthetic reinforced soil structures for a variety of cases, both simple and complex. This approach uses a spatial distribution of slip surfaces for a prescribed safety factor (typically unity) for a soil mass, and consequently attains the required reinforcement tensions needed to yield equilibrium at any location. Implemented through an iterative, top-down procedure of limit equilibrium-based slope stability analyses, the mobilized reinforcement loading can be visualized through a *Tension Map* that illustrates the required distribution of reinforcement tension to attain a prescribed limit state of equilibrium. This tension map is directly constrained by both rear- and front-end pullout capacity, providing a unified, LE-based approach towards evaluating the internal and compound stability of simple or complex geosynthetic reinforced soil structures using explainable, mechanics-based criteria. A brief overview of the method is presented, followed by several examples of internal and compound stability of geosynthetic reinforced soil structures.

As described by Leshchinsky et al. (2017), the *Tension Map* illustrates the tensile load distribution along trial reinforcement layers to ensure that a limit state defined by a prescribed safety factor – typically unity – is determined. Specifically, rather than assuming or determining the long-term strength of each reinforcement before analysis, the required reinforcement tension at the intersection of an analyzed slip surface is modified to produce a prescribed safety factor in each slip surface of concern. Consequently, the *Tension Map* yields the maximum load in the reinforcement including its connection load: T_{max} and T_o, respectively. Determination of the *Tension Map* requires application of the top-down procedure (Leshchinsky et al. 2017). This procedure is characterized by numerous trial failure geometries exiting throughout the face of the geosynthetic reinforced soil structure, which is iteratively used to develop a *Tension Map*. A detailed description of the top-down procedure

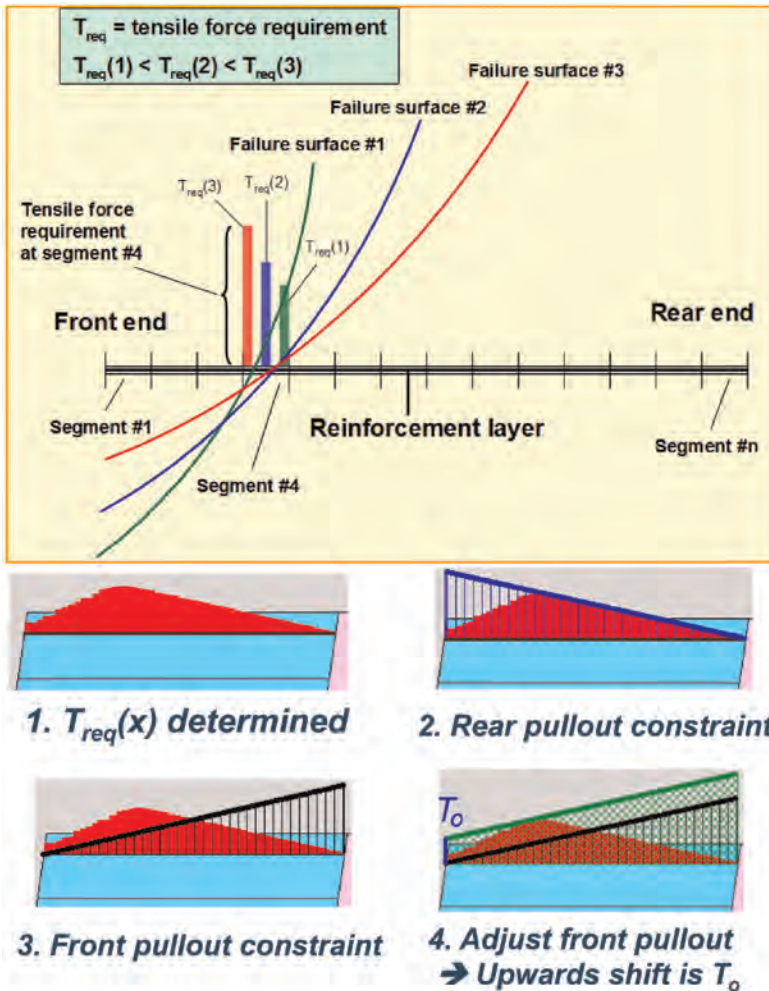
and determination of a tension map is presented in Leshchinsky et al. (2017), but a brief overview is provided below and Figure 1.


Figure 1. Overview of the top-down limit equilibrium method used to determine mobilized reinforcement loading for internal and compound stability of geosynthetic reinforced soil structures (after Leshchinsky et al. 2017).

1. Select a layout of reinforcement layers for a given set of geometric specifications and soil properties.
2. Assign a top-down arrangement for reinforcement layers whereas trial failure surfaces are analyzed starting at the slope crest and emerging at the wall face. For each layer that is intersected by a slip surface, determine the mobilized reinforcement force T that yields the predefined, specified safety factor. For each location along a reinforcement, the maximum T (defined as T_{max}) is determined and assigned spatially along its length evaluated using this procedure (Figure 1). This procedure is repeated sequentially from the crest to the toe of the trial design for each layer of reinforcement, whereas the mobilized T at the intersection of a trial surface and reinforcement layer(s) must not exceed the rear pullout

164

capacity (Figure 2). If T does exceed rear pullout capacity, the excess loading is shared with other intersection layers. If the new T determined at a given location along a reinforcement exceeds the previous T_{max}, the new T is now the maximum. This process is repeated until the toe of the structure is reached and a distribution of maximum T that satisfies rear end pullout criteria is found along each reinforcement layer, including that at the lowest elevation.

3. Thereafter, connection loads (T_o) may be determined for each reinforcement layer based on the distribution of T_{max}, where the frictional envelope of front-end pullout may be translated to determine unfactored connection loading T_o that enables sufficient pullout capacity at the front end. The magnitude of the shift from zero resistance is the minimum required connection load at each elevation (Figure 2).
Figure 2. Benchmark case geometric conditions, the dimensions, and properties of which are shown above.

4. From both T_{max} and T_o determined at each layer, the governing long-term design strength can be determined based on reinforcement demands and other relevant design factors.
5. Check global and compound stability for the actual selected reinforcement to ensure that it meets design specifications. If necessary, repeat steps 1-4 for more economical or satisfactory design. Note that compound failures are considered when assessing T for a selected layout of reinforcement.
6. If desired, numerically integrate the reinforcement tensile distribution divided by reinforcement tensile stiffness J to determine displacement, or outwards stretching, d at each reinforcement layer, proposed as: $d = \int_0^L (T_{max}/J)dL$

2.2 Benchmark example conditions

A simple benchmark example is presented, illustrating systematic comparison of the sensitivity of internal and compound stability of simple and complex geosynthetic reinforced soil structures to common design conditions. Consider a reinforced wall, $H=6$ m tall having a batter of $\omega=8°$, reinforcement spacing (S_v) of 0.6 m with a bottom layer 0.3 above the foundation soil and the top layer is 0.3 m below the horizontal crest. The length of reinforcement, L, meets typical specifications of $L/H=0.7$; i.e., $L= 4.20$ m, as shown in Figure 3.

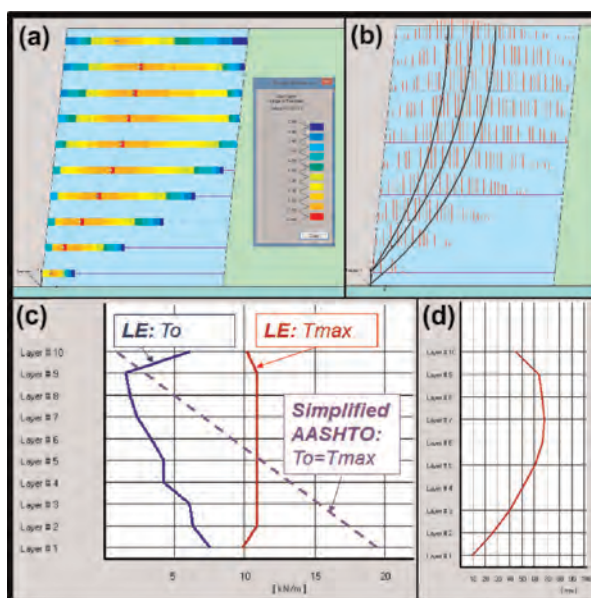
The reinforced, retained, and foundation soils have unit weights, γ, of 22, 20, and 18 kN/m^3 and internal angles of friction, ϕ, of 34, 30, and 28 degrees, respectively. No cohesion is considered. Stability analyses are performed using Bishop's method and circular failure geometries. The selected geosynthetic has long-term design strength and connection strength, T_{LTDS}, of 16 kN/m. The coverage ratio of the reinforcements is unity (i.e. continuous), the interface friction is 64% of that of internal friction, and the factor of safety against pullout is 1.5. The stiffness J of the reinforcements is assumed to be 500 kN/m. These conditions yield satisfactory global stability (Figure 3) and serve as a simplified set of conditions that can be compared against other cases.


Figure 3. (a) Tension map for benchmark conditions. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. Note the comparison to earth pressure-based design estimates of reinforcement tensile loading. (d) Estimated lateral displacement profile based on a stiffness of J=500 kN/m.

The aforementioned top-down procedure and the associated tension map that satisfies rear end pullout constraints and load shedding amongst layers is shown in Figure 4a. Note that the maximum load in the reinforcement is located closer to the slope face as lower layers are considered. This reflects the convergence of slip surface geometries at the slope toe. Interestingly, the locus of T_{max} does not necessarily lie on a singular trace of slip surface, shown in Figure 4b. This owes to the top layer being controlled by rear pullout while lower layers are affected by compound failures. Closer and/or longer reinforcements may result in uniform mobilization of reinforcement occurring along a singular slip surface. Other configurations of reinforcement length and geometry may result in non-uniform mobilization of reinforcement strength, an aspect that cannot be addressed using conventional global LE design approaches. From this tension map, front-end pullout can also be determined (Figure 4c). Front-end pullout resistance increases with depth, especially in steeper slopes such as the proposed example, owing to increased overburden and associated frictional resistance. The maximum connection load is approximately half of the maximum force in the reinforcement, which enables quantitative selection of connection strength specifications. Figure 4c

166

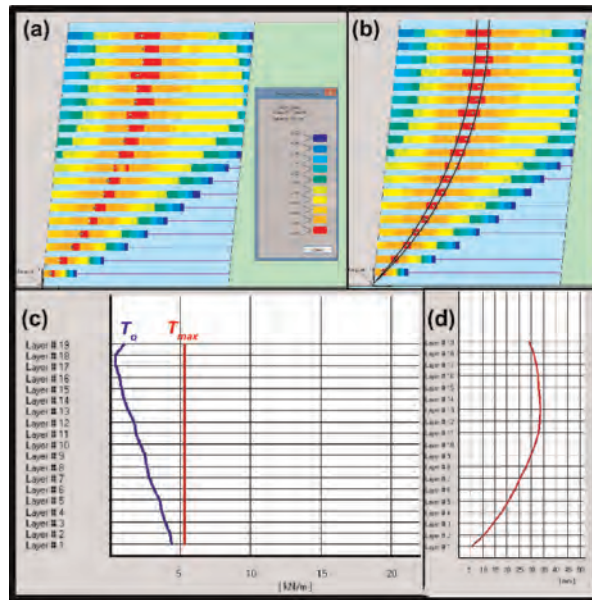
compares T_{max} and T_o as calculated by AASHTO 2010 and the LE approach, where unlike LE, AASHTO uses a lateral earth pressure-based approach that is proportional to simple overburden pressure and reinforcement spacing. Consequently, if the maximum T_{max} is used to select a reinforcement, AASHTO requires about twice the strength than that determined by LE. Lastly, Figure 4d shows that the extensibility of the given reinforcement results in a standard deflection profile observed in many reinforced walls. (e.g. Ambauen et al. 2015). Simple integration of local displacement due local loading determined from LE and stiffness provides a means of estimating a displacement profile near failure and potentially ensuring that service-state deflections are satisfactory. It can also a useful tool in assessing the severity of deformed walls as evidenced by their exposed profile. This simple benchmark problem enables systematic comparison to a variety of relevant design criteria explored herein.


Figure 4. (a) Tension map for closely spaced reinforcement (S_v=0.3m) conditions. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement profile based on a stiffness of J=500 kN/m.

2.3 Close reinforcement spacing

The vertical spacing between reinforcements is a primary design condition which may influence internal stability. Closely spaced reinforcements are being used more frequently for such structures as they enable better load-carrying capacity, enhanced serviceability, require weaker reinforcements, and facilitate consistent compaction quality. The same example problem is considered but evaluated with close vertical spacing (S_v=0.3m) vs. standard vertical spacing of 0.6m, shown in Figure 5. A comparison with benchmark conditions (Figure 4) demonstrates a drop in maximum loading (Figure 5a) and a relatively uniform maximum loading – which arguably reflects a more efficient design, demonstrated by a narrow band of maximum tensions and very few slip surfaces associated with maximum loading. Specifically, the value of max(T_{max}) drops from 11.28 kN/m for the baseline problem to 5.65 kN/m for 0.3 m spacing, a 50% drop that is effectively proportional to the spacing. More noteworthy however, is the dramatic drop in connection loads in the upper

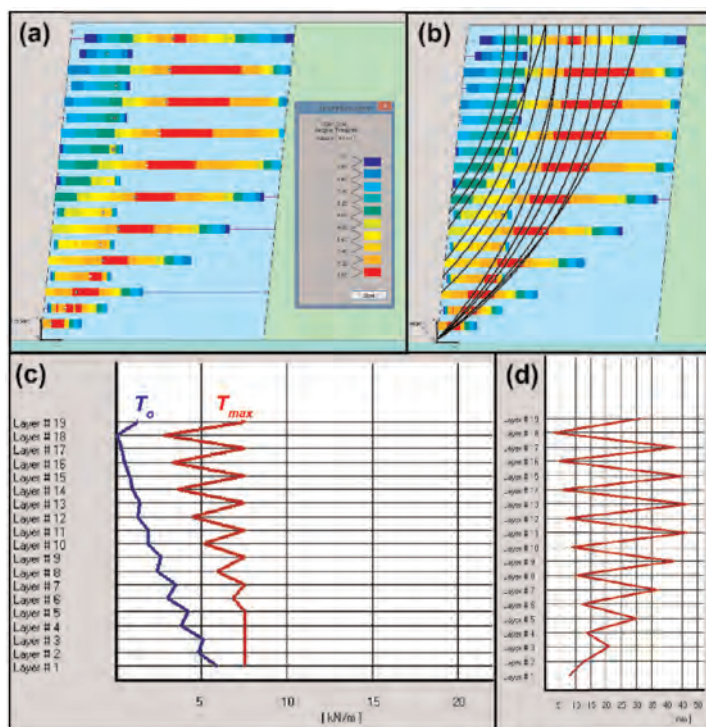
layers (Figure 5c). This owes to diminished loading within each layer, reduced pullout demands, and consequently a decrease in the required translation of the front-end pullout envelope and connection load. Lastly, the deflection profile is reduced by approximately 50%, consistent with the reduction in loading compared to the benchmark case.


Figure 5.   (a) Tension map for primary and secondary reinforcement for closely spaced (S_v=0.3m) conditions. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement profile based on a stiffness of J=500 kN/m.

2.4   *Secondary reinforcements*

Shorter, secondary reinforcements may be placed between primary reinforcements to enable a more efficient reinforced soil structure through reduced connection loading without using as much reinforcement as those systems with closely spaced reinforcements. It enables adequate compaction near the face. The benchmark problem is considered but evaluated with close vertical spacing (S_v=0.3m) and alternating reinforcement lengths of 4.2m for primary reinforcements and 1.2m for secondary reinforcements, shown in Figure 6. A comparison against benchmark conditions reduced maximum loading (Figure 6a, 6c) although tensile loads are mostly higher in primary reinforcement and lower in secondary reinforcements. This pattern owes to secondary reinforcement loads being controlled by rear-end pullout, and consequently shedding some load to primary reinforcements. As shown, max(T_{max}) drops from 11.28 kN/m for the baseline problem to 7.55 kN/m for this case. However, connection loading is now similar to the case of closely spaced reinforcements (Figure 5c), but the quantity of reinforcement is only ~65% of this case. This demonstrates that secondary reinforcements can indeed shed problematic

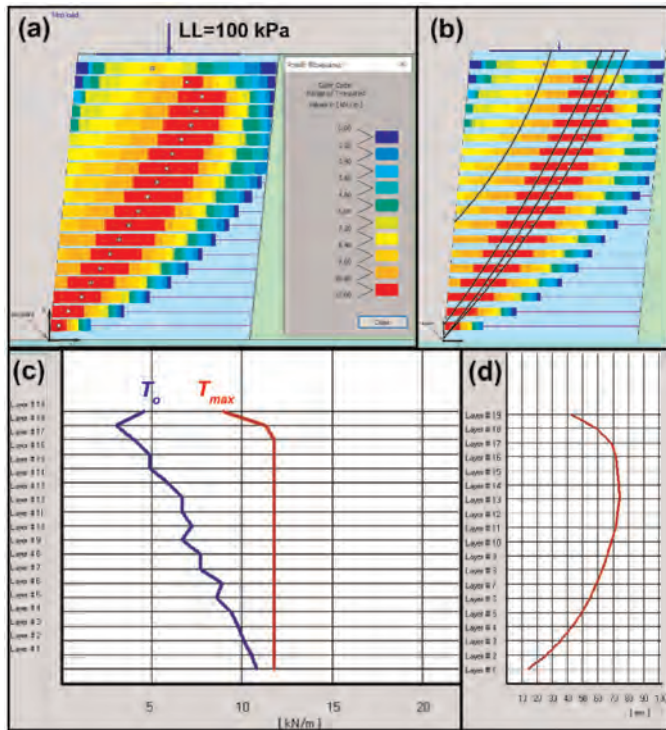
connection loads. The loci of maximum loading is associated with numerous slip surfaces, demonstrating the complexity of such a problem (Figure 5b). Lastly, the deflection profile (Figure 5d) is similar to that of closely spaced reinforcements, although significantly less reinforcement material is required.


Figure 6. (a) Tension map for closely-spaced conditions with a surcharge of 100 kPa. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement profile based on a stiffness of J=500 kN/m.

2.5 Load supporting conditions

Often, geosynthetic reinforced soil structures support surcharge loads that may be in the form of dead loads (e.g. footings, construction material, etc.) and/or live loads (e.g. traffic, temporary loads). The benchmark problem is considered but evaluated with close vertical spacing (S_v=0.3m) and a live load of 100 kPa, applied along a 3.5m area on top of the reinforced mass, shown in Figure 7. A comparison against benchmark conditions shows increased maximum loading (Figure 7a, 7c) vs. the benchmark conditions, although the max tensile loads are rather uniform when sufficient far from the surcharge. Connection loading increases monotonically with overburden, suggesting increasing loading demand with limited gain in connection strength with depth (Figure 7c). The loci of maximum loading is associated with numerous slip surfaces that either reflect local shear loading (i.e. the upper surface) or a propensity to incorporate the entire surcharge (surfaces situated near the far heel of the surcharge), again demonstrating importance to capturing reinforcement demands, both in magnitude and location (Figure 7b). The deflection profile (Figure 7d) has a more pronounced bulge owing to the increased swatch and magnitude of loading at lower reinforcement layers. Such deflection profiles are expected for such loading conditions (e.g.

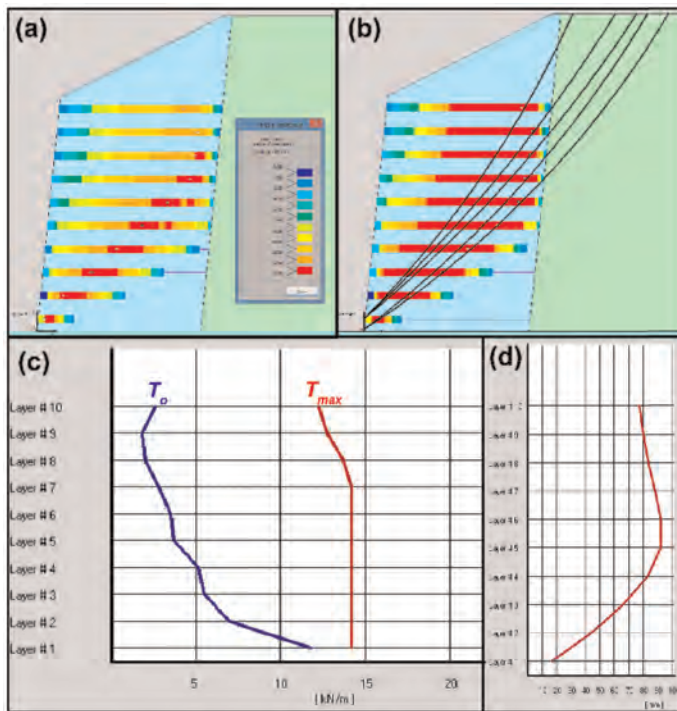
Ambauen et al. 2015). The condition presented herein – internal stability conditions accounting for a flexible surcharge considering only slope failure – will be shown to be a special case later in this study, where numerous mechanisms may control the load-carry capacity upon a reinforced soil slope.


Figure 7. (a) Tension map for the benchmark case but with a2.1m tall, 2H:1V broken backslope. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement.

2.6 Backslope and narrow walls

As reinforced soil structures are often placed in locations with limited right-of-way and/or flat ground, it is common to have backslopes adjacent to the structure itself. The benchmark problem is modified to have a broken backslope, 2.1m in height and with a 2H:1V slope. As shown in Figure 8a and 8b, the mechanisms that dictate T_{max} are largely compound, resulting in larger tensile loads than the benchmark conditions (Figure 8c). This behavior is sensible, as the unreinforced slope atop the reinforced structure has a natural propensity to drive slope failure further back from the reinforced mass owing to insufficient shear strength. The remaining shear forces are supported by the reinforced soil below. Consequently, reinforcement loads are significantly higher than the benchmark example and connection loads are particularly large, especially at lower portions of the wall (Figure 8c). Such behavior can also be reflected for narrow walls (Figure 9), where compound stability governs reinforcement loading and results in larger connection loading owing to insufficient rear-end pullout capacity and consequential enhanced loading. Similar to backslope conditions, compound failures correspond with the loci for maximum tensile loading. This behavior also demonstrates that the LE method is effective at characterizing both internal *and* compound stability

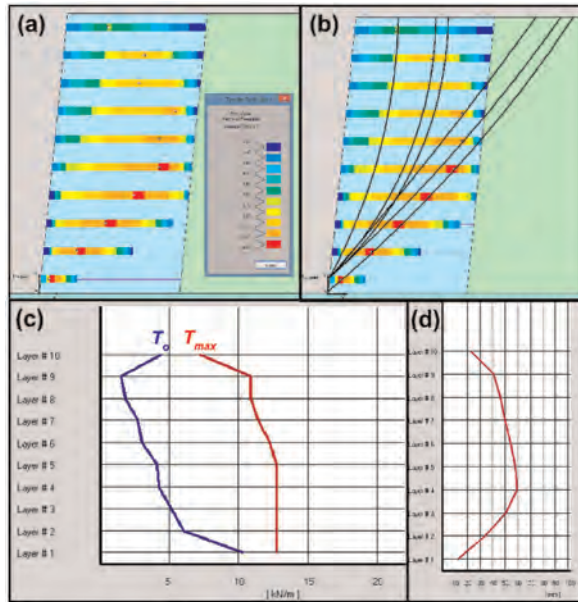
170


Figure 8. (a) Tension map for the benchmark case but for a narrow wall with L/H=0.5. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement.
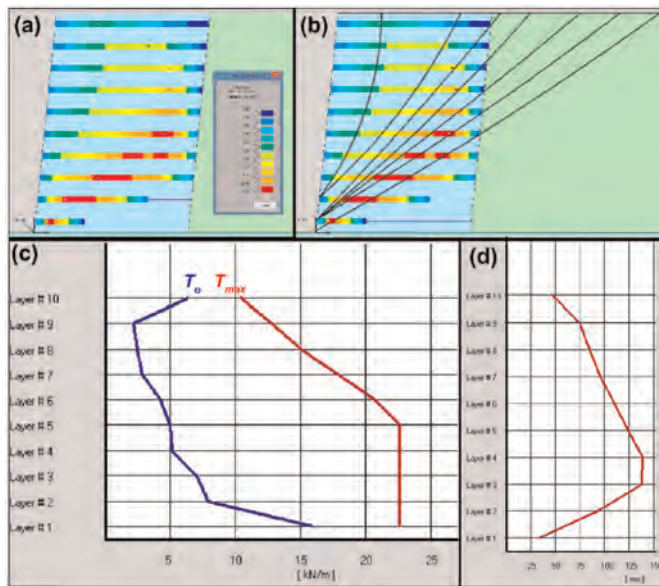

Figure 9. (a) Tension map for the benchmark case but subject to 0.2g of horizontal seismic loading. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement.

171

simultaneously, demonstrating that T_{max} may be controlled by both internal and compound failure surfaces. This complex behavior is reflected in the deflection profile, which has amplified tilt in the upper portion of the structure in comparison to the benchmark case (Figure 8d).

2.7 Seismic loading

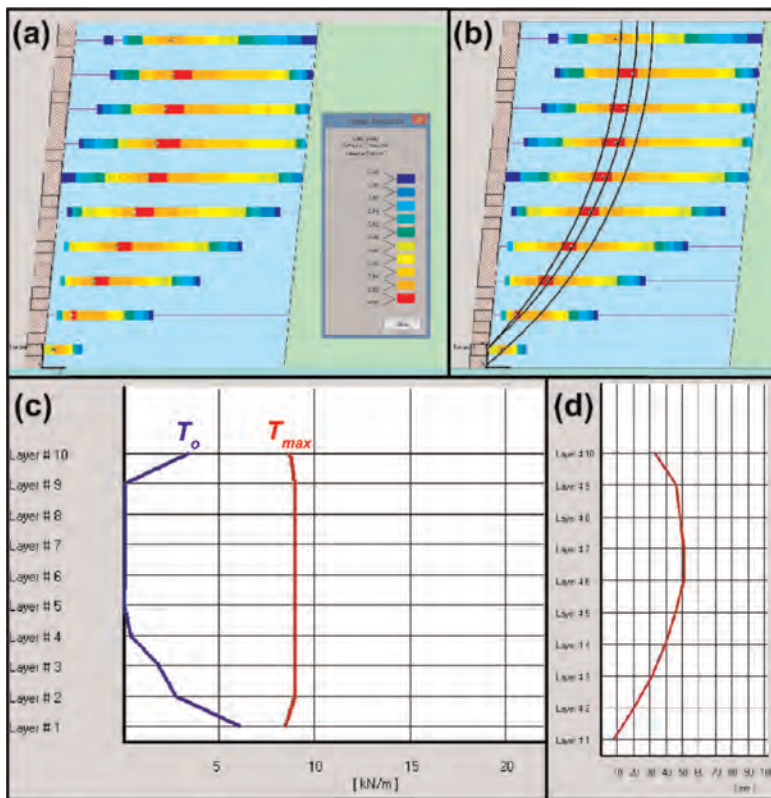
Earthquakes are known to yield deeper critical failure geometries; when reinforced soil structures are subject to earthquake loading, deeper, compound failure surfaces may govern stability. The benchmark case subjected to 0.2g of pseudostatic earthquake loading is presented in Figure 10. As shown, once again, compound failure surfaces dictate T_{max} in all reinforcement layers except the top two layers. This behavior owes to deepening of critical failure geometries from earthquake loading. The importance of compound stability is illustrated by the profile of T_{max} (Figure 10c), where the largest tensions occur in the lower reinforcement layer owing to very deep, partially reinforced failure surfaces. In these surfaces, pullout capacity is sufficient, but the overall size of the failure surface results in much larger loading than static conditions. These loads also create a unique bulge in the deflection profile (Figure 10c) that is shifted downwards in comparison to the static case.


Figure 10. (a) Tension map for the benchmark case but with a modular block facing. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement.

2.8 Influence of facing systems

Various facing elements are available for reinforced wall construction, many of which may significantly influence the observed reinforcement loading and overall internal stability. Addition of 0.2m×0.3m modular blocks with an interface friction angle of 30° and an 'adhesion' (more likely interlocking of rough interfaces between stacked blocks) of 10 kPa are added to the benchmark case, shown in Figure 10. Addition of these facing elements demonstrates a modest decrease in T_{max}, but a very significant decrease in connection loading. Such an observation is sensible as the block weight and its associated interblock shear resistance reduce T near the front due to its contribution to local stability, similar to secondary reinforcements. In fact, there is near zero connection loading throughout much of the wall owing to the localized stabilizing effects of the wall facing. Of course, the influence of facing units on overall loading should be used conservatively, based on whether this resistance is available in the long term; however, this analysis demonstrates that LE can enable the influence of such systems, which is particularly helpful for a variety of block wall systems (e.g. hybrid walls, full height panels, etc.). It is noted that that the LE analysis provides a rational assessment of connection load at a limit state; however, at working load conditions soil and interblock strengths are not fully mobilized yet meaning that the connection load might be larger.

2.9 Tiered walls

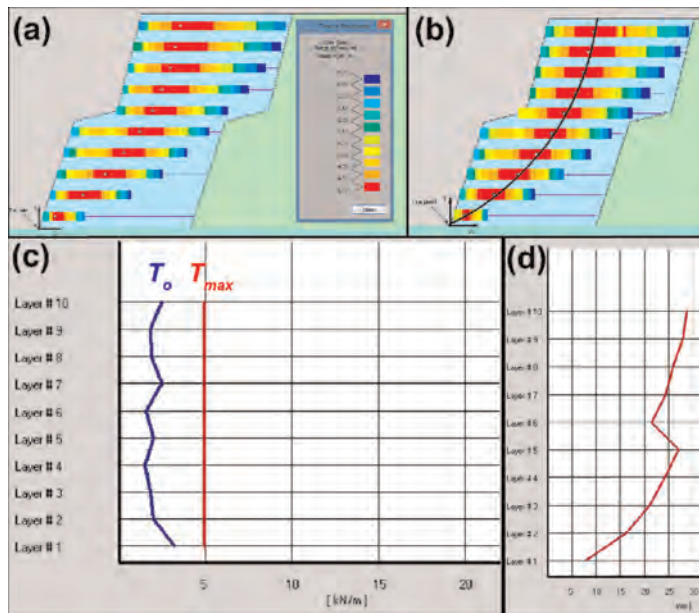
Thus far, only simple walls subject to modest complexities have been considered, demonstrating that even small complexities can greatly affect internal stability *but* may be captured using the proposed limit equilibrium approach. A tiered wall of complex structure is considered as such systems often fall outside the classification of wall or a slope (Figure 11). As


Figure 11. (a) Tension map for a complex, tiered wall system. Note that the location of the maximum T_{max} on each layer is shown with a white, hollow marker. (b) Slip surfaces associated with maximum T_{max}. (c) Distribution of T_{max} and T_o along the profile of the given geometry. (d) Estimated lateral displacement profile.

shown, increasing the batter and adding a bench between tiers reduces loading by over 50%. The locus of maximum tensile load varies, but several zones of increased loading may be observed, such as those on the lower tier, near the facing. These localized regions may be better visualized in the deflection profile, which shows a discontinuity in lateral displacement between the tiers.

The series of simple and complex examples presented demonstrate that internal and compound stability well-captured by the proposed LE approach. The LE approach demonstrates its utility for a variety of reasons, including that it (1) does not use arbitrary thresholds in geometry as a basis for design, (2) quantifies connection and maximum reinforcement loading accounting for internal design criteria such as pullout and without separate internal stability analyses, and (3) maintains the ability to holistically evaluate internal and compound stability in one framework. However, there are some instances where additional limit state tools are necessary, particularly when evaluating even more complex systems, such as geosynthetic reinforced soil structures supporting footings, which is discussed in more detail in the following section.

3   EXTERNAL, GLOBAL, AND "HYBRID" STABILITY CRITERIA

External stability is focused on ensuring that the reinforced soil mass is not predisposed to sliding, overturning, bearing capacity failure, or global failure. It may be argued that compound stability is a special case of global stability, whereas the critical failure mechanism passes through foundation soil and/or retained backfill *in addition* to the reinforced soil mass. However, as these design criteria are often evaluated after initial design of internal stability, meeting external and global stability is an iterative process that may seem to be performed independent of other design criteria. While some external design checks are rather straightforward – e.g. direct sliding – others can be complex, particularly for common but irregular design conditions and geometries. Some instances of focus discussed in this paper are the nuances of hybrid stability problems, particularly as it relates to bearing capacity on reinforced walls.

One increasingly common application of geosynthetic reinforced soil structures is use for small-span bridge supports, often relying on load-bearing resistance in addition to earth retention purposes. Typically, such structures require shallow foundations that are placed on the reinforced soil zone – for good performance, these footings must have sufficient bearing resistance as to reduce settlements and support limit state design criteria. However, the increasing prevalence of such "hybrid" structures and their demands has resulted in a significant design question: how does one do limit state design for such foundations? Is it an internal stability problem? External stability? Consequently, building upon prior limit state methods, we explore the importance of "hybrid" stability problems and where its limit state evaluation exists in context of existing methods.

The performance of reinforced soil structures supporting footing loads is more complex in terms of design than unsurcharged counterparts as localized loading that may result in complex earth pressure distributions and a variety of potential yield mechanisms that are not singularly a slope or bearing capacity failure. These complexities largely rely on several dominant design parameters, outlined herein: (1) footing location (setback, S_b), width (B) and associated dead/live loads (q), (2) wall geometry, particularly height (H), and (3) strength (T), and spacing (S_v). Herein, we synthesize prior findings surrounding the importance of these design parameters, shown schematically in Figure 12.

Intuitively, the location of a footing with respect to the wall facing (i.e. "setback") and its distributed load strongly influence deformations and potential failure within the reinforced soil mass. These design parameters are of importance for bridge-supporting GRS structures as the span of the bridge deck is a primary material expense for such structures. Consequently, the smaller the setback distance (i.e. the clearance between the footing edge
Figure 12.   Schematic of governing design variables for GRS-supported footings.

and wall facing), the more potential to decrease the bridge span length. However, short setback distances may result in excessive deformations (Ambauen et al. 2016; Doger & Hatami 2020) as well as diminished bearing capacity and ULS conditions (Xie et al. 2016, 2019; Xie & Leshchinsky 2015). Consequently, there are opportunities for improved design to shorten bridge deck length or support larger spans (i.e. larger footing loads), as well as explore the complex controls on stability.

From an ultimate limit state perspective, increased setback from the wall facing yields higher ultimate bearing capacity, which is largely dependent on reinforcement strength spacing, wall height, and to a level, batter (Xie et al. 2019). Specific combinations of these factors result in differing mechanisms and associated ultimate bearing pressures that can be supported, typically associated with a slope failure, bearing capacity, or hybrid mechanisms (Xie et al. 2019). Bearing capacity mechanisms (Figure 13a) may be one-sided (to the facing or towards unreinforced backfill), two-sided (either a Prandtl mechanism or constrained above the uppermost geosynthetic). Using the standard bearing capacity equation ignoring embedment, cohesion, eccentricity and assuming plane strain conditions, the bearing capacity equation is defined as:

$$q = 0.5\gamma B N_\gamma \qquad (1)$$

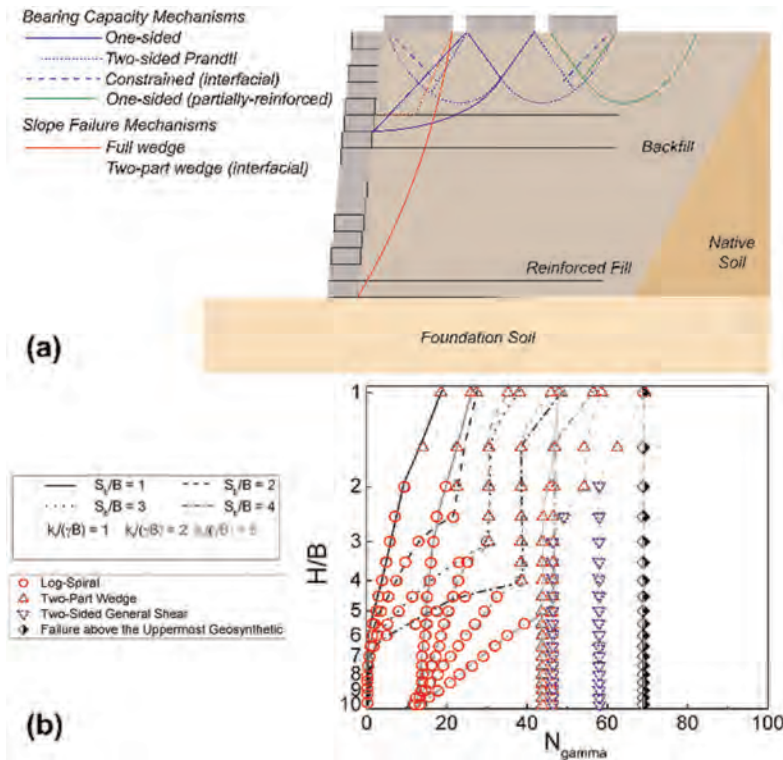
One-sided mechanisms and two-part wedge failures (red triangles) along the reinforcement interface tend yield lower bearing capacity factors (N_γ) than two-sided bearing capacity mechanisms, particularly at modest setbacks and large wall heights. Two-sided mechanisms become dominant at larger setbacks and for taller walls; however, constrained failures only occur under very high reinforcement strengths (black and white labels). For weaker reinforcements and especially taller walls, a log-spiral "wedge" is the dominant failure mechanism as the self-weight of the backfill is a large destabilizing element in addition to surcharges loading (Figure 13b). Effectively, decreased footing setback or increasing footing load will result in a predisposition towards failure above the wall toe, typically as a two-part


Figure 13. (a) Proposed failure mechanisms associated with ultimate bearing pressures. (b) Example design charts for different mechanisms and capacity based on Xie et al. (2019).

wedge or a one-sided bearing capacity failure. This is particularly prevalent when reinforcement strength is sufficiently large. In the presence of weaker reinforcement strengths or tall wall heights, the relative weight of the backfill results in a predisposition to an active failure, typically in the form of a wedge or log-spiral exiting the wall toe. Sufficient setback will result in bearing capacity failures becoming the dominant mechanism, either through Prandtl mechanisms through reinforcements or constrained above the uppermost reinforcement for relatively weak and strong reinforcements, respectively. With sufficient setback distance and proximity to the end of the reinforced fill, a one-side bearing capacity failure may occur through both reinforced and unreinforced fill; however, these bearing capacity conditions rarely govern as setbacks of this magnitude make the system uneconomical for supporting bridge spans. The predisposition of these failure mechanisms and their associated N_γ are shown in Figure 13b (based off of Xie et al. 2019). As shown, various governing failure mechanisms may be observed in the presence of weaker reinforcements as proportional wall height and setback change.

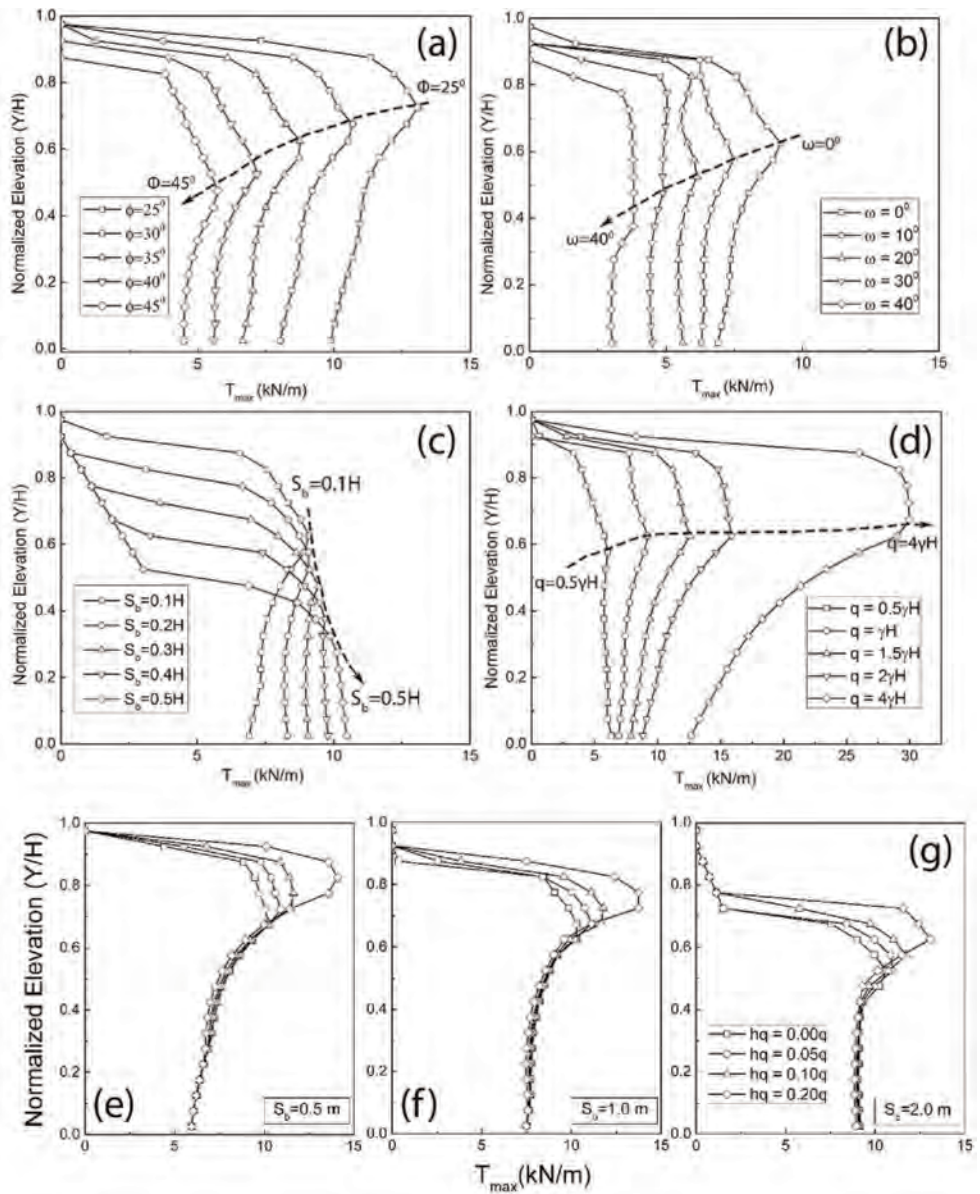
Other considerations for ULS conditions include the influence of facing-backfill interactions, nonuniform reinforcement spacing and loading inclination. Xie et al. (2016) showed that high levels of interface friction between block facings, backfill and between facing blocks may reduce reinforcement loads significantly (Figure 14), in agreement with field tests from Doger and Hatami (2020) and numerical modeling of Zheng et a. (2018), Zhang et al. (2022) which suggest that the structural importance of the facing cannot be ignored. Further, observed mobilized tension in the reinforcements is sensitive to backfill strength, footing


Figure 14.   Reinforcement tensile mobilization for GRS structures supporting footings modified from Xie et al. (2017). (Top left) Reinforcement load distribution considering a range of backfill friction angles. (Top right) Reinforcement load distribution considering a range of wall batters. (Middle left) Reinforcement load distribution considering a range of setbacks. (Middle right) Reinforcement load distribution considering increasing surcharge load. (Bottom) Reinforcement load distributions for S_b of 0.5m, 1m, and 2m for footings with horizontal inclinations.

setback, footing load, and to lesser levels wall batter and loading inclination of the footing (Xie et al. 2017). Further, ULS conditions for bearing capacity can be enhanced through strategic placement of small reinforcement spacing (S_v) in the region beneath the footing, but not necessarily throughout the wall. Xie and Leshchinsky (2015) demonstrated that

placement of stronger and/or denser reinforcements in the upper $1B$-$2B$ of the wall could yield near-full realization of bearing capacity as that of a wall constructed with dense reinforcements throughout. However, when wall height is sufficiently large, stronger and/or denser reinforcements within the wall toe help prevent an internal or compound failure. Effectively, reinforcement spacing, and strength can be tailored to create a more efficient GRS structure. This work also demonstrates that ULS failure mechanisms of GRS supporting footings can be exceedingly complex, often consisting of hybrid failures relating to both slope stability and bearing capacity.

4 CONCLUSIONS

The presented LE framework explored herein and proposed in Leshchinsky et al. (2017) has great utility towards unifying compound and internal stability of geosynthetic reinforced structures. It demonstrates that even relatively simple geosynthetic reinforced soil structures can have complex internal and compound stability conditions. This framework, however, enables exploration of internal and compound stability holistically, enabling evaluation of distributions of tensile and connection loading, as well as deflection. As expected, specific loading or geometric conditions can result in scenarios where compound failure governs. However, there are many more examples that could be explored – for example, hybrid walls, anchored MSE walls, less extensible reinforcements, etc. Future work could further describe the nuances of design under such scenarios. Further, future modifications of the LE framework could account for various failure kinematics, facing details and loading conditions. Evaluating the role of marginal soils, creep, long-term degradation and better connection with service limit state conditions would also enhance the utility of the proposed framework. Finally, better analysis of uncertainty would enable a more probabilistic approach to design and the range of wall or slope behavior observed in practice.

The importance of failure kinematics is further described by the latter section of this manuscript, where hybrid stability analyses with multiple potential failure mechanisms is possible – for example, such a scenario is available considering bearing capacity atop geosynthetic reinforced soil structures. Consequently, there is extensive need for further work on the ultimate limit state of GRS supporting footings, and there has been significant progress to evaluate a suite of important conditions. More full-scale tests are being performed (e.g. Doger & Hatami 2020; Zheng et al. 2019). For example, seismic performance is of paramount performance and extensive modeling at both full-scale and using numerical tools continues to advance this technology in earthquake-prone regions (Zheng et al. 2018). Other opportunities include improved understanding of the use of different backfills (Hatami & Boutin 2022), particularly marginal materials. Further investigation is needed regarding the importance of GRS foundations, including placement near slopes or banks subject to scour and erosion. Application in environments where hydraulic loading and or flooding is very much needed considered the preferential use of these systems for small span bridges across smaller streams that may flood. Other opportunities include improved optimization of these systems in terms of internal stability, reinforcement spacing, and especially length of reinforcements. Many of the design templates for these reinforced systems include relatively long L/H ratios (often much larger than 1.2), which precludes applications in areas where minimal right-of-way is available. Investigation of different facing systems, such as full-height rigid, gabion, and big blocks could also present opportunities for further enhancing the design of these systems. Lastly and most importantly, there is ample opportunity to further extend the growing body of knowledge surrounding these systems from research to practice, where current design guidelines are effective and economical, but very likely overly conservative and tailored to very specific applications.

Geosynthethic-reinforced foundations

S.N. Moghaddas Tafreshi

K.N. Toosi University of Technology, Tehran, Iran

ABSTRACT: Construction of structures on soft foundations presents a major challenge for geotechnical engineers due to the limited bearing capacity of foundation, resulting in excessive settlement under construction loads. To address this issue, various ground improvement techniques are used, including preloading, soil replacement, grouting, piling, and geosynthetic reinforcement. Geosynthetic reinforcement, which involves incorporating geosynthetic layers into the foundation bed, is particularly effective in enhancing the shear strength of soil and creating a well-structured foundation with high bearing capacity and minimal settlement. The choice of geosynthetic reinforcement, such as geotextile, geogrid, or geocell, influences failure modes and stress distribution within the soil. Recent advancements in understanding the technical aspects of geosynthetic reinforcement have led to their widespread application in stabilizing and reinforcing footings, buried pipes, pavements, embankments, slopes, etc. This paper provides an overview of recent scientific achievements, reinforcing mechanisms, and research findings related to the protection of footings, buried pipes, and roads.

Keywords: Geosynthetic, Two and Three reinforcements, Footing, Buried pipe, Pavement

1 INTRODUCTION

In the past few decades, geosynthetic materials have become widely used in geotechnical applications, including construction projects involving footings on soft soil, road construction, stable embankments, slope stabilization, protecting buried pipes and underground utilities. Two-dimensional (2D) reinforcements like geotextiles and geogrids, as well as three-dimensional (3D) reinforcements like geocells and tire cells, have been employed for these purposes. One of the conventional uses of geosynthetic reinforcements is in supporting paved and unpaved roads and footings on weak subsoil layers. By distributing the applied loads over a larger area of the underlying soil, geosynthetic soil reinforcements improve the bearing capacity and reduce settlement of the foundation bed. In traditional unreinforced construction, a thick layer of granular soil is required to counteract the effects of weak subsoil layers. However, using such a layer can be costly, time-consuming, or impractical, especially when high-quality granular materials are scarce. The simplicity of constructing soil reinforcements, along with the economic and time-saving advantages over conventional approaches, has motivated engineers and researchers to consider geosynthetic-reinforced foundation soil in geotechnical projects. Consequently, numerous studies have been conducted in recent years (e.g., Amiri et al. 2023; Inti & Tandon 2021; Moghaddas Tafreshi & Dawson 2010; Madhavi Latha & Pokharel et al. 2010; Rajabian & Shukla 2023; Somwanshi 2009a; b; Shukla 2012; Sitharam & Hegde 2013; Tavakoli Mehrjardi et al. 2012; Thakur et al. 2012; Wehbi & Nogy 2022; Yang et al. 2012; Zhang et al. 2010) to investigate the optimal use of geosynthetic inclusions to effectively enhance the behavior of foundation beds. These studies have examined various aspects, including reinforcing mechanisms, and

have provided valuable insights into the application of geosynthetics for protecting footings, buried pipes, roads, pavements, etc.

This paper aims to provide an overview of the reinforcing mechanisms employed by 2D and 3D reinforcements in reinforced soil foundations. Additionally, it presents research findings on the application of geosynthetics for protecting footings, buried pipes, roads, and pavements, serving as a useful reference for further studies in the field.

2 SOIL REINFORCEMENT INTERACTION

2.1 Two-dimensional reinforcement

2D reinforcement systems consist of geotextile or geogrid materials that commonly contribute to the load-carrying mechanism by virtue of frictional resistance mobilized at its interface with surrounding soil (e.g., geotextile) or combination with interlocking between the ribs of reinforcement and soil particles (e.g., geogrid). These reinforcements are arranged in the horizontal planes inside the backfill to resist the outward movement of the reinforced soil mass. The interaction between soil and geogrid consists of (1) shear strength on top and bottom plane areas of the geogrid- i.e., mobilized friction strength between the soil and the geogrid's horizontal surfaces as shown in Figure 1a and (2) passive soil resistance along the transverse ribs of the geogrid as illustrated in Figure 1b. Stress transfer between the soil and the geogrid reinforcement takes place through one or a combination of both actions which mobilize due to the elongation of the geogrid. Geotextile reinforcement transfer stress to the soil through friction and then generation of a tension force in the reinforcement layer.
Figure 1. Soil and geogrid interaction (a) stress transfer between soil and geogrid, (b) passive soil resistance by ribs of geogrid.

2.2 Three-dimensional reinforcement

Geocell as a 3D reinforcement provides a cellular mechanical soil stabilization/reinforcement method. When a geocell layer fills with soil materials, due to the unique interaction of geometry, soil, and the cell-wall material act as a mattress (or slab) that distributes a portion of applied vertical forces (e.g., footing load and vehicle wheel load) laterally. Figure 2a-c shows the typical stresses exerted on a cell of geocell reinforcement (Schary 2019). The confinement restrains the lateral movement of soil particles via hoop stress on the geocell walls. This maximizes the distribution of lateral and vertical stresses, resulting in stabilized
Figure 2. Geocell performance under loading (a) vertical stress on cell (b) lateral stress into cell wall, (c) hoop stresses on cell wall (Schary 2019), (d) interaction and interfacial behaviour of soil and geocell (Tavakoli Mehrjardi & Motarjemi 2018).

soil, basal layer reinforcement and reduced surface degradation, among other benefits (Kief et al. 2014).

Moreover, to capture the interaction and interfacial behaviour of soil-geocell, Figure 2d illustrates, the interlocking effect of geocell and soil particles which can mobilize apparent cohesion and friction at the interface, besides the confinement effect on grains within the geocell's cells, producing the interface's shear strength. Based on the acquired results, it was found that the shear strength of the interface encountered weakness in the aftermath of grain sliding alongside the geocell's walls and also, geocell's wall distortion (Tavakoli Mehrjardi & Motarjemi 2018).

3 EQUIVALENT CONFINING STRESS CONCEPT: REINFORCED AND UNREINFORCED TRIAXIAL TESTS

The behavior of granular soil specimens, whether unreinforced, 2D reinforced, or 3D reinforced, can be understood by examining their failure stresses in triaxial tests. These failure stresses are visualized in the σ (normal stress) and τ (shear stress) space using Mohr's circles, as depicted in Figure 3. Mohr's circle "1" represents the failure of an unreinforced specimen under a confining stress of $\sigma 3$ and a principal stress of σ_1. The Mohr's circle "1" is tangent to the Mohr-Coulomb failure envelope I_{Un}.

When a reinforcement layer, such as 2D materials (e.g., geotextile and geogrid), or 3D materials (e.g., geocell), is placed at specific locations within the soil specimens, it increases the ultimate principal stresses to $(\sigma_1)_1$ and $(\sigma_1)_2$, respectively, while subjected to a confining pressure of σ_3. These stresses are represented by Mohr's circles "4" and "5," which are tangent to the Mohr-Coulomb failure envelopes I_{2D} and I_{3D}, corresponding to the 2D and 3D reinforced specimens, respectively.

To achieve the ultimate principal stresses of $(\sigma_1)_1$ and $(\sigma_1)_2$ for the unreinforced specimens, the confining stress needs to be increased from σ_3 to $\sigma_3+(\Delta\sigma_3)_1$ and $\sigma_3+(\Delta\sigma_3)_2$. This results in the formation of Mohr's circles "2" and "3," representing principal stresses of $(\sigma_1)_1$ and $(\sigma_1)_2$ at failure. These principal stresses are defined as $(\sigma_1)_1=\sigma_1+(\Delta\sigma_1)_1$ and $(\sigma_1)_2=\sigma_1+(\Delta\sigma_1)_2$. The corresponding deviatoric stresses $(\Delta\sigma_1)_1$ and $(\Delta\sigma_1)_2$ are determined by multiplying $(\Delta\sigma_3)_1$ and $(\Delta\sigma_3)_2$ by k_p, where k_p denotes the coefficient of passive soil pressure. Figure 3 illustrates two Mohr's circles, labeled "2," and "3," are tangent to the Mohr-Coulomb failure envelope I_{Un}. like Mohr's circle "1".

The application of 2D and 3D reinforcement leads to an increase in normal stress from $\sigma1$ (in unreinforced specimen) to $(\sigma_1)_1$ and $(\sigma_1)_2$, respectively. This increase corresponds to a rise in confining pressure to $\sigma_3 + (\Delta\sigma_3)_1$ and $\sigma_3 + (\Delta\sigma_3)_2$ in unreinforced specimens (Mohr's circles "2," and "3,"). Figure 3 illustrates that $(\Delta\sigma_3)_1$ and $(\Delta\sigma_3)_2$ for 2D and 3D reinforced specimens are termed as "apparent confining pressure" or "internal confining pressure," while $(c_a)_{2D}$ and $(c_a)_{3D}$ represent the apparent cohesion resulting from the inclusion of reinforcement. The values of $(\Delta\sigma_3)_1$, $(\Delta\sigma_3)_2$, $(c_a)_{2D}$, and $(c_a)_{3D}$ can be determined by conducting a series of triaxial tests on both unreinforced and reinforced specimens, under the assumption that the internal friction angle of the soil (ϕ) remains constant until slippage occurs at the soil-reinforcement interface.

The superior effectiveness of 3D reinforcement, as opposed to 2D reinforcement, can be attributed to the interaction between the soil and reinforcement, as discussed in section 2.
Figure 3. Mohr's circles for unreinforced, 2D and 3D reinforced specimens.

4 REINFORCING MECHANISM

4.1 *Two-dimensional reinforcement*

Based on the experiments conducted by several researchers (e.g., Chen & Abu-Farsakh 2015; Guo et al. 2020; Madhavi Latha & Somwanshi 2009a, b), four types of reinforcing mechanisms have been observed in planar reinforcement, as illustrated in Figure 4.

(1) Lateral restraint effect: The mobilization of this effect occurs when there is relative movement between the soil layer and the reinforcement layer along the surface of the reinforcement. This movement activates the friction force at the interface between the reinforcement layer and the soil particles (Figure 4a). The interaction between the reinforcement and the soil effectively constrains the horizontal displacement of the soils, thereby increasing

the lateral confining pressure and compressive strength of the soils beneath the footing (Chen & Abu-Farsakh 2015). Consequently, the foundation's ultimate bearing capacity of foundation increases. In the case of geogrid, the grid component plays a crucial role in facilitating the interaction between the soil and the reinforcement. It effectively restricts the displacement of soils, especially in the case of gravel soil or sand with larger particle sizes, further strengthening the constraint on the soils (as depicted in Figure 1b).

(2) Tensioned membrane effect: As a result of the relatively thin profile of planar geosynthetics, the reinforcement layer experiences deflection and bending when subjected to transferred loads. This deflection causes downward movement and generates a tension force, as illustrated in Figure 4b. The vertical component of this tension force within the reinforcement layer plays a beneficial role in reducing the pressure exerted on the underlying layers. Consequently, it leads to an increase in the bearing capacity of the foundation and a decrease in deformation or settlement of the foundation bed (Chen & Abu-Farsakh 2015).

(3) Vertical stress dispersion effect: The phenomenon initially described by Binquet & Lee (1975), was based on laboratory model tests conducted on reinforced earth slabs. Figure 4c demonstrates that this effect leads to reduced pressure on the underlying bed compared to an unreinforced bed. The reinforcing mechanisms depicted in Figure 4a-c are observed when the strength of the reinforcement zone slightly surpasses that of the underlying unreinforced layer. Specifically, for values of u (the distance between the footing base and the upper reinforcement layer) and h (the distance between reinforcement layers) that are smaller than 0.5 times the footing diameter/width ($u \leq 0.5B$ or $h \leq 0.5B$), failure occurs within the reinforcement zone, as shown in Figure 5a. Conversely, when there is a significant distance between the foundation base and the upper reinforcement layer (u), likely exceeding $u > 0.5B$, failure is more likely to occur above the upper reinforced layer (Binquet & Lee 1975). Similarly, when there is a considerable distance between the reinforcement layers (h), presumably $h > 0.5B$, failure between the reinforced layers is more likely to occur (Wayne et al. 1998). In both cases ($u > 0.5B$ or $h > 0.5B$), the effectiveness of soil reinforcement on the bearing capacity of the foundation bed is compromised.

(4) Deep footing effect: Based on Figure 4d, the formation of the deep footing effect occurs when the strength of the reinforced zone significantly exceeds that of the underlying unreinforced layer, the reinforcement length is very short or equal to the footing width, and the spacing between reinforcement layers is small. This effect manifests as shear punching failure within the reinforced zone, followed by total shear failure in the unreinforced zone beneath it. Essentially, the performance of a reinforced foundation resembles that of an
Figure 4. Schematic view of four reinforcing mechanisms of 2D reinforcement (a) lateral restraint effect, (b) tensioned membrane effect, (c) stress dispersion effect, (d) deep footing effect (Guo et al. 2020).

unreinforced foundation, but with an additional embedment depth equivalent to the depth of the reinforced zone (Sharma et al. 2009). Failure occurs within the underlying unreinforced layer beneath the reinforcement zone, as depicted in Figure 5b. By increasing the embedment depth of the "equivalent footing over the underlying unreinforced layer," the bearing capacity of the footing improves, albeit to a lesser extent compared to what is illustrated in Figure 5a. This failure mechanism was initially proposed by Meyerhof & Hanna (1978) for a strong unreinforced soil layer placed on a weak soil layer. Wayne et al. (1998) further elaborated on this effect with slight adjustments to the solution presented by Meyerhof & Hanna (1978) for calculating the bearing capacity of foundations on reinforced beds.
Figure 5.   Failure (a) inside the reinforced zone (Sharma et al. 2009), (b) like footings on a two layered soil (Wayne et al. 1998)

4.2   *Three-dimensional reinforcement*

The reinforcing mechanism of a geocell layer as a three-dimensional reinforcement are defined in three main aspects as shown in Figure 6 (Zhang et al. 2010).
Figure 6.   Schematic view of three reinforcing mechanisms of 3D reinforcement (a) lateral resistance effect, (b) vertical stress dispersion effect, (c) tensioned membrane effect (Zhang et al. 2010).

(1) Lateral resistance effect: A geocell is a geosynthetic product that utilizes a 3D cellular network to contain and confine the materials it is filled with. This confinement effectively prevents lateral spreading, thereby enhancing the shear strength of the filled materials. Additionally, the interaction between the geocell reinforcement and the soils both below and above it, as illustrated in Figure 6a, leads to interfacial horizontal resistances. These resistances further enhance lateral confinement and reduce lateral strain, resulting in an increased

modulus of the cushion layer and improved vertical stress distribution on the subgrade. This phenomenon is known as the "vertical stress dispersion effect," which reduces the vertical pressure exerted on the top of the underlying unreinforced layer.

(2) Vertical stress dispersion effect: The horizontally reinforced geocell cushion acts as an immediate working slab, redistributing the applied load on the footing across a wider area, as depicted in Figure 6b. This phenomenon is referred to as the "vertical stress dispersion effect." Consequently, the soil pressure exerted on the underlying unreinforced layer, such as the soft subgrade soil layer, is lower compared to the absence of geocell reinforcement. The load applied on the footing surface, with a width of "b_n," can be distributed across an equivalent footing with a width of "$b_n+2h_c.tan \Theta$," where b_0, h_c, and Θ respectively represent the footing width, the thickness of the geocell layer, and the angle of load distribution.

(3) Tensioned membrane effect (Beam effect): The beam effect or tensioned membrane effect refers to the tension that develops in the curved geocell-reinforced mattress to resist vertical loads (Rajagopal et al. 1999; Zhou & Wen 2008). The loads exerted by footings, pavements, roads, and embankments cause deflection in the geocell reinforcement, resulting in additional tension forces, as depicted in Figure 6c. The vertical component of these tension forces in the reinforcement is beneficial in reducing the pressure on the underlying unreinforced layer, such as soft soil or subgrade soil. Consequently, the vertical deformation of the unreinforced layer beneath the reinforced zone decreases, leading to an overall increase in the bearing capacity of the foundation bed. Additionally, as the surface settles, the geocell layer undergoes further deformation, generating additional tension forces due to this membrane effect.

The behavior of the geocell mattress varies depending on the aspect ratio, h/d, where h represents the thickness and d denotes the pocket size of the geocell layer. According to Avesani Neto et al. (2013), when the geocell layer has a small thickness (i.e., $h/d \leq 1$, approximately), it behaves like a centrally loaded shallow beam. This results in increased deflection, higher contact pressure underneath, and the development of tension stress at the bottom and compression stress at the top, accompanied by significant shear stress mobilization. On the other hand, a geocell layer with a large thickness ($h/d > 1$, approximately) exhibits high rigidity and tends to behave similar to a raft foundation. It settles more uniformly, leading to a relatively even distribution of pressure (Dash et al. 2007; Han et al. 2008; Madhavi Latha & Somwanshi 2009b). In this case the confinement effect is only marginal, and the most important improvement effect is the stress dispersion.

5 PRESSURE AND SETTLEMENT IN DEPTH OF UNREINFORCED AND REINFORCED BED

Figure 7 depicts a schematic representation of the vertical pressure isobar and vertical settlement in depth of unreinforced, geogrid reinforced, and geocell reinforced beds under a load applied to a footing. As shown in Figure 7a, the pressure is distributed vertically to a depth of "h" and horizontally to a width of "W." In the case of 2D reinforcement (geogrid in Figure 7b), its reinforcing mechanism (Figure 4c), allows for the load to be distributed over a wider area with less depth compared to the unreinforced bed. The width and depth of load distribution range from $0.6h$-$0.8h$ and $1.2W$-$1.8W$, respectively. Additionally, Figure 7c highlights that 3D reinforcement further contributes to a wider area and reduced depth of pressure distribution, due to the geocell's reinforcing mechanism (Figure 6), when compared to the 2D reinforced bed. In the case of a geocell reinforced bed, the load distributes in a width range of $0.4h$-$0.6h$ and $1.5W$-$2.5W$ within the bed's depth. As shown in Figure 7, the vertical settlement in the foundation bed decreases progressively from "S," "$0.5S$-$0.6S$," and "$0.2S$-$0.3S$" for the unreinforced bed, geogrid reinforced bed, and geocell reinforced bed, respectively. This indicates the significant role of geosynthetic reinforcement in controlling

the settlement of the footing. Thus, incorporating 2D and 3D reinforcement enhances the stiffness of the reinforced bed, allowing for higher bearing pressure and reduced settlement with a smaller thickness of geosynthetic-reinforced bed. The inclusion of geocell and the confinement effect further increases the stiffness of the reinforced base.
Figure 7. Vertical pressure isobar and vertical settlement in depth for (a) unreinforced bed, (b) geogrid reinforced bed, (c) geocell reinforced bed.

6 GEOSYNTHETIC-REINFORCED BED IN VARIOUS ASPECTS

Utilizing one or multiple layers of geosynthetic reinforcement, such as geotextile, geogrid, and geocell, to reinforce foundation beds offers significant potential as a cost-effective alternative for supporting shallow footings, buried pipes, roads, pavements, and retaining walls. This section aims to present the application of geosynthetics in safeguarding footings, buried pipes, roads, and pavements.

6.1 Shallow footings supported on geosynthetic-reinforced bed

Geocell reinforcement is an advantageous soil reinforcement method that can provide stiffer and stronger foundations compared to planar reinforcement (i.e., geotextile and geogrid) methods. Due to the three-dimensional honeycomb nature of geocell, it can generate several mechanisms for improving the performance of shallow footings. A higher stiffness, bearing capacity and better pressure distributing characteristic could be achieved by incorporating single and multiple layers of geocell or planar reinforcement. In this section, the advantages of geocell reinforcement compared to geotextile reinforcement are described. Then the usage of geocell and geotextile reinforcements is extended to multiple layers of geocell reinforcement. The results presented in this section are fully obtained from scaled models or full-scale experiments and thus, could provide a solid understanding for designing and constructing geocell-reinforced foundations.

6.1.1 *Comparison of single geocell layer and multiple geotextile layers*

Comprehensive results from laboratory model tests on strip footings with a width of 75 mm supported on the geocell and geotextile reinforced sand beds with the same characteristics of geotextile are reported by Moghaddas Tafreshi & Dawson (2010). The soil used is relatively uniform silica sand with grain sizes between 0.85 and 2.18 mm, a specific gravity (G_s) of 2.68 and the maximum and minimum void ratio (e_{max} and e_{min}) of the sand were 0.82 and 0.54, respectively. The soil is classified as poorly graded sand with the letter symbol SP with particle size distribution curve, as shown in Figure 8a. The angle of internal friction of sand obtained through drained triaxial compression tests on dry sand sample at a relative density of 72% was 37.5 (all tests being run on dry sand at this relative density).

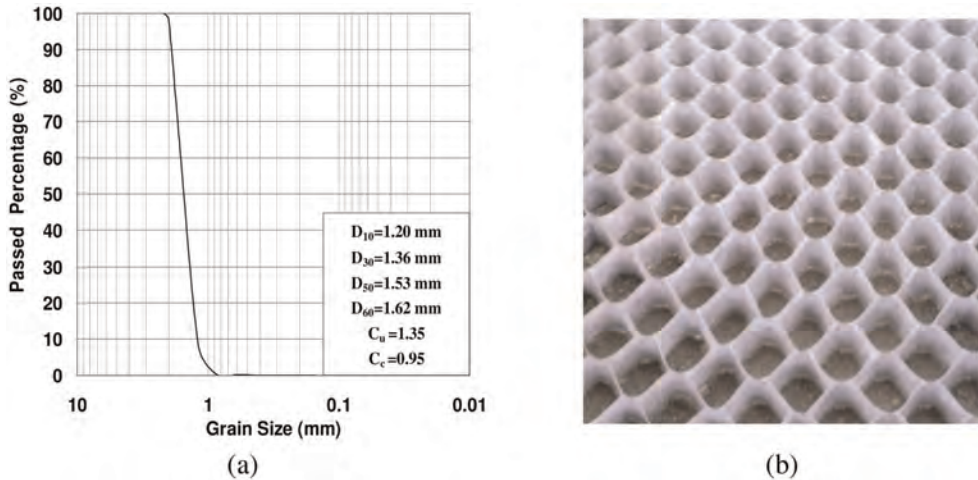
The geocell layer in Figure 8b was fabricated from the same non-woven geotextile material that forms the geotextile. This geocell comprises a polymeric, honeycomb-like structure with open top and bottom manufactured from strips of geotextile that are thermo-welded into a cellular system. The area weight, tensile strength, and thickness under a tensile stress of 200 kN/m^2 are 190 g/m^2, 13.1 kN/m and 0.47 mm, respectively. The pocket size (d) of the geocell used was kept constant (at d=50 mm). It was used at heights (H) of 25, 50 and 100 mm in the testing program.


Figure 8.   (a) Particle size distribution curve (b) Isometric view of the geocell (Moghaddas Tafreshi & Dawson 2010).

In order to provide a meaningful comparative assessment between the geotextile and geocell reinforcement, the quantity of material used must be matched. The quantity of material used in each test relative to that used in the least reinforced test is termed as '*a*', which is equivalent to the mass of a single sheet of geotextile reinforcement of the smallest width used in the tests. Assessment of performance was undertaken for arrangements with geotextile sheet and geocell reinforcement of the same mass of geotextile being paired together. For example, the experiment reinforced by 2 layers of short geotextile reinforcement has exactly the same mass of geotextile as that reinforced by the short geocell reinforcement at H/B=0.66 (see Figure 9 for definition of H and B). This pair both have 2 units '*a*' of reinforcement the same as the long pair of 1 layer for geotextile or H/B=0.33 for geocell reinforcement.

Important factors for obtaining the best performance are the embedment depth (u) of the top reinforcement layer, the vertical spacing of the geotextile layers and the width of

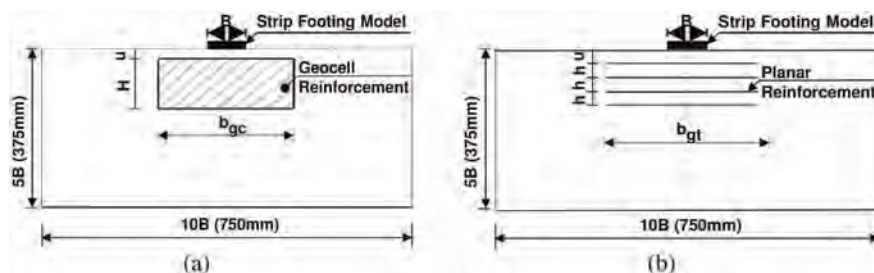
reinforced layer (b_{gc} for geocell and b_{gt} for geotextile layer- see Figure 9). The optimum depth of the topmost layer of geotextile reinforcement and geocell layers were obtained about 0.35 and 0.1 times the footing width ($u/B=0.35$ and 0.1), respectively and the vertical spacing of the geotextile layers was obtained 0.35 times the footing width ($h/B=0.35$) which not reported here as detailed. The tests performed with different reinforcement widths (short, medium and long reinforcement) indicate that increasing the reinforcement width more than 4.2 and 5.5 (i.e., long width) times the footing width for the geocell and geotextile reinforcement, respectively, would not provide much additional improvement in bearing pressure.


Figure 9.   Geometry of the (a) geocell reinforced foundation bed (b) geotextile reinforced foundation bed (Moghaddas Tafreshi & Dawson 2010).

The variation of bearing pressure with footing settlement (s/B) for the geocell-reinforced, geotextile-reinforced, and unreinforced beds is shown in Figure 10. From this figure, it may be clearly observed that with increasing the mass of reinforcement (increase in the height of the geocell layer, H/B or in the number of geotextile layers, N), both stiffness and bearing pressure (bearing pressure at a specified settlement) considerably increase but the efficiency of reinforcement decreases by increasing H/B or N. Provision of the geocell reinforcement in reinforcing the foundation bed is more than the geotextile reinforcement with the same characteristics and the same mass used. In the case of the unreinforced sand bed, it is apparent that the bearing capacity failure has taken place at a settlement equal to 12% of footing width while in the case of both the geocell and geotextile reinforced sand beds, no clear failure point is evident for the larger masses of reinforcement ($N \geq 2$ or $H/B \geq 0.66$).
Figure 10.   Variation of bearing pressure with settlement for the geocell and geotextile reinforcement with long width: $b_{gc}/B=4.2$ & $b_{gt}/B=5.5$(Moghaddas Tafreshi & Dawson 2010).

The performance improvement due to the provision of reinforcement is represented using non-dimensional improvement factor of *IF* which compares the bearing pressure of the geotextile or geocell reinforcement bed to that of the unreinforced bed at a given settlement, s_i.

$$IF_{gt} = \frac{q_{gt}}{q_{un.}} \; OR \; IF_{gc} = \frac{q_{gc}}{q_{un.}} \quad s_i/B = 2\%, 4\%, 6\%, 8\%, 10\% \text{ and } 12\% \tag{1}$$

Where q_{un}, q_{gt}, and q_{gc} are respectively the values of bearing pressure of the unreinforced bed, the geotextile reinforced bed and the geocell reinforced bed.

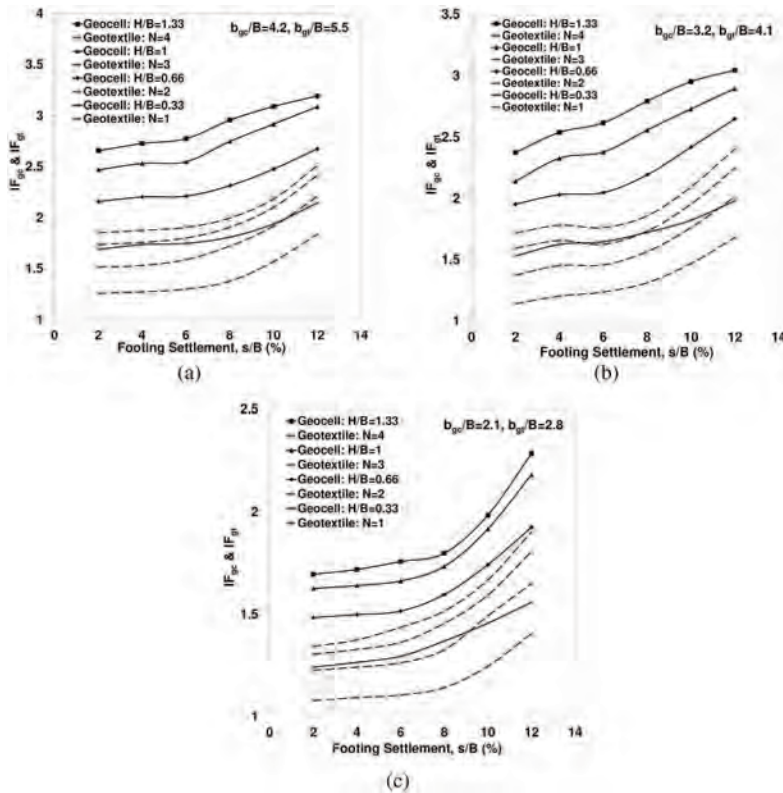
The variation of these two parameters, IF_{gt} and IF_{gc} with footing settlement for long, medium and short reinforcement width are shown in Figure 11. According to this figure, it is evident that for the same mass of geotextile material used in the tests at the settlement level of 4%, the maximum improvement in bearing capacity (*IF*) was obtained as 2.73 and 1.88 with the provision of geocell and the equivalent geotextile reinforcement, respectively (Figure 11a). Therefore, improvement of foundation performance is proved, and it can be concluded that geocell provides more benefits compared to geotextile forms of reinforcement. For amounts of settlement that are tolerated in practical applications, improvements in bearing capacity greater than 200% (*IF_gc>3*) can be achieved with the application of geocell reinforcement, whereas geotextile reinforcement arrangements can only deliver 150% (*IF_gt>2.5*) for these two quantities, respectively.


Figure 11. Variation of the bearing capacity improvement factor (*IF*) with footing settlement for the geocell and geotextile reinforcement, (a) Long width (b_g/B=4.2 & b_p/B=5.5), (b) Medium width (b_g/B=3.2 & b_p/B=4.1) and (c) Short width (b_g/B=2.1 & b_p/B=2.8), (Moghaddas Tafreshi & Dawson 2010).

6.1.2 *Comparison of multiple geocell and geotextile reinforcement layers*

The previous research (Moghaddas Tafreshi & Dawson 2010) showed that geocell reinforcement can be significantly more effective than a geotextile reinforcement at the same mass of material, in improving the behaviour of foundation beds. Geosynthetic inclusions will be most effective if used in the zone significantly stressed by the footing load, traffic load, etc. – which may be over a depth of 1 or 2 diameters beneath the loading surface width/diameter. Since the heights of commercially produced geocells for soil reinforcement are usually standard and most manufacturers of geocell produce them for reinforcement purpose only at heights less than 200 mm, the use of a thick geocell layer beneath the footing is impossible. Even if it were, such a thick geocell layer would likely make compaction of cell-fill extremely difficult, probably negating any reinforcement benefit (Tavakoli Mehrjardi et al. 2013). Hence, the use of several thin layers of geocell (say, three or four) with vertical spacing between successive layers of geocell is a practical alternative and might be a beneficial means of reinforcing the soil beneath a footings and roads.

Moghaddas Tafreshi et al. (2016) performed a series of laboratory model tests on a model circular footing with 112.8 mm diameter (D), supported on multi-layered of geocell-reinforced and multi-layered geotextile-reinforced sand beds. Figure 12 shows the layout tests and parameters used for evaluation of such multi-layered geotextile and geocell reinforced systems. In a previous study by Moghaddas Tafreshi & Dawson (2010) and regarding the model geometry in Figure 12, the optimum values of b_{gc}, b_{gt}, u_{gc} and u_{gt} in non-dimensional form with respect to footing diameter (D) were $b_{gc}/D = 3.2$, $b_{gt}/D = 4.1$, $u_{gc}/D=0.1$ and $u_{gt}/D=0.32$. The same values were used and kept constant in the tests described here. The pocket size (d) of the geocell used was kept constant ($d=50$ mm), while the geocell was used at a thickness (H_g) of 25 mm. The optimum vertical spacing of geocell and geotextile reinforcement layers are approximately 0.36 and 0.4 times footing diameter ($h_{gc}/D = 0.36$ and $h_{gt}/D = 0.4$), respectively which not reported here as detailed. The properties and classification of soil, geotextile and geocell reinforcement are as detailed in the previous section and The performance improvement due to the provision of reinforcement is represented using non-dimensional improvement factor IF_{gt} and IF_{gc} as given in Equation (1).
Figure 12. Layout of the multi-layered (a) geocell-reinforced system, (b) geotextile-reinforced system (Moghaddas Tafreshi et al. 2016).

Figure 13 presents the bearing pressure-settlement behaviour of geocell and geotextile reinforced foundations when the layers of geocell and geotextile were placed at their optimum spacings. For any matching pair of geocell and geotextile reinforcement ($N_{gc}=N_{gt}=1$,

etc.), the width of geocell and geotextile reinforcement are kept constant (as before, at b_{gc}/D= 3.2, b_{gt}/D= 4.1, respectively) and the masses of geosynthetic material are kept the same within each pairing. It may be observed that, with increasing the layers of reinforcement (increase in the mass of the geocell and geotextile reinforcement and consequently the increase in the depth of the reinforced zone, Z_R) both stiffness and bearing pressure (bearing pressure at a specified settlement) increase considerably. In the case of the unreinforced soil, it is apparent from Figure 13 that the peak bearing pressure has taken place at a footing settlement equal to approximately 13% of footing diameter while in case of both the geocell- and geotextile-reinforced soil, no clear failure point is evident. For the reinforced soil, beyond a footing settlement level of s/D=8-14%, there is a noticeable reduction in the slope of the pressure-settlement curve (the ratio $\Delta q / \Delta(s/D)$ reduces). Beyond this stage, the slope of the moderately and heavily reinforced cases remains almost constant while the footing bearing pressure continuously, but gradually, increases as further mobilization of its reinforcement and anchorage is exploited.
Figure 13.   Variation of bearing pressure with settlement for the geocell and geotextile reinforcement (h_g/D=0.36, h_p/D=0.4)- (Moghaddas Tafreshi et al. 2016).

Figure 14a shows the improvement in bearing pressure (IF_{gt} and IF_{gc}) with the number of reinforcement layers at three levels of settlement (s/D=4%, 8%, 12%) when the layers of geocell and geotextile were placed at optimum values of h_{gc}/D (= 0.36) and h_{gt}/D (= 0.4). In all situations, the values of IF_{gt} and IF_{gc} are higher at higher footing settlement for both reinforcement types (attributable to greater mobilization of tensile strain in the reinforcement layers and to the confinement provided between layers by the reinforcement).

For the multi-layered geocell, no significant improvement in performance is observed when the number of geocell layers are more than three ($N_{gc} \geq 3$). Therefore, when three layers of geocell are located at the optimum value of h_g/D (=0.36), the maximum zone of soil that can usefully be reinforced extends to a depth of approximately 1.48D (Z_R= 1.48D). In contrast, Figure 14a shows that the performance improvement due to the provision of geotextile reinforcement may continue beyond 4 layers (N_{gt}>4 with reinforcement zone of Z_R>1.52D). This comparison indicates that the effective reinforcement zone beneath the footing base is smaller for geocell reinforcement usage (for N_{gc}=3 with reinforcement zone of Z_R=1.48D) compared to that of the effective geotextile reinforcement zone (N_{gt}>4 with reinforcement zone of Z_R>1.52D). These findings serve to confirm that the reinforcing mechanism of the geocell facilitates a broader load distribution area and a shallower depth in comparison to the 2D reinforced bed.

Figure 14a also shows that improvement in bearing pressure (IF) for all the cases with the same number of geocell and geotextile reinforcement layers (and, thus, the same mass of geotextile material), is greater for geocell reinforcement than for geotextile reinforcement, irrespective of settlement ratio of the footing. For example, for $N_{gc} = N_{gt} = 3$ and a settlement of $s/D = 4\%$, the geocell installation improves performance 84% more than the comparable geotextile. Alternatively, by comparing, for example, the improvement due to two layers of geocell reinforcement (N_{gc}=2) with the improvement due to four layers of geotextile reinforcement (N_{gt}=4) at a settlement ratio of 4%, both are shown to have a similar bearing pressure (Figure 14a), yet the geocell installation contains half the mass of material. Also, the reinforcement zone depth beneath the footing (Z_R) for four layers of geotextile reinforcement (Z_R= 1.52D) are approximately 1.68 times bigger than two layers of geocell (Z_R= 0.9D).

For many practical purposes, performance of reinforced systems at low footing settlement ratios, s/D (say, less than 2%) is critical. For the tests described here, this is the subject of Figure 14b. Again, for the same number of layers (i.e. with the same mass and area) of geocell and geotextile used, the multi-layered geocell reinforcement system is both stiffer and more effective than the system with multi-layered geotextile reinforcement system and benefit of the geocell reinforcement is gained at very low settlement ratios ($S/D = 0.4\%$) whereas, in the case of geotextile reinforcement, the benefit only appears at footing settlement ratios of around 1-1.5%. At low settlements, apparently before the geotextile has attracted loading to itself, geotextile installations may actually lead to a softer response than when unreinforced. The cause of this is uncertain but is probably indicative of a lower geotextile-soil interface friction than soil-soil friction at a point in the loading sequence before the geotextile has been tensioned and is able to deliver benefit. Similar results were observed in the pressure-settlement of geotextile and geogrid reinforcement (Madhavi Latha & Somwanshi 2009b) and of geocell reinforcement (Dash et al. 2001, 2003). It is likely that the better performance at low settlement levels of the multi-layered geocell, compared with that of the multi-layered geotextile, is due to the geocell system gaining its resistance from the soil confinement that occurs when localized hoop stresses are developed in the walls of cells close (vertically and horizontally) to the footing. In a geotextile reinforcement system, reinforcing action requires outward shear stress to be developed in the horizontal plane between the geotextile and soil throughout a zone whose size is controlled by the load spreading achieved

Figure 14. Variation of IF_{gc} and IF_{gt} with (a) the number of reinforcement layers (N_{gc} & N_{gt}) at different levels of settlement (s/D=4%, 8% and 12%), (b) low footing settlement (s/D) for different number of reinforcement layers (N_{gc}= N_{gt} =1, 2, 3, and 4)- (Moghaddas Tafreshi et al. 2016).

in the soil between footing and the uppermost geotextile layer. Such shear strains are not thought to be necessary in the geocell system, as localized compression alone will be sufficient to generate the hoop strain.

Overall, the results show that the geocell system provides a better performance than does the geotextile system, so that the same or greater improvement in vertical stiffness and much shallower required zone of reinforcement can always be gained by significantly less geotextile material employed in an arrangement of geocell layers than in geotextile sheets. Whether this is also associated with an economic benefit will depend on the fabrication costs of the geocell material, the reinforcement zone depth beneath the footing (i.e., excavation and backfilling) and on any difference in soil backfill material and procedure.

6.2 *Buried pipes protection by geosynthetics*

In many cases, buried pipes, whether located in shallow or deep trench backfill, are constructed using flexible materials like uPVC (unplasticized polyvinyl chloride) and HDPE (high density polyethylene). It is crucial to ensure a prolonged service life and protect these pipes from stress caused by static and repetitive loading, such as traffic loads at the ground surface. Therefore, careful consideration must be given to the arrangement of backfill materials. To guarantee the safety of buried pipes under various loading conditions, it is essential to thoroughly understand their behavior, as well as that of the surrounding construction materials. By employing geosynthetics, it is possible to mitigate pipe deformation and minimize transferred pressure onto the buried pipe, while keeping trench settlement within acceptable limits.

6.2.1 *Buried pipes response in geogrid-reinforced trench*

The testing tank was a rigid steel box 1000 mm in length, 1000 mm in height, and 220 mm in width, encompassing the model pipe inside a geogrid-reinforced trench filled with a soil of predetermined uniform density as shown in Figure 15a (Moghaddas Tafreshi & Khalaj 2008). The test trench was constructed 550 mm wide and 220 mm long. The trench width was selected to meet the recommendations of BSI (1980) and ASTM D2321-08. The BSI (1980) and ASTM D2321-08 recommend the minimum trench width as $D+300$ mm and $1.25D +300$ mm (where D is the pipe diameter in mm), respectively.

Figure 15.   (a) Schematic layout of the model trench including pipe, geogrid layers, and geometric parameters (unit in mm), (b) General view of the testing apparatus (Moghaddas Tafreshi & Khalaj 2008).

To allow the visual observations of the sand-pipe system, as well as the photo scanning, the front face of the tank has been made of a plexiglass, which can be removed during the preparation stage. A circular hole of 50 mm diameter has been provided in the center of the back face of the tank to accommodate the displacement transducers to detect the radial deflections of the model pipe. Figure 15a shows the schematic layout of the model trench including pipe, geogrid layers, and geometric parameters trench and Figure 15b shows the general view of the testing apparatus.

Two zones of soil are prepared in the test tank. To simulate the natural ground (at bedding and two sides of the trench) in zone A, a granular soil with grain sizes between 0.08 and 20 mm was prepared by the compaction method. This soil is classified as SP in the unified soil classification system. A uniform silica sand in zone B is prepared as the main trench by the raining technique. The properties and classification of soil in zone B is as detailed in section 6.6.1 (Figure 8a). In order to study the effect of the soil density on the behaviour of the buried pipe, three different relative densities of soil trench: 42%, 57%, and 72% were selected.

Based on the dimensions of the model test, the plastic pipes with 110 mm external diameter, 4.03 mm thickness and 210 mm length, made of polyethylene (HDPE: High density polyethylene) was employed. The HDPE geogrid was used to reinforce the soil mass over the pipe. This geogrid has an aperture size of 27×27 mm, thickness of 5.2 mm, area weight of 695 g/m^2 and ultimate tensile strength of 5.8 kN/m. To investigate the effect of embedment depth of pipe and geogrid reinforcement, four burial depths of $1.5D$, $2D$, $2.5D$ and $3D$ and one to five geogrid layers were examined. All the tests were carried out under repeated loads with an amplitude of 550 kN/m^2 and frequency of 0.33 Hz which imposed through a rectangular plate of 100×220 mm located at the center of the trench surface.

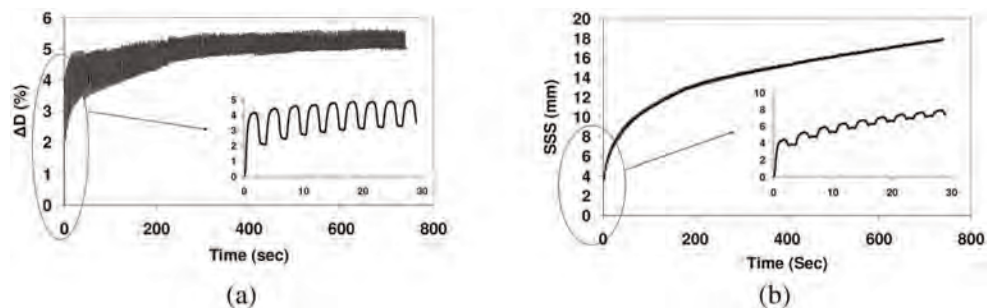
Figure 16 shows the typical trends of pipe deformation in term of change in ΔD (percent vertical diameter change) of the pipe and SSS (Settlement of Soil Surface) with the time under repeated loading. This figure shows that, the rate of change of peak ΔD (or SSS) and residual ΔD (or SSS) reduce as the number of cycles increase, and a small reduction in amplitude [i.e., peak ΔD (or SSS) minus residual] is also apparent. It shows that, the variation of ΔD is stabled after short time (almost 400 sec) whereas the variation of SSS tend to be continued. This constant value of ΔD reaches after few passes of the load. This indicates that the early process of reorientation of particles in the side fill of the pipe, causing local side fill stiffening, ceases relative rapidly and the system reaches an elastic stability. The reason of continuing the value of SSS relates to confining effect of the soil surface.


Figure 16. Typical trend of ΔD and SSS during repeated load: (a) ΔD and (b) SSS (Moghaddas Tafreshi & Khalaj 2008).

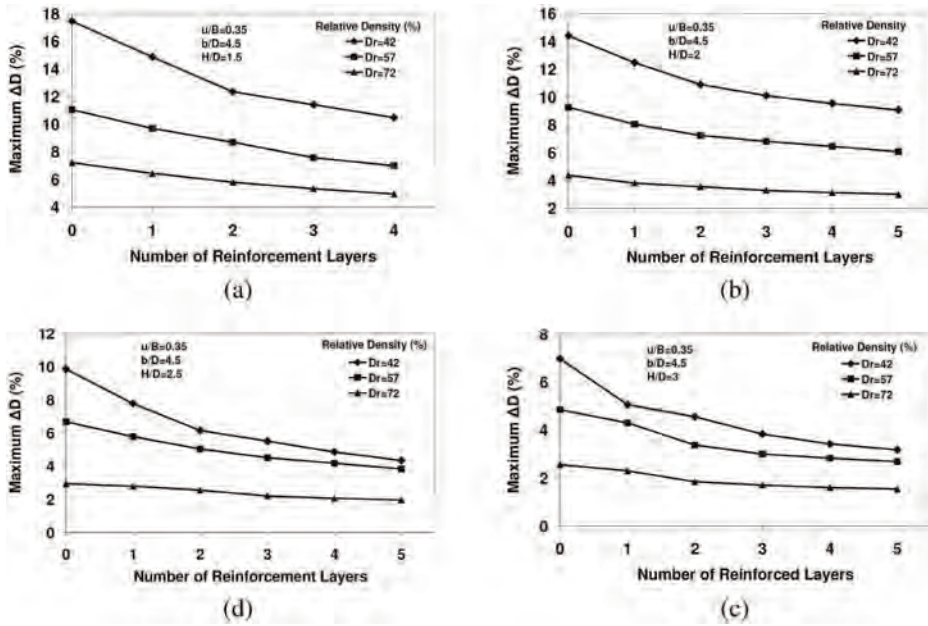
The influence of the soil reinforcement on the maximum ΔD and SSS at different relative density and embedment depth are shown in Figure 17 and Figure 18, respectively. As expected, the value of ΔD and SSS decrease with increase in the reinforcement layers, embedment depth of pipe and soil relative density.


Figure 17. Variations of the maximum ΔD with number of reinforced layers for (a) H/D=1.5, (b) H/D=2, (c) H/D=2.5 and (d) H/D=3 (Moghaddas Tafreshi & Khalaj 2008).
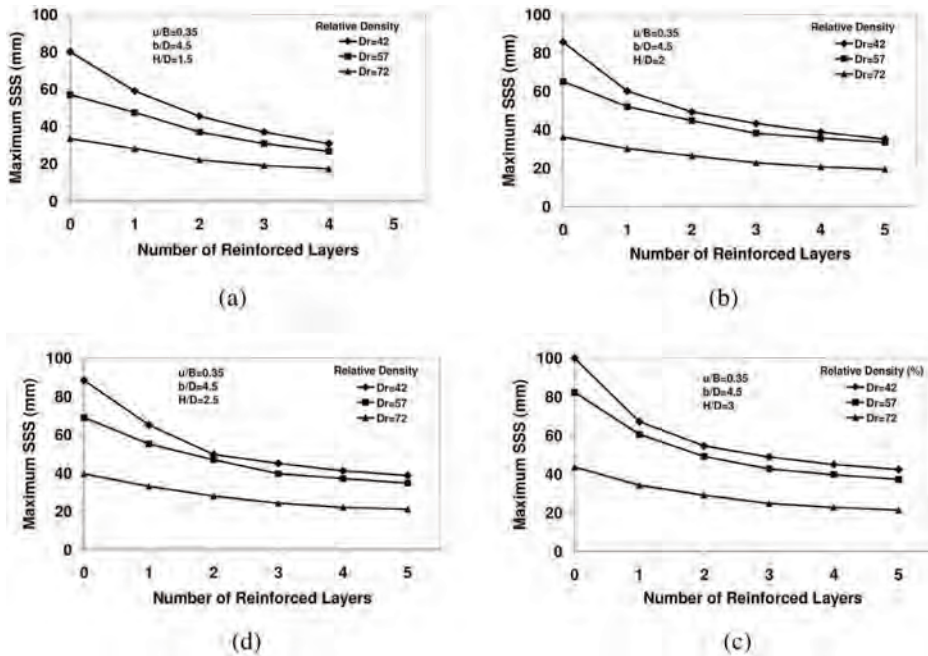

Figure 18. Variations of the maximum SSS with number of reinforced layers for (a) H/D=1.5, (b) H/D=2, (c) H/D=2.5 and (d) H/D=3 (Moghaddas Tafreshi & Khalaj 2008).

It can be observed that the decrease in ΔD and *SSS* due to additional layers of reinforcement begin to converge at around the fourth layer and almost constant at the fifth layer of reinforcement. The reason is that the reinforcement considerably increases the stiffness of reinforced trench compared with unreinforced trench. This matter is similar to enhancement of the soil density which increases the stiffness of the backfill or embedded depth of pipe which causes more soil available for load sharing in unreinforced sand. Consider, for example in $2.5D$ of embedment depth and relative density of 42%, ΔD reduces 21% at one layer of reinforcement, whereas there is 56% reduction at five layers of reinforcement. Similar pattern is observed for variation of *SSS* with the number of reinforced layers.

Figure 19 shows the trench deformation at three different conditions corresponding to unreinforced and reinforced sand with two and five layers of geogrid at the end of tests. The movements of soil layers and settlement of soil surface are clearly shown in this figure by using the colored lines in the front face of the trench. This figure implies that with increase in the reinforcement layers, the soil surface settlement is reduced significantly.
Figure 19.   Photograph of trench deformation at the end of tests under embedment depth of 2D and relative density of 42% (a) unreinforced sand, (b) reinforced trench with 2 layers, (c) reinforced trench with 5 layers (Moghaddas Tafreshi & Khalaj 2008).

6.2.2   *Buried pipes response in geocell-reinforced trench*

Figure 20 schematically shows the full-scale model test of buried pipe in geocell-reinforced trench. The model of the test containing the pipe and geocell layer was prepared in a test pit with plan dimensions of 2200×2200 mm and depth of 1000 mm (Moghaddas Tafreshi et al. 2020). The test trench was constructed 750 mm wide and 750 mm deep, as shown in Figure 20, and 1750 mm long. The trench width was selected to meet the recommendations of BSI (1980) and ASTM D2321-08 (see section 6.2.1). The maximum buried depth of the pipe was selected as two times the pipe's diameter ($2D=500$ mm), as proposed by Moghaddas Tafreshi & Tavakoli Mehrjardi (2018), being an optimized value of burial depth for a pipe embedded in geogrid-reinforced soil.

To simulate the loads imposed by traffic, loading, unloading and reloading were imposed through a circular plate located at the centre of the trench surface. In all tests, 150 cycles of repeated loading with amplitude of 800 kPa and frequency of 0.33 Hz were applied to the loading plate. The diameter of the loading plate (250 mm) and the maximum applied pressure of 800 kPa were chosen to replicate that of a heavy vehicle half-axle (40 kN) as used on a common heavy trailer (mean tyre pressure 792 kPa) as recommended by Brito et al. (2009).

In order to simulate likely usage conditions, a granular soil was used around the two sides of the pipe and to cover the crown and to fill the geocell pockets (in geocell-reinforced installations), as shown in Figure 20. The soil has a maximum grain size and mean grain size of 20 mm and 4.3 mm, respectively and a specific gravity of 2.66 ($G_s=2.66$). According to the Unified Soil Classification System, this soil is classified as well-graded sand with letter symbol "SW" which satisfies the grain size limits for pipe backfill materials according to ASTM D 2321-08. The maximum dry unit weight and the optimum moisture content of this
Figure 20. Schematic view of model test, including pipe, geocell layer, instrumentation and geometric parameters (unit in mm) (Moghaddas Tafreshi et al. 2020).

soil were about 20.42 kN/m3 and 5.1%, respectively. The angle of internal friction (φ) of the soil, obtained by consolidated undrained triaxial compression tests of specimens at a wet unit weight of 19.72 kN/m3 and a moisture content of 5% (corresponding to 92% of maximum dry unit weight, similar to the compacted unit weight of soil layers in backfill was 40.5°. In all the tests, the unreinforced soil layers around both sides of the pipe and over the pipe were prepared, respectively at wet unit weight of 17 and 19.72 kN/m^3. The wet unit weight of soil in geocell layer with pocket size of 55×55 mm^2 and 110×110 mm^2 were about 19.20 and 18.53 kN/m^3, respectively.

The geocell layer with the described properties in section 6.1.1, was used in two pocket sizes of 55×55 mm^2 and 110×110 mm^2 and one height of 100 mm. When spread out, it occupied an area of 1250×1250 mm^2 in plane (5 times the loading plate in each direction), centered on the axis of loading. A high-density polyethylene pipe (HDPE 100), designed to withstand a pressure of 4 bar, having an outer diameter (D) of 250 mm, a wall thickness (t) of 4 mm and, thus, a Standard Dimension Ratio (SDR) = D/t =40 was selected. Based on the manufacturer, this pipe has an elastic modulus of 1000 MPa, a Poisson's ratio of 0.3 and a weight per unit length of 4.83 kg/m. A pipe length of 1740 mm, approximately equal to the length of the trench in the full-scale model test was chosen.

The data measurement system was developed to read and record the applied repeated load, loading plate settlement, pipe deformation and soil pressure automatically. An S-shaped load cell, with a full-scale capacity of 100 kN, was used to precisely measure the applied repeated load. To measure the settlement of the loading plate and the pipe defor-mation during loading, unloading and reloading, respectively one LVDTs and six LVDTs (linear variable differential transducers) were installed on the loading plate and inside the pipe. Figure 21 provides a schematic of the LVDTs inside the pipe in the middle and along the pipe's axis at distances of 150, 300, 450 and 600 mm from the mid-point of the pipe's length, a photograph of pipe installation and defining the vertical pipe deflection meanings. The soil pressure on the crown of the pipe (as shown in Figure 20) was monitored and measured by one soil pressure cell with a diameter of 50 mm.

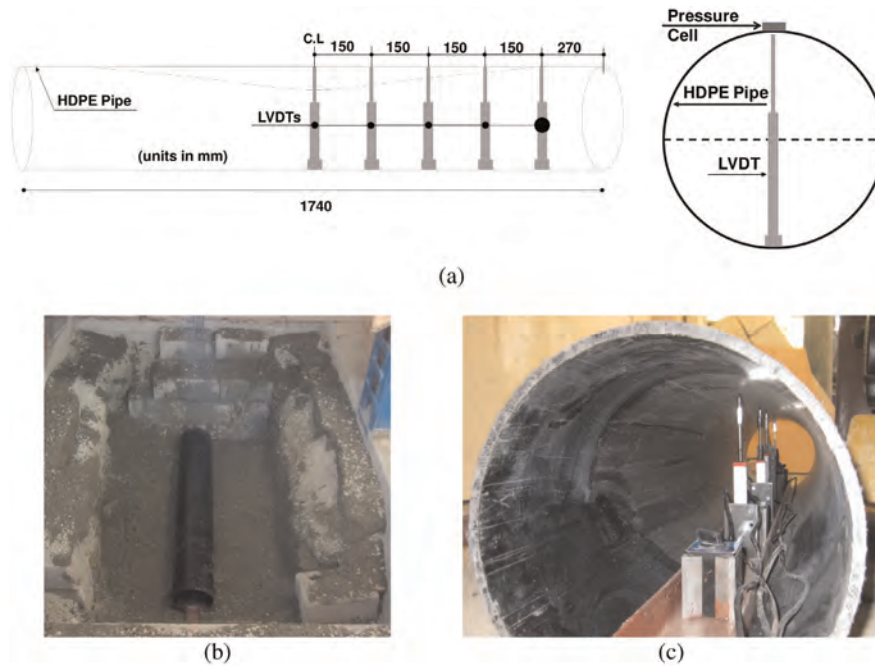
Figure 22a-b shows the typical trends of the vertical diametral strain of the pipe (ΔD: reduction in vertical diameter divided by the pipe diameter) and the soil surface settlement (SSS) with the number of load cycles during the repeated loading. As seen in this figure, the rate of increase in ΔD (or SSS) decreases as the number of load cycles increase. It illustrates


Figure 21.   (a & b) Schematic installation of LVDTs inside the pipe, (c & d) Photograph view of pipe and steel U channel solid base, magnet base/rod and LVDTs inside the pipe (Moghaddas Tafreshi et al. 2020).

that, in this condition of test and due to 150 load cycles, the variation of ΔD and SSS becomes approximately stable, and it can be anticipated to reach a fully stabilized condition with only a few additional cycles of load. This may be attributed to the early process of reorientation of particles in the side fill of the pipe and beneath the loading, causing local side fill stiffening, but which ceases relative rapidly allowing the system to reach elastic stability (Faragher et al. 2000) (i.e., a shakedown condition).

The pressure-SSS or pressure-ΔD plots derived from these tests are shown in Figure 22c-d. Although initial plastic strain occurs, it is clear that for repeated loads on the soil surface, a steady response condition was approximately achieved when the load path formed a closed hysteresis loop, indicating only a small amount of energy lost in the system. The other fact seen in Figure 22, associated with the general behavior of the buried pipes subjected to repeated loads, is the large proportion of the pipe deformation/soil surface settlement at the end of the first pulse compared with its total pipe deformation/soil surface settlement due to many, later, load cycles. Again, this helps to support the conjecture that the first pulse is largely causing compactive action on, i.e., large plastic strain in, the surrounding soils. In this case, 30 or 27% of the total ΔD or SSS, respectively, occurs during the first cycle. A similar behaviour is obtained for variation of pressure on the pipe crown as measured by soil pressure cell.

Figure 23 compares the response of the buried pipe in the unreinforced and geocell-reinforced systems through 150 cycles of repeated loading. Both soil surface settlement, SSS (rut depth on soil surface) and vertical pipe diameter, ΔD change are smaller when the geocell is in place, evidence of beneficial stiffening and load-spreading abilities of the geocell installation under repeated loading. As seen in Figure 23a, the soil surface settlement of the reinforced installation, at the last load cycle decreased by 25% to 45%, respectively, for small and large pocket geocell installations (compared to the unreinforced installation). From
Figure 22.   Typical trend of (a) *SSS* with load cycles, (b) Δ*D* with load cycles, (c) hysteresis curve of *SSS*, (d) hysteresis curve of Δ*D* (Moghaddas Tafreshi et al. 2020).

Figure 23b, the values of Δ*D* of the pipe at the end of load cycling for unreinforced and geocell-reinforced tests with small and large geocell pocket sizes were obtained as 8.74%, 7.12% and 6.35%, respectively. These values indicate an improvement in Δ*D* by about 27.4% due to the large pocket geocell reinforcement. Thus, the competent performance of the geocell reinforced system in reducing the pipe deformation is evidenced as well as that in decreasing the soil surface settlement.

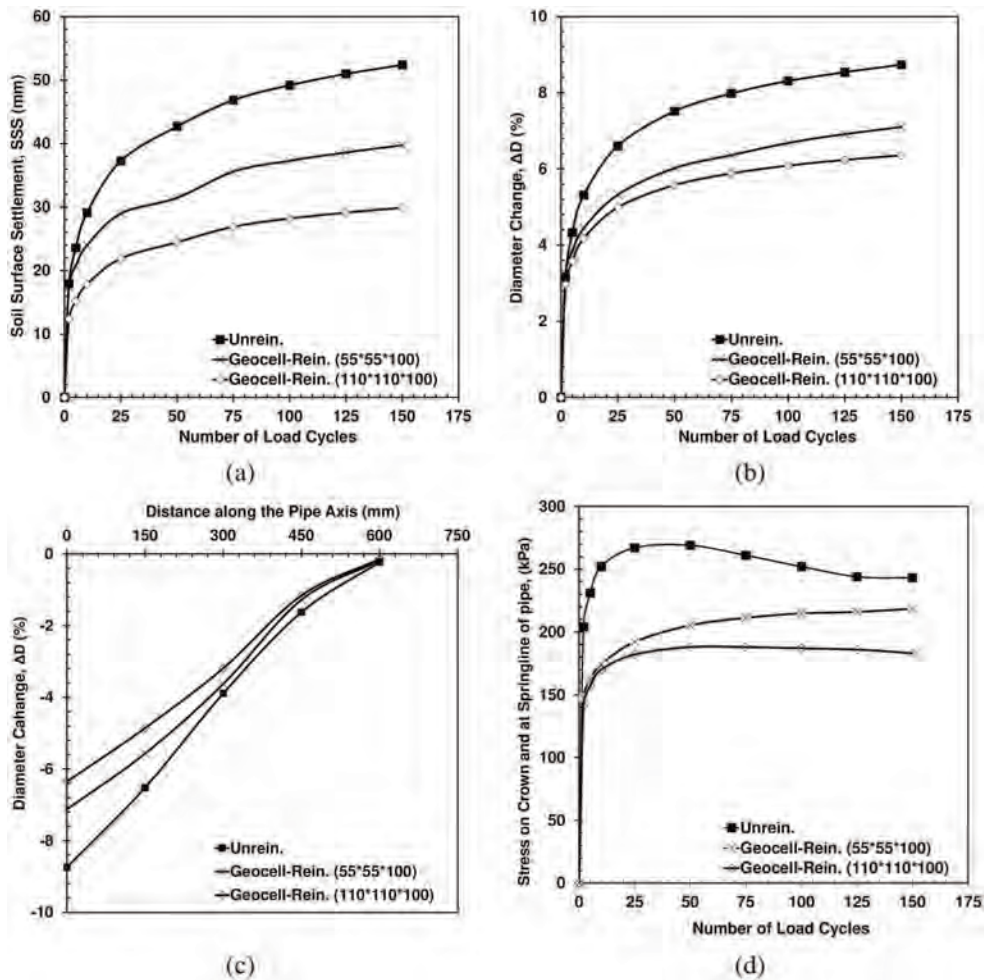
   To gain a better assessment of the pipe deformation, the variation of the pipe's vertical deflection at its crown, along the pipe's longitudinal axis (at distances of zero, 150, 300, 450 and 600 mm from the middle of pipe's length) at the end of load cycling is presented in Figure 23c. The zero-value on the horizontal axis of this figure indicates the point on the crown beneath the center of the loading surface and the axis indicates the distance along the pipe's axis from zero point. As expected, the deflection of the pipe's crown decreases away from the centre of loading for both unreinforced and reinforced systems. From Figure 23c, for the buried pipe in unreinforced backfill, the vertical deflection of pipe (Δ*D*) at the distances of zero, 150, 300 and 450 mm from the middle of pipe length were about 8.74%, 6.52%, 3.89%, 1.63% and 0.23%. The corresponding values for geocell-reinforced system with small pocket size are about 7.12%, 5.56%, 3.62%, 1.28% and 0.19% and for geocell-reinforced system with large pocket size are about 6.35%, 4.86%, 3.18%, 1.16% and 0.15%. It indicates that using the geocell layer beneath the soil surface, rendered the buried pipe system


Figure 23. Comparison between geocell-reinforced and unreinforced installations for (a) *SSS*, (b) Δ*D* (c) pipe deformation in longitudinal axis, and (d) Soil pressure on crown of pipe (Moghaddas Tafreshi et al. 2020).

considerably protected. As can be seen in Figure 23c, there was a non-linear variation of pipe crown deformation along the pipe's longitudinal axis, and it converges to an insignificant value over 600 mm from the centre of the loaded area.

Figure 23d demonstrates the variation of the measured pressure on the crown with load cycles, for both unreinforced and geocell-reinforced systems. The readings show that, in the last cycle of loading, the transferred stress on the crown of the pipe was about 75% and 86% of the values in the unreinforced installation, respectively, for large and small pocket size geocell. However, Figure 23d indicates that the observed reduction in pipe deflection in Figure 23b could be attributed to a lower transferred pressure on the pipe crown. It is assumed that this reflects improved load spreading achieved by the geocell which is spreading load away from the crown (with a matching reduction in deflection there) and spreading it somewhat to the pipe margins. There, it is assumed, passive, horizontal earth pressure is now developed by smaller pipe deflections than before, due to the better com-pacted soil that has resulted from the increase in vertical load that has been spread to it. The

improvement in the behaviour of pipes due to provision of reinforcement is in the line with the finding of Moghaddas Tafreshi & Khalaj (2008), Tavakoli Mehrjardi et al. (2012), Hegde & Sitharam (2015) and Elshesheny et al. (2019).

Figure 23 shows that the $110 \times 110 \times 100$ mm geocell installation delivers greater benefit, for all tests, than does the $55 \times 55 \times 50$ mm geocell arrangement. It proved impossible to achieve as great a density of pocket infill in the small pockets as in the large - despite preparing and compacting the infill soil in the same manner. Probably, the greater number of vertical pocket sides found in the smaller geocell than in its larger 'brother' offered a greater hindrance to compaction. A further factor may be the greater number of (inevitable) break-ups between otherwise interlocked soil particles. These reductions in density and in stone-stone interaction are unavoidable, as noted by previous authors (Tavakoli Mehrjardi et al. 2013).

6.3 *Geosynthetic-reinforced flexible pavement*

Geosynthetics are commonly employed in pavement applications to fulfill various functions such as filtration, separation, sealing, drainage, and reinforcement. In this section, the focus lies on the role of soil reinforcement in increasing pavement bearing pressure and reducing settlement, which is important. Geotextile, geogrid, and geocell are commonly used as reinforcement elements in transportation geotechnical applications (Bueno et al. 1987). The enhanced performance of pavements attributed to geosynthetic reinforcement can be attributed to the factors discussed in sections 2–5. The results presented in this section are derived from full-scale experiments aimed at demonstrating the effectiveness of multi-layered geocell reinforcement in reducing road deformations caused by traffic loads.

6.3.1 *Cyclic response of multi-layered geocell-reinforced flexible pavement*

In order to showcase the capabilities of geosynthetics in enhancing the strength and minimizing deformation in pavement foundations, this section will delve into the results of a comprehensive full-scale model test (Moghaddas Tafreshi et al. 2013). The test specifically focuses on the utilization of multiple layers of geocells within the foundation bed under cyclic loads. The findings from this study hold significant potential for application in pavement foundation systems.

The backfill soil was a sandy soil passing through the 38 mm sieve (Figure 24a) with a specific gravity, G_s, of 2.65. According to the Unified Soil Classification System, the soil is classified as well graded sand with the letter symbol *SW*. The maximum dry density was about 20.62 kN/m^3, which corresponds to an optimum moisture content of 5.7%. The angle of internal friction (φ) of sand obtained through triaxial compression tests at a wet density of 19.58 kN/m^3 (corresponding to 90% of maximum dry density) was 40.5°.

The natural ground soil, at the bottom and four side walls of the test pit, has a maximum particle size of about 20 mm (Figure 24a) and a specific gravity, G_s, of 2.62. This soil is classified as SP in the Unified Soil Classification System. The wet density and the natural moisture content of this soil were measured as 17.9 kN/m^3 (it corresponds to 90% of maximum dry density of 20.25 kN/m^3) and 9%, respectively. The angle of internal friction (φ) of the natural soil at a wet density of 17.9 kN/m^3 was 32.5°. The dimensions of the excavated test pit relative to the loading plate diameter are sufficient to minimize boundary effects. The natural ground soils were selected so as not be excessively soft and weak. In this way the assessment of reinforcing benefit from the installations investigated might be conservative. However, the use of a softer subgrade might show the benefits of rubber-soil with geocells to be even better.

The geocell layers with the described properties in section 6.1.1, were used in pocket size of 110×110 mm^2 and height of 100 mm and spread out in plane to 5 times the loading plate in

each direction), centred on the axis of loading plate. Figure 24 shows particle size distribution curves for backfill and natural soils and a view of geocell layer spread over soil in the test pit.

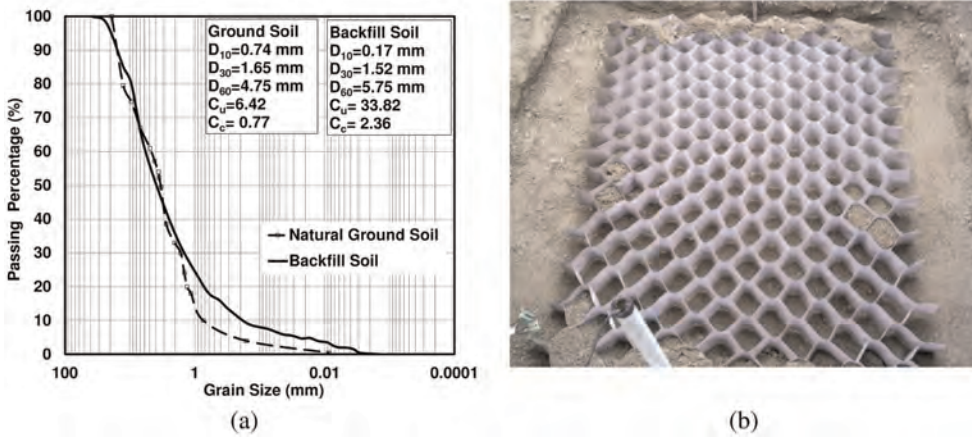
(a)   (b)


Figure 24. (a) Particle size distribution curves for backfill and natural soils (b) A view of geocell layer spread over soil in the test pit (Moghaddas Tafreshi et al. 2013).

Figure 25a shows the schematic cross-section of the full-scale model test set-up of the foundation bed, its geometry and data measurement system (dial gauges and soil pressure cells). All plate load tests on the steel rigid circular plate of 300 mm in diameter were conducted in an outdoor test pit, measuring 2000 mm × 2000 mm in plan, and 700 mm in depth. A photograph of the test installation prior to testing, showing the reaction beam, load plate, hydraulic jack and three dial gauges is presented as Figure 25b. In all the tests, the unreinforced layers and geocell reinforced layers were compacted with a walk-behind vibrating plate compactor at an optimum moisture content of 5.7% with two and three passes, respectively to achieve the dry density of about 18.56 and 18.2 kN/m^3.

(a)   (b)
Figure 25. (a) Schematic cross-section of the test set-up (not to scale), "T.SPC", "M.SPC", and "B. SPC" indicate the location of soil pressure cells, (b) Photograph of test installation prior to loading include reaction beam, load plate, hydraulic jack and three dial gauges (Moghaddas Tafreshi et al. 2013).

In order to simulate the effect of wheel loading, unloading and reloading, the maximum applied pressure of 792 kPa (i.e., a heavy vehicle half-axle with "Super-Single" tire, as used on a common heavy 6 axles trailer) (Brito et al. 2009), was divided into two stages being 400 and 800 kPa to simulate half and full traffic loadings. For each stage, fifteen loading and unloading cycles were applied through the plate at a rate of 1.5 kPa per second.

The optimum depth of the first layer of geocell layer beneath the loading plate (u), and the vertical spacing of the geocell layers (h), are obtained approximately 0.2 times the loading plate diameter ($u/D=h/D=0.2$) which not detailed here. To investigate the effect of the number of geocell layers on the deformation response of pavement, the unreinforced test and geocell-reinforced tests conducted by varying the number of geocell layers (N_g=1, 2, 3, 4), when the layers of geocell were placed at the optimum values of u/D and h/D.

The variation of the loading plate deformation (including the accumulated residual (plastic) deformation and resilient (elastic rebound) displacement) with the number of load cycles for the unreinforced system and the multi-layered geocell reinforced system with one, two, three, and four layers of geocell (N_g=1, 2, 3, 4), when the layers of geocell were placed at the optimum values of u/D and h/D ($u/D=h/D=0.2$), is shown in Figure 26a. Also, the residual plastic deformation of the unreinforced and reinforced bases with the number of loading cycles is shown in Figure 26b. This figure shows that for the unreinforced and reinforced bases, an initial, rapid total deformation (Figure 26a) and rapid residual deformation (Figure 26b) during the first load applications is followed by secondary deformation that develops at a slower rate. Both the total and plastic deformations caused by the first cycle of applied load form a large portion of the final deformation after all cycles. Overall, in most of the tests performed on the unreinforced and the geocell reinforced foundation, the initial, rapid deformation that took place due to the first cycle of loading gave rise to between 25% and 70% of the accumulated plastic deformation. This ratio is greater for the unreinforced foundation than for the reinforced foundation. The actual proportion appears to depend on the mass of reinforcement and on the magnitude of the applied cyclic load.

Figure 26 shows that the total and residual deformations of the unreinforced pavement foundation material tend to increase with the number of load cycles. There is a non-stabilizing response, eventually leading to plastic failure, particularly at higher levels of
Figure 26. Variation of (a) loading plate deformation, and (b) residual deformation with number of applied load cycles for the unreinforced and geocell reinforced systems with one, two, three, and four layers of geocell. The fifteen first cycles and the fifteen second cycles were applied with amplitudes of 400 and 800 kPa, respectively (Moghaddas Tafreshi et al. 2013).

cyclic loads (i.e., 800 kPa). It should be noted that a large deformation in these tests is not the primary means of judging unsuitability of the arrangements under test but, rather, a non-stabilizing response. Large deformations could largely be dealt with in practice by compaction, whereas instability responses are destructive.

For the reinforced bases, regardless of the number of geocell layers, the rate of change of both total and the residual deformation of the loaded surface reduces as the number of load cycles increases, so that their response has become, approximately, stable after fifteen load cycles (of both 400 and 800 kPa applied load), particularly for the reinforced bases with three and four layers of geocell. The performance of geocell reinforcement in decreasing the deformations may be attributed to the superior confinement offered by the geocell layers in all directions. Thus, the multi-cell geometry allows the soil in the cells to develop a passive resistance that increases the soil's bearing capacity and decreases the deformations within the pavement foundation. This behavior is a consequence of the shakedown process as the granular structure of the sand becomes arranged into a progressively more stable arrangement better able to behave resiliently without undergoing plastic deformation. It implies that the reinforced system as compared with unreinforced system (Figure 26) is storing energy (and releasing it in resilient recovery) rather than the energy being used to cause further damage. This stabilizing response suggests that the early process of reorientation of particles inside the geocell layers, causing local fill stiffening, ceases relative rapidly and the system then reaches a "plastic shakedown" condition, in which subsequent deformation is fully recovered in each cycle. In such a case no yield condition is reached at conventional stress levels. The final deformation value can be referred to either as the "maximum deformation" or the "shakedown deformation (settlement)" (Werkmeister et al. 2005). The behavioral patterns observed in these tests (Figure 26) is in-line with those observed in the repeated load testing of unreinforced granular materials as observed by several authors (Werkmeister et al. 2005) and as predicted from mechanical interaction considerations (García-Rojo and Herrmann 2005). Thakur et al. (2012) reported similar results of the total and residual deformations with number of loading cycles and with height of single geocell-reinforced bed.

The variation of maximum measured pressure with the number of load cycles, inside the foundation at the three levels of 190 mm (T.SPC), 350 mm (M.SPC), and 510 mm (B.SPC) beneath the center of loading plate (Figure 25a) for the unreinforced system and the multi-layered geocell reinforced system is illustrated in Figure 27. The readings of the three soil pressure cells for unreinforced and reinforced bases show an immediate large increase in the vertical stress when the first cycle of loading is applied and then a further, smaller increase over the next 6-8 cycles of loading, thereafter stabilizing to a constant value. This pattern is observed irrespective of applied pressure or of cell depth.

The figure also demonstrates the performance of geocell layers, as anticipated, in reducing the pressure transferred through the pavement foundation. For instance, as can be seen in Figure 27c, with increase in the number of geocell layers from one layer to three, the vertical stress transferred to a depth of 510 mm beneath the center of loading surface, as measured by the bottom soil pressure cell ("B.SPC"), almost halves. For example, under the applied cyclic pressure of 800 kPa, at the end of the load cycles (cycle number 30), the stress measured at 510 mm depth ("B.SPC") is about 284.5, 223.5, 159.7, 125.2 kPa for unreinforced and the reinforced pavement foundations with one, two and three layers of geocell, respectively. This comparison illustrates the excellent performance of the geocell reinforcement, so that the pressure at a depth of 510 mm decreases to about 35.6%, 27.9%, 20%, and 15.7% of the applied surface pressure (=800 kPa) for the same sequence of constructions. Thus, as reinforcing geocell layers are added, the effective load spreading continues to improve, consequently delivering a better performance, as compared with unreinforced base. It confirms the pressure distribution in depth (beneath the footing) as shown in Figure 7, which describes for the 3D (geocell) reinforced bed, the wider area and less depth of pressure distribution are contributed by the geocell due to its reinforcing mechanism as compared to the unreinforced bed. On the whole, the data presented in Figures 26 and 27 show that multiple geocell layers, particularly the use
Figure 27. Variation of transferred pressure with number of applied load cycles at different depths in the geocell-reinforced and unreinforced pavement foundations (a) at a depth of 190 mm (T.SPC), (b) at a depth of 350 mm (M.SPC), and (c) at a depth of 510 mm (B.SPC). The fifteen first cycles and the fifteen second cycles were applied with amplitudes of 400 and 800 kPa, respectively (Moghaddas Tafreshi et al. 2013).

of three and four layers of geocell, are able to limit the soil surface deformation and the soil pressure through the depth of the reinforced pavement foundation. Consequently, an increase in road life may be anticipated under the same heavy traffic loading.

Considering both the deformation and stress effect, it appears that, cell-pocket structure of the geocell layer prevents the encased soil from easily moving away from the point of load application. This is probably achieved by hoop confinement provided by the pocket walls. Thereby the infill cannot easily spread laterally, hence the shear strength of the composite system is increased.

This mechanism would allow the geocell layer to act like a soft plate with high flexural stiffness, spreading the applied load over an extended area, and decreasing the stress at depth in the pavement foundation (Moghaddas Tafreshi & Dawson 2012; Thakur et al. 2012).

7 CONCLUSIONS

This paper presents an overview of the soil-reinforcement interaction and the reinforcing mechanism of 2D and 3D reinforcements in enhancing the performance of foundation beds.

It also provides a summary of research findings from experimental studies on the application of 2D and 3D geosynthetics for protecting footings, buried pipes, roads, and pavements. These findings serve as a valuable reference for future studies in this field. Based on the analysis and discussion of the presented research, the following conclusions can be drawn:

- The optimal depth of the topmost layer of 2D reinforcement is approximately 0.33-0.4 times the width or diameter of the footing. In contrast, the depth to the top of the 3D reinforcement should be around 0.1-0.2 times the width or diameter of the footing.
- The optimal width of 3D reinforcement is approximately 4 times the width or diameter of the footing, while for 2D reinforcement, it is about 5 times the width or diameter of the footing. The smaller required width of 3D reinforcement is due to its superior anchorage compared to 2D reinforcement.
- The optimal spacing between reinforcement layers for 2D and 3D reinforcements is approximately 0.35 and 0.2 times the width or diameter of the footing, respectively.
- The effective reinforcement zone beneath the footing base is smaller when using 3D reinforcement (less than 1.5 times the footing width/diameter) compared to the effective zone for 2D reinforcement (greater than 1.5 times the footing width/diameter). This difference in reinforcement zones confirms the better reinforcing mechanism of the geocell that facilitates a broader load distribution area and a shallower depth in comparison to the 2D reinforced bed.
- By employing a lesser quantity of 3D reinforcement, such as geocell, compared to 2D reinforcement, such as geotextile, a significant improvement in bearing pressure and footing settlement can be achieved.
- For buried pipes, the safety of the system depends on factors such as embedment depth, backfill quality, and the amount of reinforcement in the backfill trench. The use of geogrid and geocell reinforcement demonstrated beneficial performance on the buried pipe system. Adding reinforcement layers above the pipe reduced vertical deflection, soil surface settlement, and pressure on the pipe crown.
- In road and pavement applications, the inclusion of geocell layers helps prevent punching shear or rutting that can occur in unreinforced surfaces. It also leads to a significant reduction in vertical stress spread through the pavement foundation by distributing the load over a wider area.

Advancements in understanding the technical aspects of geosynthetic reinforcement instill confidence in societies, encouraging widespread application of these materials in various areas, including the stabilization and reinforcement of footings, pavements, buried pipes, underground utilities, railway and road embankments, slopes, and retaining walls.

Sustainability with geosynthetics

Geosynthetic damage due to installation stresses in ultra-light weight foamed glass aggregate versus conventional aggregate

J. Schuller
Rowan University Glassboro, NJ, USA

ABSTRACT: Several large-scale laboratory tests were conducted on multiple geosynthetic specimens to assess damage effects from ultra-light weight foamed glass aggregates (UL-FGA) versus AASHTO #57 stone. When geotextile or geogrid design strengths are needed for geosynthetics used in separation or reinforcement applications, one needs to define the long-term design allowable strength. This value utilized in design, is arrived at by first determining the ultimate wide strip tensile strength and then reducing this value to an allowable one by the applying partial factors of safety for creep potential, installation damage and degradation potential. Favorable results were realized with UL-FGA compared to AASHTO #57 stone.

1 INTRODUCTION

Lightweight fill, including geofoam and expanded shale, are becoming increasingly popular in the United States in terms of construction. UL-FGA is a new member to this group. With its rise starting in Europe in the late 20th century, UL-FGA quickly became a sustainable alternative to traditional lightweight aggregate fills; not only is it made from 100% post-consumer recycled glass, but it also increases the lifetime of other materials within the construction project. Benefits of UL-FGA are that it is extremely lightweight and highly insulating (Aaboe & Oiseth 2004); UL-FGA is also closed-cell, making it non-absorbent, as well as slightly buoyant in water. Lastly, the unique shape of each piece of UL-FGA allows water to drain around it, which prevents the buildup of pore water pressures in the layer. These properties make UL-FGA a viable option for civil engineering projects where soft soil, utilities, or other sensitive materials are unavoidable (Loux *et al.* 2019, 2022) as well as where sand or other small, lightweight particles would not be best suited due to the need for draining. Specifically, when working with geosynthetics that can be easily damaged during the installation of aggregates, UL-FGA is a great option.

2 GEOSYNTHETICS PRODUCTION, INSTALLATION, AND PROPERTIES

There are many types of geosynthetics, but the two types used in these tests and discussed in this report are geotextiles and geogrids.

Geotextiles are custom-made depending on their intended use. A majority of geotextiles are made from polypropylene (95 percent), and use one of five principal fiber types: monofilament, multifilament, staple fiber yarn, slit-film monofilament, or slit-firm multifilament. After this, the fibers are then made into either woven or nonwoven fabrics. Geotextiles

usually have a mass per unit area between 150 and 750 grams per square meter, and usually have a thickness between 0.25 and 3.5 millimeters. The strength of geotextiles can vary between 20 and 60 kilonewtons per meter, depending on the fabric. Geotextiles are most commonly used for separation and filtration (Koerner 2016).

Geogrids are most commonly used for reinforcement of soils. There are three types of geogrids: homogeneous, coated yarn, and laser-bonded. The homogeneous variety is made by punching holes into sheets of either high density polyethylene for unidirectional or polypropylene for bidirectional, then drawing the sheets under controlled circumstances to avoid fracture until a grid is achieved. The coated yarn variety is made from polyester yarn which is woven into an open structure; junctions are either knitted together or physically intertwined to create a grid before being coated with polyvinyl chloride or latex for stability. Lastly, the laser-bonded variety is made by joining straps of polyester or polypropylene together using either lasers or ultrasonic welding. Geogrids can have a mass per unit area anywhere between 200 and 1000 grams per square meter, and a percent open area anywhere between 40 and 95 percent. Properties such as strength, creep, and degradation depend largely on which type of geogrid is being considered (Koerner 2016).

The long term design allowable strength (LTDA) for geotextiles and geogrids is arrived at by first determining the ultimate wide strip tensile strength (using ASTM D4595 or ASTM D6637) and then reducing this value to an allowable one by applying partial factors of safety as in the following equation 1 below:

$$T_{all} = T_{ult} * (1/(FS_{cr} * FS_{id} * FS_{cd})) \tag{1}$$

where T_{all} = the long-term design allowable load (lb/in or lb/ft); T_{ult} = the ultimate wide strip tensile strength (lb/in or lb/ft); FS_{cr} = the partial factor of safety for creep potential; FS_{id} = the partial factor of safety for installation damage; and FS_{cd} = the partial factor of safety for degradation potential.

Regarding the partial factor of safety for installation damage, it is well known how reinforcement geosynthetic behave with conventional soil and aggregate. Installation damage is the loss of strength properties resulting from the act of installation. In some situations, where aggressive backfill and heavy equipment are used in construction, the resultant loss of strength can be significant. Cases have been reported where only 30% of the original strength properties remain after installation (AASHTO 1990). Although this high loss level is unusual, it points out the need to address installation conditions.

It should be clearly pointed out that the range of partial factor of safety for installation damage is usually 1.1 to 1.6 for conventional geosynthetic materials installed in AASHTO #57 stone with moderate ground pressure equipment. The design engineer can control several variables which impact installation survivability conditions, including the choice of backfill and installation equipment. Specifications requiring sand backfill will reduce the installation damage significantly. However, this option does reduce ability for water to drain and the strength of the fill. Furthermore, light ground pressure equipment and greater lift thickness will reduce installation stresses. Unfortunately, neither is possible when a 90 to 95% requirement of standard proctor is desired for the fill (ASTM D698 2021).

3   TESTING PROCEDURE

The Geosynthetic Institute, or GSI, recently conducted installation survivability tests with UL-FGA manufactures by Aero Aggregates and AASHTO #57 aggregate. Test specimens were cut from geotextile and geogrid samples expose according to ASTM D5818; Standard Practice for Exposure and Retrieval of Samples to Evaluate Installation Damage of Geosynthetics. The UL-FGA exposure and retrieval was conducted at Aero Aggregates' plant in Eddystone, PA (Site 1) or the Philadelphia International Airport Remain Overnight

Apron (PHL RON) project in Philadelphia (Site 2). The AASHTO #57 exposure and retrieval was conducted at GSI in Folsom, PA (Site 3).

Either ASTM D4595: Test Method for Determining Tensile Properties of Geotextiles by the Wide-Width Strip Method or ASTM D6637: Test Method for Determining Tensile Properties of Geogrids by the Single or Multi-Rib Tensile Method was performed on the retrieved and as received, or new, materials at GSI in Folsom, PA.

Four total batches of each sample were tested, one as received (i.e. new) and one after being exposed at each of the three sites. The unexposed sample was used as the baseline for calculating the strength reduction factor. The samples that were exposed were installed under a sample of each aggregate at the designated location, and the aggregates were compacted over top of them, as per the manufacturer's instructions. Both the geogrids and the geotextiles were restrained, so they were not allowed to float or move through the aggregate. After installation was complete, the samples were left for a brief period of time before being exhumed. The geosynthetics were only left for a few minutes after installation, as survivability after installation is being tested; if it were left for a longer period of time, it would be a durability test. Upon being removed from the aggregate, the geosynthetics were visually inspected for any cracks, tears, or punctures. Lastly, these samples, as well as the new samples, were sent to the Geosynthetic Institute for strength testing, as well as further evaluation and analysis.

Figures 1–6 respectively show samples being installed, as well as the different aggregates and installment equipment, at Aero Aggregates, GSI and the PHL RON project.

Figure 1.   Photograph of UL-FGA installation.

Figure 2.   Close-up of UL-FGA and geogrid.

Figure 3.   Photo of AASHTO #57 installation.

Figure 4.   Photograph of AASHTO #57.
Figure 5.   Photo of GS installed at PHL Ron.

Figure 6.   Photograph of PHL Ron installation.

After both the exposed and the new materials were received at the Geosynthetic Institute, testing was completed to determine the break load, break strength, break deflection, and break strain. Specifically, ASTM D4595 was followed to test the geotextiles, and ASTM D6637 was followed to test the geogrids. Both tests utilize a Constant Rate of Extension Tensile testing machine; ASTM D4595 elongates a 200 by 200 millimeter rectangular specimen to failure at a rate of 10 percent per minute, whereas ASTM D6637 elongates a section of a geogrid (either 1, 3, or 7 ribs) to failure at a rate of 10 percent per minute. All materials were tested in the machine direction, and twenty specimens were tested for each of the four batches of samples. After testing was concluded, the average, standard deviation, and the coefficient of variation were calculated for each sample. Lastly, the strength reduction factor was calculated to determine, on average, how much strength was lost in each batch of samples.

4   RESULTS

Table 1 summarizes the strength reduction factors, or the results of the material testing and analysis, for the geosynthetics from all three sites. For the purpose of anonymity, the geosynthetics is not identified. The strength reduction factor (SRF) was determined by using the Equation 2 below:

$$SRF \; = \; F_{rec} \, / \, F_{exp} \tag{2}$$

where SRF = the strength reduction factor; F_{rec} is the average break load of the as received (new) material; and F_{exp} is the average break load of the exposed material.

Table 1.   Strength reduction results from material testing.

Geosynthetic Material Tested	SRF for AASHTO #57 exposed at GSI (Site 3)	SRF for UL-FGA at Aero Aggregates (Site 1)	SRF for UL-RGA exposed at PHL RON (Site 2)
Geotextile A	1.8	1.3	1.1
Geotextile B	1.7	1.2	1.7
BX Geogrid A	1.6	1.1	1.2
BX Geogrid B	1.4	1.0	1.1
UX Geogrid A	1.6	1.3	1.2

5 DISCUSSION

As can be seen from the data above, UL-FGA causes much less damage to geosynthetics upon installation. Each SRF is less for the materials exposed to UL-FGA compared to those exposed to AASHTO #57. The geosynthetics exposed to AASHTO #57 are, therefore, weaker than those exposed to be UL-FGA. Specifically, when AASHTO #57 was installed over the geosynthetics, strength was lost from the damage, making the geosynthetic 1.4 to 1.8 times weaker; however, when UL-FGA was installed over geosynthetics, little to no strength was lost, making it only 1.0 to 1.3 times weaker, with the exception of geotextile B at PHL RON, which yielded a SRF of 1.7. This overall trend can mainly be attributed to how lightweight UL-FGA is compared to AASHTO #57, as well as the care taken to install UL-FGA in relatively thick lifts, per the recommended installation procedure.

It is also worth noting that, with the exception of geotextile B at PHL RON, all the SRFs for the UL-FGA are within the rang 1.0 to 1.3, showing consistency both throughout testing and installation as well as within the production and performance of the UL-GFA. Potential reasoning for this outlier could be mishandling during the exhumation of the geotextile; the PHL RON site had active construction activities occurring at the time and the authors were conscious of contractor's time – and work progression. Ultimately, this outlier is not a cause for concern given the trend for the other geosynthetic materials, and the SRF calculated for geotextile B at Aero Aggregates. Consistency within the product is important when discussing survivability because less frequent checking and replacing of the material is needed.

Since UL-FGA is so lightweight, it causes less damage upon installation, which is one of the major benefits to using it as backfill compared to regular aggregates. Also, since a very specific procedure is recommended when installing UL-FGA, additional care is taken not to damage the geosynthetic material underneath. In terms of survivability, this is important because it will allow the geosynthetics to perform at a high level for longer, since little to no strength is lost during installation. When material strength is lost, it is not as efficient, which means that more material must be used to achieve the same long-term design performance. Taking care not to damage materials during installation leads to an increase in survivability of the whole system, which means less frequent repairs and less cost to maintain or fix the system down the line.

6 CONCLUSION

UL-FGA is a lightweight aggregate that is used as a backfill in many construction and other civil engineering projects. It is favorable due to its extreme lightweight, high insulating, and draining properties. Additionally, UL-FGA is installed in such a way that helps limit damage to the material underneath it, which is important when fragile material is being covered. Specifically, when using geosynthetics in construction and other civil engineering projects, use of a lightweight aggregate such as UL-FGA is appropriate in order to maintain the strength and integrity of both the aggregate and the geosynthetic; this increases the survivability of the entire system. As can be seen from the results of the testing discussed in this report, UL-FGA causes significantly less installation damage to the geosynthetic material being used than AASHTO #57 does, which increases its ability to perform well and survive longer. Installation of UL-FGA only made the geosynthetics 1.0 to 1.3 times weaker, whereas installation of AASHTO #57 made the geosynthetics 1.4 to 1.8 times weaker. When discussing survivability, it is paramount to maintain the strength and integrity of materials, especially during installation, so that the material can survive and perform well for longer.

Contribution to the study of mechanical degradation of geosynthetic products in a saline environment

L. Naga, M. Chikhaoui* & L. Djerbal

LEEGO Laboratory, Faculty of civil engineering, University of Science and Technology Houari Boumediene, Algeria

ABSTRACT: The durability of geosynthetics used in aggressive environments can be affected by many degrading agents. This is why this paper is devoted to the study of the mechanical resistance of a geogrid based on polypropylene with respect to sulfuric acid (to create a medium rich in sulfur). To do this, the geogrid was subjected to an immersion test in the laboratory, considering different concentrations of sulfuric acid (in this case: 4% (0.8 mol.L^{-1}) 10% (1.2 mol .L^{-1}) and 16% (3.2 mol.L^{-1})). The damage caused by the accelerated degradation test was evaluated through the analysis of the results of the tensile test carried out on intact and degraded samples. The results show that the maximum tensile strength, as well as the tensile strength at 2%, 5% and 10% strain of the geogrid, did not undergo significant changes after the immersion tests regardless of the concentration. sulfuric acid. However, the corresponding strain to the maximum tensile strength underwent an increase in particular for acid concentrations greater than or equal to 1.2 mol.L-1. This result clearly shows the effect of the aggressive environment on the behavior of the geogrid is well as the observation of irreversible damage after only 1 month of immersion in sulfuric acid.

1 INTRODUCTION

Geosynthetics are products based on synthetic or natural polymers, used to fulfill several functions in the construction of numerous civil engineering infrastructures such as roads, tunnels, retaining structures, dams and coastal protection (Müller et Saathoff 2015). These relatively new products offer many advantages over the traditional product and technique: facilitate construction even in unfavorable conditions, reduce construction costs, increase the life of the structure.

Nowadays, there are different types of geosynthetics fulfilling different service requirements of the work (Shukla 2016), geogrids, are part of this large family of products, which are widely used for the reinforcement of slopes, walls, roads and foundations.

During the lifetime of the structure, the geosynthetic product can be in prolonged contact with several degradation agents (Greenwood *et al.* 2012; Hsuan *et al.* 2008) insofar as the lifetime required for a structure can be extremely long (up to one century in civil engineering) which can negatively alter the chemical, physical and mechanical behavior of geosynthetics by reducing their functional life (Bartolomeo 2003). These undesirable modifications are mainly related to the type of polymer used and the application conditions of the geosynthetic.

The polymers used for the production of geosynthetics (such as polyolefins, polyester or polyamides) generally suffer during prolonged contact with aggressive liquids from problems of extraction of chemical additives or gain mass by absorption of solution (physical aging).

---

*Corresponding Author: mch_gcg16@yahoo.ca

In addition, the absorbed solutions can interact with the polymer chains of the geosynthetics (chemical aging) (Kay *et al.* 2004; Koerner *et al.* 2007; Santvoort 2017). Polypropylene is extremely resistant to the inorganic environment (José Ricardo Carneiro, Morais, et Lopes 2018; Gulec, Benson, et Edil 2005; Jose Ricardo Carneiro, Almeida, et Lopes 2019; José Ricardo Carneiro, Almeida, et Lopes 2018; José Ricardo Carneiro, Almeida, et Lopes 2014). However, it is susceptible to being affected by oxidizing agents such as sulfuric acid, halogens, etc. Remember that additives added to improve the properties of polypropylene can be attacked by aggressive chemicals to which PP is resistant (Tripathi 2002).

The main objective of this research is to study the resistance of a PP geogrid to sulfuric acid. For this, an accelerated degradation test in the laboratory has been developed, in order to evaluate the resistance of the product in an environment rich in sulfur. The main indices adopted in this work are based on the results of the tensile test carried out on intact samples and subjected to degradation in different concentrations of sulfuric acid for 1 month. The evolution of the test parameters (tensile strength and tensile strain) according to different concentrations of sulfuric acid will be developed and studied.

2 EXPERIMENTAL DESCRIPTION

2.1 *Geogrid*

In this work, an extruded biaxial geogrid made-up from polypropylene with a minimum of 2% carbon black (percentage by weight), see Figure 1 below.

Figure 1. Visual aspect of intact biaxial geogrid (ruler in centimeters).

The main characteristics of the geogrid are summarized in Table 1.

2.2 *Immersion test*

The geogrid product was immersed, at a constant temperature of 80°C, in different concentrations of dilute sulfuric acid: 4%, 10%,16% (The stock solution has a purity of 95%). The immersion tests were carried out in the dark (the sample is protected from UV rays) and lasted 1 month.

Table 1. Main characteristics of the geogrid (reference specimens).

Parameters	Quantity
Structure	Extruded geogrid
Polymers	Polypropylene
Minimum carbon black content	2%
Tensile strength at 2% strain (MD-CMD)[a]	9.10 ($\pm$0.28) - 10.47 ($\pm$0.73) KN/m
Tensile strength at 5% strain (MD-CMD)[a]	18.07 ($\pm$0.06) - 20.92 ($\pm$1.36) KN/m
Tensile strength at 10% strain (MD-CMD)[a]	28.15 ($\pm$0.22) - 32.22 ($\pm$1.66) KN/m
Ultimate tensile strength (MD-CMD)[a]	32.89 ($\pm$1.07) - 36.18 ($\pm$1.04) KN/m
Elongation at ultimate tensile strength (MD-CMD)[a]	17.90 ($\pm$0.54) - 15.77 ($\pm$0.58) %
Unit area mass[b]	0.33kg/m^2

In brackets are the 95% confidence intervals.
[a]Determined according to ASTM 6637 (ASTM 6637).
[b]Determined according to ASTM 3776 (ASTM D3776).
MD: machine direction – CMD : cross-machine direction.

The composition of the solution was checked by measuring the pH. The monitoring results showed that the concentration of the solutions changes slightly over time. In order to keep a stable concentration, the solution was replaced every 15 days.

After collection, the specimens were rinsed with deionized water and wiped with water-absorbent paper towels. All specimens were conditioned at 23°C and 65% RH for at least 24 h prior to testing.

2.3 *Evaluation of the damage suffered by the geogrid*

The damage suffered by the geogrid product (during degradation tests) was evaluated by tensile tests according to (ASTM 6637), to determine the changes in the tensile properties of the geogrid under the effect of an accelerated aging treatment. The tensile tests were carried out on the Instron universal testing machine equipped with a 250 kN load cell (Figure 2).

Figure 2. Tensile test machine.

The method used in this study is to perform tensile tests on a single rib in the cross-machine direction only, each tensile test included a minimum of 5 specimens with a length equivalent to the distance between 3 junctions in the direction of the test.

Maximum tensile strength (MTS in KN/m) and corresponding strains at the maximum tensile strength ε_{ML} (%), The tensile strength at 2% (TS 2% in KN/m), at 5% (TS 5 % in KN/m) and at 10% (TS 10% in KN/m) were obtained from the load versus strain curves for a single rib (Figure 3) converted over the entire unit width (1m). The deformation was determined by expressing the relative displacement of the jaws as a percentage of the original length (120 mm). Results are shown with a 95% confidence interval.
Figure 3.   Rib tensile force-strain curves obtained before and after the immersion tests.

3   RESULTS AND DISCUSSION

The maximum tensile strength as well as the tensile strength at 2%, 5% and 10% strain of geogrid did not undergo significant changes after the immersion tests and this whatever the sulfuric acid concentration. Moreover, the small decreases in these terms show the negative effect of the aggressive environment on the long-term behavior of the geogrid, particularly in the event of prolonged contact with aggressive substances. In addition, the results obtained confirm good tensile strength for an immersion time not exceeding 1 month.

However, the minor variations observed in these parameters (between 0.64% and 7.27%) are not statically significant and can be attributed to the heterogeneity of the geogrid product resulting from their manufacturing process. It is necessary to increase the immersion time and to vary the products in order to better quantify the effect of sulfuric acid on the mechanical resistance of the geogrid. In terms of tensile strain corresponding to the maximum tensile strength, the results obtained clearly show a significant increase of approximately 10% and 16% corresponding respectively to concentrations of (1.2 mol.L^{-1}) and (3.2 mol.L^{-1}) of H_2SO_4 (Figure 4) after only one month of immersion.

The change in strain at maximum strength after immersion in sulfuric acid may have several possible explanations:

– High temperature immersion tests favored the extraction of carbon black, or a chemical interaction that occurs between sulfuric acid and carbon black which reduces their
Figure 4. Retained mechanical property against purity of sulfuric acid.

stiffening effect and makes them more deformable (the carbon black in addition to their protective role against UV, it improves the mechanical behavior of certain polymers by increasing their rigidity (Donnet *et al.* 1993).

– Appearance of the plasticization phenomenon of PP under the effect of sulfuric acid. Moreover, two or more of the preceding phenomena could have occurred simultaneously. Further research will be addressed in our future work to clarify previous hypotheses through thermal and chemical analyses. (No previous studies were found in the literature on this subject).

4 CONCLUSION

The main objective of the research work carried out in this paper is to identify the mechanical behavior of a geogrid product subjected to an accelerated aging test at the laboratory level. Tensile tests were performed on undamaged samples immersed in different concentrations of sulfuric acid (the most dominant chemical compound of selected aggressive soil). for one month at a temperature of 80°C.

The test results show a slight influence of sulfuric acid, for an immersion time not exceeding 1 month, on the tensile strength (maximum or which corresponds to 2% 5% 10% strain). Moreover, the strain corresponding to the maximum tensile strength increased by up to 16% at relatively high acid concentrations. Some hypotheses have been put forward to explain this increase. However, additional research is needed to better understand the problem and identify the causes of degradation through a microstructural study.

The results presented in this study correspond to particular degradation conditions and to the specific characteristics of the geogrid (the geosynthetic structure and its physical properties, base polymer used, type of stabilizer) and cannot be generalized at this state of knowledge. to other geosynthetic products.

In search of an alternative surfactant for stress cracking tests for HDPE geomembranes

G.R. Koerner

Geosynthetic Institute, Folsom, Pennsylvania, USA

ABSTRACT: Igepal CO-630 is referenced in ASTM & CEN norms-test methods as the reagent for the stress cracking test. Unfortunately, it has now been listed as a priority pollutant by several counties because of a benzene ring in its formulation. As a result, it is no longer available for laboratory use in several locations, particularly in Europe (EU) and Canada. This event has manifested itself over the past several years. Obviously, our industry is searching for an alternative surfactant for this important performance test which can be used and is available globally. This paper will describe the search and round robin tests which lead to an alternative surfactant that conceivably will fill the need internationally.

1 INTRODUCTION

Improved stress cracking resistance in high density polyethylene (HDPE) geomembranes has been a quest of our industry for many years. The Geosynthetic Institute (GSI) has been working in this area since the mid 1980's. GRI GM13 standard specification for HDPE geomembranes has moved the ASTM D5397 (appendix) single point notch constant tension load result requirement from 200 to 300 and finally to 500 hours over the last thirty years. It is interesting to note that some current HDPE geomembrane formulations have Single Point – Notch Constant Tension Load Test (SP-NCTL) values greater than 1,000 hours.

The European Union no longer allows the sale of Rhodia Solvay Group Igepal CO-630 to anyone in production industries (i.e., large quantities) due to ecological and health issues. This is apparently a REACH directive, not a law. As such, GSI has been tasked with finding a replacement for the surfactant used in several stress cracking tests. Trying to be proactive, we know that there are hundreds of commercially available non-ionic surfactants in the family of detergents. The task is daunting but necessary.

2 PROCEDURES

The stress crack test method developed in the late 1980s Koerner, R. M., Halse, Y. H. and Lord, A. E. Jr. (1990) is used to determine failure times from which the susceptibility of polyolefin geomembrane is evaluated for durability in use. The test is run under a constant tensile load condition and an accelerated environmental condition as described in ASTM D5397 "Standard Test Method for Evaluation of Stress Crack Resistance of Polyolefin Geomembranes Using the Notched Constant Tensile Load Test". One can generate the entire stress crack curve, which requires measurement of the failure time associated with a given test specimen at a specified tensile load level. Results from a series of such tests utilizing a range of load levels can be used to construct a stress-time plot on a log-log axis for the geomembrane. We did not generate complete curves for this investigation. In contrast, we only conducted SP-NCTL tests per the

appendix of the standard. This stress crack test utilizes five (5) ASTM D1833 Type "L" specimens. One determines the thickness and yield stress of the geomembrane and then notches it 20% of its nominal thickness (i.e. resulting in a ligament 80% of the no minal thickness). We run the SPNCTL test at 30% of the yield stress and record the failure time in hours. The apparatus used for the stress cracking test is shown in Figures 1 and 2.

Figure 1.   Frame and specimens.

Figure 2.   Immersion baths.

The notching of the specimens for this test is critical. One should use a precision (i.e., rigid) notching apparatus like the one shown in Figure 3 to control the notch depth to plus or minus 0.01mm (0.5 mil). The blade in the notcher should be a single-edged razor made of carbon steel. The profile of the blade should be like that of an arrow rather that a chisel point. The sharpness of the point is critical to the cleanliness of the cut, which affects the results of the test significantly. It is highly recommended that double honed razor blades are used in the notcher for no more than twenty specimens. It is also important that the notched depth is controlled by verification. This is typically done optically in cross section and plan view (pre and posttest). A photograph of a notch specimen pretest is shown in cross section in Figure 4 and in the end-plan view posttest in Figure 5.

Figure 3.   Notching.
Figure 4.   Verifying sharpness.
Figure 5.   Verifying notch depth.

A group of surfactants were used for this investigation. The group included four (4) surfactants, which were chosen based on efficacy and availability. Efficacy is critical as explained by Bobsein, R. L. (1998). The surfactants used were as follows:

- IGEPAL CO-630 (10% by volume) at 50 degrees Celsius
- Solvay: Rhodasurf LA-9 (10% by volume) at 50 degrees Celsius
- DOW: Tergitol 15-S-15 (5 % by mass) at 70 degrees Celsius
- BASF: Dehyton PL (10% by volume) at 70 degrees Celsius

In addition, we implemented a group of five (5) geomembranes for this investigation in the round robin test program. The geomembranes were chosen based on their association with the GAI-LAP proficiency test program. Each had a known stress crack resistance that was developed by several international laboratories. The geomembranes used were as follows:

- GM-71, ADS pipe resin, (SP-NCTL = 3 hours +/−2)
- GM-72, NSC 60 mil UC resin, (SP-NCTL = 165 hours +/−24)
- GM-73, SOLMAX CP Chem resin, (SP-NCTL = >500 hours)
- GM-74, Well researched Field failure, (SP-NCTL = 375 hours +/−67)
- GM-75, Layfield DOW Bimodal resin, (SP-NCTL = >1,000 hours)

3 TEST RESULTS

3.1 *Round Robin #1*

Three sets of round robin tests were run in three different laboratories. Testing included three surfactants and five different geomembranes. The results of the first-round robin are presented in Table 1.

Table 1. Round robin #1 results (all entries are in hours).

GM Number	Lab 1 Igepal	Lab 2 Igepal	Lab 3 Igepal	Lab 1 Rhodasurf	Lab 2 Rhodasurf	Lab 3 Rhodasurf	Lab 1 Tergitol	Lab 2 Tergitol	Lab 3 Tergitol
GM-71	1	2	2	2	5	27	2	3	1
GM-72	141	192	144	>500	410	>500	>800	315	278
GM-73	>800	>1000	>1000	>500	>1000	>500	>800	>500	372
GM-74	554	525	565	>500	487	>500	>800	267	400
GM-75	>800	>1000	492	>500	>500	>500	>800	230	241

In short, the results look poor. Originally six labs were solicited and sent samples, but only three labs ended up participating. In addition, the availability of some surfactants during the COVID pandemic was a challenge and there were supply chain issues experienced by some labs. As can be seen form Table 1, there is little consistency in results beyond Igepal CO-630. Lastly we found that the Rhodasurf is unavailable to many labs and its stability at elevated temperature over long test times is an issue.

3.2 *Round Robin #2*

The second-round robin results were better than the first. We had six labs participating, testing only two surfactants. It should also be noted that we arrived at 5 % by mass criteria

after much experimentation in GSI's laboratory. During the testing, we found that the DOW Tergitol 15-S-15 (5 % by mass) at 70 degrees Celsius is a bit of a challenge to work with. Tergitol is a solid at room temperature and needs to be diluted in very hot water before entering the stress cracking bath, which questions its viability as a replacement surfactant for Igepal.

The results of the second-round robin test are presented in Table 2. Six laboratories participated in the activity utilizing two surfactants and five different geomembranes.

Table 2.   Round Robin #2 results (all entries are in hours)

GM Number	Lab 1 Igepal	Lab 2 Igepal	Lab 3 Igepal	Lab 4 Igepal	Lab 5 Igepal	Lab 6 Igepal	Lab 1 Tergitol	Lab 2 Tergitol	Lab 3 Tergitol	Lab 4 Tergitol	Lab 5 Tergitol	Lab 6 Tergitol
GM-71	2	1	2	2	2	3	2	3	1	1	1	1
GM-72	141	192	144	139	152	139	508	315	278	267	411	524
GM-73	>800	>1000	>1000	–	>1000	>500	>800	>500	372	334	>500	325
GM-74	554	525	565	488	624	629	>800	267	400	>500	>500	>500
GM-75	>800	>1000	492	316	>1000	470	>800	230	241	224	>500	>500

3.3   *Round Robin #3*

The results of the third-round robin are presented in Table 3. Five laboratories participated in the activity utilizing two surfactants and five different geomembranes.

Table 3.   Round Robin #3 results (all entries are in hours).

GM Number	Labi Igepal	Lab 2 Igepal	Lab 3 Igepal	Lab 4 Igepal	Lab 5 Igepal	Labi Dehyton	Lab 2 Dehyton	Lab 3 Dehyton	Lab 4 IDehyton	Lab 5 Dehyton
GM-71	2	1	3	1	4	6	5	4	7	11
GM-72	141	192	144	139	152	215	225	290	275	342
GM-73	>1000	>1000	>1000	–	>1000	>500	>500	>500	>500	>500
GM-74	554	525	565	488	611	697	753	822	>500	783
GM-75	>800	>1000	492	316	>1000	>1000	>1000	>1000	>500	>500

The results of the third-round robin test look pretty good. However, I wish the alternative surfactant, Dehyton PL would shorten the time horizon for the test and not lengthen it. This was the case even at elevated temperatures. It should be pointed out that all results are averages from sets of five (5) specimens for round robin testing run per SPNCTL in the appendix of the ASTM D5397 standard. It also should be made very clear that the 10% Igepal CO-630° was tested at 50 degrees Celsius, where the BASF 10% Dehyton PL was tested at 70°degrees Celsius as a result of different cloud point numbers given by the manufacturers.

4   DISCUSSION

We can divide what was learned from these studies into two sections: lessons learned from the study results, and lessons learned regarding procedural issues. The major takeaway from the results of the concluded studies is that between-participant variation plays a larger role than within-participant variation in the standard uncertainty. In most of the cases, good

notching is imperative for repeatable stress cracking results. The variation in characteristics between participants was statistically significant, even when using the same raw materials and machine settings. This leads to the conclusion that unknown variables exist between participants (or there are unknown machine differences, e.g., age of machine, maintenance, calibration, history, etc.) that were not adequately controlled.

Looking toward future round robins, it appears that increasing the number of participants, or at least the number of machines, will have a larger effect on reducing the standard uncertainty in the consensus values rather than by having each participant produce more samples. The difficulty with the results is that while the variability in the results is clear, the causes of the variability are not. Without specific knowledge of which aspects are to blame, there is no quantitative basis for modifying the standard to produce more consistent results. This top-down approach illustrates that there are unknown sources of unknown variability in the testing, which is troubling.

One common take away from all three round robin studies is that the procedure is vitally important. It is clear from these different studies that the procedure must address more issues than stress level and notch depth. Running a stress crack test is much more than, machine calibrations, setup, material handling, operation and maintenance of the immersion bath. A robust round robin plan must address all these areas to avoid confusion and assumptions by the different participants. Furthermore, a more focused study using only one material, notch by a single laboratory may be needed going forward to identify an alternative surfactant to IGEPAL CO-630.

"Planning the ILS" section of ASTM E691-13 is broken into seven subsections: ILS membership, basic design, test method, participating laboratories, materials, number of test results per material, and protocol. The ILS membership discusses the scope and details of the study and assigns a coordinator, and a statistician. Similarly, the basic design section notes the importance of keeping the design simple. The remaining sections require consideration specific to the test method in question. We realize that a detailed round robin study defined by ASTM ILS does not allow for an abbreviation like having only one material and letting one central lab do all the notching. However, it is important to note that this is a complicated test with many variables. After three attempts at conducting round robin studies, it is still not unequivocally clear that an alternative surfactant to IGEPAL CO-630 has been identified for ASTM D5397.

To our knowledge, all known substitute surfactants to date have unique characteristics that will affect stress cracking in HDPE GMs differently. Unfortunately, we know of no REACH (EU) compliant surfactant that has the same SP-NCTL signature as Igepal CO-630 to use with polyethylene geomembranes common to our industry. As stated by Sheirs, J (2022), "Unfortunately, Igepal CO-630 will become harder to purchase with restricted supply in many countries because it can cause long-lasting harmful effects to aquatic life. Alternative surfactants should have physiochemical properties like Igepal CO-630, should be readily soluble, should be easy to remove, should have a similar critical micelle concentration (CMC), should be eco-friendly and should not degrade to toxic phenolic metabolites." This is an onerous list of conditions that are proving difficult to attain.

Therefore, our work here is ongoing and in need of a new direction. Perhaps the work with strain hardening modulus referenced by Engelsing, K. and Zanzinger, H. (2012) will change the paradigm of our industry away from actual accelerated aging performance tests to a mechanical index test.

5 CONCLUSION

After extensive round robin testing, it has been determined that no known REACH directive compliant surfactant has the equivalent efficacy as Igepal CO-630 for ASTM D5397 testing. Therefore, if performing this test with an alternative surfactant one will have to first

determine a correlation between the substitute-alternative surfactant and Igepal CO-630. Comparative experiments will have to show a correlation coefficient greater than 0.9 as well as a coefficient of variation within any given SP-NCTL data set of less than 5 for validation on a specimen set of at least thirty (30) data points. At which point an effectiveness ratio may be used to extrapolate results between the substitute-alternative surfactant and Igepal CO-630.

ABSTRACT: The use of reinforcement geosynthetics to prevent localized collapses over cavities is now relatively common. During the REGIC research project, an innovative geosynthetic solution has been developed. It includes a specific reinforcement geosynthetic coupled with an autonomous and remote warning device to detect, to locate and then monitor a localized collapse or sinkhole. This study identifies technically and environmentally the implementation conditions of this innovative instrumented geosynthetic solution compared to the traditional solution. The Life Cycle Analysis is realized to carry out this comparison from an environmental point of view. The results, including a sensitivity analysis aim to provide information on the environmental performance of the developed instrumented solution in a R&D framework. This detailed analysis is extended to most current other possible solutions with same level of performance and safety. This life cycle analysis finally resulted in the publication of an EPD® for the geosynthetic range concerned.

1 INTRODUCTION

The coupling of an auscultation and warning system to a reinforcement geosynthetic is a judicious innovative solution in case of sensitive structures like areas with high risk of soil subsidence. Although there exist already some reference studies on the Life Cycle Assessment of solutions incorporating geosynthetics, it seems important to evaluate the influence of auscultation and warning system on the environmental impact and to compare it with other currently used solutions as concrete solution. During the REGIC (Reinforcement using Intelligent Geosynthetics over Natural or Anthropic Cavities) research project, an innovative and warming geosynthetic solution has been developed. The Life Cycle Analysis is realized to carry out this comparison from an environmental point of view. It presents a sensitivity analysis for identifying the most influencing parameters; it is then extended to other solutions offering the same level of performance and security to the Owner.

2 OBJECTIVE AND SCOPE OF THE STUDY

The data of this study is based on the characteristics of a real construction site in Lille (France). It concerns the reinforcement above a 2 m diameter cavity. The solutions require

zero residual settlement for a service life of 100 years. Different technical solutions and monitoring and warning methods are proposed:

– Reference solution: concrete slab with a 16 m^2 and 25 cm thick of concrete. A volume of 24 m^3 of soil is excavated for pouring the 4 m^3 concrete slab. Then 20 m^3 of soil is covering the concrete slab and 4 m^3 is deposited. The slab is reinforced with 50 kg/m^3 of iron. Monitoring is planned with a visit every 7 years.
– Solution (a) - Reinforcement by geosynthetic without auscultation: This is designed in accordance with standard NF XP G 38065, for a service life of 100 years with zero residual settlement on the surface. Monitoring by the project owner is planned with a visit every 7 years. This geosynthetic will be called FPET-600.
– Solution (b) - Reinforcement by geosynthetic FPET-600 with automatic monitoring and inspection: As the same design as the solution (a) but with instrumented monitoring. Monitoring by the project owner is planned with a visit every 7 years.
– Solution (c) - Optimised reinforcement geosynthetic FPET-150-I with automatic monitoring and inspection: As the same design as other solutions but with optimized characteristics. Monitoring by the project owner is planned with a visit every 7 years. The optimization considers the reduction of the intervention time of the project owner linked to the alert system.
– Solution (d) - Pre-instrumented geosynthetic without a warning system: It allows the measurement of possible deformations of the geosynthetic but assumes a follow-up by the project owner through an annual visit.

3 LIFE CYCLE ASSESSMENT

The Life Cycle Assessment (LCA) study is conducted based on the standards ISO 14040, ISO 14044 and ISO 14025. In accordance with the European standard EN 15804 + A1, the "cut-off" approach is applied to the systems studied. This means that the materials resulting from recycling or reuse are considered free of any environmental impact. In order to be able to compare the different solutions, it is necessary to determine a Functional Unit (FU) common to all the products compared and defined in the ISO 14044 standard as "the quantified performance of a product system, intended to be used as a reference unit in an LCA". The FU will be used to weight and base the results of this LCA on a common basis in order to make optimal choices.

In this LCA, the functional unit considered is the following: Reinforcement of a cavity of 2 m diameter for 100 years.

The surface to be covered (64 m^2, to take into account the lateral anchors) is excavated to a depth of 1.5 m. A volume of 95.4 m^3 is excavated. The machinery used for the earthworks is estimated on the basis of (Suer P. & Andersson-Sköld, Y. 2011) which considers the use of a hydraulic excavator and a compactor. The same volume of soil is excavated and backfilled.

3.1 *Production data*

As the concrete slab is produced on site, only the production of geosynthetics, whether instrumented or not, is considered. For geosynthetic solutions, the production data is based on that of the factory in Saint-Didier-de-la-Tour (France) for the year 2019. They include raw material consumption including losses related to the manufacture of geosynthetics, consumption by suppliers of reinforcement yarns, considering the energy mix of the country where these yarns are manufactured and the consumption for assembly at the Saint-Didier-de-la-Tour plant (France). They also include packaging consumption, production waste and transport stage.

In the case of instrumented geosynthetics, the production of optical fibres should also be considered. For the purposes of this study, it is assumed that one metre of optical fibre is

required for the design of 1 m^2 of instrumented geotextile and the data is based on the data provided by (Unger & Gough 2008).

3.2 *Data for the completion of the project*

The construction data considers the phasing and quantities defined in paragraph 2.

The data from the operation phase considers the different scenarios defined in 2. For this study, it was assumed that an average distance of 100 km was covered during the visits to the structure. For the scenarios based on instrumented solutions, the use phase requires to consider the electricity consumption of the monitoring system, or even the use of a measurement box. The electrical consumption depends on the type of box, depending on the type of optic fibre used. For the present study, a box for Bragg gratings was considered, with a 15 minutes per day were devoted to measurements. In the case of a connection to the electrical network, the site being in Lille, the French mix was used. For data transfer, sending and storage of emails, different options were considered. The electrical consumption required for the transmission and storage of emails is taken from the studies (Pflueger 2010) and (Schmidt *et al.* 2009). The data on the Bragg grating measurement box takes into account different electronic components with a weight of 800 g. The steel casing was heavier than normal (7 kg) to allow for the later integration of components such as batteries and solar panels. The lifetime of the electronic components is estimated at 7 years.

As the use of the geosynthetics, or the concrete slab, is considered permanent (100 years), no end of life is considered in the analysis.

4 ENVIRONMENTAL IMPACT ASSESSMENT AND SENSITIVITY ANALYSIS

For the assessment of environmental impact, the indicators selected are those recommended by the EN 15804 + A1 standard for environmental declarations of construction products, to which is added the cumulative energy consumption.

For a complete sensitivity analysis to optimize the impact of the system, the study carried out in the framework of the research project integrated the influence of the following parameters:

– energy consumption for monitoring;
– the power source of the monitoring box: solar panels or others;
– the duration of daily use of the monitoring system
– the service life of the structure;
– the duration of storage of the e-mails sent by the box;
– the size of the site;
– the end of life of the geotextiles: in the case of a short-term application (e.g., reinforcement of cavities in a mining activity), next to the excavation and transport activities, a treatment by incineration can avoid the consumption of fossil resources.
– the country of implementation of the structure; in addition to the transport from the production plant to the construction site, this has an impact on the electricity mix used for monitoring and on the impact of alternative solutions.

4.1 *Impact on the cumulative energy consumption*

The global LCA analysis assesses environmental impact through several categories of impacts such as global warming, cumulative energy consumption, photochemical oxidation, resource depletion, water consumption, ozone depletion, etc. In this article we focus on the environmental impact on the cumulative energy consumption.

The cumulative energy consumption of the concrete slab solution is 20.8 GJ/FU, compared to 13.6 GJ/FU for the non-instrumented geosynthetic reinforcement solution (a) and 34.1 GJ/FU for the instrumented geosynthetic reinforcement solution (b) (Figure 1).
Figure 1. Comparison of the impact on cumulative energy consumption of the 3 reinforcement scenarios.

The instrumented geosynthetic reinforcement solution (b) requires the most energy resources over its life cycle. The impacts of the 'concrete slab' and non-instrumented geotextile (a) solutions are respectively 39 % and 60 % lower.

For the "concrete slab", the first contributor corresponds to the production of the reinforcement (48 %). The second is related to the project owner's travel (24 %), followed by the production of the concrete (17 %). For the non-instructed geosynthetic (a), the first contributor is linked to the production of the product (50 % of the total impact); this is mainly due to PET fibres. The second contributor is related to the project owner's travel (29 %), followed by earthworks (21 %).

For the instrumented geosynthetic (b): the first contributor is linked to the production of the monitoring and warning box (approximately 50 %), followed by the production of the geosynthetic and the transfer and storage of emails. The impact of the monitoring, assessment, and warning system ("box and optic fibre") is 60 % attributable to the production of the box and 40 % to electricity consumption.

The mechanical dimensions of the non-instrumented (a) and instrumented (b) geosynthetics are identical, which is debatable insofar as it does not consider the important contribution to safety made by the monitoring and warning system. Moreover, the high level of consumption related to the monitoring and warning system reveals a significant potential for optimization of the system design. Possible improvements include the power consumption of the monitoring and alert system, its type of power supply (electrical, solar, etc.), the daily duration of monitoring (geosynthetic measurement), the daily duration of the connection to the monitoring server (permanent, one-off in case of a local alert, etc.) and the storage of e-mails (in the cloud, locally).

4.2 Trends in the evolution of Life Cycle Assessment as a function of reinforcement design parameters

The parametric study carried out in this research project has enabled the following trends to be identified: First of all, in the case of a solution with an instrumented geosynthetic (b) with an associated monitoring and warning system:

– as the service life of the structure increases, the daily duration of monitoring has a significant impact on the cumulative energy consumption;
– reducing the storage of emails on the cloud to 1 week instead of 1 year significantly reduces the environmental impact;
– the power consumption of the monitoring box has little impact on the results;
– the electricity mix of the country where the instrumented geosynthetic solution is implemented has a strong impact on its environmental performance.

Then, by comparing of the "concrete slab" and instrumented geosynthetic solution (b) with an associated monitoring and warning system:

– the increase in the service life of the structure has a greater influence on the environmental impact of the "concrete slab" solution than on that of the instrumented geosynthetic with an associated monitoring and warning system;
– similarly, the larger the area of the structure treated, the lower the environmental impact of
– the instrumented geosynthetic solution with an associated monitoring and warning system compared to the concrete slab solution.

5   COMPARISON OF DIFFERENT SOLUTIONS ACCORDING TO THE LEVEL OF SAFETY ENVISAGED AS A FUNCTION OF THE RISK OF THE STRUCTURE

This section summarizes how, for a given level of safety, it is advisable to adapt the design of the geosynthetic reinforcement according to the use, or not, of a monitoring and warning system. It is important to analyse structures that are comparable in terms of safety and technically justifiable.

The following comparison (Figures 2, 3 and 4) is based on the example of a potential cavity, similar to the one presented in paragraph 2 and considering different hypotheses of risk evolution:

– The cavity is not likely to expand beyond the nominal diameter: If it is considered that there is no risk of the cavity enlarging beyond the nominal diameter, the competing solutions may be the "concrete slab" solution and a non-instrumented geosynthetic (a). For these two solutions, it was planned that the project owner would carry out a monitoring visit every 7 years.
– The risk of the cavity expanding beyond the nominal diameter is not well known but a priori is not very high: Considering that the risk of the cavity expanding beyond the nominal diameter is not well known but not very high at least at the beginning, the competing solutions can be the "concrete slab" solution and an instrumented geosynthetic with an optical sensor but without continuous monitoring (d). This geosynthetic solution allows for modular monitoring, punctual at the beginning (e.g. one measurement per year) which can be accelerated over time and can even be converted into continuous monitoring if things get worse.
– Analysis of the impact on the environment of the different solutions according to the hypotheses of risk regarding the cavity: For this analysis, assumptions were made for the electricity consumption of one hour per measurement, if the optic fibre measurement is carried out punctually; however, in the case of continuous monitoring, solar panels are systematically used. We also consider the daily transmission of measurement data to the central server, without online storage, except in the event of an alert.
Figure 2. The cavity is not likely to expand beyond the nominal diameter.
Figure 3. The cavity may present a non-negligible risk of expanding beyond the nominal diameter.
Figure 4. The risk of the cavity enlarging beyond the nominal diameter is unknown but not very high at least at the beginning.

6 CONCLUSION

The analysis of the Life Cycle Assessment of solutions integrating instrumented geosynthetics, with monitoring and warning devices, showed how important this assessment was to optimize the design of the reinforcement system, especially for sensitive structures such as those above areas at high risk of localized collapse. It was possible to evaluate and quantify the influence of the different design parameters of the system (geosynthetic, instrumentation, monitoring and warning system) on the impact on cumulative energy consumption.

The tool developed shows that it is possible to adapt and optimize the treatment and monitoring solution for an area at high risk of localized collapse according to the level of risk linked to the potential evolution of the cavity.

The addition of instrumentation and an optimized monitoring system is particularly relevant from an LCA point of view as well as from a safety and technical aspects. This study validates the expected benefits of this innovative instrumented geosynthetic solution compared to the traditional reinforcement solution, under optimized conditions adapted to each site, as in this case in the Lille region on a 2 m diameter cavity.

This Life Cycle Assessment has finally led to the publication of an EPD® Environmental Product Declaration for the range of geosynthetics concerned, which provides data on the environmental impact of the geosynthetic. This document presents the data in a standardized format for comparison with other solutions on the market.

Department of Engineering, University of Trás-os-Montes e Alto Douro, Vila Real, Portugal

ABSTRACT: This paper presents an overview of the research project CDW_LongTerm - Valorisation of Construction and Demolition Wastes in geosynthetic reinforced structures - Prediction of long-term behaviour and summarizes its main conclusions. Mixed fine-grain recycled aggregates obtained from non-selected C&D waste, with low market acceptance for other applications such as pavement base layers and concrete production, were used in this study. Changes on the geotechnical and geoenvironmental behaviour of recycled C&D materials induced by real weather conditions and other agents (such as, compaction or wet-drying cycles), the durability and creep behaviour of the geosynthetics, the long-term behaviour of geosynthetic/C&D material interfaces and the long-term performance of a full-scale model have been studied. In general, the results show an acceptable long-term performance of the materials, of the recycled C&D materials/geosynthetic interfaces and of full-scale model.

1 INTRODUCTION

Waste generation and its efficient management is currently recognised as a key area of concern within the construction industry. In fact, construction and demolition (C&D) waste is one of the heaviest and most voluminous waste streams generated worldwide, accounting for over 35% of all waste produced in the European Union, EU (EC 2020). On the other hand, the responsible use of natural resources is among the fundamental pillars for the sustainable development demanded to modern societies. Since the construction sector is one of the main contributors to the consumption of natural resources, the use of alternative (recycled) materials in the construction and rehabilitation of civil infrastructure can make a significant contribution towards sustainable development.

In 2015, the European Commission (EC) presented the EU Circular Economy Action Plan to help European businesses and consumers to make the transition to a circular economy, where resources are used in a more sustainable way. C&D was among the priority sectors identified in this Circular Economy Package, because of the vast amounts produced across the EU and their high potential to be reused and recycled. More recently, a new EU Circular Economy Action Plan for a cleaner and more competitive Europe has been launched, in which Construction and Buildings (with special reference to C&D waste) is among the key priority value chains (EC 2020).

In recent decades, several studies on the use of recycled C&D wastes in a variety of civil engineering works have been reported in the literature with encouraging results (e.g. Arulrajah *et al.* 2013; Ferreira *et al.* 2021; Lu *et al.* 2021; Santos *et al.* 2014; Vieira *et al.*

2016). However, most of these previous studies have investigated the short-term response of recycled C&D materials, and hence the knowledge about their long-term behaviour, as well as the overall long-term response of the structures where they are used is still limited.

In this context, the CDW_LongTerm research project focuses on the use of recycled C&D waste as an alternative backfill material for geosynthetic-reinforced structures (such as embankments and retaining walls), with special emphasis on the long-term response. As opposed to the majority of previous related studies, this research involves mixed recycled aggregates obtained from non-selected C&D wastes (the materials actually available on the Portuguese market). One of the main aims of this project is to demonstrate that geosynthetic-reinforced structures built with C&D materials are durable and fully capable of maintaining satisfactory performance throughout the design working life. This, in turn, will increase the confidence of owners, designers and constructors in the usage of recycled C&D wastes and promote the valorisation of waste materials, thus contributing towards the implementation of circular economy in the construction sector.

2 OVERVIEW OF THE RESEARCH PROJECT

The valorisation of recycled C&D waste as filling material, particularly in geosynthetic-reinforced structures, where it is possible to reach large heights and very steep slopes, represents significant economic and environmental benefits. On the one hand, the valorisation of C&D wastes contributes to achieve the recycling targets set out by the European Commission and prevents these wastes from ending up in landfills, and on the other hand, it avoids the environmental and economic costs related to the extraction of large volumes of borrow soils.

The research project CDW_LongTerm has dealt with the study of the long-term behaviour of geosynthetic-reinforced structures (GRS) constructed with recycled C&D materials. Thus, changes on the physical, mechanical and environmental properties of recycled C&D materials were studied, the durability and creep behaviour of geosynthetics after exposure to recycled C&D materials and the long-term behaviour of the interfaces between the geosynthetics and the recycled materials were assessed, and the overall performance of a full-scale instrumented geosynthetic-reinforced structure, as well as its numerical model were also carried out.

The long-term behaviour of geosynthetics when inserted into recycled C&D materials was investigated by exposing the geosynthetics to the recycled wastes under real environmental conditions (Figure 1a) and under artificial conditions (wet-dry cycling tests, Figure 1b). After
Figure 1. Exposure of the geosynthetics to the recycled C& D wastes: (a) under real environmental conditions; (b) wetting-drying cycles.

exposure the geosynthetic samples were subjected to tensile and creep tests to characterise the effects on the short-term and long-term behaviour, respectively. Scanning Electron Microscope (SEM) analyses were carried out on intact and exhumed samples.

An extensive laboratory test programme has been conducted involving conventional and multistage direct shear and pullout tests to investigate the long-term response of recycled C&D waste-geosynthetic interfaces.

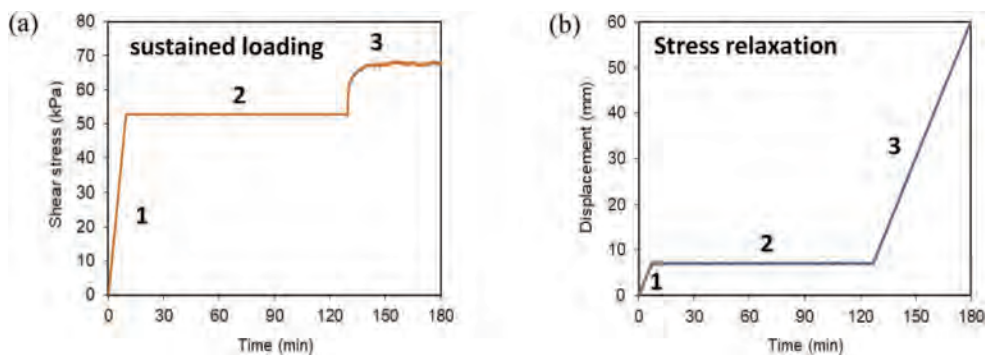
The direct shear tests were performed using a large-scale direct shear test apparatus (Vieira el al. 2013). Apart from conventional direct shear tests, two types of multistage tests were also carried out to simulate the effects of creep (Figure 2a) and stress relaxation (Figure 2b) at the interfaces (i.e. time-dependent behaviour).


Figure 2. Different setups of the multistage direct shear tests: (a) sustained loading; (b) stress relaxation.

Sustained load pullout tests were also carried out on recycled C&D material/geogrid interfaces on a large scale apparatus (dimensions in plan of 1.53m x 1.0m and 0.8 m high). The test procedure is similar to the one schematically shown in Figure 2(a), although much longer: the pullout force was applied under load controlled model until a predefined value (equal to 40% or 70% of the pullout resistance under monotonic loading), in a second stage the pullout force was held constant for a predefined time slot (30 or 120 minutes), during which the geogrid pullout displacement was monitored and in the last stage, the test proceeded until the failure of the interface.

A full-scale experimental embankment with two geosynthetic-reinforced slopes has been constructed using recycled C&D materials as backfill material (Figure 3a). The full-scale

Figure 3. Full-scale instrumented geosynthetic-reinforced structure: (a) during construction; (b) readings on the inclinometers; (c) pressure cells readings.

instrumented model consists of a 3.1 m high, 10.4 m long and 3.0 m wide geosynthetic-reinforced embankment composed of two wrapped-face slopes with a face inclination of 63.4° with the horizontal (batter of 1H:2V). Fine-grained recycled C&D materials were sourced from a Portuguese recycling plant and used as backfill. The southern slope was reinforced with a uniaxial woven geogrid, GGR3 (Figure 5c) and a uniaxial geocomposite reinforcement, GCR2 (Figure 5e) was used to reinforce the northern slope. The geosynthetic reinforced structure was built in a reinforced masonry block container with a reinforced concrete foundation.

To monitor the performance of the geosynthetic-reinforced structure. geotechnical instrumentation was installed during its construction. Specifically, the instrumentation system included: 4 inclinometer casings, 4 magnetic extensometers (with a total of 20 magnetic targets), 2 soil settlement gauges, 10 earth pressure cells, 35 electrical strain gauges attached to the geogrid, 12 mechanical extensometers (tell-tales) attached to the geocomposite, 4 settlement plates and 50 survey points at the slope faces and on the side walls. Figures 3(b) and 3(c) illustrates the collection of some readings during a monitoring campaign. In order to assess the long-term performance of the reinforced structure, the monitoring process is expected to remain for several years beyond the project end. Additional information regarding the full-scale model, instrumentation and monitoring can be found in Vieira *et al.* (2023).

The numerical modelling of the behaviour of the full-scale geosynthetic-reinforced structure was also performed using the three-dimensional explicit finite-difference software FLAC 3D (*Itasca Consulting Group, Inc.*). Five 0.6 m thick layers of recycled C&D material were simulated with the geosynthetic reinforcement layers placed at the appropriate locations along the height of the lateral slopes. The slopes were modelled with wrap-around facing, resembling actual field conditions.

3 MATERIALS

The fine grained recycled C&D materials used in the current research consisted of the finer fraction (0–10 mm) obtained during the recycling process of C&D wastes. The materials used in the project were obtained from three different batches (i.e. collected from the recycling plant at different times, but after being subjected to the same recycling process) and consisted mainly of soil, unbound and hydraulically bound aggregates, concrete and mortar products. Figure 4 illustrates the type of recycled material used in this study.

Figure 4.   Visual appearance of the recycled materials used in the study.

Figure 5 presents the photographic views of the geosynthetics tested in CDW_LongTerm project. It should be mentioned that not all the geosynthetics were subjected to the same test or exposure conditions.
Figure 5.   Geosynthetics used in the study (ruler in centimetres): (a) uniaxial high-density polyethylene geogrid (GGR1); (b) polyester welded geogrid (GGR2); (c) polyester woven geogrid (GGR3); (d) geocomposite reinforcement 1 (GCR1); (e) geocomposite reinforcement 2 (GCR2).

4   RESULTS AND DISCUSSION

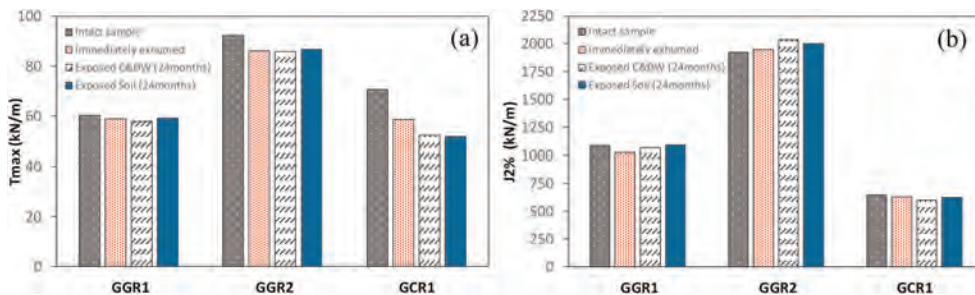
Figure 6 presents the effects on the tensile strength of geosynthetics GGR1, GGR2 and GCR1 (Figure 6a) and on their tensile stiffness for 2% of strain (Figure 6b) of different exposure conditions (specimens immediately exhumed, exposure to recycled C&D material, exposure to soil).


Figure 6.   Effects of exposure of geosynthetics to a recycled C&D waste and other conditions: (a) on maximum tensile strength; (b) tensile stiffness at 2% strain.

From Figure 6 it can be concluded that the effects of exposure to recycled C&D material and to soil are similar and, with the exception of geotextile GCR1, in general the tensile strength after immediate exhumation is close to that obtained after exposure for 24 months. The loss of tensile strength of GCR1 is most likely due to the less effective binding of the PET yarns to the nonwoven geotextile, caused by handling during installation, rather than damage induced by the compaction or exposure to the filling materials.

Figure 7 shows the creep behaviour of intact specimens (as provided by the manufacturer) of the geocomposite GCR1 (Figure 5d) and of specimens that were previously exposed to the recycled C&D waste for a period of 24 months.

When subjected to the same tensile force, the intact specimens exhibited higher tensile strength properties than the exhumed specimens However, the estimate of the long-term available strength, considering the extrapolation of the creep rupture curves, for the

242

specimens that were previously exposed to recycled C&D waste will be more optimistic when compared to the intact specimens (higher retained strength), (Figure 7). This finding suggests that the conventional approach (use of intact specimens) to estimate the long-term tensile strength of geosynthetics through creep rupture tests is a conservative procedure (Ferreira *et al.* 2022).
Figure 7.   Applied creep loads *vs* time to rupture and associated rupture curves (modified from Ferreira *et al.* 2022).

Figure 8 compares the results of conventional and stress relaxation direct shear tests (Figure 2b) to characterize recycled C&D material/geotextile GCR2 interface. As shown in Figure 8, and for the test conditions analysed in this project, the effect of stress relaxation on the interface behaviour was almost negligible, implying that the conventional large-scale direct shear tests can be considered suitable to characterise the long-term interface strength properties under direct shear mode (Ferreira *et al.* 2021).

5   MAIN CONCLUSIONS

The main goal of the research project CDW_LongTerm was to demonstrate the good long-term performance of geosynthetic-reinforced structures constructed with recycled C&D wastes, reducing the barriers on the use of alternative materials and giving an important

contribution to the reduction of human carbon footprint. Based on the results obtained in the extensive laboratory programme and the satisfactory behaviour of the full-scale geosynthetic-reinforced structure (even though it has been subjected to very adverse weather conditions - at least one extremely rainy winter) it is considered that these objectives have been achieved.

Among the main conclusions of this study, the following must be highlighted:

- Laboratory leaching tests carried out on all the recycled C&D materials have shown that only the sulphates exceeds the maximum value established by the European legislation for inert landfill. All the other pollutants are significantly below the limits.
- In general, the changes induced by the compaction procedures, weather conditions and adverse artificial conditions on the physical and mechanical behaviour of the recycled C&D materials are not significant.
- The effects of stress relaxation and sustained loading on interfaces direct shear strength and pullout resistance can be considered almost negligible, which suggests that good performance can be expected in the long term.

Study of the damage induced by recycled aggregates coming from Construction and Demolition Waste (C&DW) on the short-term tensile behaviour of a PET geogrid

P.M. Pereira & C.S. Vieira
CONSTRUCT, Department of Civil Engineering, Faculty of Engineering (FEUP), University of Porto, Porto, Portugal

ABSTRACT: The valorisation of Construction and Demolition Wastes (C&DW) is nowadays an imperative since it reduces the use of natural resources and avoids congesting landfills with these inert materials. The use of C&DW in geotechnical works, such as geosynthetic reinforced structures, is an interesting alternative from an economic and environmental perspective. This paper presents the mechanical, chemical and environmental degradation induced by fine grain recycled aggregate coming from C&DW on the short-term tensile behaviour of a uniaxial geogrid manufactured of extruded polyester (PET). In order to study the chemical and environmental degradation a damage trial embankment was constructed using C&DW as filling material. The damage caused by the mechanical actions during installation was also simulated by mechanical damage under repeated loading tests. Wide width tensile tests were carried out on geogrid samples exhumed from the trial embankment after 12 months of exposure, on laboratory damaged samples and on intact samples. Their short-term tensile behaviour is compared. Scanning electron microscope (SEM) images of intact and exhumed specimens are also presented.

1 INTRODUCTION

Minimizing the consumption of non-renewable natural resources for the production of construction materials is considered one of the key aspects to achieve sustainability in the construction sector. The recovery of construction and demolition waste (C&DW) as aggregate is an efficient way to achieve this purpose. Adopting and implementing this principle is particularly relevant for an industry that consumes more raw materials than any other economic activity and produces huge amounts of waste.

Considering the need to find new ways of avoiding landfilling of inert waste and preserving natural resources, recent studies have been carried out on the reuse of recycled aggregates from C&DW in geosynthetic reinforced structures (Arulrajah *et al*. 2014; Soleimanbeigi *et al*. 2019; Santos *et al*. 2013; Vieira & Pereira 2015; Vieira & Pereira 2021; Vieira *et al*. 2016). However, one of the main issues regarding the use of geosynthetics in contact with alternative materials is their durability.

The damage caused by mechanical actions during installation and the chemical and biological degradation are important issues to be considered in geosynthetics behaviour. The changes in their physical, mechanical and hydraulic properties, induced by the above-mentioned degradation processes, can control the performance of the structures where these materials are used.

Within the framework of a research project damage trial embankments have been constructed to study degradation induced by recycled C&DW on different geosynthetics. The

exhumation of geosynthetic samples from these embankments was done after 6, 12 and 24 months of exposure.

The results herein presented are related to polyester (PET) geogrid samples exhumed after 12 months of exposure to recycled C&DW. The mechanical damage induced by this recycled material on the geogrid was simulated by laboratory installation damage tests.

2 MATERIALS AND METHODS

The geosynthetic used in this study was a uniaxial geogrid manufactured of extruded polyester (PET) (Figure 1a) with aperture dimensions of 30 mm × 73 mm. To minimize the influence of external factors all the samples (intact - as provided by the manufacturers, damaged in the laboratory and exhumed samples) were taken from the same roll of material and tested using the same methods and equipment.
Figure 1.   Visual appearance of the material: (a) PET geogrid. (b) recycled aggregate from C&DW.

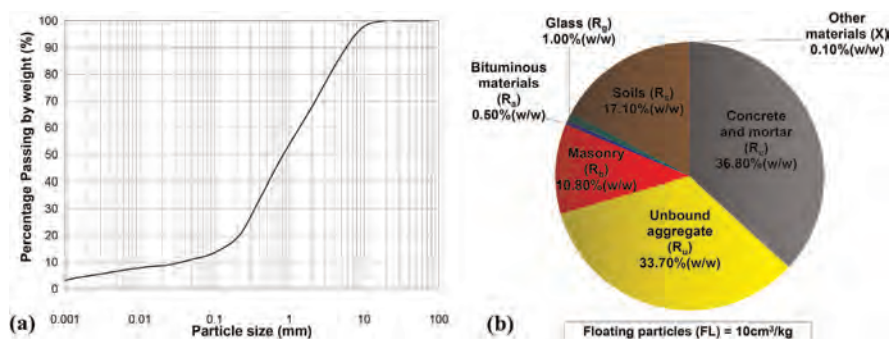
To study the chemical and environmental degradation induced by a recycled aggregate coming from C&DW (or recycled C&DW) on the short-term tensile behaviour of the geosynthetics, damage trial embankments were constructed. The damage trial embankments were constructed using fine grain recycled C&DW coming mainly from maintenance works or demolitions of small buildings and cleaning of lands with illegal deposition of C&DW (Figure 1b). The particle size determined by sieving and sedimentation is represented in Figure 2a. The predominant constituents of this fine grain recycled C&DW used are concrete, masonry, unbound aggregates, natural stones, as well as, a significant portion of soil (Figure 2b). These recycled materials were provided by a Portuguese Recycling plant located in Centre region.


Figure 2.   Recycled aggregate from C&DW: (a) particle size distribution; (b) portions of constituents.

After cleaning the foundation from the existing vegetation, a 5 cm-thick layer was placed and compacted and the geosynthetic samples of the first level were carefully positioned without overlapping. Geosynthetic samples were then covered with a first layer of recycled C&DW placed manually to prevent mechanical damage. Additional quantities of filling material were disposed, evenly spread and compacted to reach a lift with final thickness of approximately 0.20 m (Figure 3a). To minimize the installation mechanical damage on the geosynthetics, a lightweight compaction process was adopted (forward compaction plate with weight of 94 kg). Details on embankment construction are available in Vieira & Pereira (2015).

The tensile behaviour of exhumed specimens presented in this paper is related to geogrid samples exhumed after 12 months of installation (Figure 3b). The samples were carefully exhumed to prevent additional damage, being the material just above the geosynthetics removed carefully with the hands.
Figure 3. Study of the degradation induced by recycled C&DW on PET geogrid: (a) trial embankments construction; (b) geogrid specimens' exhumation.

SEM analyses were performed using a high resolution Environmental Scanning Electron Microscope with X-Ray Microanalysis and Electron Backscattered Diffraction analysis (Quanta 400 FEG ESEM / EDAX Genesis X4M) from the Materials Centre of University of Porto.

Laboratory installation damage tests were also carried out, using recycled aggregate from C&DW similar to the one used in the embankments construction (coming from the same batch), to study the mechanical damage induced by these recycled materials on the geogrid tensile behaviour.

The mechanical damage tests were performed using a laboratory prototype developed at the University of Porto (Lopes & Lopes 2003). The apparatus is composed by a rigid container (300 mm × 300 mm × 150 mm) divided in two boxes (where the geogrid and the recycled aggregate from C&DW were placed), a loading plate and a hydraulic compression system.

The geogrid specimens were cut with a width of 200 mm (5 longitudinal bars) and length of 380 mm. Each specimen was placed between two layers of C&DW and submitted to repeated loading. The layer placed under the specimen consisted in two sublayers (each 37.5 mm high) compacted by a flat plate loaded to a pressure of 200 ± 2 kPa, during 60 s, over the whole area of the test container. The layer placed over the specimen consisted in loose recycled C&DW with 75 mm high. Each specimen was subjected to dynamic loading (ranging between 5 ± 0.5 and 500 ± 10 kPa) at a frequency of 1 Hz and for 200 cycles. Finished the loading, the specimen was removed carefully from the test container, avoiding additional damage.

Tensile tests carried out on intact (as provided by the manufacturers), exhumed and damaged specimens were performed in accordance with the European Standard EN ISO 10319 (2015). Five specimens (for each condition) and a strain rate of 20%/min. were used.

3 RESULTS AND DISCUSSION

3.1 *Specimens exhumed from the embankment*

Although the preliminary visual inspections of the exhumed samples have not revealed significant damages. Scanning Electron Microscope (SEM) analyses were carried out to evaluate potential damages in more detail

Figure 4 illustrates SEM images (at 100 × magnification) of intact (Figure 4a) and exhumed specimens of geogrid (Figure 4b). From the analysis of Figure 4 it is visible that small particles of the backfill material have stuck to the geogrid but there is no relevant damage in the exhumed geogrid. Load-strain curves of exhumed geogrid specimens resulting from tensile tests are illustrated in Figure 5a. The mean curve is also represented. The maximum tensile strength (T_{max}), the geogrid strain for T_{max} (ε_{Tmax}), the secant stiffness modulus at strain of 2% ($J_{2\%}$) and the secant stiffness modulus at ε_{Tmax} (J_{Tmax}) for the five specimens are summarized in Table 1. The mean values of these parameters and the 95% confidence intervals assuming a Student's t-distribution were also included in Table 1. Analysing Figure 5a and Table 1 it is clear the low variability of the results.
Figure 4. SEM images of PET geogrid specimens (× 100): (a) intact; (b) exhumed after 12 months.
Figure 5. Load-strain curves of tensile tests performed on: (a) exhumed geogrid specimens; (b) geogrid specimens damaged in laboratory.

Table 1. Summary of results of tensile tests carried out on exhumed geogrid specimens.

	T_{max} (kN/m)	ε_{Tmax} (%)	$J_{2\%}$ (kN/m)	J_{Tmax} (kN/m)
Specimen 1	97.5	5.1	1892	1908
Specimen 2	87.8	5.9	1366	1489
Specimen 3	79.3	4.5	2134	1750
Specimen 4	86.5	4.9	2164	1747
Specimen 5	85.7	5.3	1925	1618
Mean value	87.4	5.2	1896	1703
Confidence interval of 95%	87.4 ± 8.1	5.2 ± 0.6	1896 ± 397	1703 ± 196

The tensile behaviour of exhumed and intact specimens will be compared and discussed in section 3.3.

3.2 Specimens damaged in laboratory

After the laboratory mechanical damage tests the specimens were subjected to tensile load tests following similar procedures to those used for intact or exhumed specimens. The load-strain curves of damaged geogrid specimens, as well as the mean curve corresponding to the 5 samples are represented in Figure 5b. Table 2 summarizes the values of maximum tensile strength (T_{max}), geogrid strain for T_{max} (ε_{Tmax}), secant stiffness modulus at strain of 2% ($J_{2\%}$) and at ε_{Tmax} (J_{Tmax}). The mean values of these parameters and the 95% confidence intervals assuming a Student's t-distribution were also tabulated.

Table 2. Summary of results of tensile tests carried out on geogrid specimens damaged in laboratory.

	T_{max} (kN/m)	ε_{Tmax} (%)	$J_{2\%}$ (kN/m)	J_{Tmax} (kN/m)
Specimen 1	82.1	5.2	1941	1579
Specimen 2	85.9	4.7	2048	1829
Specimen 3	90.8	5.0	2024	1817
Specimen 4	80.3	4.0	2180	2008
Specimen 5	91.0	5.5	1931	1641
Mean value	86.0	4.9	2025	1775
Confidence interval of 95%	86.0 ± 6.1	4.9 ± 0.7	2025 ± 125	1775 ± 211

3.3 Comparison and discussion of results

The tensile behaviour of intact specimens was reported in a previous publication (Vieira & Pereira 2021). Table 3 summarises the main results. The tensile strength reached in laboratory tests of intact specimens exceeded the mean value provided by the manufacturer. It should also be noted that the maximum tensile force is achieved for a low value of strain (5.6%), meaning that it is a geogrid of high tensile stiffness (around 2025 kN/m for 2% of strain). The comparison of these results with those presented in Tables 1 and 2 points out that of the loss of strength caused either by the exposure to the recycled C&DW for 12 months or by the laboratory installation damage tests is very small (loss of 5% and 7% on average, respectively).

Figure 6 compares the mean curves for intact, exhumed and damaged specimens. The shape of curves is quite similar but the coordinates at failure were shifted. Figure 6 enhances the little influence of this damage processes on the tensile behaviour of this geogrid. It should also be emphasized that the geogrid tensile strength after 12 months of exposure to C&DW and laboratory damage remains higher than its nominal value (80 kN/m).

Table 3. Summary of results of tensile tests carried out on intact geogrid specimens (Vieira & Pereira 2021).

	T_{max} (kN/m)	ε_{Tmax} (%)	$J_{2\%}$ (kN/m)	J_{Tmax} (kN/m)
Specimen 1	89.9	5.5	2037	1635
Specimen 2	100.7	5.8	2078	1736
Specimen 3	82.1	5.2	1942	1579
Specimen 4	91.0	5.5	1931	1641
Specimen 5	97.9	6.0	1971	1631
Mean value	92.3	5.6	1992	1645
Confidence interval of 95%	92.3 ± 9.1	5.6 ± 0.4	1992 ± 79	1645 ± 71
Figure 6. Comparison of mean load-strain curves of intact, damaged in the laboratory and exhumed specimens.

The geogrid tensile stiffness for very small strains (initial stiffness) did not change significantly while an increase on the secant stiffness modulus at ε_{Tmax} (J_{Tmax}) is noticeable. The increase on the secant stiffness was slightly higher in samples damaged in laboratory than in samples exposed 12 months to the recycled aggregate from C&DW.

The damage on geosynthetics used as reinforcement is currently quantified by the retained values of relevant parameters, such as, the tensile strength, the strain at maximum load or the secant stiffness modulus. The retained value of the parameter X can be defined as the ratio between the mean value of the parameter X for damaged or exhumed specimens and the corresponding mean value for intact specimens.

The mean values of the retained tensile strength, R_T, retained peak strain, $R\varepsilon$, and retained secant modulus at 2% of strain, $R_{J2\%}$ are presented in Table 4. As previously mentioned, the mechanical damage induced in laboratory was slightly more pronounced than the effects of exposure for 12 months.

Table 4. Mean values of retained tensile strength, R_T, retained peak strain, $R\varepsilon$, and retained secant modulus, $R_{J2\%}$.

Exhumed after 12 months			Mechanical damaged		
R_T (%)	$R\varepsilon$ (%)	$R_{J2\%}$ (%)	R_T (%)	$R\varepsilon$ (%)	$R_{J2\%}$ (%)
94.7	92.9	95.2	93.2	87.5	101.7

4 CONCLUSIONS

The mechanical, chemical and environmental degradation induced by fine grain recycled C&DW on the short-term tensile behaviour of an extruded uniaxial PET geogrid was presented. The research herein reported has shown that the mechanical damage induced in the laboratory is more aggressive than that caused during trial embankments construction. That means that, it is possible to consider that the installation damage during the construction of the trial embankments was, as expected, insignificant and therefore, the damages recorded on exhumed specimens could be attributed to the chemical and environmental degradation.

Results of tensile tests carried out on exhumed specimens have shown that the exposure of this geogrid to fine grain C&DW under real atmospheric conditions for 12 months did not induce geogrid degradation.

Despite the fact that the exposure period of the geogrid to the recycled C&DW was very short compared to the lifetime of the structures, this study allows us to conclude that it is not expected that the use of recycled materials will induce the degradation of geogrids.

Mechanically Stabilized Tire Derived Aggregate (MSTDA) retaining walls

J.S. McCartney*
Department of Structural Engineering, University of California, San Diego, CA, USA

ABSTRACT: Waste tires have been used in a variety of forms in civil engineering applications as a lightweight fill, insulation layer, or drainage layer. This approach to recycling and reusing waste tires has significant environmental benefits over other methods of disposal or incineration due to the quantity of waste tires generated by society. Although many civil engineering applications have used waste tire shreds mixed with mineral soils, there are advantages to using shredded tires in monolithic layers. For example, a greater number of waste tires can be recycled when using monolithic layers and there are lower construction costs associated with avoiding mixing with soils. Further, monolithic layers of tire shreds have similar shearing properties to soils, superior thermal insulating properties, excellent drainage, and high damping ratio. When shredded tires are used in a monolithic layer a civil engineering application they are referred to as tire-derived aggregate (TDA). This paper focuses on the use of TDA as a backfill material in the construction of internally stabilized retaining walls referred to as "Mechanically Stabilized TDA" or MSTDA retaining walls.

1 INTRODUCTION

There is an urgent need for sustainable reuse of "End of Life Tires" (ELTs) due to the large number of tires being generated by society and the lack of environmentally friendly disposal options. The number of ELTs generated each year in the US has increased by approximately 18% over the past decade [1]. Historically, these waste tires would be sent to stockpiles as they are not accepted by most landfills. However, stockpiles have risks associated with tire fires and act as a breeding ground for disease spreading insects and rodents. As tires are combustible and can be used as fuel source when mixed with coal, approximately 36% of ELTs are used as a fuel source [2]. However, there are environmental concerns with this strategy as burning ELTs release toxic air pollutants [3]. Because of these concerns, CalRecycle seeks to reuse or recycle 75% of waste tires. An effective and environmentally friendly approach for reducing ELT stockpiles is the reuse of waste tires as an alternative backfill material in civil engineering applications. This includes use as a lightweight embankment fill, in landslide repair/slope stabilization, as insulation layers for landfill clay liners, as alternative drainage layers in landfills, as a retaining wall backfill, as stress reduction backfill over pipes, as storm water infiltration gallery media, and as vibration mitigation layers for foundations and railroads embankments [e.g., 4–19]. Through the reuse of waste tires in civil engineering applications, the quantity of stockpiled waste tires has reduced from 800 million in the mid-1990's to 200 million today [3]. Approximately 5.1% of waste tires were reused in civil engineering applications in the US [1], while 3.0% were reused

---

*Corresponding Author: mccartney@ucsd.edu

in civil engineering applications in California [2]. The percentage of waste tires reused in civil engineering applications is increasing each year.

An advantage of reusing waste tires in civil engineering applications is that both older tires from stockpiles and freshly recycled tires are suitable. While early studies investigated tire shreds mixed with soils, the cost associated with mixing and the reduction in the volume of tires reused increases the cost of this approach. Instead, it most economical to reuse tire shreds in civil engineering applications is as a monolithic layer. In this case, the shredded tires are referred to as tire-derived aggregate (TDA) to emphasize that they are similar to a granular aggregate. Due to the growing popularity of reusing waste tires in the form of TDA, ASTM D6270 [20] was developed to provide guidance on the classification of TDA and how it should be used in different civil engineering applications to minimize the likelihood of self-heating. Self-heating was encountered in large TDA fills in the 1990s without provisions for drainage control or in the amount of exposed steel. Two categories of TDA are permitted in ASTM D6270: Type A TDA, with particle sizes ranging from 75 to 100 mm, and Type B TDA, with particle sizes ranging from 150 to 300 mm. Both types of TDA have limits on the amount of sidewall tire pieces and the quantity of particles having exposed steel wire. However, Type B TDA requires less processing than Type A TDA and is therefore more cost effective and has less exposed steel due to the larger particle sizes. ASTM D6270 limits the height of fills constructed using Type B TDA to 3 m (approximately 10 ft), while it limits the height of fills constructed using Type A TDA to 1 m (3 ft). Further, ASTM D6270 requires that monolithic layers of TDA be encapsulated with inorganic mineral soil to help dissipate heat and isolate the TDA from exposure to water.

The use of TDA as backfill in civil engineering applications not only helps reduce stockpiles and reuse waste tires, but TDA also has favourable engineering properties. For example, the total unit weight of TDA is 5 to 9 kN/m^3, which is about one-third to one-half that of most granular backfill soils. Despite this low total unit weight that is less than that of water (9.8 kN/m^3), the tire shreds are heavier than water (specific gravity of approximately 1.15) and will not float when submerged. Its low total unit weight makes TDA favourable for use as a fill above deformable subgrade soil or on soils with global stability issues. In addition to the lower unit weight, TDA has shear strength that is comparable to soils [21], a hydraulic conductivity of 0.01 m/s (on the same order of magnitude to gravel), a thermal conductivity of approximately 0.17 W/mK, which is approximately 8 times smaller than most soils, and a high damping ratio that provide TDA with favourable cyclic shearing properties [22]. Differences between TDA and granular backfills are that TDA may deform more than soils upon loading, and that the displacement at peak shear strength is greater than in dense backfill soils. These differences in deformation response require careful consideration in the construction of civil engineering infrastructure with TDA backfill to accommodate the more flexible response of TDA to external loading but can be overcome with careful planning and design.

TDA has been widely used as a backfill in gravity-type, reinforced concrete retaining walls [11–16]. These gravity retaining walls with TDA backfill had good performance in terms of lateral earth pressures exerted on the retaining wall. However, recent civil engineering applications in California have explored the approach of creating internally reinforced TDA walls that are similar to Mechanically Stabilized Earth (MSE) walls, referred to herein as Mechanically Stabilized TDA (MSTDA) walls. Internally reinforced retaining walls have lower material costs and faster construction times. Like MSE walls, MSTDA walls are fill-type retaining walls that are used when to provide a change in grade, lane widening, or repair of slope instability. MSTDA walls have a unique feature over gravity-type retaining walls in that the weight of the TDA backfill will not induce as large a stress on the underlying subgrade material. This can be advantageous in areas with compressible subgrade soils or when there is global instability influenced by the weight of the retaining wall. McCartney [23] presented a design methodology for MSTDA walls that built upon MSE wall design methodologies [24] incorporating experimental data on TDA deformation and shearing

properties. This paper presents a summary of an MSTDA wall design and design details from MSTDA projects.

2 TYPICAL MSTDA CONFIGURATIONS AND DESIGN CONCEPTS

Like MSE walls, MSTDA walls have a wide range of possible geometric configurations, facing types, reinforcement types, and heights. However, based on current practice in California, the most common type of MSTDA walls involves a horizontal back-slope used to support a roadway, flexible gabion-style facing elements, extensible geosynthetic reinforcements, and granular backfill within the gabions and overlying a reinforced TDA layer, as shown in Figure 1(a). Although the wall height is typically a major design choice in MSE walls, the height of MSTDA walls is typically governed by a reinforced TDA layer having a maximum thickness of 3 m (10 ft) overlain by a granular soil layer having a thickness of 0.8 to 2.0 m according to recommendations in ASTM D6270-20, with a total wall height of 3.8 to 5.0 m (12.5 to 16.4 ft). It is possible to construct a taller MSTDA wall by including multiple layers of TDA separated by granular backfill layers, an approach used in a TDA embankment at the Dixon Landing Interchange in Milpitas, CA [14]. It is clear from the typical design configurations in Figure 1(a) that geosynthetics are used as separation layers, reinforcements, filters, and drains. The definitions of the nominal loads in an MSTDA wall with a gabion facing are shown in Figure 1(b). The internal and external stability of this wall under static and earthquake loading must be considered for different factored load and resistance combinations.
Figure 1. (a) Typical MSTDA configuration; (b) Definition of nominal loads.

3 TDA PROPERTIES AND TDA-GEOSYNTHETIC INTERACTION

Several studies have recently been conducted at the University of California San Diego focused on understanding the shear strength, deformation, and geosynthetic interaction of Type B TDA. Testing materials with large particle sizes requires the use of a large testing device, which was summarized by Fox et al. [25]. This type of TDA is recommended for use in MSTDA walls due to the greater permissible layer height and because it requires less processing to manufacture. Two critical properties of TDA are shown in Figure 2, including the volume change of Type B TDA during application of high stresses [21] and the shear strength of TDA and TDA interfaces [21,26]. TDA has a nonlinear compression curve which can be represented approximately using a bi-log linear relationship as shown in Figure 2(a), and also has a nonlinear failure envelope, with a secant friction angle of 30.2° at a normal stress of 100 kPa decreasing at a rate of 14.4° per log cycle of normal stress at failure.
Figure 2. Key properties of TDA: (a) Compression curve; (b) Failure envelope.

TDA-geogrid interaction was studied using large scale pullout tests by Ghaaowd and McCartney [26]. The pullout factor is a key component to the internal stability calculations of MSTDA walls. Ghaaowd and McCartney [26] tested the pullout of 3 geogrids, Tensar UX1100 (GGA), Miragrid 5XT (GGB) and Tensar BX1500 (GGC). The pullout-displacement curves for GGB are shown in Figure 3(a), and the pullout factor versus vertical stress is shown in Figure 3(b). GGB had a combination of high pullout resistance under a wide range of vertical stresses and was used in the design calculations.
Figure 3. Pullout results from Ghaaowd and McCartney [26]: (a) Pullout force from TDA vs. displacement for GGB; (b) Pullout factors for three geogrids as a function of vertical stress.

4   MSTDA WALL DESIGN OUTCOMES

McCartney [23] summarized the design requirements of an MSTDA wall with a TDA fill height of 3 m and an overlying granular fill of 1.2 m, supporting both a pavement section and a heavy traffic surcharge, as shown in Figure 4. The wall was designed for expected earthquake conditions near Santa Barbara, CA. The TDA was reinforced with geogrid GGB with the pullout factor relationship shown in Figure 3(b). Based on the design steps considered in McCartney [23], the TDA reinforcement length was found to be 5 m, mainly to resist the earthquake loading at the site. An interesting aspect of the design was the consideration of the overbuild requirements for the TDA due to its high compressibility. An analysis was performed to consider the required overbuild for a range of granular fill thicknesses overlying the TDA layer along with the surcharge from traffic and the pavement section. When the 3 m TDA fill was split into 10 lifts, each lift should be overbuilt by a certain amount to ensure that the final fill height will be 3 m, as shown in Figure 5(a). The compression of the TDA will lead to an increase in TDA unit weight as shown in Figure 5 (b), which will change the effective stress profile and the stress-dependent friction angle of the TDA used in the analysis, as summarized by McCartney [23]. Overall, the design features of
Figure 4.   Final MSTDA wall configuration accounting for all design checks.
Figure 5.   (a) Overbuild calculations for TDA to reach target TDA fill height; (b) Final TDA unit weights after compression under overlying lifts.

this wall are consistent with those encountered in an MSTDA wall constructed on the Ortega Ridge road near Montecito, California. Design drawings and construction photographs of this MSTDA wall are provided in McCartney [23].

5   CONCLUSIONS

This paper introduces the concept of Mechanically Stabilized TDA (MSTDA) walls, and notes some of the key TDA properties and design considerations necessary to ensure the stability and serviceability of these walls. TDA has similar mechanical properties to soils albeit with greater compressibility that should be considered in the wall design through appropriate overbuild.

Pavement rehabilitation with polymeric reinforcing grids – economic and environmental benefits

Fabiana Leite-Gembus & Andreas Elsing
Huesker Synthetic GmbH, Gescher, Germany

Luis Eduardo Russo
Huesker Srl, Trieste, Italy

ABSTRACT: For more than 50 years, asphalt reinforcing grids manufactured with polymeric fibres have been used to delay or even prevent the development of reflective cracking in pavement rehabilitation. Their positive performance has contributed to increase maintenance periods and to provide substantial economic and environmental benefits, reducing traffic disruptions and the use of exhaustible resources. This paper will present results of recent researches, which show the importance of some factors and their respective influence in the durability and performance of reinforced asphalt overlays, such as interlayer bonding and grid resistance to installation damage. Through practical experiences will be demonstrated the effect of the asphalt reinforcement on the long-term asset pavement performance. Additionally, a cost comparison and a detailed description of the calculation of CO_2 emissions savings between a reinforced and a not reinforced rehabilitation solution is given.

Keywords: asphalt reinforcement grid, pavement rehabilitation, long-term performance, cost reduction, CO_2 emission

1 INTRODUCTION

The need for sustainable designs and construction methods has become a debated topic due to the growing concerns over global warming, climate change and the finite nature of resources. These events are causing increased pressure on the construction industry to reduce their environmental impact. Therefore, sustainable construction procedures and green building technologies are playing an important role in pavement rehabilitation.

Asphalt reinforcing grids have been used all over the world to delay the development of reflective cracks in asphalt layers and to extend the service life of rehabilitated pavements (Montestruque 2002; Monser *et al.* 2010). This solution has not only the positive effect that the maintenance costs per year are reduced but also the amount of carbon emissions can be significantly decreased.

The use of appropriate asphalt reinforcement should ideally be considered for future maintenance and rehabilitation surfacing contracts, which have a history of cracking at surface. Currently there are several types of geosynthetic products available in the market, which are made of different raw materials (e.g., polyester, glass fiber, polyvinyl alcohol, carbon fiber and polypropylene). It is not disputed that each of these systems has a positive effect in the battle against reflective cracking (Norambuena-Contreras & Gonzalez-Torres 2015; Vanelstraete & Francken 1996). However, there are differences in the behavior and effectiveness of each system.

The objective of this paper is to present important required characteristics for the asphalt reinforcement, so that a good performance and durable pavement rehabilitation can be achieved. Typical applications for the use of asphalt reinforcement, described by basic theory and practical experiences, will be demonstrated. Finally, a simplified comparison to estimate the carbon dioxide (CO_2) savings between a conventional and a reinforced pavement rehabilitation is presented.

2 REFLECTIVE CRACKING AND ASPHALT INTERLAYERS

A conventional rehabilitation of a cracked flexible pavement involves milling off the existing top layer and installing a new asphalt course, but cracks are still present in the existing (old) asphalt layers. As a result of the horizontal and vertical movements at the crack tip, the cracks will propagate rapidly to the top of the rehabilitated pavement. This phenomenon is called reflective cracking and is a serious challenge associated with pavement rehabilitation, as it allows water infiltration in the structure, causing stripping in the asphalt layers and weakening in the base and subgrade (Elseifi 2015).

To delay the propagation of cracks is the use of geosynthetic asphalt interlayers between the old pavement and the new overlay one of the most popular methods among new techniques recommended (Nejad *et al.* 2016). Basically, there are three types of geosynthetics designed for pavement rehabilitation: geotextiles (nonwovens or paving fabric), geogrids (grids) and geocomposites. To further improve confidence in the utilization of these materials, there is since 2008 mandatory CE marking for the products in Europe. According to the European standard EN 15381, an asphalt interlayer can fulfill three tasks: reinforcement, stress relief and/or interlayer barrier.

While the stress relief function concerns to soft products (as nonwovens) to dissipate strain energy by deforming itself, the reinforcement function regards stiff products (as grids) to compensate the lack of asphalt concrete tensile strength (Elseifi 2015). In providing reinforcement, the grid structurally strengthens the pavement section by changing the response of the pavement to loading (Koerner 2012). The reinforcement increases the resistance of the overlay to high tensile stresses and distributes them over a larger area, thereby reducing the peak shear stresses at the edges of the cracks in the existing old pavement.

Many products have been promoted as a reinforcement when in fact these products serve only as moisture barrier or stress relief layer. Designers should have a clear understanding of the limitations all the different asphalt interlayer products offer in terms of position and stress-strain characteristics within the pavement structure (Asphalt Academy 2008). Asphalt reinforcement grids made of polyester (PET) have been used for more than 50 years to control reflective cracking in asphalt layers. The wider benefits of polymeric grids in delaying reflective cracking were discussed in previously publications (Elsing & Horgan 2019; Leite-Gembus *et al.* 2020; Russo 2011) and as the example shown in the following.

3 PRATICAL EXPERIENCE

In 2006 the Olympic Winter Games took place in Torino, Italy. Prior to this major event the "Corso Giovanni Agnelli", which is one of the main roads passing the Olympic Stadium, was greatly in need of rehabilitation. The existing asphalt pavement showed severe cracking where almost every joint from underlying concrete slabs had reflected through the asphalt overlay. Therefore, the city of Torino decided to carry out a rehabilitation. Over a length of approx. 500m a bituminous coated polyester (PET) asphalt reinforcement grid was used. In order to obtain a comparison, a second area was rehabilitated without reinforcement (Russo & Simini 2011).

In June 2005 the reinforced area was rehabilitated. After milling off the existing asphalt wearing course, an asphalt levelling course was laid on the concrete slabs. The polyester asphalt reinforcement grid was then installed in accordance with the manufacturer's installation guidelines (Figure 1a) and was covered with a 40 mm layer of asphalt wearing course. Two weeks later, the second area was rehabilitated without reinforcement. Here a new 50mm asphalt layer was installed directly on top of the concrete slabs (without reinforcement), also after milling off the existing wearing course (Figure 1b).

Figure 1. Installation of the HaTelit C 40/17 asphalt reinforcement (a) and asphalt placement on unreinforced section (b) (June 2005).

In May 2006 the first assessment of the road took place. The reinforced area did not show any cracking, however in the unreinforced area, first signs of cracking were visible over the expansion joints of the concrete base. In July 2009, some 4 years after the rehabilitation, the second assessment of the road took place. At that time the reinforced area still did not show any cracking (Figure 2a). In contrast, almost every expansion joint from the concrete slabs had reflected through the new overlay in the unreinforced area (Figure 2b).

Figure 2. HaTelit C 40/17 reinforced area without cracks (a) and unreinforced section presenting reflective cracking (b) (July 2009).

Due to the widespread crack pattern in the unreinforced section, in August 2010, five years after the rehabilitation, the unreinforced section had to be again repaired. The asphalt

layer was removed and in the sequence an asphalt overlay was placed. Overall condition of the pavement in the reinforced section was very good, showing no reflective cracking, despite Corso Agnelli is always under intensive traffic. In 2015, a third resurfacing of the unreinforced section was carried out. The asphalt layer was once more in bad condition, presenting significative reflective cracking. The reinforced section was still in good condition; however, the first ones barely visible cracks could be seen. In 2019, after 14 years from the first mentioned rehabilitation, the whole section was presenting reflective cracking and in need of remediation works.

This example has proven in the practice that the use of a polyester asphalt reinforcement grid can considerably delay the propagation of reflective cracks. The unreinforced section presented the first cracks already 10-11 months after the rehabilitation, demonstrating how reflective cracking can cause a premature failure of the asphalt overlay. The poor performance of this section has resulted in additional maintenance costs and in the need of complete rehabilitation every 4-5 of road operation. Conversely, the reinforced section has received no maintenance during 14 years of traffic operation, leading to significant cost savings. Based on the difference of required rehabilitation intervals and the overall performance, it is possible to conclude that the polyester asphalt reinforcement grid achieved an improvement factor of 3 with respect to the life time of the rehabilitation. Considering the gain in reflective cracking resistance of the asphalt overlay, the improvement factor observed in this case was well above 5.

4 EMBODIED ENERGY (EE) AND EMBODIED CO2 (ECO2)

Since the 1980's sustainability has been used in the sense of human sustainability on planet Earth and this has resulted in the most widely quoted definition of sustainability and sustainable development, that of the Brundtland Commission of the United Nations: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." (United Nations General Assembly 1987)

In the context of the construction industry this does mean that different construction techniques and designs for a specific project are compared for their ECO2 as an indicator for their sustainability. As a matter of fact, the ECO2 is only one criterion beside social and economic considerations. Recent commitments signed at Cop26 in Glasgow saw many countries signing up to net zero carbon emissions by 2050. By assessing and quantifying the embodied energy (EE) and embodied carbon dioxide (ECO2) for the materials used on site without considering the individual transport distances and their installation. The authors of this paper appreciate that this comparison is not in line with the typical "cradle to grave" approaches used in this field, but it has been previously shown that the following comparison is sufficiently detailed to compare the two construction techniques without compromising on the accuracy of the results.

The ECO2 values ("Carbon Footprint") used in the following are taken from the latest Inventory of Carbon & Energy (ICE) V2.0. The University of Bath has created the ICE embodied energy & embodied carbon database which is the freely available (Hammond & Jones 2011). The aim of this work is to create an inventory of embodied energy and carbon coefficients for building materials. The data base is structured into 34 main material groups (i.e. aggregates, aluminum, asphalt, etc.).

The amount of embodied carbon dioxide per kg of material can vary significantly. The more processing and energy that is required to achieve the final product the higher is the ECO_2. Energy intensive processes like the production of cement are producing a high amount of CO2. Cement manufacturing releases CO2 in the atmosphere both directly when calcium carbonate is heated, producing lime and carbon dioxide, and also indirectly through the use of energy if its production involves the emission of CO2.

Based on a specific Environmental Product Declaration (EPD) the embodied CO2 for HaTelit C 40/17 eco asphalt reinforcement, made of recycled PET, has been assessed and externally verified as 1.05 kg ECO2/m^2 of material (3.88 kg ECO2/kg of material). This assessment is based on a cradle to grave approach and thus exceeds the system boundaries for the examples presented in in Table 3.

4.1 Comparison of embodied carbon dioxide for reinforced and unreinforced asphalt overlays

The report "Sustainable geosystems in civil engineering applications" commissioned by the Waste and Resource Action Plan (WRAP 2010) has analysed geosystems as alternatives to standard designs used by civil engineers.

Parallel to geosystems for ground engineering the report has identified that "Reinforcement of the asphaltic or bound layers can increase the life of the surface layers, again by contributing to a strengthening of the bound layers. Such strengthening increases their ability to resist cyclic fatigue, thermal stresses during extremes of winter and summer temperatures, as well as increasing resistance to near-surface crack propagation." (WRAP 2010). The report clearly identifies that asphalt reinforcements can extend pavement life by limiting reflective cracking and thus providing more sustainable pavements consequently. This paper aims to demonstrate the above referenced effect by comparing the ECO2 based on the material consumption per year of lifetime of two construction techniques. One construction technique is the conventional rehabilitation of cracked overlays by milling and repaving, the second is a rehabilitation using polyester asphalt reinforcement in the same process.

The example chosen for this comparison is a typical rehabilitation project with 5,000 m^2 of cracked wearing course to be replaced. Although the project size does not have any effect on the relative saving of ECO$_2$ it helps to give a better assessment for the saving potential (Table 1).

Table 1. Basis for calculation.

Job size	5,000 m^2
Asphalt thickness to be replaced	40 mm
Density of asphalt	2,500 kg/m^3 (compacted)
Bituminous emulsion (70%)	0.3 kg/m^2 (unreinforced)
Bituminous emulsion (70%)	1.0 kg/m^2 (reinforced)[a]
PET asphalt reinforcing grid	0.27 kg/m^2 (made of recycled polyester)
Improvement factor	3 [-][b]
Design life (unreinforced):	4 years[c]

[a]Required amount of bituminous emulsion for HaTelit asphalt reinforcement over milled surfaces acc. to manufacturer's recommendations.
[b]The improvement factor of 3 for the life time of reinforced asphalt as compared to unreinforced asphalt has been selected
[c]The design life of the unreinforced asphalt overlay has been chosen as 4 years since a typical crack propagation rate of approx. 10 mm / year would result in cracks reaching the surface of the new overlay after 4 years. The crack propagation rate of approx. 10 mm / year is of course project specific and could vary.

In the comparison in Table 2 it can be seen that a conventional (unreinforced) rehabilitation method results in 7.72 kg embodied CO2 per m^2 for the materials used. The alternative design using a PET asphalt reinforcement results in 9.04 kg embodied CO2 per m^2 due to the additional asphalt reinforcement and a higher amount of bituminous emulsion.

Table 2. Comparative calculation of embodied carbon dioxide (ECO$_2$).

Material	Material consumption	kg embodied CO$_2$ per kg of material	embodied CO$_2$ in kg/m^2	
			unreinforced	PET grid reinforced
Asphalt ($\sim$25 kg/cm)	100 kg/m^2	0.076	7.60	7.60
Bituminous emulsion (70%, 0.3 kg/m^2)	0.21 kg/m^2	0.55	0.12	–
Bituminous emulsion (70%, 1.0 kg/m^2)	0.70 kg/m^2	0.55	–	0.39
HaTelit C 40/17 eco asphalt reinforcement	0.27 kg/m^2	3.88	–	1.05
Total embodied CO$_2$ for rehabilitation	kg/m^2		7.72	9.04
Improvement factor	[-]		1	3
Design life (improved)	years		4	12
Total embodied CO$_2$ per year design life	kg/m^2/year		1.93	0.75
CO$_2$ saving per m^2 and year of design life				61%
Total CO$_2$ saving for improved design life				70,800 kg

The comparison of the ECO2 for the rehabilitation project has to be put into relation with the design life. The design life for the unreinforced overlay is set to 4 years until first cracking is likely to have reached the surface again. The reinforced overlay on the other side would last at least 3 times longer, i.e. 12 years.

The result is a saving of 61 % of ECO$_2$ per m^2 and year of design life for the HaTelit reinforced overlay as compared to the unreinforced overlay. For a project of 5,000 m^2 to be repaved this would mean a total ECO$_2$ saving of 70,800 kg based on the significantly improved design life of 12 years.

Many conscientious manufacturers provide Environmental Product Declaration (EPD) for their products and thus provide a basis for project owners to assess all potential environmental impacts of a product, system or solution during its entire life cycle (cradle to grave). Such EPDs are independently assessed and verified as per ISO 14025 and EN 15804. On this basis individual products, systems or construction methods can be compared for their environmental impact during initial construction and over the full service life of the infrastructure asset as shown here.

5 CONCLUSIONS

Reflective cracking occurs in cracked asphalt or concrete pavements rehabilitated with a simple asphalt overlay. To delay the development of reflective cracks, an asphalt reinforcement interlayer can be placed before the new asphalt wearing course. The presented research results and case study has shown that the use of an asphalt reinforcement made of high tenacity polyester (PET) in pavement rehabilitation can be advantageous, significantly improving the resistance to reflective cracking of the structure. This increase in service life has a number of financial and social economic benefits. The increased uptake of these asphalt reinforcement products, in particular those produced from recycled polyester, will help support the move towards a more circular economy and achieve net zero carbon emissions in the future.

ABSTRACT: Asphalt mixtures overlays are applied to an existing road pavement (flexible or rigid) when the structural or functional conditions of the pavement have reached an unacceptable level of deterioration. Most of the overlays are designed against fatigue and rutting failure mechanisms. Pavements that are structurally sound after the placement of the overlay and that are adequately designed against rutting and fatigue distresses may show cracking patterns after a short period of time that is similar to those that existed in the old pavement. This distress is known as "reflective cracking." Although reflective cracking is the most common failure mechanisms in rehabilitated pavements, it is rarely considered in the overlay design.

1   INTRODUCTION

During the last decades, the number of vehicles per citizen as well as the traffic speed and load has dramatically increased. This sudden and somehow unplanned overloading has strongly shortened the life of pavements and increased its cost of maintenance and risks to users (Polacco *et al.* 2015). In order to limit the deterioration of road networks, it is necessary to improve the quality and performance of asphalt pavements and designed to be resistance to fatigue and/or rutting failure mechanisms and mitigating reflection cracking. One of the most common techniques used to rehabilitate severely cracked pavements (load associated fatigue cracking, thermal cracking) consists in placing a Hot Mix Asphalt (HMA) overlay on the existing pavement (Romeo *et al.* 2014). Rarely this approach is a long-term efficient solution since deficiencies in the old pavement are very rapidly reflected at the surface as a result of the combined effects of thermally induced stresses and traffic loading.

The ability to distinguish crack resistance behavior and rank mixture performance in the laboratory can be a crucial asset to pavement engineers and also can serve in forensic analysis of pavement failures. In recent years, interlayer systems have received considerable

attention as viable solutions to the problem of improving flexible pavement resistance to reflection cracking in asphalt overlays, as well as to extend the pavement's fatigue life (Al-Qadi *et al*. 2003; Romeo & Montepara 2012).

2 LITERATURE REVIEW

The attempt to provide tensile reinforcement for asphalt pavements goes back to 1950s. At the beginning, all attempts to do so experience installation difficulties in laying the mesh flat but, later, with new technology (Marienfeld & Guram 1999). There was evidence of possible benefits related to the use of interlayers in road construction. The reason for the continued interest in interlayer systems is that, in terms of the mechanics of the materials, interlayers theoretically can reduce the occurrence of reflective cracking in AC overlays. Nowadays, interlayers can be used for both long-term road and cost-effective maintenance (Brown 2006). In particular, the reinforcement function in a continuum body is obtained by the insertion of reinforcing materials able to improve the mechanical properties of the continuum body. The reinforcement function in bound layers can be summarized in:

1. The extension of fatigue life or reduction of layers' thicknesses,
2. The elimination or limitation of reflective cracking,
3. The reduction of rutting and permanent deformation,
4. Interlayer systems to control reflective cracking.

Several remedial techniques have been used to control reflective cracking, including placing a thin layer or an interlayer system at the interface between the old and new layers, rubblizing the existing concrete pavement, crack-sealing the existing pavement, and increasing the thickness of the hot mix asphalt (HMA) overlay. Among these techniques, interlayer systems have been the most effective in controlling reflective cracking (Figure 1). Interlayer systems, which are relatively thin layers placed between HMA overlay and existing pavements, have two different mechanisms to delay reflective cracking:

1. By absorbing strain energy which occurs in HMA overlay;
2. By reinforcing the low tensile strength HMA overlay.

The efficiency of the interlayer depends on the appropriate selection of the interlayer system type, the interlayer conditions, correct installation, and the conditions and characteristics of the existing pavement and HMA overlay (Button & Lytton 2007).
Figure 1. Use of interlayers in mitigation of reflective cracking in asphalt overlays.

High modulus geogrids, such as fiberglass grids, are commonly used as reinforcing materials to control and retard reflective cracking in asphalt pavements. High modulus polypropylene grids, glass fabrics, and glass grids are classified as reinforcing geosynthetics and, if constructed properly, can redirect the reflective cracks along the interface and retard their progress (Lytton 1989). Grids are designed to have high modulus values at low strain levels so that they can engage in reinforcing the system and transfer loads throughout the grid system before the protected pavement layer fails in tension. Interlayer characteristics, including the interlayer bond, play an important role in the structural stiffness of the pavement system and in the distribution of the stress and strain within the pavement; thus, the long-term performance of pavements and cracking patterns depend on the interlayer bond and interlayer conditions (Canestrari *et al.* 2005). The retardation effect of fiberglass grids, which is an important mechanism that affects the performance and life cycle of the pavement, needs to be assessed and, if possible, quantified. To understand the various effects of interlayer systems more fully and to be able to predict the performance of reinforced pavements that incorporate different interlayer conditions, it is necessary to investigate the ways that different interlayer conditions affect the damage mechanisms, crack propagation rates, and crack patterns in the pavement structure.

3 GEOSYNTHETICS

The prevention of reflective cracking in asphalt overlays was one of the earliest applications involving geosynthetics in paved roads. Reflective cracks can occur in new flexible pavement overlays where pre-existing cracks are located within the old paved road. Reflective cracking may be triggered by bending and/or shear stresses induced by repeated traffic loads, as well as by tensile stresses caused by thermal variations (Button & Lytton 2003). Figure 2 shows the development of stresses resulting from lateral movements induced by flexing of the paved road located directly below the traffic load. Such stresses may end up causing a reflective crack that propagates through the new pavement overlay, making it susceptible to early failure facilitated by moisture intrusion.
Figure 2.   Use of geosynthetics in mitigation of reflective cracking in asphalt overlays: (a) roadway designed without geosynthetics, (b) roadway designed with geosynthetics (Zornberg 2017).

(Perkins & Ismeik 1997) illustrates the three reinforcement mechanisms geosynthetics can provide for roadways: lateral restraint, modified failure surface, and tensioned membrane. They explained how interlocking and friction between the geosynthetic and the soil provides a lateral restraint for the aggregate base layer. Under repeated loads, the aggregate base layer tends to spread laterally; however, if the geosynthetic is placed at a depth of high lateral strain, the shear stress in the soil can be transferred to tensile stress in the geosynthetic. If the geosynthetic used is stiff, it will act to restrain the lateral spreading and result in a stiffer road.

Geosynthetics are divided into seven major categories: geotextile, also known as paving fabric; geogrid; fiberglass; geocell; geomembrane; geonet; and geocomposite. Geotextile, geogrid, fiberglass, and geocomposite have been tested as reflection cracking control treatments by acting as reinforcement or as a strain energy absorber, also known as stress relieving layer. The effectiveness of these products as crack control treatments has been mixed and was reported to depend on many factors including the installation procedure and conditions of the existing pavement. Table 1 introduces the major types of geosynthetics that have been evaluated to control reflection cracking.

Table 1. Major types of crack control Geosynthetics.

Geosynthetics	Performance
Geogrids or Grid-reinforced	Reinforcement
Polyester geogrids	Reinforcement
Fiber glass geogrids	Reinforcement
Carbon geogrids	Reinforcement
Biaxial grids	Reinforcement
Geonets	Reinforcement
Paving fabric	Stress relief
Geocomposite	Stress relief
Woven geojute mat	Stress relief
Geotextile	Stress relief

4 EVALUATING EFFECT OF USING INTERLAYERS ON PERFORMANCE OF FLEXIBLE PAVEMENTS

Evaluation of the effectiveness of various antireflective cracking alternatives is a significant task and mainly realised by three methods: field project observation, finite element model (FEM) simulation and laboratory simulation. In addition to Digital image correlation (DIC) appears the most suited image processing technique for asphalt mixture investigation since it has shown to adequately detect anisotropies and heterogeneities typical of bituminous materials, i.e. defect or cracks within the skeleton.

4.1 Digital Image Correlation (DIC)

Digital Image Correlation (DIC) was used to track and measure the deformations, displacements, and strains on the surface of the specimens and especially at areas around the interlayer. Digital image correlation (DIC) appears the most suited image processing technique for asphalt mixture investigation since it has shown to adequately detect anisotropies and heterogeneities typical of bituminous materials, i.e. defect or cracks within the skeleton. Kim and Wen (Fallah & Khodaii 2015) first proposed the use of a DIC technique as a possible displacement/ strain measurement method for asphalt mixtures. They applied the DIC technique to determine the proper gauge length for a 100-mm diameter IDT specimen. Safavizadeh and Kim (Abe N. 2000; Anderson 2017; Smith 1983), Romeo and Montepara (Perkins & Ismeik 1997), used digital imaging techniques to evaluate the microstructure of

Grid-Reinforced asphalt Specimens, as well as Strain localization and damage distribution. They found that the most important advantages of using DIC for asphalt mixture testing can be summarized as follows:

1. It is a noncontact technique; this reduces setup timing and mounting errors;
2. It provides pointwise analysis pinpointing the location of crack initiation;
3. It accounts for non-uniform strain distributions (i.e. fracture process zone);
4. It provides flexibility since it allows a ''back analysis'' of the resulting strain field over an area of finite extent, preventing to mount multiple sensors in different locations.

4.2 *Modeling of interlayers- reinforced flexible pavements*

The finite element method (FEM) currently offers the level of sophistication needed to analyze a pavement section under applied wheel and environmental loading conditions. Numerical modeling is a useful tool for understanding the crack initiation and propagation in asphalt mixtures. Currently, two different numerical methods are employed. One is the finite element method and the other is the discrete element have been widely used to study the cracking behavior of homogeneous materials.

A mechanistic model based on the FEM is currently best suited to evaluate the effectiveness and benefits of including geosynthetic reinforcement in flexible pavements for improving the response behavior. (Eiksund *et al.* 2002) developed a 2-D axisymmetric finite element model for geogrid-reinforced flexible pavements using the ABAQUS^{TM} program. The Coulomb interface friction contact was used to model the soil/ aggregate–geosynthetic interface. The researchers examined the ability of the linear elastic constitutive models considering cross-anisotropic characterization of the unbound aggregate layer. They reported that the predicted pavement responses were affected by the material and numerical model properties such as reinforcement tensile stiffness and contact interface friction properties. The geogrid reinforcement limited lateral strains throughout the pavement section, and thus decreased pavement critical responses. The improvement from geogrid reinforcement was higher when a cross-anisotropic model was used in the unbound aggregate base. (Kwon *et al.* 2005) used the finite element method for modeling geogrid interface behavior, and reported that the predicted pavement responses obtained from 3-D ABAQUSTM analyses. FEMs of specimens with and without the stress-absorbing interlayer were constructed in accordance with the HWTT by finite element software ABAQUS, respectively (Kwon *et al.* 2005).

5 COST EFFECTIVENESS OF INTERLAYERS IN FLEXIBLE PAVEMENTS

Life-cycle costing can consider many cost components, particularly initial construction costs, maintenance costs, user costs (vehicle damage, user delay in work zones), and salvage value. Life-cycle costs were computed for two analysis cases, containing the following groups of cost components:

- Case 1 (neglecting maintenance and milling costs):
  – Hot mix asphalt overlay cost, in-place (material plus construction costs), and
  – In-place reflective crack control cost.

- Case 2 (maintenance and milling costs included):
  – Hot mix asphalt overlay cost, in-place (material plus construction costs),
  – In-place reflective crack control cost,
  – Periodic crack-sealing costs, and
  – Milling costs (removal of previous overlay lift).

The in-place costs of geosynthetics and other interlayers to address reflection cracking are influenced by (a) the specific product used, (b) the quantity to be placed, (c) local experience

with its installation, (d) local labor costs, and (e) the general condition of the market place. The in-place cost of fabrics has fallen significantly since the early 1980s, apparently because of stiff competition and perhaps improved contractor experience and acceptance of geosynthetics. In 1991, NCHRP Synthesis 171 offered the following rule of thumb: The in-place cost of a full-width paving fabric is roughly equivalent to the cost of approximately 0.5 in. to 0.6 in. of asphalt concrete.

Interlayer systems have been successfully used as a cost-effective method to alleviate reflective cracking (Baek *et al*. 2009). A study performed by (Morian *et al*. 2004) in Pennsylvania evaluated the performance and cost-effectiveness of cold-in-place recycling and SAMI in 49 sections. Results showed that the use of SAMI and cold in-place recycling improved pavement service life when compared to normal milling and leveling rehabilitation procedures (Heitzman 1992). While cold-in-place recycling extended the overlay service life by four to five years, the use of SAMI increased pavement service life by two years and proved to be cost-effective when compared to conventional leveling and milling procedures. Further, the application of the overlay when the pavement is in fair condition proved more cost-effective as compared to its application when the pavement reaches a poor condition. (Herbst *et al*. 1993) reported that overlays using stress-absorbing interlayers typically cost about 10 percent more than a conventional overlay. A few authors have reported that geotextiles are cost-effective treatments for prolonging overlay life (Collios 1993, Zapata 1958). A few more have reported that geotextiles are not cost effective for use on both flexible (Maurer *et al*. 1989, Button 1989) and rigid (Allen 1985; Heins 1992; Maurer *et al*. 1989) pavements. The economic justification of the geotextile must be derived from a combination of:

- An increase in pavement serviceability due to reduced reflective cracks,
- An increase in pavement life,
- A decrease in pavement maintenance costs, and
- An increase in structural capacity due to dryer base and subgrade.

ABSTRACT: In this study, the structural performance of road pavements with reduced layer thicknesses at different rates using geogrids was examined, and the benefits of geogrids in preventing rutting were investigated. Within the scope of the study, a total of 16 test sections of 50 meters in length, 12 with geogrids and four without geogrids, were constructed on the Adana - Kozan road determined by the General Directorate of Highways of Turkey (KGM). The constructed sections were divided into two, and besides the reference sections, two types of geogrids with different geometric structures were used in successive sections. Some layer thicknesses used in the study were determined following the specification, and the other part was determined through a pavement design program. In addition, to compare the effect of using geogrids in different locations on the pavement performance in the application sections, the geogrid was used in two positions, on the subbase layer and between the base layer. Data from the load, displacement and temperature sensors placed between the layers during the construction phase and on-site Heavy Weight Deflectometer (HWD) data at certain time intervals were used to observe the structural performances of the constructed pavement sections. In addition, GPS and IRI measurements are made regularly. The traffic values of the trial section are also monitored. Examining the obtained data aims to compare the economic gain achieved by reducing the layer thicknesses, the cost to be spent for the geogrid, and to make cost-benefit analyses.

Keywords: Highway pavement, geogrid, geosynthetics.

1 INTRODUCTION

This study examines structural performance by using geogrids in highway pavements and providing economic gain by reducing layer thicknesses. Kind of gains are obtained with the use of geogrid that will arise as a result of the achievement of the purpose of this study, and how these gains change with the place of geogrid in the pavement will be parameters that the outputs of the study can determine. The road pavement is expected to have excellent structural performance and comfort and be economical. When these parameters are taken into account, in addition to all the positive outputs to be obtained as a result of the study, the use of geogrid allows for a reduction in layer thicknesses, which means saving enormous amounts of labor, materials and natural resources.

The development of geosynthetics, a polymeric material, has brought about positive changes in geotechnical engineering (Das 2021). Geosynthetics are synthetic products widely used to solve many civil engineering problems and provide one or more functions such as protection, separation, filtration, erosion control, drainage and reinforcement (Giroud & Han 2004; Han J. & Thakur 2015). Specific properties are needed for geosynthetics to undertake different uses in different applications and perform various functions. First of all, it is necessary to know which of the functions, as mentioned earlier, are needed in order to determine the reason for the application. It should be determined which type of geosynthetic will be used and which properties will be according to the conditions where the application will be made (McGown & Brown 2008).

In terms of the applications of geosynthetics, roads can be considered in two categories as paved and unpaved roads (Wasti 2007). Yang *et al.* (2012), it has been observed that the use of geosynthetics has a significant effect on providing durability and reducing permanent deformations on unpaved roads.

Geosynthetics in road pavements started with woven and non-woven geotextiles with unscientific methods. While these materials had some advantages with their separation and filtering functions, they were ineffective for stabilisation (Brown *et al.* 1982). Due to the low stiffness of the geotextiles and their weak interaction with the surrounding materials, they cannot reduce the stresses accumulated during repeated loads. Later, Chan *et al.* (1989) used a medium stiffness geogrid in their work. Showed that a much more tightly woven geotextile reduced rutting depth in pavements with granular layers. Geogrids can reinforce unpaved roads (Benmebarek *et al.* 2013; Calvarano *et al.* 2016; Calvarano *et al.* 2017; Gabr 1998; Tingle & Webster 2003). One of the main reasons for the plastic deformations on the surface under cyclic loads is the inability to reduce the stresses reaching the granular layers and the subgrade. Minimizing the stresses that can reach the lower layers would be necessary (Dawson *et al.* 1994; Harianto 2022). Geogrids minimize the stresses that can reach the lower layers by interlocking and strengthening according to their region (Ibrahim *et al.* 2017). Using geogrid enables carrying the maximum load with minimum stress and increasing the elastic modulus of the place where it is used (Geosynthetic materials Association 2000; Laughs *et al.* 2009; Tensar Corporation 2017).

When geosynthetics are used between the subgrade and foundation layers, it ensures the separation of the two layers and prevents the mixing of granular foundation materials with the subgrade. In addition, geosynthetics used between the subgrade and the base layer increase the bearing capacity of the subgrade and strengthen the layers applied to it (Giroud & Han 2004).

2 CONSTRUCTION OF TEST SECTIONS

As a result of the preliminary studies, base, and subbase layer thicknesses were determined, some following the specifications, as shown in Table 1, and some by reducing as a result of modeling and analysis made in pavement design software.

Table 1. The layer thicknesses used in the study and the sections where the layer thickness is reduced.

Application Sections		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Layers and Thickness (cm)	Binder	11	11	11	11	11	11	11	11	7	7	7	7	7	7	7	7
	Bituminous Base	0	0	0	0	0	0	0	0	9	9	9	9	9	9	9	9
	Base Granular	15	15	15	20	20	20	20	20	10	10	10	20	20	20	20	20
	Subbase Granular	15	15	15	20	20	20	20	20	15	15	15	20	20	20	20	20

Base and subbase layers are applied by decreasing their thickness at sections 1, 2, 3, 9, 10, and 11, as shown in Table 1. After the first eight sections, the thickness of the binder layer was reduced by 4 cm to 7 cm, and a 9 cm thick bituminous base course was applied to the 10 cm aggregate base course. It is planned to evaluate the data obtained from type-1 and type-2 geogrids by comparing the plastic deformations in the sections where the layer thicknesses are reduced. In addition, productivity analyses could be made by comparing the sections prepared without using geogrids with the same layer thicknesses and using type-1 and type-2 geogrids in the study.

Type-1 and type-2 geogrids are applied in the sections:

- In sections 1, 2, 3, 4, 9, 10, 14, and 15, between the base and sub-base layers,
- Sections 6, 7, 12, and 13 were placed in the middle of the base layer (Figure 1).

As a result of the positive results that can be seen in the sections where the use of geogrid reduces the layer thicknesses, it is foreseen that the amount of material to be used in similar applications and the labor force will be reduced. Thus, both time and economic gain are provided. The sensors to be used in the study, their number and equipment were determined, and their procurement was carried out by the General Directorate of Highways (KGM). After the region where the test sections will be applied has been determined in line with the purpose of the application, the construction process has been completed, and the process of obtaining data from the sensors has been started. Basic information such as road profiles, geogrid layouts, sensor types, and placements are shown in Figure 1.
Figure 1. Schematic representation of the trial road.

The test road, built 850 meters, has the following elements:

- Four different road sections
- Two types of geogrids
- 8-channel fibre optic data acquisition device
- 16 test sections and measuring stations
- Dedicated server and control board
- 92 sensors

Types and numbers of sensors used at measuring points are:

- Sixteen soil pressure sensors (They are placed on the subgrades to determine the stresses reaching the subgrades).
- Sixteen vertical displacement sensors (placed in each section to determine the vertical displacements between the subgrade and the surface layer).
- Sixteen horizontal displacement sensors (They are placed under the coating layer to determine the horizontal displacements).
- Sixteen transverse and longitudinal strain sensors (For cable-type strain gauges to be placed on the pavement surface, channels were opened using an asphalt cutter, and cable-type strain gauges sensors were placed in these channels fixed with bitumen).
- Twelve temperature sensors (Channels were opened for temperature sensors to be placed on the subgrade, subbase layer, base layer and surface layer interface, and the sensors were placed and fixed).

Geogrids, which will be used in the construction of the test sections and which form the basis of the study, were determined in line with the purpose of use, and samples were obtained from the companies. After the strength tests of these samples were carried out in the laboratory, two different types of geogrids (Type-1 and Type-2) suitable for the study were shipped to the construction site in rolls. The biaxial and triaxial geogrids that are being provided by the two different companies feature rib openings that are 40 mm by 40 mm. The fiber optic sensors and data collection systems provided for monitoring the structural performance of the test road made within the scope of the study were tested in the Accelerated Pavement Test Device available in the Civil Engineering Transportation Laboratory of Süleyman Demirel University for trial purposes before the field application to be made. After the applicability of the relevant equipment was seen, all equipment was brought to the area where the application would be made, and assembly processes were carried out.

3 EVALUATION OF MEASUREMENT DATA

The performance of the road was also evaluated by on-site heavyweight deflectometer (HWD) tests performed at certain time intervals. There were no significant differences in the measurements made at different time intervals, but the conditions of the layer thicknesses and the sections using geogrids could be observed. It also provides information on the effects of two different geogrids on pavement performance (Figure 2).
Figure 2.   Heavyweight deflectometer (HWD) test results at different sections.

In order to determine the performance and road comfort, IRI (International Roughness Index) values were obtained by measuring the unevenness of the test road. Four years after the road was opened to traffic, the values obtained as a result of the tests

carried out to determine the unevenness were examined, and the conditions of the sections with and without geogrid were evaluated. It was observed that the unevenness values obtained from the sections without using geogrid were higher than the sections using geogrid (Table 2).

Table 2. Measurement of the International Roughness Index (IRI) of trial sections.

| Trial Sections | IRI | Layer Thicknesses | | | | With geogrid / without geogrid | Geogrid Location |
		Subgrade	Subbase	Base	HMA		
1	2.49	90cm	15cm	15cm	11cm	Type A Geogrid	Between Base and Subbase
2	2.38	90cm	15cm	15cm	11cm	Type B Geogrid	Between Base and Subbase
3	3.8	90cm	15cm	15cm	11cm	Without Geogrid	- - - - - - - -
4	2.23	80cm	20cm	20cm	11cm	Type A Geogrid	Between Base and Subbase
5	1.39	80cm	20cm	20cm	11cm	Type B Geogrid	Between Base and Subbase
6	1.45	80cm	20cm	20cm	11cm	Type A Geogrid	Middle of the Base
7	1.31	80cm	20cm	20cm	11cm	Type B Geogrid	Middle of the Base
8	1.56	80cm	20cm	20cm	11cm	Without Geogrid	- - - - - - - -
9	1.09	90cm	15cm	10cm	16cm	Type A Geogrid	Between Base and Subbase
10	1.06	90cm	15cm	10cm	16cm	Type B Geogrid	Between Base and Subbase
11	1.47	90cm	15cm	10cm	16cm	Without Geogrid	- - - - - - - -
12	1.22	75cm	20cm	20cm	16cm	Type A Geogrid	Middle of the Base
13	1.23	75cm	20cm	20cm	16cm	Type B Geogrid	Middle of the Base
14	1.17	75cm	20cm	20cm	16cm	Type A Geogrid	Between Base and Subbase
15	1.22	75cm	20cm	20cm	16cm	Type B Geogrid	Between Base and Subbase

While making IRI measurements, road sections are photographed separately, and the resulting deterioration is visually examined. In the image in Figure 3, when the rut settlement differences between section 7 with geogrid and section 8 without geogrid are observed, the rut settlement formed in the section without geogrid can be seen more clearly.

Figure 3. The difference in plastic deformations in the seventh and eighth sections.

4 RESULTS

This study carefully determined the principles be applied for the test sections and the materials used. The study aims to reduce construction costs by reducing layer thicknesses using geogrids. In order to increase the efficiency of the work carried out for the purpose and to prevent the adverse effects that may occur afterward, the materials to be used, their settlements and how they will give results were determined by conducting experiments in the Transportation Laboratory of Süleyman Demirel University before the construction started. Some of the pavement layer thicknesses used in the study were determined following the KGM (General Directorate of Highways of Turkey) specification, and the other part was determined using pavement design software.

Following the stages determined in the light of the data obtained as a result of the experiments, the application was carried out on the 850 m road section on the Adana - Kozan road. When the last data obtained are examined, since there is no significant deterioration in the trial sections, tests continue to be carried out at specific periods to see the performance of the applied geogrids. However, when the final IRI data is examined, it was observed that the IRI values obtained from the sections without using geogrid were larger than those used geogrid. This shows that the deterioration occurs more rapidly in sections with no geogrid. In the following periods, the data obtained from the test sections will be taken and analyzed, and the effects of different types of geogrids according to layer thickness will continue to be examined.

Carbon footprint of HDPE geomembrane *vs.* traditional waterproofing barrier

J.M. Muñoz
Sotrafa S.A. Almería, Spain

ABSTRACT: Lowering the Carbon Footprint is one of the most important reasons for using HDPE geomembrane instead of traditional ways of waterproofing such as compacted clay. An HDPE liner in 1.5 mm thickness could give similar watertight properties as using 0.60 m of high quality and homogeneous compacted clay with lower permeability than $1 \times 10\text{-}11$ m/sec (ASTM D 5887). Based on several scientific surveys, and when considering all resources and energy needed to install both products as a waterproofing barrier, the geosynthetic option (HDPE Geomembrane 1.5 mm) means a lower carbon dioxide equivalent, therefore it is a more environmentally friendly solution.

1   INTRODUCTION

The transition to a carbon neutral economy is a move to which most countries, as well as thousands of companies and a large part of civil society, are committed.

One of the ways to achieve this objective is to replace traditional waterproofing systems (clay-based) with a geosynthetic barrier, such as HDPE Geomembrane.

1.1   *Features of HDPE geomembrane and its carbon footprint*

The main component of HDPE is the monomer ethylene, which is polymerized to form polyethylene. The main catalysts are aluminum trialkylitatanium tetrachloride and chromium oxide.

The polymerization of ethylene and co-monomers into HDPE occur in a reactor in the presence of hydrogen at a temperature of up to 110° Celsius degrees (230 degrees Fahrenheit). The resulting HDPE powder is then fed into a pelletizer to produce pellets.

Then, SOTRAFA, as a manufacturer with the latest calandering (flat die) technology, manufactures ALVATECH HDPE Geomembrane from these pellets. The ALVATECH HDPE constantly retains its outstanding features whether it is a dry or wet season.

2   GHG IDENTIFICATION AND CO2 EQUIVALENTS

The GHGs (**G**reen**h**ouse **G**as protocol) included in the calculation were the three (3) primary GHGs, namely carbon dioxide, methane, and nitrous oxide. Each of these gases has a different Global Warming Potential (GWP), which is a measure of how much the given mass of a greenhouse gas contributes to global warming or climate change.

Carbon dioxide issues a GWP of 1.0. by definition. To quantitively include the contributions of methane and nitrous oxide to the overall impact, the mass of the methane and nitrous oxide emissions are multiplied by their respective GWP factors and then added to the

mass emissions of carbon dioxide to calculate a "carbon dioxide equivalent" mass emission. For purposes of this paper, the GWPs were taken from the values listed in the USEPA regulations "Mandatory Reporting of Greenhouse Gas Emissions" (USEPA 2010). The GWPs for the GHGs considered in this analysis are:

1. Carbon Dioxide = 1.0 GWP 1 kg CO_2 eq/Kg CO_2
2. Methane = 21.0 GWP 21 Kg CO_2 eq/Kg CH_4
3. Nitrous Oxide = 310.0 GWP 310 kg CO_2 eq/kg N_2O

Using the relative GWPs of the GHGs, the mass of carbon dioxide equivalents (CO_2eq) was calculated as follows:

$$kg\ CO2 + (21.0\ x\ kg\ CH4) + (310.0\ x\ kg\ N2O) = kg\ CO2eq \qquad (1)$$
Figure 1.   Energy required for production of common packaging polymers.
6 million Btu = 156 liters fuel equivalent = 1,758 KW*hour
(Franklin Associates, a Division of ERG 2007).
Figure 2.   Greenhouse gas emissions generated in polymer production.
(Franklin & Vink et al. 2007)

281

Assumption

The energy, water, and waste information from the extraction of the raw materials (oil or natural gas) through to production of HDPE pellets and then the manufacture of geo-membrane HDPE:

1. 1.5 mm thick HDPE geomembrane, with density 940 Kg/m3
2. HDPE carbon footprint is 1.60 Kg CO2/kg polyethylene (ICE 2008).

$$940 \ Kg/m3 \ x \ 0.0015 \ m \ x \ 10,000 \ m2/hectare \ x \ 1.15(waste \ and \ overlaps)$$

$$= 16,215 \ Kgr \ HDPE/hectare \tag{2}$$

$$E = 16,215 \ Kg \ HDPE/Ha \ x \ 1.60 \ Kg \ CO2/kg \ HDPE => 25,944 \ Kg \ CO2 \ eq/hectare \tag{3}$$

Assumed Transport: 15,600 sqm/truck, 1,000 km from manufacturing plant to project site.

1. 10.15 kg CO2/ gal diesel $\times$ gal/3.785 liters = 2.68 Kg CO2 /liter diesel
2. 0.26 g N2O/gal diesel $\times$ gal/3.785 liters $\times$ 0.31 kg CO2 eq/g N2O = 0.021 kg CO2 eq/ liter diesel
3. 1.44 g CH4/gal diesel $\times$ gal/3.785 liters $\times$ 0.021 kg CO2 eq/g CH4 = 0.008 kg CO2 eq/ liter diesel

Transport by road - transport emissions:

$$E = TMT \ x \ (EF \ CO2 + 0.021 \cdot EF \ CH4 + 0.310 \cdot EF \ N2O) \tag{4}$$

$$E = TMT \ x \ (0.972 + (0.021 \ x \ 0.0035) + (0.310 \ x \ 0.0027)) $$

$$= TM \ x \ 0.298 \ Kg \ CO2 \ eq/ton - mile \tag{5}$$

Where:

1. E = Total CO_2 equivalent emissions (kg)
2. TMT = Miles Travelled
3. EF CO_2 = CO_2 emission factor (0.297 kg CO_2/ton-mile)
4. EF CH_4 = CH_4 emission factor (0.0035 gr CH_4/ton-mile)
5. EF N_2O = N_2O emission factor (0.0027 g N_2O/ton-mile)

Converting to Metric Units:

$$0.298 \ kg \ CO2/ton - mile \ x \ 1,102 \ tons/tonne \ x \ mile/1.61 \ km = 0.204 \ kg \ CO2/tonne - km \tag{6}$$

$$E = TKT \ x \ 0.204 \ kg \ CO2 \ eq/tonne - km \tag{7}$$

Where:

1. E = Total CO_2 equivalent emissions (kg)
2. TKT = tonne – kilometers Travelled

Distance from Manufacturing Plant (Sotrafa) to Project Site (Hypothetical) = 1,000 km

– Typical Loaded truck weight: 15,455 kg/truck + 15,600 sqm $\times$ 1.5 $\times$ 0.94/truck = 37,451 kg/truck
– 0.641 truck/hectare

$$E = (1,000 \; km \; x \; 37,451 \; kg/truck \; x \; tonne/1,000 \; kg \; x \; 0.641 \; truck/hectare) \\ x \; 0.204 \; kg \;\; CO2 \; eq/tonne - km \tag{8}$$

$$E = 4,897.24 \; Kg \; CO2 \; eq/hectare \tag{9}$$

3 FEATURES OF COMPACTED CLAY LINERS AND ITS CARBON FOOTPRINT

Compacted clay liners have been historically used as barrier layers in water lagoons and waste containment facilities. Common regulatory requirements for compacted clay liners are a minimum thickness of 0.6 meters, with a maximum hydraulic conductivity of 1×10^{-11} m/sec.

Table 1. Summary of geomembrane HDPE 1.5mm carbon footprint.

Process Step	Kg CO_2 eq/Ha	Assumptions
Manufacturing Geomembrane HDPE 1,5mm	25,944	From ICE 1.6a (polyethylene) = 1.6 tonnes CO_2/tonne PE
Transport to site	4,897	1,000km from Manufacturing Plant to site
TOTAL	30,841	Kg CO_2 eq/10,000 sqm

The process:

Clay at source is excavated using standard construction equipment, which also loads the material onto tri-axle dump trucks for transport to the site. Each truck is assumed to have a capacity of 15 m^3 of loose clay. Using a compaction factor of 1.38, it is estimated that over 550 truckloads of clay would be needed to construct a 0.6-meter-thick compacted clay liner over a one-hectare area.

The distance from the source to the job site is, of course, site-specific and can vary greatly. For the purpose of this analysis, a distance of 16 km (10 miles) was assumed. Since transport from the clay source and the project site is such a large component of the overall carbon emissions, the sensitivity of the overall carbon footprint to changes in this site-specific variable is investigated later in this study.

4 CONCLUSION

Considering everything mentioned above, this study clearly demonstrates the huge advantage of using geosynthetics over traditional materials. When it comes down to waterproofing, ALVATECH HDPE Geomembrane in 1.5 mm is by far the best choice, as not only does it ensure outstanding long-term features (high chemical resistance and strong mechanical properties) but it is also a much more environmentally friendly solution.

It has 3 times less carbon footprint, even when using good quality clay transported 16 km from extraction source to site, as this can be compared with geomembrane HDPE supplied by truck and travelling 1,000 km from manufacturing plant to site.

That is why ALVATECH HDPE is being installed in a wide range of applications for cover and ground protection in demanding industries such as mining, oil, landfills, waste-water treatment and irrigation lagoons.

Table 2. Summary of compacted clay liner carbon footprint.

Step	Kg CO_2 eq/Ha	Assumptions
Excavate clay at Source	2,656	CAT 329 Excavator, Operation 40 hours/ha. Assume 24,5 litres/hr fuel consumption, based on medium work application and medium engine load factor (CAT performance handbook)
Haul Clay to Job Site	93,527	Assume site is 16km from source, and 552 truckloads (each carrying 15m^3 of clay) are needed Process to cover 1 hectare.
Construct Clay liner CAT D6 Bulldozer	2,789	Operation 40 hours/ha. Assume 25,7 litres/hr diesel fuel consumption
Construct Clay liner CAT 815 Sheepsfoot compactor	4,553	Operation 40 hours/ha. Assume 42 litres/hr diesel fuel consumption
Construct Clay liner CAT 815 Smooth drum compactor	4,553	Operation 40 hours/ha. Assume 42 litres/hr diesel fuel consumption
38,000 litres water truck	1,518	Operation 40 hours/ha. Assume 14 litres/hr diesel fuel consumption
TOTAL	109,593	Kg CO_2 eq/10.000 sqm lined area with compacted clay

Ultimately, we hope you find it interesting, and we appreciate your consideration on the limitations of our research, as we are aware that there are some recent and interesting studies that incorporate the calculation of geomembrane life cycle and water footprint, among others.

Vertical drainage of compressible soils subjected to artesian pressure under the Moroccan high-speed railway line

A.H. Mridakh
Department of Mines, Mines School of Rabat, Resources Valorization, Environment and sustainable Development Research Team (RVESD), Morocco

H. Ejjaaouani
Laboratoire Public D'Essais et D'Etudes, Casablanca, Morocco

ABSTRACT: Due to the environmental concerns, sustainable soil improvement methods are considered an essential part of the modern infrastructure development. Today's environmental sustainability policy often expects noise-free, chemical-free and low-carbon processes, while being economical. In this context, the application of prefabricated vertical drains (PVD) with preloading is considered a sustainable soil improvement Method. However, the presence of some unique hydraulic systems such as the artesian pressure and its effect on geo-structures is rarely discussed in the literature. Furthermore, the effect of the artesian pressure on the PVD's performance is one of the most important questions that needs to be addressed. For that, a numerical modeling approach is used to study the performance of a well instrumented section of the high-speed line Embankment, over a shallow artesian aquifer in Drader compressible area, Morocco. In addition, a comparison between the performance of PVD-Preloading system with and without the artesian pressure is presented.

1 INTRODUCTION

The presence of artesian pressure in Drader area under the Moroccan High-speed railway line was first noticed during the subsoil in situ investigation campaign. However, its presence is known by early geological and hydrogeological investigations (Cirac 1985; Combe 1963). A few case studies have mentioned the subject of artesian pressure induced head (Kim 2008; Kim & Do 2010) in the literature. Meanwhile, recently Mridakh *et al* (2022) investigated the dispositional characteristics of Drader under artesian pressure. Mridakh *et al* (2022) investigated the deposition and the artesian aquifers (shallow and deep) location, soil characteristics, soft soil compressibility and behavior. He also reported that artesian pressure from shallow aquifer had affected the deformation magnitude and rate.

In a similar case study in Busan marine clay, Nakdong river, south Korea; Kim and Do (2010) examined the leaching effect on the compressibility indexes. Kim *et al* (2018) studied the soft soil in a large one-dimensional column test in the laboratory with and without artesian pressure. In addition, Kim *et al* (2018) matched the predicted settlement from Busan marine clay with measured settlement from the field.

To understand the effect of artesian pressure on the PVD (Prefabricated vertical drains) performance in Drader basin, Morocco; we investigated the consolidation behavior in a well instrumented embankment section. For that, a series of artesian pressure mean values were performed based on sessional artesian pressure variation, from which we included only a selected value of an artesian pressure of 40 kPa that was drawn from the study. We compared the measured settlement and lateral movement with the predicted settlement and lateral movement with and without artesian pressure effect.

2 SITE DESCRIPTION AND MONITORING

2.1 *Site description*

Drader area is located in the N-W region of Morocco (Figure 1). It is marked by marine and continental deposits, formed during the recent Plio-quaternary epoch (Cirac 1985; Le coz 1964). Plio-quaternary soft soil deposits are mainly present in Drader area the central part between two hills (Lalla Zahra hill *et al*. 2022), in form of blackish compressible soils and loose sands (Combe 1963). From the tectonic structures and sedimentary mode, the deposition configuration has been described as a lacustrine deposition environment.
Figure 1.   Location of the high-speed railway line.

2.2 *Data-base*

The data-base collected during the geotechnical investigation campaigns used a number of boreholes, CPT's (Figure 2) to identify subsoil layers to construct a comprehensive cross-section (Figure 2, Mridakh *et al* 2022). Samples from boreholes were prepared for laboratory testing, such as oedometer tests (for obtaining modified compressibility index λ^* and the modified swelling index K^*), direct shear tests, density, water content.
Figure 2.   Soil characteristics variation based on CPT measurement.

As shown in Figure 2, the choice of the laboratory test is based on CPT's, and borehole logs. The maximum resistance shown in Figure 2 indicate sandy layers, and low cone resistance values identify soft soil layers where oedometer tests have been performed.

2.3 Field monitoring

The cross-section in Figure 3 shows the instrumentation equipment installed under the selected embankment section, such as settlement cells (SC), inclinometers (INC), interstitial pressure sensors (IPS). The embankment construction was done during 3 phases; phase 1 for constructing 5 m embankment, phase 2 attaining 9 m height, phase 3 to reach 10 m height plus 1.5 m surcharge (30KPa). In addition, Figure 3 shows the PVD arrangement under the embankment with 25 m depth and 1 m spacing.
Figure 3.   Field monitoring and PVD's arrangement.

3   NUMERICAL MODELING

3.1   Constitutive models

The constitutive models are selected based on the embankment-soft soils types used in the lithological model, to precisely capture the overall soil behavior during the embankment construction. Herein, we used 3 constitutive models such as Mohr-Coulomb model for sand layers (the embankment and layer 1 see Table 2), soft soil model (SSM) for sandy silts, soft soil creep (SSCM) for clay layers.

3.2   Input parameters

The input parameters indicated in Table 1, shows the PVD configuration and parameter and Table 2 the subsoil input parameters.

Table 1.   The parameters of PVD-improved soft soil ground.

s (m)	r_s (m)	r_w (m)	d_s/d_w	k_h/k_s	D_e/d_w	q_w ($m^3/year$)
1	0.15	0.03	4,4	20	17	100

Table 2. The input parameters of SSM and SSCM in numerical analysis.

Layer	Depth (m)	K^*	λ^*	μ^*	μ^*/λ^*	k_h (m/day)	k_v (m/day)	k_{ve} (m/day)
L1	0–1	–	–	–	–	2.5E-2	2.5E-2	1.0E-1
L2	1–3.5	0.020	0.08	1.80E-3	0.022	2.6E-4	1.3E-4	1.0E-2
L3	3.5–5.5	0.006	0.03	–	–	2.0E-3	1.4E-3	6.4E-2
L4	5.5–10.5	0.016	0.07	1.9E-3	0.027	3.0E-4	4.3E-4	3.5E-4
L5	10.5–13	0.04	0.02	–	–	5.5E-4	3.7E-4	2.1E-2
L6	13–14	0.020	0.07	1.6E-3	0.023	1.2E-5	6.0E-6	1.0E-5
L7	14–17	0.006	0.02	–	–	8.3E-3	5.5E-3	1.5E-1
L8	17–18.5	0.04	0.09	1.2E-3	0.017	1.3E-4	1.9E-4	1.1E-2
L9	18.5–38	–	–	–	–	2.5E-2	2.5E-2	1.0E-1

The equivalent vertical permeability parameter (k_{ve}) values present in Table 2, represent a method developed by Chai *et al.* (2001). The k_{ve} is calculated based on the following expression:

$$k_{ve} = \left(1 + \frac{2.5l^2}{\mu D_e^2}\frac{k_h}{k_v}\right)k_v \qquad (1)$$

Where l = drainage length, D_e = diameter of unit, k_h, k_v = horizontal and vertical hydraulic conductivity respectively. The parameter μ is calculated by the following expression:

$$\mu = \ln\frac{n}{s} + \frac{k_h}{k_s}\ln(s) - \frac{3}{4} + \pi\frac{2l^2 k_h}{3q_w} \qquad (2)$$

Where $n = D_e/D_w$ (d_w = diameter of vertical drain); $s = D_s/D_w$ (d_s = diameter of smear zone), k_s = horizontal hydraulic conductivity in the smear zone; q_w = discharge capacity of the PVD . r_w and r_s are the radius of the mandrel and the smear zone respectively.

4 RESULTS AND DISCUSSIONS

To apply the artesian pressure effect in the numerical model, we assumed that the artesian pressure is acting upward on soft soil layer layer above the confined aquifer, and the artesian pressure is decreasing linearly in the upward direction until reaching the top layer. Figure 4 shows the estimated effective stress and pore pressure distribution when applying a selected AP of 40 KPa.

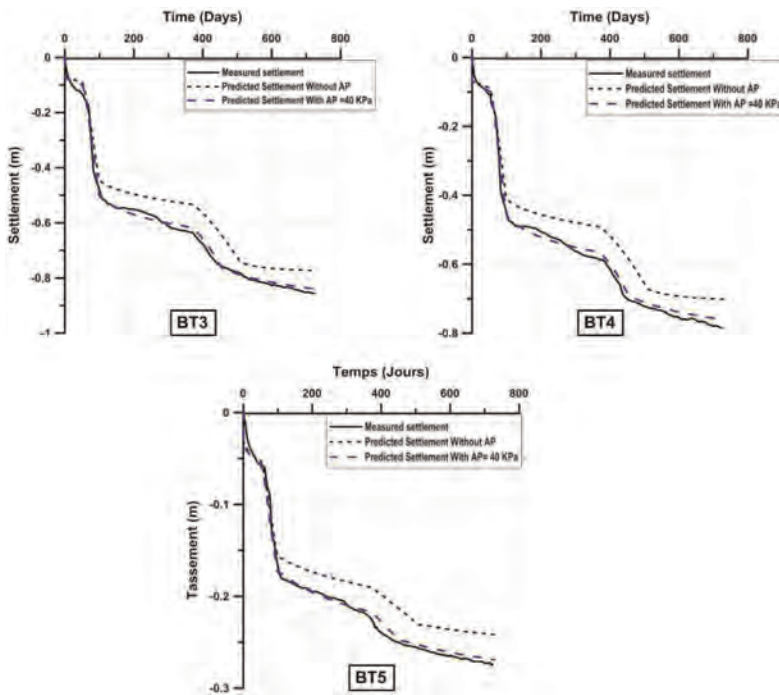
Figure 5 shows a comparison of vertical deformation from numerical analysis and measured results in three positions, under the embankment centerline, crest and slope (BT3, BT4 and BT5 respectively). The numerical results of the PVD improved deposits using an artesian pressure has shown a good agreement with the measured settlements under the embankment centerline, crest and slope when including the 40 KPa artesian pressure in the analysis. Whereas when excluding the artesian pressure, the model under predicts the settlement in all position under the embankment. Hence, the artesian pressure has an important effect on consolidation in regard of the PVD improved Drader area deposits. Therefore, the artesian pressure interferes with PVD effect on speeding up the consolidation by increasing the artesian pressure played an inversed role, by decreasing the undrained shear strength, which affects the performance of the PVD role during the embankment construction.
Figure 4. Distribution of mean pore pressure and resulting effective stress as a function of depth.


Figure 5. Measured and predicted settlements under the embankment.

Figure 6 shows a comparison between the predicted lateral movement and the measured results for the whole embankment construction period. The predicted lateral movement when including the artesian pressure of 40 KPa showed a fairly close agreement with the measured results. Hence, including the artesian pressure in the numerical model is of a big importance for predicting accurate lateral movement values under the embankment Toe.
Figure 6. Measured and predicted lateral movements.

5 CONCLUSIONS

This paper describes a detailed numerical analysis that was conducted to analyze the effect of artesian pressure on the consolidation behavior of a PVD improved subsoils in Drader area under the Moroccan High-speed-railway line. The subsequent conclusion can be presented:

1. The consolidation process in the PVD improved Drader area, was affected by the artesian pressure upward flow.
2. PVD effect on consolidation was negatively affected by the artesian pressure. Meaning that, the soil supposed to gain more shear strength when using PVD's and also speeding up the consolidation process. However, the artesian pressure players an important role on decreasing the Shear strength of the subsoil, thus increasing deformations during the embankment construction.
3. When including artesian pressure in the numerical analysis, the predicted vertical and lateral deformation were in good agreement with the measured in situ deformation.

Dowaco, The Netherlands

ABSTRACT: This article presents an overview of climate change research, predictions of global sea level rise, the increasing effects on coastal and riverine areas all over the world and furthermore an extensive overview of geosynthetic applications for flood defenses and coastal protection. Sea level rise, an important consequence of climate change, will lead undeniably to increasing problems concerning the safety against flooding and major challenges in design and construction of embankments. Where coastal and riverine areas are highly populated or have high economic value (business areas/industrial sites), flood protection schemes will require increasing efforts and capital investments. For climate adaption of flood defenses the application of geosynthetics can be of major importance. Building with geosynthetics is highly sustainable and enables the use of local less suitable soils. This results in reducing the use of primary granular building material, limiting transport distances and most importantly: decreasing substantial CO_2 emission. Other distinctive aspects are increasing construction speed, optimized building cost efficiency and reducing the amount of required space. Geosynthetics can be applied to ensure stability (embankments with reinforced soil and geogrids), top soil erosion control (3D structural mats, reinforced grass), coastal protection (sand-filled elements with bags, tubes or containers), controlling water level differences (drainage mats) or sealing levees (Geosynthetic Clay Liners - GCL). Implementing geosynthetics to meet one of these various functions to levees or coastal protection can give a considerable boost to the ambitions of global flood protection programs. For the big challenge to climate adaption geosynthetics will contribute to adapt safe and resilient living areas for humanity.

1 INTRODUCTION

The consequenses of global warming are evident and undeniable. More extreme weather conditions as well signs of sea level rise can be seen all around the world. The global sea levels have risen about 0.20 m during the last 100 years. However, the speed is increasing and research predicts 0.70 m sea level rise in 2100 with appr. 66% reliability [1]. Due to climate change also other hydraulic conditions are changing rapidly, with heavier rainfall conditions, more severe storm conditions, higher river discharges, increased flow velocities and wave overtopping. As billions of people are living in low laying areas near rivers and coastlines this will give major challenges to secure and improve flood defenses and flood

protection schemes worldwide. Inevitable some living areas will be abandoned. All these threats influence already political decisions on transferring societies to more sustainable living. In the coming decades, huge improvement operations have to be initiated to keep as far as possible human living areas safe and resilient to climate change.

2   CLIMATE CHANGE IMPACT

2.1   *Sea level rise*

Sea level rise is one of the consequences of global warming. This relation is almost universally accepted today. The effect and consequences for people on earth are enormous. The IPCC (Intergovernmental Panel on Climate Change) has made global assessments of possible scenarios with predictions of sea level rise between 0.3 m and 1.5 m up to 2150 depending on the climate scenario [1]. A combination of measurements and predictions of sea level rise is given in Figure 1. A probabilistic study from 2017 indicates that with accelerated land ice loss in Antarctica the projected sea level rise could even increase to 1.8 m in 2100 (median value, scenario DP16, [4]). To compare, global sea level rise over the past 100 years was about 0.2 metres. Evaluations of measured sea levels between 1993 and 2018 in Australia show an increase of about 0.08 m over the last 25 years, already showing an accelerating trend (Australian Government Meteorological Office [5]). This presents clearly the major challenges in reinforcing or realising new flood defenses.
Figure 1.   Projected global mean sea level rise under different SSP scenarios in timeframe 1950-2150 given in different colours and reliability range by IPCC (Box TS.4 Sea Level, [1]).

2.2   *Impact climate change*

The predictions of sea level rise obviously contain uncertainties, but even if values reach only half the predicted values, this already will have significant consequences for the safety, liveability and sustainability of residential, commercial and agricultural areas. Effects such as dune and beach erosion along coastlines as a result of high-water conditions will become increasingly frequent and intense (see Figure 2). The costs of maintaining coastlines will increase rapidly. Furthermore, sea level rise will lead to an increase in saline seepage. This salinization of groundwater will have considerable consequences for agricultural production in coastal areas. For the Netherlands the possible consequences of accelerated sea level rise have been charted [6]. Considerably more beach nourishment is to be expected, structural measures to maintain the fresh water supply and water safety, higher and wider flood defenses, and considerably higher frequencies in closing storm surge barriers like the Eastern Scheldt barrier in The Netherlands. In addition to increased sea levels, there are also other

climate effects, like more extreme weather conditions having longer periods of intense drought or on the contrary more severe rainfall. Extreme discharges in the large European rivers such as the Meuse, Rhine, Donau and Volga will be higher and more frequent. The opposite is also possible: in 2018 large areas of Europe experienced a period of extreme drought with virtually no precipitation between the months of May and November [8]. In 2022 there was again exposure with sever droughts between April and August, resulting in extreme low river levels in large parts of Europe. Dehydration can have disastrous consequences to flood defenses. Extreme droughts affects deterioration and disappearance of peat layers and crack formation in impermeable clay layers [7]. The extreme droughts caused the major collapse of a peat levee near Wilnis NL in 2003 (Figure 3), resulting in flooding of the residential area behind and major capital damage.

Figure 2. Severe dune erosion after storm surge, Egmond aan Zee lighthouse, The Netherlands.

Figure 3. Arial picture peat levee collapse, caused by dehydration during extreme draught, 2003 Wilnis Netherlands.

2.3 *Impact damage or protection measures*

The global damage costs as a result of flooding's due to sea level rise are expected to increase enormously. A study published in 2018 [2] shows that at 0.86 cm sea level rise (RCP8.5 scenario, median value) and without additional measures for flood defenses, the worldwide estimated annual flood damage costs in the year 2100 are 11600 billion Euro/year. If measures are taken to improve coastal protection, these annual damage costs could be reduced by about a factor 10. But the amount still remains enormous, indicating that the impact of sea level rise and consequential costs of flooding will be very high for all coastal areas worldwide.

By Deltares a study is done to look on the possible effects of accelerated sea level rises [6]. One effect is beach nourishment. The current situation involves the annual implementation of 12 million m^3 of sand on or in front of the beaches in The Netherlands to protect the existing coastline coasting appr. 42–60 million Euro. With a sea level rise of 15 mm/year there is a quantity needed 4 to 5 times as much, which could already be reached in 2050. In case of acceleration the amount and costs for maintaining the shoreline will be unprecedental. Another effect is the time period of protective measures. From the 90's safety measures could be taken with a functional lifetime of appr. 65 years. In case of acceleration this would be around 2060 reduced to a period of 20 years and upto the year 2100 even reduced to 10 years cycle. This would mean that steps for climate adaption will become increasingly difficult based on planning, efforts and financial costs. This results to an infeasible task living and fighting against rising water. Drastic measures and building methods to strengthen levees and coastlines will be needed.

Table 1. Amount of sand annually needed and related costs beach nourishment in The Netherlands [6].

Sea level rising speed (mm/year)	Required volume of sand (million m3/year)	Cost of beach nourishment (million Euros)
2	8	28–40 €
3	12 (current *)	42–60 €
5	20	70–100 €
12,5	50	175–250 €
30	120	420–600 €
40	160	560–800 €
60	240	840–1200 €

* current situation 12 million m^3 annual required sand for protecting the existing NL coastline.

3 GEOSYNTHETIC APPLICATIONS IN FLOOD DEFENSES

3.1 *Functions and applications to flood defenses*

For flood defenses, geosynthetics can contribute to many functions, like erosion protection, reinforcement, separation, sealing, drainage and filtration. The potential contribution using geosynthetics in levee reinforcements is considerable. For a long time, the construction of flood defenses has been focused on traditional methods using natural materials like sand, clay and stones [9]. However, increased safety requirements, preservation of landscape and buildings, rising sea levels and other climate effects continuously increase the complexity of levee reinforcements. Alternative and innovative techniques are increasingly seen as necessary and highly desirable, given the challenges for levee reinforcements in time. Also financial budgets for flood control will be more under pressure. Figure 4 shows a cross section of a flood defence construction, with multiple geosynthetics for various functions. These multiple geosynthetic applications in flood defences reduce the use of primary soil building materials, stimulate the use of locally available soil and reduce the environmental impact by a significant lower CO_2 emission.

Figure 4. Systematic section of a high-performance flood defence construction with soil reinforcement, geosynthetic clay liner as a barrier, nonwoven geotextile for filtration and separation and erosion control products on the embankments.

To ensure flood security levels the speed and frequency of levee reinforcements will increase in the coming decades. Knowing this, it is very important that the design is made in such a way that the structure as easily as possible can be adapted during the next dyke

reinforcement. In doing so, (geosynthetic) materials should also be easily removable from the ground again or structures which are extendable.

Embedding geosynthetics on larger scale into designs can result in a better, faster and/or cheaper construction of new flood defenses, levee reinforcements or coastal protections. This could give a considerable boost to the ambitions of global flood protection programs. Large-scale application with high performance geosynthetic building material in flood defenses has major potential. This paper illustrates the potential and added value of engineered materials to flood defenses to support the use of these alternative materials by designers, contractors and authorities.

3.2 Geotextile filter constructions under stone revetments

3.2.1 Single nonwoven filter systems

Construction of hydraulic filters can traditionally be done by using rock gradings in multiple layers according to filter rules concerning soil gradings, properties and hydraulic wave conditions. Doing so, traditional filtersystems can result in construction layers of 1–2.5 meter thickness. In lot's of countries rock is not widely available, and the rock must be transported over far distances. Single non-woven filter systems can be installed on the profiled subsoil and can fully replace the bottom filter layer. This can save between 0.3–1.0 m of granular filtermaterial. Beside these savings also CO_2-emissions can be reduced with appr. 40–50% due to far lesser transport of materials. Due to the easiness of installation and cost efficiency. Geosynthetic filtersystems in rock revetments are widely used in hydraulic engineering projects. In Figure 5 an example is given of the construction of rock revetment, placed on a nonwoven filter. For the application it's very important to consider the filter rules and add adequate robustness to avoid damage by dropping stones (see paragraph 3.2.4).

Figure 5.   Filter construction using a non-woven geotextile underneath a rock top layer.

Figure 6.   Fascine mattress with geotextile filter layer and brushwood wickerwork as a filter construction underneath riprap.

3.2.2 Fascine mattress applications

A fascine mattress is a floating filter system which is prefabricated on land, towed onto the water to the construction site and submerged on location by controlled rock dumping. Initially, fascine mattresses were completely built up with natural materials, using willow branches and reed. Developments with geosynthetics made it possible to replace the reed and most of the willow branches by a geotextile since '70's. Willow branches are attached to the loops of the geotextile, making a square pattern (see Figure 6). This pattern stabilizes the fascine mattress for moving the fascine mattress into position. As towing and positioning by cranes can initiate large forces to the geotextile attention should be paid to the robustness of the materials used.

3.2.3 Sand mattress applications

A sand mattress is a geocomposite, existing of 2 layers of non-woven with a sand fill in between. By needle punching a firm heavy product is obtained for underwater installation. A sandmattress is delivered on rolls and can directly be installed from the slopes of banks into the water. Installation can be done by rolling out using a crane with a long reach, equipped with a hydraulic spreader bar (see Figure 7).

Figure 7.   Installation of geocomposite sandmattress as filter layer below a stone revetment.

3.2.4 Rock dumping impact on geotextiles

Rock dumping on the geotextiles can cause serious damage. Various innovation and research programs are running to understand failure mechanisms of filter systems and improve design and application rules. Example is a CROW working group for geotextiles in rock revetments, active since 2019. This working group initiates field- and laboratory tests to understand the behaviour of geosynthetics with the energy impact by dropping stones. Multiple fieldtrial drop tests are done to analize the failure mechanism and dependency of the subsoil (clean loose sand, stiffer layering or intermixed with gravels). This is illustrated in Figures 8 and 9. Before the performance and failure mechanisms are also tested with laboratory research in Ghent [13,19].

Figure 8.   Fieldtrial drop tests with selected stone classes on nonwoven geotextile and analysis of failure mechanism and test conditions subsoil.

Figure 9.   Fieldtrial drop tests with selected stone classes on nonwoven geotextile and analysis of failure mechanism and test conditions subsoil.

Figure 10.   Drop tests with standardized stone shapes and weight on composite geotextiles (woven/non-woven) at Ghent University.

These imply large scale droptests in laboratory conditions to single products and geocomposites (woven/nonwoven) with standardized stone shapes and weights (Figure 10). All data will be analyzed and embedded to an update of the NL design guide on geotextile filtersystems in rock revetments. See also Bezuijen [22].

3.3   Water barriers with Geosynthetic Clay Liners (GCL)

Traditionally, natural clay has been used to create artificial low permeable layers in flood defenses, both for the construction of the entire levee, sealing embankments or sealing the foreshore. In order to obtain adequate water retardation and erosion resistance, this clay must meet high requirements. Erosion-resistant clay is becoming increasingly scarce near project sites and often has to be transported from far away regions. This results in increasing construction costs and environmental impact. As an alternative to a thick layer of natural clay, it's possible to implement a Geosynthetic Clay Liner (GCL) to river levees. These mats with a thickness of approximately 1 cm, consist of multilayer high-quality geotextiles with bentonite powder in between. GCL's can be used to seal the foreland as an anti piping measure, or the levee itself. In addition to cost savings, the application of GCLs offers other major advantages to the use of clay: sustainability (energy requirement and CO_2 emissions for transport), construction speed (less deep excavation, no dewatering required), more use of near-site soil and less soil investigation required. Due to the swelling capacity of the bentonite, the mat is self-healing to a certain extent. Leakage through small holes (in the order of centimeters) for instance caused by mice or root growth will be stopped by swelling of the bentonite.

In Germany multiple projects with GCL's on flood defenses have been executed in the last decades, like along the Oder levee. The introduction of GCL's to in The Netherlands is done in 2 pilot projects initiated by Water Authority Limburg NL, being the levee reinforcement in Beesel and Neer. In Beesel the GCL is applied on the crest and slopes of the levee to replace a natural clay layer (see Figure 11). At the project in Neer the seepage length is extended by using GCL's to prevent piping (Figure 12).

Figure 11.   Installation Geosynthetic Clay Liner (GCL) on a levee reinforcement to replace a 1 meter thick clay layer (Beesel Netherlands).

Figure 12.   Horizontal installed Geosynthetic Clay Liner (GCL) in the levee foreland to enlarge the seepage length from the flood defense base.

3.4   Geosynthetic Sand Containers (GSC's) for coastal protection and anti-scour

One of the oldest applications of geotextiles in flood defenses is large geobag elements filled with sand. In 1957 these were already used to seal the Pluimpot, a small estuary near Tholen, The Netherlands. In the following years geotextile elements were further developed. Small elements like geobags can be filled on site and installed on beaches to stabilize the coastline

(Figure 13). Sand filled geotextile bags can also be used in deeper water to prevent scouring or to fill-up (big) scourholes. Scouring can occur in riverbeds by floods with extreme discharges, in harbours or by hydraulic turbulence to structures like dams and outlet structures. An example is the North Sea flood barrage in the river Eider (Germany), were major scouring was detected. After extensive research on the remedial measure to be taken, it was decided to fill the scourhole with 48.000 sandfilled geotextile bags to stabilize the underwater slope.

Geotextile elements are regularly used as breakwaters, dune foot defense structures, erosion protection or water retaining structures. These applications are used globally. The use of geotextile elements in coastal or flood defense structures could substantially reduce the risks and effects of beach and dune erosion. This may reduce the number of beach nourishments, cost and maintenance frequency of beaches and dunes after severe storms. Much literature is available on the application of geotextile sandfilled elements. A good overview of possibilities, research and calculations is given in several publications [16, 17 and 18].

In the area of Lubmin on the Baltic Sea, the existing coastline with sand dunes has been severely impacted by multiple storm surges. A solution is being implemented with a hidden underground protection using Geotextile Sand Containers (GSC). To reinforce approximately 2 kilometers of coastline, in total 34,000 sandfilled elements were installed. The elements weigh approximately 1.4 tonnes each and are used to construct the underground coastal defence structure below the beach surface. The bags are laid in two rows, inclined to the long side and stacked in an offset manner (see Figure 14). Being covered with sand, the structure is no disturbing factor in the landscape. Also important is that after implementating the hidden protection measure the beach area has no restrictions for tourism and beachlife.
Figure 13. Schematic cross-section dune protection with Geotextile Sand Containers (GSC) underground structure, covering with beach sand and planting with helm grass.

Figure 14. Installation of Geotextile Sand Containers as coastal protection measure in the dune core of the sandy beach, Ludmin Germany.

3.5 *Erosion protection with 3D structure mats*

As a result of climate change there are higher waterlevels, currents, waves or heavy rain to be expected. Based on this more robust and intelligent erosion protection systems of flood defences will become increasingly important. Water levels will rise and the question is whether we can continue to build fully flood-resistant structures, or whether a certain degree of water spillover should be accepted. In the case of overflow levee structures, robust erosion protection is key.

Embankments can be protected against erosion in a natural way by a good (grass) vegetation with a clay under layer. This requires deep and good grass rooting of which the development takes in general at least two growing seasons. In The Netherlands it is mostly accepted that the turf has insufficient strength in the first months or even years, relying on

the erosion resistance of the underlying clay layer. Also additional measures are taken at floods by installing so called cramming mats (geotextiles) over young turf to protect these from erosion. In other countries the requirements for initial strength of vegetated slopes at embankments are often higher. For example anchored three-dimensional geosynthetic structure mats are often used in America, but this application is also increasing to the European continent.

These 3D structure mats can be used to reinforce the top soil layer on embankments (see Figure 15). This mat provides protection of the bare soil or early vegetation, thus providing extra resistance to erosion. This prevents grass seed or young vegetation from being washed away, thus ensuring homogeneous germination. The effect of this is the development of a better-quality grass vegetation. In addition, the structure mat provides a permanent reinforcement of the top layer in the root zone. This may be necessary at locations where higher loads are expected, such as wave action, overtopping water and currents. In addition, the mat provides reinforcement in the case of a poor subsoil (grass on sand conditions) or where local damage can occur (animal burrows, sheep pathways, bicycle tracks, along stairs, structures, side's road pavements on the crest, etc.). During wave overtopping tests carried out on vegetated embankment slopes, it was observed that accelerated failure can occur in the event of local damage to the grass vegetation [20]. Extensive tests [21] were carried out to determine the erosion resistance including HPTRM (high performance turf reinforcement mats).

Figure 15. Installation of a reinforced High Performance Turf Reinforcement Mat (HPTRM) for slope protection.

In case of desirable rapid vegetation development, the choice can be made not to use grass seeds, but to apply hydro-mulching. In this process, a mixture of grass seed, nutrients and organic fibers is sprayed hydraulically into a 3D structure mat. For hydro-seeding or -mulching, attention must be paid to the quality of the seeds, nutrients and structure mat as all components have a major influence on obtaining a well-covered slope. Related to climate change seeds are to be chosen that are suitable for the changing climate conditions (more intense periodes wet and dry conditions). Research is also done to use different herb-mixtures, which stimulate also bio-diversity to levees.

Special attention should be paid to all types of transitions on slopes as often the loads are higher and the strength is less. In The Netherlands field tests on reinforced transitions are planned.

3.6 *Soil reinforcement for stability and steep slopes*

Raising embankments on soft soils can cause stability problems. A regularly applied solution is the installation of high strength soil reinforcement below the embankment. High strength

reinforcement can be in the range of 300–1500 kN/m and can exist of woven-fabric, knitting or high-strength geogrids.

At the Oder levee along the German-Polish border a levee stretch with a length of 3 kilometres was reconstructed to withstand more extreme flood conditions. Soil investigations below the dyke stretch revealed relatively deep soft layers of peat, organic silt and clay. In order to ensure sufficient stability of the new dyke, a high strength geogrid of 1000 kN/m was installed as basal reinforcement (Figure 16).

Figure 16.   Installation of high strength geogrids as basal reinforcement below the flood defence at the Oder dike, Germany.

Another application of geogrids to flood defenses is the realisation of steep slopes to reduce area use. Next to many flood defenses there are existing structures, like houses. In case of levee crest raising the footbase of the flood defence would be enlarged also. In case of space shortage, vertical constructive elements are designed to flood defenses, like sheet pile or concrete walls. When hard constructions like sheet piling are used in a levee, calculations show that these are heavily loaded, because this is a relatively stiff (settlement free) structure within the more flexible soil body.

As alternative steep slopes or even vertical retaining walls to flood defenses can be realized using geogrid reinforced soil structures. A description of implementation of geogrid reinforcement to flood defences is described in [11]. A comprehensive overview of possibilities, research and calculations is included in a publication on retaining structures of reinforced soil [15]. Retaining walls using geosynthetic reinforcement are generally flexible and are able to deform together with subsoil settlements. This makes geosynthetics ultimate suitable for levee reinforcements to soft soil areas. By using Finite Element Models (FEM) the effect between forces, deformation and interaction between soil and geosynthetics can be determined in detail. Due to the interaction, geosynthetics constructions behave as a block stabilization with considerable redistribution capacity. Another consideration is from research in Japan it is observed that reinforced soil structures behave very stable during earthquakes and big hydraulic impacts like tsunami's [14].

3.7   *Geosynthetic 3D composite drainage systems at levee structures*

As a result of higher water levels outside the levee and subsidence in the polders, the hydraulic loads on flood defenses will increase. The increase of the hydraulic head will have a negative effect on the stability of flood defenses. The hydraulic pressures can be positively influenced by using geosynthetic drainage systems, described in a publication of drainage techniques to levee structures [10]. Figure 17 shows the installation on a slope with a

geocomposite drainage system and a Geosynthetic Clay Liner (GCL) on top. Levee drainage can be useful to avoid failure mechanisms such as macro and micro stability, but also piping. Examples of drainage are vertical wells, gravel boxes, horizontal drains or geosynthetic drainage mats. These drainage mats consist of geosynthetic 3D structure composites, which must be pressure-stable under the given conditions. These drainage mats can be installed vertically (for example as toe drainage), horizontally (partly under the embankment core or berm) or on the slope. This is illustrated in Figure 18.

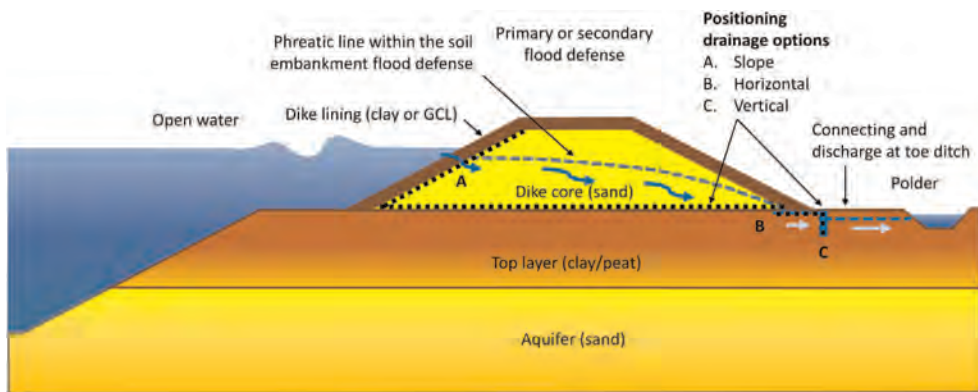
Figure 17. Geosynthetic drainage composite mat (white color) with a Geosynthetic Clay Liner (GCL, light brown) on top as sealing system.


Figure 18. Schematic cross-section with freatic head in a river levee and options to decrease that phreatic head applying geosynthetic drainage systems, at slope (A), horizontal (B) and vertical (C).

4 CONCLUSIONS

Climate change will have significant effects on flood defenses globally. Aspects such as sea level rise and extreme weather conditions will have major consequences for the safety, quality of life and sustainability of residential, industrial and agricultural areas. In the coming decades huge and costly operations to flood defenses have to be initiated to keep local areas, larger regions or full countries safe and sustainable.

This article discusses the problems and effects of climate change and the potential positive role that geosynthetics can play in new or existing coastal and riverine flood defense systems: more sustainable, faster and/or cheaper construction. There are also major challenges in making (future-proof) designs with geosynthetics in embankments. Levees must be adaptable for subsequent levee reinforcements, in which case applied geosynthetics in the levee should not be an obstacle. When adapting future flood defences, geosynthetics should then be easily removable, re-usable or recyclable. In some application areas geosynthetics in flood defenses are still in an initial stage of development. Development of integrated concepts with geosynthetics offers a major potential to flood protection. Implementing geosynthetics to levees or coastal protection can give a considerable boost to global flood protection programs. For the big challenge to climate adaption geosynthetics can contribute to adapt safe and resilient living areas for humanity.

Integrating engineered and nature-based solutions for riverbank stabilization

D. Loizeaux, J. Hill, M. Patton & J. Hoilman
Solmax, Chattanooga, Tennessee, USA

ABSTRACT: Adding resilience to flood defense structures is critical to mitigating the impacts of climate change and natural disasters. Integrating engineered erosion control systems with nature-based infrastructure provides an effective solution for hazard mitigation that yields environmental and economic benefits. This presentation will highlight how Engineered Earth Armoring Systems can be combined with vegetation to provide resilient and long-term flood mitigation. It will also highlight fieldwork from a bank stabilization project on the Des Moines River. Palo Alto is the 13th largest agricultural producing county in Iowa, with an estimated $468,000,000 in crops and livestock reported in 2017. The West Fork of the Des Moines River cuts diagonally through the County, providing drainage for approximately 4,660 square kilometers of farmland. During rain events, the river would often flood this area, causing erosion on an upstream bend. The flooding impacted nearby roadways and a historic bridge, resulting in a nearly 40-kilometer detour for travelers. Between 2006 and 2019, flooding events caused severe bank erosion to occur on the river bend. Along roughly 215 linear meters of riverbank, up to 65 m of horizontal erosion occurred, losing over 1.25 hectares to erosion within this timeframe. If an erosion control solution was not implemented, then the historic bridge and surrounding roadway would continue to be at risk. The Sioux City Natural Resource Conservation Service (NRCS) and Palo Alto County originally considered the use of rock riprap or gabion hard armoring to control the erosion, but ultimately looked for a more cost-effective, nature-based solution. A combination of the Engineered Earth Armoring Systems was used to stabilize the bank and protect against scour, erosion, and surficial slope instability while promoting vegetation.

1 INTRODUCTION

Palo Alto is the 13th largest agricultural producing county in Iowa, with an estimated $468,000,000 in crops and livestock reported in 2017. On average, each farm in Palo Alto County covers about 175 hectares and each acre is essential for the farm's livelihood. Simply put, land is important and losing it to erosion is not an option.

The West Fork of the Des Moines River cuts diagonally through Palo Alto County, providing drainage for approximately 4,660 square kilometers of farmland. 485th Avenue and 425th Street intersect along the West Fork of the Des Moines River and are connected by the Kirby-Flynn Bridge, a historic pin-connected Pratt high-truss bridge dating back to 1881. During rain events, the Des Moines River would often flood in this area, causing erosion on an upstream bend and flood waters to inundate the bridge, resulting in a nearly 40-kilometer detour for travelers.

Between 2006 and 2019, flooding events caused severe bank erosion to occur on the river bend just upstream of the Kirby-Flynn Bridge. On this roughly 215 linear meters of riverbank, up to 65 m of horizontal erosion occurred, losing over 1.25 hectares to erosion

within this timeframe (Figure 1). If an erosion control solution was not implemented, then the historic bridge and surrounding roadway would continue to be at risk. The NRCS and Palo Alto County originally considered the use of rock riprap or gabion hard armoring to control the erosion, but ultimately looked for a more cost effective, nature-based solution.

Figure 1.   Erosion along West Fork of Des Moines River in 2020 upstream of the Kirby-Flynn bridge.

2   ENVIRONMENTAL CONSIDERATIONS

The West Fork of the Des Moines River flows generally southeast across western Iowa converging with the East Fork at the Frank A. Gotch Park south of Humboldt, IA. The project site is located approximately at river mile 44.5 of the West Fork of the Des Moines River which is environmentally regulated by the by the Iowa Department of Natural Resources (IA DNR). The IA DNR is responsible for managing fish and wildlife programs, ensuring the health of Iowa's forests and prairies, and providing recreational opportunities in Iowa's state parks. Additionally, the DNR carries out state and federal laws that protect air, land, and water through technical assistance, permitting and compliance programs.

To ensure compliance, the IA DNR Water Quality Monitoring and Assessment Section assess streams, creeks, waterbodies, etc. to determine if they are meeting state and Federal water quality standards. The IA DNR does not list the West Fork in the vicinity of the project location as a 303(d) impaired stream, meaning that its pollution does not exceed the standards for one or more water quality criteria.

A great variety of wildlife are common along the West Fork, including herons, shorebirds, songbirds, owls, hawks, eagles, beavers, and turtles. Per IA DNR, several threatened and endangered species including birds, fish, insects, plants and reptiles are located in Palo Alto County. Wildlife are particularly abundant as the river flows through several wildlife management areas including the Brushy Bayou Wildlife Area located approximately 2.4 kilometers upstream of the project site. Additional recreation areas including the West Fork Wetlands are located downstream of the project area. The West Fork Wetlands provide an excellent habitat for ducks and geese, wild turkeys, many fur bearing animals as well as non-game species.

Using satellite photos of the project site from 2006 to 2019, the right descending bank has eroded as much as 65 linear meters horizontally into the adjacent agricultural fields (Figure 2). From these same photos, it was determined that approximately 1.25 hectares of land was lost to erosion over the 13 years. Using an average vertical height of 1.8 m over this area yields nearly 2,300 CM of soil loss. This volume would equate to almost 8 hectares of stream bed covered in 30 cm of soil.
Figure 2.   Des Moines Riverbank Erosion: Blue 2006, red 2016, green 2019.

3 HYDRAULIC DESIGN

From 2006 to 2019, 1.25 hectares of streambank was lost to erosion. The design goal of the project was to restore the channel back to its 2006 alignment. The NRCS provided design criteria that protection would be needed for whichever was greater between ½ of the height of the bank or the 5-year storm event. In 1984, the United States Army Corp of Engineers (USACE) performed a study on the West Fork of the Des Moines River. In that study, storm flows were developed for the 2-year, 5-year, and 10-year storm events. The results from that study can be found below in Table 1.

Table 1.   Storm events for design.

Storm Event	Flow Rate (m^3/s)	Flow Depth (m)
2-year	56.9	2.03
5-year	131.4	3.29
10-year	207.6	4.19

The bank was measured to have a maximum height of 4.9 m. Therefore, for this design, the 5-year storm event depth of 3.3 m controlled the portion of the slope that would require protection. In order to protect the riverbank, Palo Alto County chose to use a combination of the SCOURLOK® and ARMORMAX® Engineered Earth Armoring Solutions.

SCOURLOK is a solution designed to resist extreme hydraulic and non-hydraulic stresses and provide riverbank stabilization that can be vegetated. SCOURLOK is constructed of PYRAMAT® 75 High Performance Turf Reinforcement Mat (HPTRM) and interlocking, zinc coated carbon steel baskets lined with GEOTEX® nonwoven geotextile. The vegetative pockets and tops of SCOURLOK are designed to be filled with organic growth media for vegetation. SCOURLOK provides permanent erosion protection from the time of initial construction. The 1.2 m high by 0.9 m wide SCOURLOK units can be stacked and offset for various configurations and can be filled with on-site soil or granular fill, depending on the suitability of the soil. SCOURLOK has superior ultraviolet (UV) resistance, strength, and durability withstanding the most demanding environments.

ARMORMAX 75 is an Engineered Earth Armoring System used for erosion control and surficial slope stability applications. It is composed of two components: PYRAMAT 75

306

HPTRM and Engineered Earth Anchors. The PYRAMAT 75 component provides resistance to erosion and distributes the load amongst the anchors. The anchor component is specifically designed and tested for compatibility and performance with HPTRM and works to permanently secure the PYRAMAT 75 HPTRM as well as increase erosion resistance.

Two SCOURLOK units were placed along the 2006 alignment to provide enough height to provide protection for the 2-year storm events, which occur more frequently. A 12 m wide floodplain bench, protected by ARMORMAX 75, extended behind the first section of SCOURLOK to provide increased erosion resistance above the 2-year events. An additional SCOURLOK unit was placed at the edge of the 12 m floodplain bench to provide protection for the 5-year storm events. The ARMORMAX system utilized above the second tier of SCOURLOK helped provide increased erosion resistance for the 5-year and 10-year events. This riverbank SCOURLOK and ARMORMAX engineered earth armoring configuration is depicted in Figure 3.
Figure 3.   SCOURLOK / ARMORMAX Riverbank cross-section configuration.

4   GEOTECHNICAL EVALUATION

From a geotechnical perspective, the stability of a slope or wall is a complex interaction of soil layers and the pore water pressure within those layers. Understanding the soil layers within a given project site, and the overall subsurface characteristics of the area, will allow a licensed geotechnical engineer to be less conservative with the design and get a more accurate factor of safety (FS). The calculated FS is a ratio of resisting forces (such as the friction angle of the soil) to driving forces (such as weight/gravity). A FS value less than 1.0 means the slope or wall is unstable and failure is imminent, while a FS value greater than 1.0 means the wall is stable and some outside force will have to interact with the area to cause a failure. Knowing what types of soil comprise a given slope or wall is imperative to calculating an accurate FS.

When evaluating the proposed bank stabilization solution, the soil information available consisted of an NRCS soil map that depicted the soil type to be Wabash silty clay for the project area. This was incorporated into the design as a low strength clay, using an angle of internal friction (ϕ) of 23 degrees and a cohesion (c) of 0 kPa for conservative purposes. The clay on site was classified as an MH/CH which is a high-plasticity clay or silt. This highly plastic material is not self-consolidating and hard to compact, so it was deemed unsuitable for infill within the SCOURLOK units. A suitable fill material would need to be imported for the infill of the units.

Since this project involved the design of SCOURLOK and ARMORMAX, it was best to start the design of the wall or earth retaining structure with SCOURLOK first. The design of an earth retaining structure incorporates three separate analyses. The first two analyses are base sliding and overturning, which follow Coulomb's theory for lateral earth pressure. The

weight of the SCOURLOK wall needs to resist the driving force generated by the weight of the retained soil and any external forces. The third analysis is for bearing capacity to evaluate the foundation soil when the SCOURLOK wall is placed on top of it. Typically, the FS targets for base sliding, overturning, and bearing capacity are 1.5, 2.0, and 2.0 respectively.

For the bank stabilization of the Des Moines River in Palo Alto, two separate SCOURLOK configurations were considered as previously depicted in Figure 3 for the different size storm events. Each configuration considered the Wabash silty clay as the foundation and retained soil, and a more self-consolidating, free draining soil as the infill in the SCOURLOK units. The first was a 1-1 configuration used for the 2-year event, incorporating 1.8 m long Engineered Earth Anchors in each cell and a flat slope above (Figure 4). The factors of safety for this configuration were as follows: 1.57 for base sliding, 2.89 for overturning and 2.19 for bearing capacity. The second was a 1-unit configuration for the 5-year event, incorporating 1.8 m long B2 anchors in each cell and a 5H:1V slope above (Figure 5). The factors of safety for this configuration were as follows: 1.85 for base sliding, 4.14 for overturning and 2.78 for bearing capacity. Both configurations met all three target factors of safety.
Figure 4.   1-1 Anchored SCOURLOK configuration.
Figure 5.   1-Unit anchored SCOURLOK configuration.

When arriving on site for the installation, the Wabash silty clay was found to only be present on the surface of the soil. Most of the soil on site consisted of free draining sand.

While this caused some unexpected challenges during the installation process, the increase in the retained soils overall internal angle of friction added to the FS for the gravity wall calculations. The highly plastic clay described in the NRCS soil map was expected to aid more in water retention during construction than the sand that was on found on site. Instead of water coming into the project area from one location, the river, water was coming into the area from all directions. While the installation conditions were different than originally assumed, SCOURLOK was able to be installed due to its flexibility in application (Figure 6). While the installation had its challenges, the SCOURLOK system was designed to meet these challenges as it can be used in a wide range of environments and situations.

Figure 6.   Installation conditions for SCOURLOK.

5   SOLUTION AND INSTALLATION

Installation of the bank stabilization solution began in November 2020, beginning with the lower 1-1 section of SCOURLOK. Once the lower section was completed, the upper 1-unit section of SCOURLOK was then installed, followed by the ARMORMAX system between the SCOURLOK sections and along the above sloped area (Figure 7). The contractor was able to use material from a sand bar to fill the SCOURLOK units, providing an efficient installation and minimizing the import of any fill or rock. "Propex provided a high level of technical direction to ensure a successful project even with a contractor who was unfamiliar with the SCOURLOK product. We feel the project will stop the severe erosion that had been occurring on the riverbank and will save the bridge that would be in danger of washing out otherwise," said Rick Hopper, Director of Engineering at Jacobson-Westergard & Associates. The

Figure 7.   Installation of SCOURLOK and ARMORMAX, January 2021.

installation was completed by February 2021 and vegetation had begun to establish by the summer of 2021.

The SCOURLOK and ARMORMAX Engineered Earth Armoring Solutions have been able to provide a vegetated, nature-based solution for severe riverbank erosion. The systems have been engaged several times during flow events since installation and are performing as designed. Their durability and ability to incorporate reinforced vegetation will allow for a long term, environmentally friendly solution (Figures 8, 9, and 10).

Comparative life cycle assessment of geosynthetics versus conventional construction materials in infrastructure, filter function in a river construction, a study on behalf of the EAGM

H. Ehrenberg
Naue GmbH & Co. KG, Espelkamp, Germany, on behalf of EAGM

ABSTRACT: The European Association of Geosynthetic product Manufacturers (EAGM) commissioned ETH Zürich and ESU-services Ltd. to quantify the environmental performance of commonly applied construction materials (such as concrete, cement, lime, or gravel) versus geosynthetics for 4 cases. Geosynthetic materials are used in many different applications in civil and underground engineering. In most cases, the use of geosynthetic material beneficially replaces the use of other construction materials. To this end, a set of comparative life cycle assessment studies are carried out, concentrating on various functions or application cases. The environmental performance of geosynthetics is compared to the performance of competing construction materials used. Further new cases have been evaluated since 2020. This paper presents the results of a case with a filtration function (the construction of a filter, where geosynthetics are used, is compared to the case of a mineral filter) in a river construction with a typical geotextile filter in comparison to a gravel/sand filter. The study shows benefits in sustainable constructions using geosynthetics.

1 INTRODUCTION

Geosynthetic materials are used in civil engineering in many different areas. In most cases, the use of geosynthetics replaces or improves the use of other materials. For the first time in 2010, the European Association of Geosynthetic Materials Manufacturers (EAGM) commissioned ETH Zürich and ESU-services Ltd. to quantify the environmental impact of commonly used construction materials (such as concrete, cement, lime, or gravel) compared to geosynthetics in civil engineering.

To this end, a series of comparative life cycle assessment (LCA) studies were conducted focusing on different use cases, namely filtration, foundation-stabilised road, landfill construction, and slope stabilisation structures. The environmental performance of geosynthetics and competing construction materials was compared.

In 2018, it was verified if the obtained results were still up to date or whether the study needs to be renewed. EAGM commissioned treeze Ltd (the successor company of ESU-services Ltd) with the review.

The assessment confirms the timeliness of the study. The full study, including the results of the critical reviews, is available at: http://www.eagm.eu/. The latest results were presented in detail at EUROGEO 7 in Warsaw in 2022. In 2021 and 2022, another study was prepared based on the findings, which are presented in detail below.

2 FILTRATION FUNCTION INFRASTRUCTURE IN A RIVER CONSTRUCTION

This paper presents the results of a case with a filtration function (the construction of a filter where geosynthetics are used is compared to the case of a mineral filter) in a river construction

with a typical geotextile filter in comparison to a gravel/sand filter. The study shows benefits in sustainable constructions using geosynthetics. treeze Ltd. evaluated the study.

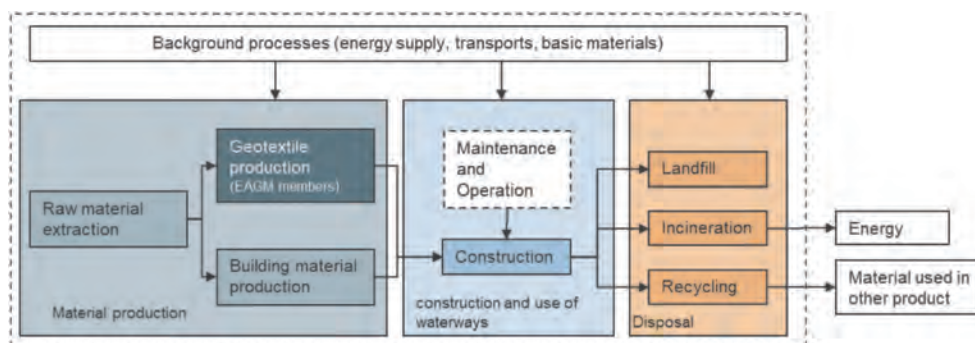
The life cycle assessments carried out within this study follow a cradle-to-grave approach. The product systems of the waterway analysed encompass the extraction of the raw materials, their processing into building materials, the construction and disposal of the waterway (infrastructure element, see Figure 1). Operation and maintenance of the waterways are excluded. Transport processes and infrastructure are included. All processes describe average European conditions.


Figure 1. Simplified process flow chart showing the most important process steps. Maintenance and operation of the infrastructure element are not included in the system boundaries.

The lifetime of the waterways is expected to be the same (100 years) for both options assessed in this study.

7 European producers, all members of the EAGM, provided data on the production of geosynthetic materials. The required data were collected by means of prepared questionnaires. An industry expert provided data on construction and de-construction efforts. The primary source of background inventory data used in this study is UVEK LCI data DQRv2:2022. The LCA software SimaPro v 9.3.0.3 was used to model and calculate the life cycle based environmental impacts.

The first seven environmental impact category indicators form part of the Environmental Footprint method v3.0 published by the European Commission (2017). The cumulative non-renewable energy demand is based on the approach published by Frischknecht *et al.* (2015).

– climate change (greenhouse gas emissions),
– photochemical ozone formation (summer smog),
– particulate formation,
– acidification,
– freshwater eutrophication,
– land use impacts,
– abiotic resource depletion (minerals and metals)
– cumulative energy demand (primary energy consumption), non-renewable

Sensitivity and uncertainty analyses were carried out to learn more about the stability of the comparative results. Not included are:

– Operation and maintenance of the infrastructure element (e.g. shipping, cleaning) because these activities do not differ between the alternatives;
– Manufacturing equipment (machinery) at the geosynthetics manufacturer's site, because of its minor importance (see e.g. Frischknecht *et al.* 2007);

– Operation of the storage of raw and geosynthetic materials at the manufacturer's site because the energy consumption is considered negligible;
– Packaging of the geosynthetics because they are of minor importance (less than 3% of mass contribution);
– Efforts and emissions of thorough end-of-life cleaning (decontamination) of the filter materials because of missing information and empirical data.

The study refers to the year 2019. Foreground data about geosynthetic materials gathered by questionnaires refer to 2019 or, in a few exceptional cases, 2018. Data available about further material inputs and the use of machinery are somewhat older. The characterisation of the waterway analysed represents current best practices. Age differences are discussed in the data quality section of the results chapters.

All data refer to European conditions. Some background data referring to Switzerland are used to estimate European conditions, particularly regarding landfilling and incineration of wastes.

3 EVALUATED CASES

The waterways assessed in this report are defined in a way that they represent commonly applied new constructions. Nevertheless, construction methods may vary from one EU member state to the other. Thus, the case should be perceived as an exemplary model of the common and frequent application of geosynthetic materials in waterways. The functional unit is 1 meter of an inland waterway with a width of about 34 meters (water level, see Figure 2). The upper layer consists of water stones in both cases. The filter layer is either gravel/sand of two times 20 cm (left side see Figure 2) or a geosynthetic filter (right side see Figure 2).
Figure 2.   Cross-section of the waterway analysed in this study (left: gravel filter; right: geosynthetics filter).

The two alternatives are defined such that they can be considered technically equivalent or at least comparable. The geosynthetics used represent a mix of different brands suited for waterways. Scenario 2 and 3 include a typical geosynthetic as used in Germany in this application. The conventional systems represent the most common type of construction.

3.1 *Base scenario*

The base scenario shows a geosynthetic filter with a specific weight of 350 g/m^2 and a shipping distance of mineral material (water stones and gravel/sand filters) of 20 km. Based

on the evaluation with 7 manufacturers of the EAGM for the year 2019, the delivery distances and the type of transports are determined.

For the raw materials, an average distance of 820 km was evaluated, with a weighted distribution of 600 km per truck and 220 km per ship.

For the nonwovens, an average distance of 795 km was evaluated, typically by truck (62%) and in special cases by train (38%).

Alternatives to the base scenario are described in detail in the following Table 1.

Table 1.   Overview of different scenarios.

	Unit	Base	Scenario 1	Scenario 2	Scenario 3
Geosynthetics basis weight	g/m^2	**350**	350	750	
Distance supply of mineral materials	km	**20**	50	20	50

3.2 *General information*

The calculated nonwoven geosynthetics used in waterways construction are made from polypropylene staple fibres and have a specific weight of about 350 g/m^2. In some countries like Germany, geosynthetics with a specific weight of 750 g/m^2 are used. The life cycle inventory of manufacture of nonwoven geosynthetics is based on data and information provided by seven European manufacturers. They collected data on consumption of raw materials, working materials, packaging materials, fuel, steam and electricity consumption, water consumption and release, pollutants emissions to air and water, wastes (including the kind of treatment), supply and delivery logistics, as well as land use and infrastructure (such as factory halls and office buildings). Production volume weighted average datasets on the manufacture of nonwoven geosynthetics with a specific weight of 350 g/m^2 and 750 g/m^2 were established.

The material demand of gravel/sand was determined by Norbert Kunz, BAW (Bundesanstalt für Wasserbau, Germany; Federal Waterways Engineering and Research Institute, Germany) based on the regular cross-section of a typical inland waterway. The material additionally excavated is assumed to be shipped to a landfill site over a distance of 20 km.

4 RESULTS OF THE SCENARIOS

4.1 *Detailed results base scenario*

Figure 3 shows the comparison of all impact categories and gives in detail the proportion of each construction / production step.

For example, the first part shows

– in the first line the highest proportion of greenhouse gas emissions with e.g. roughly 30% (light blue) for the construction efforts and
– in the second line the highest proportion of greenhouse gas emissions with e.g. roughly 20% (brown) for the deconstruction efforts

In general, the first line (greenhouse gas emissions) shows that the geosynthetic construction method reduces the production of greenhouse gas emissions by more than 25% compared to the classic construction method.

The results for the scenarios 1, 2 and 3 are similar and can be seen in detail at www.eagm.eu.
Figure 3.   Environmental impacts and their main contributors caused by 1 m of the inland waterway (width of about 34 m, water surface) relative to the environmental impacts of the waterway with gravel/ sand (which equal to 100%); base scenario.

5   SUMMARY OF RESULTS

Two significant impacts discussed in the last years are climate change (greenhouse gas / CO_2 emissions) and cumulated energy demand. In the last years, the saving of natural resources, e.g. minerals (abiotic resource depletion), is coming more in mind.

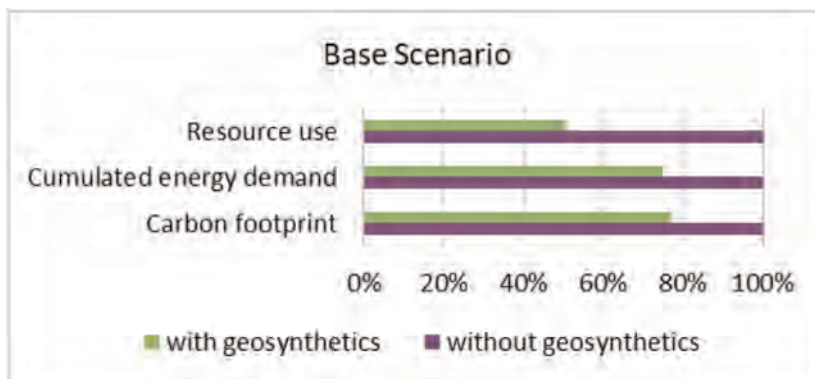
Figure 4 shows that the use of a filter nonwoven leads to lower impacts compared to the classic construction with a mineral filter layer in the base scenario.


Figure 4.   Relative differences in resource use, cumulated energy demand and carbon footprint; base scenario (details see Table 1, 350 g/m^2 geosynthetic, 20 km transportation distance for minerals).

The results for the scenarios 1, 2 and 3 are similar and show that the use of a filter nonwoven in all three above-mentioned impact categories leads to lower impacts compared to the classic construction with a mineral filter layer in all four evaluated scenarios. The results can be seen in detail at www.eagm.eu.

6 CONCLUSION

Given the goal in the European Climate Law of the European Union to become climate neutral by 2050, a further and substantial reduction in greenhouse gas emissions and other impacts is required. This involves low CO_2 construction equipment and freight transports, and the reduction in greenhouse gas emissions during the manufacture and disposal of geosynthetic materials. Filters constructed in Europe may differ in cross-section and materials used. Thus, generalised assumptions were necessary to model a filter layer of a typical channel.

In this study, the environmental impacts of construction and deconstruction of two different alternatives for inland waterways were quantified and assessed. The results show that the alternative with a geosynthetic filter causes up to 50% less environmental impact than the alternative with a gravel/sand filter. Even with the least favourable alternative for geosynthetic filters with a relatively heavy geosynthetic (750 g/m^2) and in comparison, a rather short transport distances (20 km) for the mineral components, emissions are reduced when using the geosynthetic filters.

Furthermore, it was shown that the use of geosynthetics means a high saving of natural resources, as minerals such as sand and gravel from a mineral filter are saved.

Displacement-based design method to increase sustainability of pile-supported embankments: Practical application

V. Mangraviti
Chalmers University of Technology, Gothenburg, Sweden

ABSTRACT: Concrete piles and geosynthetic reinforcements are commonly used to reduce settlements at the top of embankments. The use of geosynthetic layers at the embankment bottom leads to several advantages: (i) faster construction, (ii) better control of differential settlements and (iii) a fewer number of piles is needed for equal admissible settlements at the embankment top. Because of the latter point, the use of geosynthetic reinforcement reduces the Embodied Carbon related to concrete. Unfortunately, since existing design methods for Geosynthetic-Reinforced and Pile-Supported embankments do not allow to calculate settlements at the embankment top, they cannot be used to optimize the number of concrete piles to increase sustainability. In this note, an innovative model for assessing settlements induced by the embankment construction process is applied to the preliminary design stage of a practical example. The mass of CO_2 saved by using geosynthetics and optimizing the number of piles is calculated.

1 INTRODUCTION

Civil engineering is enormously contributing to the consumption of both global energy reserves and raw materials such as gravel, sand, and water (Dixit *et al.* 2010). In a context where all civil engineers can have a major influence towards a more sustainable development, geotechnical engineers have a crucial role in highly increasing the sustainability of a project. In fact, geotechnical engineering is one of the key fields contributing to a sustainable development, since it faces a challenging dichotomy between delivering project goals (environmental, economic, and social) and maintaining sustainability (Abreu *et al.* 2008).

From a practical point of view, the exploitation of increasingly large areas of territory has led also to the construction of infrastructures under difficult geological and geotechnical conditions, requiring geotechnical engineers to find new (and not always "environmentally friendly") solutions. As an example, embankments for major infrastructures are more often realized in areas where soils are deformable and, to avoid unacceptable settlements, concrete piles are commonly employed as settlement reducers. Such "geo-structures", composed of embankment, foundation soil and concrete piles, are named Conventional Pile-Supported Embankments (CPSE). The rigid inclusion (i.e. the pile) causes the development of the "arching effect", that reduces the portion of embankment load transferred to the soft soil (alleviating differential settlements within the embankment), while stresses flow through the piles towards more competent soil layers. Depending on both the overall length of the infrastructure to be realized and the mechanical properties of the ground to improve, CPSE may require the installation of a huge number of concrete piles along different kilometers of infrastructure, leading to a huge outflow of both economic and environmental resources.

To further reduce settlements in CPSE, geosynthetic reinforcements (GR) are often installed at the bottom of the embankment. Studies on Geosynthetic-Reinforced Pile-Supported

Embankments (GRPSE) have proven that the GR effectively increase the arching effect, leading to both a reduction of differential settlements as well as a reduction in the number of piles needed. This latter aspect is fundamental to increase the sustainability of the project, by reducing the Embodied Carbon (EC, which is defined as the carbon dioxide emitted during the manufacturing, transport, construction and the "end of life" of a material) related to concrete piles.

According to the actual standards (BS8006-1, 2010; EBGEO, 2010), the design of GRPSE is carried out in Ultimate Limit State (ULS) conditions, leading to extremely conservative estimation of the loads applied on GR and piles (Bhasi & Rajagopal 2015). Despite the very simplistic approach suggested by the standards, it is hard to use those methods to optimize the design of both piles and GR to reduce the number of piles (and EC) needed for GRPSE.

Furthermore, the standards do not allow for the estimation of settlements at the top of the embankment, even though King *et al.* (2017) recently stated that the assessment of settlements to ensure the serviceability of the infrastructure over its all lifetime is necessary. In this perspective, (Mangraviti *et al.* 2022) developed a displacement-based (DB) method for the estimation of settlements at the top of the embankment during the construction of GRPSE under drained conditions, validated against field tests in (Mangraviti *et al.* 2023a). The simplified method proposed by the authors applies for smooth end-bearing concrete piles located in the central part of the embankment. Based on this new DB method, Mangraviti (2022) conceived a simplified DB procedure to optimize the design of GRPSE (i.e. pile spacing and GR stiffness) in a preliminary design stage.

In this note, the procedure developed by Mangraviti (2022) is introduced (§2) and a practical application of the procedure is presented (§3), together with some concluding remarks (§4).

2 DB PROCEDURE TO INCREASE SUSTAINABILITY OF GRPSE

In this study, settlements induced by the embankment construction process in GRPSE (Figure 1a) are considered. When studying the mechanical behavior of the central part of the embankment, it is common in the literature to consider as representative one central axisymmetric cell. The representative unit cell (Figure 1b) of diameter s, assumed to be equal to the pile spacing (different values can be considered in case of squared pile pattern) includes: (i) one pile of diameter d and length l, (ii) a homogeneous soft soil stratum of thickness l resting on a rigid bedrock, (iii) an embankment of which height h evolves during the construction process and (iv) the geosynthetic reinforcement laid at the embankment base. The pile shaft is assumed to be smooth (leading to a conservative estimation of settlements), and the construction process is assumed to occur under drained conditions.
Figure 1.   (a) Geosynthetic-reinforced and pile-supported embankment and (b) representative unit cell.

In Mangraviti et al., (2023b), the mechanical response of the representative unit cell was modelled with finite difference numerical analyses by using simple constitutive models: the pile was assumed to be elastic, the GR was modelled as an elastic isotropic membrane (of axial tensile stiffness J) and the soil was modelled with non-associated elastic-perfectly plastic constitutive relationship with a Mohr-Coulomb failure criterion. This constitutive modelling, despite of its simplicity, can capture the main aspects of the mechanical processes taking place in the representative unit cell, which are:

a) the arching effect, that is the stress transfer mechanism towards piles occurring within the embankment (Terzaghi 1936);
b) the plane of equal settlements, that is the plane above which differential settlements are negligible (McGuire 2011);
c) the process height, that is the height of the portion of embankment where plastic shear strain accumulate during construction (di Prisco et al. 2020).

It is worth mentioning that, when the construction process is considered, the plane of equal settlements is where the increments of differential settlements are nil, even though differential settlements are larger than zero (Mangraviti et al. 2023b). According to di Prisco et al. (2020), differential settlements in CPSE stop increasing during construction when the height of the embankment is larger than a critical height value (h^*). The non-dimensional critical height (H^*) value is:

$$H^* = \frac{h^*}{d} = \frac{1}{2} \sqrt{ \left[\frac{E_{oed,e}}{E_{oed,f}} \frac{l\,d}{s^2} \right]^2 + \frac{(s/d)^2 - 1}{\overline{k}\,\tan\phi'_{ss}} \left(\frac{E_{oed,e}}{E_{oed,f}} \frac{l\,d}{s^2} \right) } - \frac{1}{2} \left(\frac{E_{oed,e}}{E_{oed,f}} \frac{l\,d}{s^2} \right) \tag{1}$$

where $\overline{k}$ is a parameter uniquely depending on the dilatancy angle of the embankment ($\overline{k}$ = 0.83 for dilatancy angle equal to zero); $E_{oed,e}$ and $E_{oed,f}$ are the oedometric moduli of the embankment and foundation soil, respectively. ϕ'_{ss} is the embankment friction angle in simple shear:

$$\tan\phi'_{ss} = \frac{\cos\psi_e \sin\phi'_e}{1 - \sin\psi_e \sin\phi'_e} \tag{2}$$

Equation 1 gives a conservative estimation of H^* in case of GRPSE (Mangraviti et al. 2022).

In the design practice, it is convenient (and strongly recommended by the current standards) to keep differential settlements at the top of the embankment in the r-direction (r defined in Figure 1b) negligible, by having an embankment higher than the critical height value ($u_{t,\text{diff}} = 0$, if $h > h^*$). Under this conditions, differential settlements at the top of a GRPSE induced by the application of a distributed load Δq are always nil, regardless of the value of Δq (Figure 2). However, average settlements at long term ($u_{t,av}$ in Figure 2) due to Δq are larger than zero (Mangraviti et al. 2023c) and need to be evaluated. In fact, also average settlements can be problematic when becoming differential settlements in the y-direction (y defined in Figure 1b). In this paper, average and differential settlements at the embankment top are defined as:

$$u_{t,av} = \frac{u_{t,f}\,(s^2 - d^2) + u_{t,p}\,d^2}{s^2} \quad \text{and} \quad u_{t,diff} = u_{t,f} - u_{t,p} \tag{3}$$

where:

$$u_{t,p} = \frac{2\pi \int_0^{d/2} u_t(r)\,dr}{\pi d^2/4} \quad \text{and} \quad u_{t,f} = \frac{2\pi \int_{d/2}^{s/2} u_t(r)\,dr}{\pi(s^2 - d^2)/4} \tag{4}$$
Figure 2.   Problem geometry.

are the weighted average values of u_t above the pile ($0 < r < d/2$) and the foundation soil ($d/2 < r < s/2$), respectively. u_t are the vertical displacements accumulated during construction at the top of the embankment.

In engineering practice, engineers might be requested to design GRPSE in a way that settlements at the top of the embankment would be less than an admissible value ($u_{t,av}^{amm}$). By assuming that the increment of average settlement induced by Δq is equal to the value of $u_{t,av}^{amm}$ for the project, the efficiency of GRPSE in terms of settlements can be defined as:

$$efficiency = 1 - \frac{u_{t,av}^{amm}}{u^*} \tag{5}$$

where u^* is the increment of average settlements at the top of the embankment that would be induced by Δq if nor piles neither GR were installed:

$$u^* = q\left(\frac{l}{E_{oed,f}} + \frac{h}{E_{oed,e}}\right). \tag{6}$$

Usually, $h/E_{oed,e} \to 0$ since the embankment soil is very stiff.

Mangraviti (2022) used the meta-model by Mangraviti *et al.* (2022, 2023a) to define efficiency isolines in the $s/d - (Jl)/(E_{oed,f}\,d^2)$ non-dimensional plane (Figure 3). The plot reported in Figure 3 refers to friction angle and dilatancy angle of the embankment equal to $\phi'_e = 40°$ and $\psi_e = 0$, respectively. During a preliminary design stage, efficiency isolines can be a very effective tool to optimize pile spacing (s) and GR stiffness (J) considering the required
Figure 3.   Mangraviti (2022): non-dimensional efficiency isolines for $H (= h/d) > H^* (= h^*/d)$, $\phi'_e = 40°$ and $\psi_e = 0$.

320

average settlement at the top ($u_{t,av}^{amm}$). In fact, by calculating the efficiency (Eqs. 5,6), one isoline is individuated in Figure 3 and, knowing the mechanical properties of the foundation soil ($E_{oed,f}$) and its thickness (l), the value of s and J can be chosen in order to get the larger value of pile spacing to reduce the number of concrete piles.

3 RESULTS

The case from Feng *et al.* (2017) of a GRPSE, with $h = 5$ m and built for 3.5 km of linear infrastructure, is here considered. The homogeneous foundation soil deposit of thickness $l = 16$ m has mechanical properties chosen as average values from Feng *et al.* (2017) (Table 1). A conservative estimation of GRPSE response is obtained by considering cohesionless soils.

Table 1. Materials mechanical properties for GRPSE.

	Unit weight kN/m^3	Young modulus MPa	Poisson ratio -	Oedometric modulus MPa	Friction angle °	Cohesion kPa	Dilatancy angle °
Foundation soil	19.2	10.2	0.3	13.69	24	0	0
Embankment soil	18	40	0.3	53.85	40	0	0

A uniformly distributed vertical load $\Delta q = 12.5$ kPa is applied at the top of the embankment (Figure 2) and the resulting admissible settlement at the top of the embankment is 3.5 mm.

The piles have $d = 0.5$ m, whereas the spacing needs to be designed together with the stiffness of the GR. The procedure previously described to optimize the design of GRPSE is here used to increase s and J in order to improve the sustainability of the project.

To identify the isoline corresponding to this case, the *efficiency* $= 1 - 0.0035/(12.5 \times 16/13690) = 0.76$ (Eq. 5) is calculated. A first tentative value of J is chosen (Table 2) and, by entering the plot in Figure 3 with $Jl/(E_{oed,f}d^2) = 120 \times 16/(13690 \times 0.5^2) = 0.6$ value, a pile spacing of $s = 1.4$ m is found on the isoline of *efficiency* $= 0.76$. Knowing s, the value of critical height is calculated (Eq. 1) to verify that $h^*(= 1.4m) > h(= 5m)$. The same procedure is used for one higher value of J ("optimized value" in Table 2), and the number of piles needed in the central part of the embankment along 3.5 km in this case results in 658 piles less than the first tentative case.

To calculate the tons of CO_2 saved by choosing the optimized option, an average value of EC (generally measured in mass of CO_2 emitted per mass of material) of concrete is considered (Table 3). Knowing the mass of concrete needed for each pile (7.9 t) and the tons of

Table 2. Optimizing the preliminary design of GRPSE.

	GR axial stiffness, J kN/m	Pile spacing, s m	Number of piles in 3.5 km –
First tentative value	120	1.4	2501
Optimized value	5000	1.9	1843

Table 3. Reinforced concrete mass and EC.

	Embodied Carbon, EC tCO$_2$/t	Mass kg/m^2
Concrete	1.08 (Koerner 2019)	2500

CO_2 emitted for each pile (1.08 tCO_2/t × 7.9 t = 8.5 tCO_2), the total amount of CO_2 saved by reducing the number of piles is calculated (8.5 tCO_2 × 658 = 5580 tCO_2).

4 CONCLUSIONS

In this paper, an innovative and simplified displacement-based method to design Geosynthetic-Reinforced and Pile-Supported Embankments in a preliminary stage was presented. The methodology was applied to a practical example, where two different configurations of pile spacing and stiffness of the geosynthetic reinforcement were considered. The mass of CO_2 emitted was calculated for both the cases, and the optimized design led to reducing the number of piles needed in the project, by reducing the mass of CO_2 emitted (related to concrete piles) of 26%.

ABSTRACT: Pit Thermal Energy Storages sealed with geomembranes have proven to be vital applications for long term storage of solar thermal energy or excess heat in large volumes at affordable costs. Energy content and its utilization depends on the system integration, so does the temperature profile, which impacts the liner material lifetime. During the transformation of energy systems a thorough demand for energy storage can be expected in the future. The project in Høje Taastrup vastly increases scope of functions as permanent high temperatures ($\geq 90°C$) enable more advanced operation strategies with additional measurable economic outcomes for operators. For lifetime prediction of liner materials, a methodological approach was implemented based on micro-specimen. Due to the reduction of specimen thickness an acceleration factor of up to 20 was achieved. The best performing novel PP-HTR liner material revealed a predicted lifetime of up to 35 years at a temperature loading profile ranging from 60 – 90°C.

1 INTRODUCTION

The implementation of low carbon climate action plans expectably leads to an increase of renewable energies within the next decades. Fifty percent of the European energy demand is used for heating and cooling including domestic hot water and space heating. While 66% of the thermal energy is produced by fossil fuels, only 13% comes from renewable energy sources (Mathiesen 2017). Efficient integration of renewables is challenging due to its fluctuating production times (Dyrelund 2016), however for future energy systems combining heating and cooling (CHP) sector with the electricity and/or transport sectors results in the most effective and economical solution (Lund 2014). Latest experiences show that it will become essential to stabilize the smart grid with other energy carriers, leading to a smart energy system in which energy storage plays an important role. Electrical storage as an evident solution is costly and limited in its capabilities (Heller 2019). Water can therefore be an alternative carrier for thermal energy. It has a high thermal capacity, is non-toxic and easily available almost everywhere.

Many CHP plants in district heating networks, i.e., use thermal energy storages (TES) in form of steel tanks to increase flexibility in short-term storage and supply. The water

temperatures are typically either close to 100°C (unpressurized) or, in a few cases, beyond (pressurized tank) (Sørensen 2013). In Denmark, pit thermal energy storage (PTES) is typically used for long term thermal storage, since it can be charged and discharged quickly besides be employed for short-term storages (Pauschinger 2020), hence an alternative to steel tanks.

2 PIT THERMAL ENERGY STORAGE (PTES)

Since the 1980's PTES have been developed in Denmark (Pauschinger 2020) with projects of a volume up to 220,000 m^3. The structure is a large inverted truncated pyramid with an inclination of 1:2 to 1:1.5. The sides, the bottom and the water surface are typically covered with a geomembrane, made of either polyethylene (PE) or polypropylene (PP). A standard for pit designs to reduce costs is considering a soil balance by using the excavated soil from the storage's bottom as surrounding embankments (Kallesøe 2019). Favorable geotechnical conditions made this an obvious approach in Denmark. After filling with water, the floating geomembrane gets covered with thermally insulating materials. The exchange of thermal energy takes place through diffusers connected via pipes to a nearby pumpstation with heat exchangers and grid connection. Water temperatures inside can reach up to 90°C, depending on the system integration of the storage.

2.1 PTES as seasonal storage

The energy utilization cycle in a PTES used as a seasonal storage is based on a surplus of thermal energy production in summer (i.e., solar thermal, waste heat) compared to a low heat demand at the same time. This surplus is stored over time (charge) and utilized in winter (discharge). The temperature profile reaches up to 90°C for a limited period during the year (Figure 1). Beside energy independence and price stability for connected customers, this shift of otherwise unutilized thermal energy creates an opportunity for transition to a circular carbon energy future. Tests according to the test method (hot water of i.e., 110°C on one side of a liner sample, air on the other) developed at the Danish Technological Institute (DTI) showed that service life of high temperature resistant HDPE liners achieve more than 20 years in a seasonal temperature profile (Jensen 2014; Paranovska 2016). To further accelerate the ageing process a novel methodological approach was implemented, based on micro-specimen (Grabmann 2017; Grabmayer 2014 & 2015; Peham 2022; Wallner 2016). Depending on the polyolefinic liner material, a test acceleration factor of up to 20 was proven to shorten the oven ageing exposure time at elevated temperatures significantly.

2.2 PTES as buffer storage – the case study Høje Taastrup, Copenhagen

The Energy Technology Development and Demonstration Program Denmark (EUDP) invested 1.3 Mio€ in the FLEX_TES (Flexible Thermal Energy Storage) project, which is a new 70,000 m^3 pit storage constructed in Høje Taastrup, Copenhagen. It acts as a buffer storage with a capacity of 3300 MWh. The PTES is linked to a transmission line that connects different heat producers (4 CHP plants – 2050 MW, 3 waste incineration plants – 400 MW, reserve and peak load power plants – 1.900 MW, 2 TES – 660 MW) in the greater area of Copenhagen with the local district heating network in the city. With an amount of 20 to 25 energy utilization cycles per year and permanent 90°C in the uppermost water level (Figure 1), it is designed to optimize the heat- and electricity production of the connected power plants.
Figure 1. Comparison of water surface temperature and energy content inside a storage over the course of a year. Forecast for the multifunctional PTES in Høje Taastrup for 2025 by Ea Energy Analyses during the project FFH50 using Balmorel Power System Model (left panel) and actual measurements of the seasonal PTES in Dronninglund in 2019 by PlanEnergi (right panel).

The storage adds value due to the additional production of the most efficient CHP and waste incineration plants, saved peak loads and bypass operation. This has an expressive impact especially during winter months and an optimization of the CHP plants with respect to the electricity market price. Annual operational benefits are estimated between € 800k – € 900k, whilst further benefits in the business case are expected. This particular project aims for the development and demonstration of PTES as a more advanced and flexible manner compared to all other plants before, expecting using PTES as flexible weekly or daily storage. The Technology Readiness Level for the FLEX_TES project brings the application PTES as accumulation tank from TRL 6/7 to 8 (Bruus 2019). Implementation costs of the storage in Høje Taastrup are in the range of 71 €/m^3 water volume. For larger volumes (500,000 m^3 and more) calculations show approximate investment costs of 40 €/m^3 for both PTES used as seasonal and as multifunctional or buffer storage. In comparison, Danish experiences show that a steel tank of a similar capacity like the PTES in Høje Taastrup can be implemented at costs in the range of 133 €/m^3 (Bruus 2019).

3 LIFETIME ESTIMATIONS FOR POLYMER LINERS

Due to significantly higher operating temperatures (Figure 1), more durable liner materials are of utmost importance for PTES buffer storages. To develop and screen novel liner material formulations in a highly accelerated manner, a testing approach based on miniaturized specimen has been implemented at the Institute of Polymeric Materials and Testing (University of Linz, AT). Methodological approach

First, liner materials are extruded to sheets with a thickness of 2 mm. Second, strips with a width of 20 mm are cut and positioned in a CNC milling machine (Figure 2 left). Micro-sized specimen with thickness ranging from 50 to 500 μm are prepared using a home-built cutting tool. These specimens are clamped onto a sample holder and exposed to hot air or water in a convection oven (Figure 2 middle). For water exposure, micro-specimens are positioned in autoclaves and filled with deionized water. After defined exposure intervals, specimens are removed and characterized by tensile testing (Figure 2 right). As sensitive ageing indicator strain-at-break values are deduced (Kahlen 2010; Wallner 2004). Ultimate mechanical failure is achieved when strain-at-break drops below strain-at-yield ($\varepsilon_b < \varepsilon_y$). At the yield point of semi-crystalline polymeric materials, usually inter-spherulitic voiding is initiated. In the post-yield regime, failure of the spherulites and rearrangement of crystal lamellae associated with fibrillation takes place (Maier

325

2005). The considered ultimate failure criterion strain-at-break below strain-at-yield indicates failure due to critical degradation and chain scission of inter-spherulitic tie molecules (Grabmann 2017).
Figure 2. Methodological approach for accelerated ageing testing of polyolefin micro-specimen.

3.1 Lifetime assessment

For lifetime estimation an approach based on cumulative damages is used (Wallner 2016). The lifetime assessment is based on various inputs: the simulation of temperature loading profiles, the extrapolation of experimental aging data from elevated to service-relevant temperatures, the extrapolation of specimen thickness to the liner thickness and the accumulation of damages at different temperature levels. Exposure temperatures range from 65 to 135°C. For lifetime estimation, a high- and low-temperature loading profile was considered with temperatures ranging from 60 to 90°C and 35 to 80°C, respectively (van Helden 2021).

3.2 Results

In Figure 3, the effect of exposure temperature in air and specimen thickness on the strain-at-break values of a selected PP-R grade is depicted. Failure times are indicated by open symbols. Depending on the polyolefin grade, the temperature rises by 20°C resulting in 3 to 5 times shorter endurance times. Due to the diffusion limited oxidation (DLO, Celina 2013), semicrystalline polyolefins degrade by a factor of 2 to 20 faster when the specimen thickness is reduced from 2 mm to 50 μm. Based on the extrapolation of temperature and thickness effects to service relevant levels, estimated failure times can be calculated. Considering this endurance times as a cumulative damage model including seasonal temperature loading profiles used to ascertain lifetime estimations.
Figure 3. Effect of air temperature and specimen thickness on strain at break values of a random propylene copolymer (PP-R) reference grade.

It was shown by Grabmann (2018) that the ageing behavior of PE liner materials is more critical in hot water. In contrast, novel PP-R liner materials are more prone to degradation in hot air than in water. Overall, a much better ageing performance was ascertained for novel PP-R formulations compared to well established PE liner materials.

Predicted lifetime values are stated in Table 1. All lifetime value of 15 years was obtained for PE liners used in conventional PTES (low temperature profile). This value is about 5 years lower than the lifetime estimated by Paranovska (2016). The deviation could be attributed to differences in the experimental setup, the calculation procedure, and the investigated PE grade. While established PE liners (PE-HTR) can only be used in low temperature thermal energy storages, PP-R is suited for both applications. Replacing the PE liner with a conventional PP-R liner increases the lifetime by a factor of more than 2, from 15 to 34 years at a low temperature loading profile. Additional stabilization is improving the endurance time by a further factor of 1.7. At a high temperature loading profile, lifetime values of 20 and 35 years were deduced for PP-R and optimized PP-HTR grades, respectively.

Table 1.   Lifetime predictions for PE, PP-R and PP-HTR for high- and low-temperature profiles.

Predicted lifetime [years] for a 2 mm liner Temperature profile/Polymer grade	High 60–90°C	Low 35–80°C
PE-HTR		15
PP-R	20	34
PP-HTR	35	

4   PERSPECTIVE

According to Hay (2022) the district heating production in Germany, i.e., mainly is done by CHP plants consuming 82% of fossil fuels. For heat generation without CHP process 75% fossil fuels as energy source are used. The vulnerability and dependence on fossil fuels for energy production has moved into the political spotlight, especially since February 2022, in the course of partly drastic price increases for the end consumer.

The decarbonization of heat supply by substituting of heat generation systems requires adjustment of the system operating parameters. The current supply temperatures of networks in Germany are between 90 and 112°C in average with maximum peaks up to 140°C. In the future a significant reduction of supply temperatures for large network temperatures of < 100°C and for smaller ones < 80°C are to be expected (Hay 2022). Since the area of most European cities will increase (Alberti 2019), existing district heating networks can be expected to grow and new ones to be established.

Due to the relatively low investment cost per m^3 of water volume, the integration of a PTES into future systems can also have potential for electricity storage by converting the electrical into thermal energy (Power to Heat, P2H), i.e., for wind farms to prevent grid overloads (energinet.dk). Thermal energy can be utilized in district heating networks, combined with heat pumps for mutual benefits amongst different stakeholders. Another possibility is the combination with an Organic Rankine Cycle (ORC) turbine and a cold thermal storage, as recently built in a CSP plant in Carwarp, Australia (Bellini 2021).

In the application there is not only a perspective for geomembranes but also for reinforced soil. For thermal stratification purposes it is beneficial to reach a certain water column (i.e., 16 m depth in Høje Taastrup). Difficulties can occur in areas with a low groundwater level, as groundwater can cause heat loss especially when it is floating. Unfavorable soil conditions on the other hand can lead to increased costs if disposal or purchase of soil is required. Soil reinforcement and steeper slopes can address these matters and furthermore lead to an

improved surface/volume ratio. This, according to the Danish Energy Agency (2018), is a "characteristic figure for the heat loss per amount of stored energy". Additionally, the potential location area can be optimized, a practical approach similar as to increase volume in landfills (Cazzuffi 2021).

Further potential for polyolefins in PTES also exists for geotextiles and geocomposites as protective layers to the ground, as well as inside the lid construction, in where a combination of polymers can be used to address the different challenges: water tightness, water vapor handling, release of oxygen from the water side, entrance of oxygen into the water or rain/snow on the floating surface.

5 SUMMARY

Storage will expectably become an essential part of future energy systems, for both thermal and electrical energy. The storage technology PTES has been developed to a high level of maturity and offers scalability to extremely large volumes at attractive costs compared to other technologies to date. The application scenarios increase enormously if a PTES can be used as a multifunctional or buffer storage instead of a seasonal one. Operation strategies for such demand permanent high temperatures inside; a stressful environment partially beyond temperature operation ranges for typical geosynthetic products. To meet service life and operational requirements of the FLEX_TES in Høje Taastrup a PP-HTR liner with enhanced durability has been chosen.

For lifetime estimation a cumulative damage approach was implemented. Based on micro-specimen ageing studies were carried out at various environmental conditions at temperatures ranging from 95 to 135°C. The lifetime could be improved by a factor of more than 2 by replacing the PE liner by a PP-R liner. Additional stabilization allows for further increase of the estimated lifetime by a factor of 1.7 resulting in an endurance time of 35 years.

How the use of cementitious geocomposites in tunnels will reduce our impact on the planet?

Paul Guinard
ESTP Civil Engineer
Director Civil Engineering, SOPREMA Group
President of the Geomembranes French Producers Association (APRODEG)

ABSTRACT: During the PVC geomembrane installation for waterproofing of tunnels and structures and in order to mechanically protect the product, we usually pour a 6 cm thick slab of concrete. This screed allows the installation of reinforcement bars for the internal structure.

After dynamic and static tests, we realized that we could use cementitious geocomposites instead of this on site poured concrete. In fact, the presence of a big quantity of poly-propylene fibers in the product offers a subsequent resistance which is sufficient in most of the cases.

It has a real impact on resiliency as the use of this type of product instead of a thick concrete slab is reducing: 1. the depth for the digging and 2. the quantity of concrete poured on site.

The example of this use in tunneling applications demonstrates it can be used in many other situations for protection: basins, basements, buried structures, temporary protection ... offering on each project a reduction of energy compared to traditional solutions.

1 PRESENTATION

The awareness of recent years concerning our environmental responsibility and the worrying studies in terms of the carbon footprint of our achievements has pushed us, for several years now, to embrace our environmental responsibility and to develop viable solutions to reduce the environmental impact on our way to build.

A recent study (Carbone 4 for FNTP - Fédération Nationale des Travaux Publics = French Federation for Civil Works: acteurspourlaplanete.fntp.fr/actualites/travaux-publics-quel-est-le-cout-carbone-des-chantiers/) shows that the construction of infrastructures in France emits approximately 23 million tons of CO2eq per year. This corresponds to 3.5% of France's carbon emissions. Among these emissions, around 14.5 million tons of CO2eq are generated by products, raw materials, and land use.

There are many ways to approach this challenge, but the simplest of them is to reduce the quantities of materials used. In the construction of tunnels, between 60 and 80% of embodied carbon is contained in the concrete linings (International Tunnelling Association - IATTech). Solutions to reduce the quantity of concrete or the thickness used are therefore among the most interesting to limit the carbon footprint of our projects.

During the studies conducted by SOPREMA Group, we realized that the use of cementitious geocomposites made it possible to significantly reduce the quantities of concrete used to protect our PVC geomembranes under rafts.

This article describes the materials used and compares the methods both from an environmental and a financial point of view.

2 CEMENTITIOUS GEOCOMPOSITE

In recent years, we have seen some new geosynthetic solutions for many different applications often relative to soil reinforcement and water management. The cementitious geocomposite is an innovative type of product which can be used in many applications and offers the possibility of new domains to geosynthetics uses.

Depending on the area or the producer, they are named geocomposite or mats but are all grouped in the family of GCCM: (Geosynthetic Cementitious Geocomposite Mats).

2.1 *Concrete in rolls*

The concept of a GCCM is simple: to deliver and install a layer of concrete in a new way.

Use of this product allows to deliver on site, only rolls made from geosynthetics containing a sand and cement mixture which once hydrated will form a thin layer of fiber reinforced concrete.

It is concrete delivered in rolls!

It can be used in many applications in which erosion control or mechanical protection are required: on slopes, for ditches and canals lining, as a protection of geomembranes or as a temporary protection and many other applications as concrete blinding, reinforcement support, temporary support, etc …

There are different ways to produce GCCM: needle punching, injection of cement within a prefabricated matrix … The importance is to create a regular cementitious layer on the full surface of the product embedded between geotextiles.

For our application, we used a TILTEX® which is produced as follows:

- A non-woven geotextile in 100% polypropylene fibers is placed in the production line.
- The requested quantity of mixture sand/cement is placed on this first layer.
- These two layers are covered by a second layer of a non-woven geotextile in polypropylene.
- All is then maintained by an intense needling made in line to allow the fibers to bind the two geotextile layers together, strengthen the base of the mortar and make the product workable. A mesh of polypropylene fibers is then dragged between carrier and cover layers allowing cohesion between them and thus giving an excellent hold to the product.
- The products are then cut, rolled and packed.
Figure 1.   Sectional view of a cementitious geocomposite.

The amount of sand / cement mixture placed between the geotextiles is chosen according to the desired product applications: mechanical resistance (to puncture for example), resistance to erosion ... For protection applications, we are using geocomposites containing 10 or 12 kg/m^2 of mixture. This offers products from 10 mm to 12 mm thick.

The geocomposite is produced in maximum 5 m width and different dimensions (width and length) and are proposed in order to adapt to the requirement of the projects (size, installation method, accesses ...):

- 5 m × 20 ml and 2.5m × 20ml for large flat surfaces or slopes.
- 1 m × 5 ml for small applications or difficult accesses.

2.2 Installation

The cementitious geocomposite rolls are delivered directly on site. They are individually wrapped in a watertight plastic protection covering the roll and sealed at the ends. Depending on the weight of the rolls, they are unloaded with the use of lifting straps predisposed on each roll (for large ones) or in pallets (for small or medium size ones). Handling of large or medium size rolls must be done using a lifting device and a suitable lifting beam. For small rolls, it is possible to handle them with 2 or 3 people using a pin placed in the roll core.

Once unpacked, the geocomposite is positioned by unrolling it directly on the prepared substrate or on the geomembrane to protect. As the product is flexible, it is easy to install it with the desired shape. An overlap of the ends of 0,10 to 0,20 m ensures the continuity of protection.

Of course, the product can be cut to fit specific dimensions or shapes. Providing it is not hydrated, it remains flexible and can be repositioned.

Once the layer has been positioned correctly, hydration by abundant watering is necessary to set the concrete. It is set by spraying water without pressure directly on the whole surface of the product. The prescribed quantities of water are at least 0.5 liter per m^2 and per kg of sand / cement mixture. In case of strong wind or hot temperature, further watering may be essential. It is necessary that the surface geotextile be kept wet for 48 hours.

About 48 hours after the completion of the hydration, the concrete will be hardened enough for the geocomposite to fulfill its role of protection.

3 USE AS WATERPROOFING PROTECTIVE SCREED

3.1 Traditional and GCCM solutions to protect PVC geomembranes in tunnel

The use of PVC geomembrane waterproofing systems under the foundation rafts requires a protection between the waterproofing layer and the reinforcement bars of the raft. This protection allows the implementation of the reinforcements without damaging the geomembrane. Traditionally, this protection is made of lean mix concrete to a thickness of 6 cm. The proposed alternative is to use the geocomposite, which is much easier and quicker to implement, especially on inclined areas, and allows a sufficient level of protection.

Figure 2.   3D view of the alternative with geocomposite as protection screed.

This alternative presents both savings in the quantities of concrete used but also the ground to be excavated under the raft. The savings are as follow:

- The 6cm of lean mix concrete poured on site for the protection screed are removed.
- As the geocomposite has a thickness of only 1 cm, it affords a reduction in the excavated depth of 5 cm which can be important for urban projects.

Not only this can have an economic advantage (depending on the location, the depth, the type of ground, etc.), but it also has a significant impact on the CO_2 emissions of the projects.

3.2 Are GCCM sufficient to protect geomembrane?

The resistance of the cementitious geocomposite is mainly due to the presence of a high density of polypropylene fibers in the concrete part which give both good strength and excellent puncture resistance (static and dynamic).

We saw multiple advantages to use this product to protect a geomembrane placed under the raft, but we had first to prove its resistance for this specific use. We then made specific tests in order to comply with each respective requirements for this application.

The first step is to use the appropriate CE marking of this type of product as it is mandatory to apply it in Europe. The EN 13256 (Geotextiles and geotextile-related products – Characteristics required for use in the construction of tunnels and underground structures) has been used with the function Protection (P).

In the DoPs (Declaration of Performances) and in the technical data sheet, it is important to detail if the values are measured before or after hydration.

Table 1. Example of declared performances.

Essential characteristics	Characteristics	Before or after hydration
Thickness (mm)	EN 9863-1	Before hydration
Mass per unit area (kg/m2)	EN 14196	Before hydration
Maximum tensile strength MD/CMD (kN/m)	EN 10319	Before hydration
Elongation at break MD/CMD (%)	EN 10319	Before hydration
Static puncture resistance (CBR) (N)	EN 12236	After hydration
Dynamic puncture resistance (mm)	EN 13433	After hydration

The requirement of the CE marking as geocomposite with the appropriate standards needs the assessment and the verification of constancy of performance of the product in a system 2+. It means the initial values have to be controlled by a notified body which is accredited for these types of products.

The second step was to ensure that the product protects the PVC geomembrane sufficiently. For this we carried out two series of specific tests:

- Compressive strength:
  To validate the quality of the cement/sand mixture used, its process of integration in the geocomposite and of hydration, we confirmed the value of the compressive strength with the two used standards: EN 13791 and ASTM C109-2.
- Dynamic puncture:
  The most representative way to evaluate the level of protection the GCCM offers to a geomembrane is the one proposed by the French standard NF P 84-506. This test is highly demanding but ensures the required level of protection against any puncture due to the application of backfills or reinforcement bars.

This test simulates a dynamic shock by the drop of a specific impact tool on a specimen composed by a geomembrane (or the system used as waterproofing barrier) protected by the geocomposite. The energy of the system is set at the specified value (named Class II, I or 0) depending on the required protection level. Impacts may cause the tool to penetrate through the protection and into the membrane. The integrity of the membrane is then checked by vacuum tests.

To be used in applications under any type of backfills or reinforcement, the requirement is to have a protection of class 0 (which correspond of an impact of 14,75 Joules) (AFTES Guidelines on "Design of protection barriers to geomembrane waterproofing systems", June 2004 – www.aftes-asso.fr).

In our case, the geocomposite TILTEX 10 passed the test with not only a class 0 but also under the same test with double impact on the same position. To be sure to reach a sufficient protection on every project, we decided to use this geocomposite thickness as a minimum.

The use of this product as an alternative to protect PVC geomembranes has been validated and is now authorized in many underground projects.

3.3 *Case study – grand paris project – line 16*

As an example, the geocomposite $10kg/m^2$ has been used as a protection screed on waterproofing PVC geomembranes full system in the following project:

Site: Mandella well, Paris metro new line 16 (France)
Owner: Société du Grand Paris
Surface: 4,500 m^2 installed

Figure 3.   Geocomposite installed on the PVC geomembrane in Paris Line 16.

We found multiple benefits in this solution:

• Easy and quick to install even with difficult access or on slopes.
• No need to be cast on joints and along the compartmentalization.
• Less digging (the bottom level is 5 cm higher).
• Less concrete used …

Depending on the project, this solution will afford both economic and environmental advantages to the designers.

4 CARBON FOOTPRINT

What does "carbon footprint" mean?

According to the French Ministry of Ecological Transition, the carbon footprint is an "indicator estimating the quantity of greenhouse gases emitted to satisfy consumption in the broad sense (goods, services, use of infrastructure) of an individual, a population, a territory or an activity, taking into account emissions related to imports and exports regardless of where these goods and services are produced (domestic production or imports)."

It therefore takes stock of the carbon emissions associated with goods or services produced on a national scale, but also those that we import each year.

For simplicity and homogenization, we use a single standard related to CO2 for all greenhouse gases (there are in fact 6 of them: Carbon Dioxide (CO2), Methane (CH4), Hydrofluorocarbon (HFC), Protoxide of Nitrogen (N2O), Perfluorocarbon (PFC) and Sulfur Hexafluoride (SF6)).

We speak of "CO2 equivalent", or "CO2e" (or sometimes even "CO2eq").

One of the big advantages of using the carbon footprint is that, in the case of calculating the carbon impact of a product, we must consider its entire "life cycle", from the research & development phase to that of its final production (also including its packaging up to the recycling stage). Indeed, the carbon footprint of materials used in the world of construction is calculated by considering all the stages of their life cycle:

- Production: supply of raw materials, transport from the manufacturer and manufacturing.
- Construction: transport of construction and implementation.
- Use: use, maintenance, repair, replacement, rehabilitation, use of energy or water.
- End of life: dismantling, transport, waste treatment and disposal.

The carbon footprint is therefore measured by considering the quantity of CO2 emitted by a unit of product used (liters of gasoline, m2 of surface, kg of steel, m3 of concrete, etc.).

If the carbon footprint, which does not take into account pollution, the extinction of biodiversity, etc., is not perfect, it remains a very interesting, indisputable and important tool to use because it makes it possible to quickly measure the impact of our climate activities.

To give a realistic idea of the significance of the carbon footprint, you may consider that an adult tree absorbs an average of 50 kilos of CO2 per year (it depends on its species, its age, its size or even the climate but it is a medium range ...).

5 COMPARATIVE IMPACTS

In order to compare the impact of our two solutions, we can add up all the carbon footprints relating to each element of the construction.

These data are available either in material-specific documents (based on the dedicated protocol and the EN15804 standard) or in databases giving average values. For example, the French INIES database (available free of charge on the internet www.inies.fr) makes it possible to find most of the data related to the average carbon footprints of materials.

To carry out this comparison we are going to base it on a metro station of approximately 2.000 m^2 located in Paris (the location is necessary to include the transportation of the GCCM, but we will have an approx. same result for all cities in Europe) and consider only the elements that differ between the 2 solutions

Traditional solution:

- Lean mix concrete:
  Quantity: 6 cm on 2.000 m^2 = 120 m^3
  Medium carbon footprint = 180 kgCO2eq/m^3

Total: 21.600 kgCO2eq

Note: The carbon footprint of concrete depends on their dosage and varies from 150 to 400 kgCO2eq/m3. Here we have taken the average value for lean concrete as presented in the INIES base (www.inies.fr). If we have a project with difficult access, long distance from a concrete central or with a deep raft, we will have to consider a higher rate of CO2eq.

<u>Solution with use of GCCM:</u>

- GCCM:
  Quantity: 2.000m^2
  Carbon footprint = 3.13 kgCO2eq/m^2 (value issue from the "Carbon Footprint Report" of TILTEX 10)

  <div align="right">Sub Total: 6.260 kgCo2eq</div>

- Transport of the GCCM:
  Quantity: 1.250km for 2.000 m^2 of product which weighs 10 kg/m^2
  Medium carbon footprint = 0.076 kgCO2eq/t/km

  <div align="right">Sub-Total: 1900 kgCO2eq</div>

Note: We considered the installation impact as negligeable as it includes only unrolling and watering.

- Reduction of the excavated volume:
  Quantity: 5 cm less on 2.000 m^2 = -100 m^3
  Medium carbon footprint = 0.82 kgCO2eq/m^3

  <div align="right">Sub-Total: -820 kgCO2eq</div>

- Transport of the excavated volume:
  Quantity: 100 m^3 (or 250 tons) on 20 km
  Medium carbon footprint = 0.76 kgCO2eq/t/km

  <div align="right">Sub-Total: -3.800 kgCO2eq</div>

Note: We consider the excavated ground with a small depth (which can be important in many metro stations in cities) and to be directly re-used on another project. If it is not the case, we will have to consider a higher medium CO2eq and a treatment and storage additional CO2eq.

<div align="right">Total: 3.540 kgCO2eq</div>

6 CONCLUSION

As presented in this article, the alternative use of cement geocomposites to replace protections made of lean mix concrete above PVC geomembrane waterproofing not only creates financial savings but also greatly limits the environmental impact of our works.

For example, for an underground station with a plane surface of 2000 m^2, the use of a geocomposite allows a reduction of its carbon footprint by more than 18,000 kgCO2eq (it divides by 6 the impact due to the protection).

For the record, it means that for each metro station built, this excessive CO2eq corresponds to the average absorption of a 360 adult trees forest in one year.

This study has been performed for a protection on PVC geomembrane within a tunnelling application, but the same GCCM can be used on basins, basements, buried structures or landfills with similar positive environmental impact.

If this is not enough to save it, it helps to limit our impact on our planet.

How an enhanced lateral drainage geosynthetic provides resilience to civil structures

R.B. Laprade, P.Eng. & J.M. Lostumbo, P.E.
Solmax, Jefferson, Georgia, USA

ABSTRACT: According to The Resilience Shift, infrastructure resilience is defined as the ability to withstand, adapt to changing conditions, and recover positively from shocks and stresses (The Resilience Shift, 2020). Four properties are associated with engineering resilience: (1) Robustness to withstand unforeseen demands; (2) Redundancy to tolerate the loss or damage to a component; (3) Resourcefulness to identify a problem and to respond effectively; and (4) Rapidity to restore functionality quickly. This paper will examine the contribution of a unique enhanced lateral drainage reinforcement geosynthetic (ELDRG) towards the resilience of current and future infrastructure projects, especially roadways and working surfaces. Research summaries will demonstrate how the ELDRG is incorporated in civil projects to provide separation and mechanical stabilization as well as moisture management in saturated and unsaturated conditions. We will also show how to quantify the mechanical and hydraulic benefits of this moisture management system in pavement designs.

1 INTRODUCTION

Resilience and sustainability go hand in hand. The ability to satisfy our immediate demands without compromising the welfare of others in the future is what is meant by sustainability (Brundtland 1987). A system's resilience is its ability to withstand stress while maintaining its essential structure and function (Walker & Salt 2006). In essence, resilience prioritizes the processes that lead to these outcomes while sustainability emphasizes the outcomes.

Bruneau *et al.* (2003) consider engineering resilience as desired outcomes that are reached through measurements of improvement when looking at roads and other civil constructions. The targeted outcomes are: (1) Robustness, which is the capacity to resist a specific degree of stress or demand without degrading or losing function; and (2) Rapidity, which is the capacity to fulfil priorities and complete tasks quickly to stem losses and prevent disruption in the future. The units of improvement are: (3) Redundancy: the extent to which elements, systems, or other units of analysis exist that are substitutable in the event of a disruption; and (4) Resourcefulness: the ability to identify problems, prioritize, and mobilize resources when conditions exist that threaten to disrupt some element, system, or other unit of analysis. These are the four R's of resilience.

Geotechnical engineering serves as the basis for the design of project components such as roadways and foundations. Due to it being at the start of many projects, geotechnics presents a huge opportunity for resilient development methods. To that end, an improved lateral drainage reinforcement geosynthetic is now available, providing the functions required for roadway and civil applications (separation, filtration, reinforcement), as well as unique moisture management capabilities that move the needle toward structures that have all four R's of resilience.

2 ENHANCED LATERAL DRAINAGE REINFORCEMENT GEOSYNTHETIC (ELDRG)

The ELDRG is a woven high-modulus geotextile made primarily of polypropylene resin, which provides strength and reinforcement. The polar hydrophilic (naturally attracted to water molecules) and hygroscopic (absorbs moisture from the air) yarns interwoven within the non-polar hydrophobic (repels water molecules) polypropylene yarns provide the enhanced lateral drainage capability.

2.1 Saturated vs. Unsaturated water flow

There are several traditional methods to remove water from roadways. The primary route is through surface runoff from a paved roadway. Water does, however, find its way into aggregate base and subbase materials through infiltration through cracks and joints in the asphalt or concrete surface, as well as through roadway shoulders. The rate of drainage in such cases is determined by the quality of the aggregate materials. This method only considers water in saturated ground conditions. In unsaturated conditions with negative pore water pressures, the effectiveness of an aggregate base in removing water is greatly reduced. Polypropylene nonwoven geotextiles and geocomposites excel at draining water in saturated conditions. However, due to the hydrophobic nature of their polymer constituents and large pore sizes, their efficiency is significantly reduced in unsaturated soils.

Zhang *et al.* (2009) performed rainfall infiltration soil column tests in which they compared the drainage performance and behaviour of saturated columns of silt that were underlain by four different geosynthetics; two woven geotextiles, one geocomposite and the ELDRG. The results of the tests are depicted in Figure 1. The ELDRG removed significantly more water than the other geosynthetics. According to the researchers, "differences in moisture content distributions in the soil columns are therefore mainly caused by unsaturated water flow induced by suction head difference." This is a significant conclusion because, at the time of writing, the ELDRG is the only geosynthetic available capable of removing water in unsaturated conditions.
Figure 1.   Rain infiltration tests (Zhang *et al.* 2009).

2.2 Air entry value for the ELDRG

Lin *et al.* (2019) determined that the ELDRG's inner-yarn air entry value is approximately 250 kPa and that of a nonwoven geotextile is less than 1 kPa. This means that the ELDRG can draw water out of any soil until the reduced moisture content causes the suction value to reach 250 kPa. The Soil Water Characteristic Curves for various soils, as well as the

Geosynthetic Water Characteristic Curves for the ELDRG, are shown in Figure 2. To illustrate the significance of these curves, the ELDRG can reduce the moisture content of fully saturated silt from approximately 20% to 10%. Suction is inherent in clays, particularly those with high plasticity indices. This means that the overall moisture reduction is lower than it is in non-cohesive silts and sands. However, Budhu (2011) claims that for every 1% decrease in moisture content, the undrained shear strength of fine-grained soils can increase by about 20%. According to this statement, a 3% to 4% decrease in moisture content in cohesive soils has a major impact on the soil's bearing capacity.
Figure 2. Soil and geotextile water characteristic curves (Lin *et al.* 2019).

3 THE FOUR R'S OF RESILIENCE AND ELDRG RESEARCH

3.1 *Robustness*

The ability of a system to withstand unforeseen demands without degradation or loss of function is referred to as robustness. The ELDRG provides robustness by mechanically stabilizing soft subgrades, extending the life of the overlying roadway while minimizing rutting. This geosynthetic can also reduce differential movement caused by (1) freeze-thaw cycles in frost-susceptible soils and (2) shrinking and swelling of expansive clays due to its hydraulic stabilization ability.

3.1.1 *Frost susceptible soils on the Dalton Highway – Alaska, USA*
Beaver Slide is an unpaved section of the Dalton Highway in Alaska, located at Mile 110.5. It has an 11% downward gradient looking north. Since its construction in 1974, frost boils and soft areas have appeared during the spring thaw, healed during dry summer periods but reappeared after a heavy rain. The soft areas vanished when the ground froze during the winter. Previous conventional repair efforts were ineffective.

A 20-metre ELDRG test section was constructed in August 2010 (Zhang *et al.* 2012). The section was excavated to a depth of one metre, and two layers of ELDRG were placed at different elevations. Moisture and temperature probes were placed throughout the section, above, between, and beneath the layers of ELDRG. Since the installation, hourly probe readings have been recorded and will continue until the end of 2023. Water within the roadway freezes between October and April, and the system goes hydraulically dormant. At the time of freezing, the materials in the upper 0.6 m of the road section are below saturation levels, which is 26% volumetric moisture content. Since soils are unsaturated when they

freeze, no ice lenses form, mitigating seasonal frost heave and subsequent spring thaw weakening of the subgrade. Figure 3 depicts the temperature and moisture contour graphs on May 22, 2011. The top 1.2 m of the roadway has thawed while the soils in this section of the roadway have remained unsaturated. Every year, the Beaver Slide is inspected, especially during the spring thaw. The surface failures that had existed since the roadway's construction have vanished since the installation of the ELDRG.
Figure 3.   Contour Plots (May 22, 2011).

3.2   *Rapidity*

The ability of a system to quickly restore function after a disruption is referred to as rapidity.

3.2.1   *Effect of water on the resilient modulus of a granular base and pavement deformation*
The primary mechanical property required in both the Mechanistic-Empirical Pavement Design Guide (MEPDG) and AASHTO pavement designs is resilient modulus. Water entering the granular base of a roadway can have a significant negative impact on its resilient modulus. Lin *et al.* (2019) demonstrated, using tri-axial testing, that decreasing an aggregate base's moisture content by 2% from optimal compaction levels could increase its resilient modulus several times. (Figure 4).
Figure 4.   Resilient modulus vs. Moisture content (Lin *et al.* 2019).

Guo *et al.* (2018) used large-scale cyclic plate loading tests with simulated rainfall to determine the ELDRG's improved lateral drainage ability. Each test section had a 0.9-meter-thick subgrade layer (CBRs of 3% and 5%) and a 0.3-meter-thick base course layer. They included a control section (no geosynthetic), a second test section with a high-modulus woven geosynthetic with similar physical properties to the ELDRG but without the moisture management yarns, and a third with the ELDRG. Moisture and pressure sensors were installed throughout the box. The researchers used simulated rainfall for 24 hours, then waited six days before conducting their cyclic plate loading tests, which included 1000 loading cycles. This cycle was repeated twice with different wait times between rainfalls and testing. Moisture content in the ELDRG test sections was reduced by up to 2% compared to the control and other geotextile sections. Permanent deformation was reduced in the ELDRG section by more than 70% compared to the other sections.

3.3 *Redundancy*

The extent to which elements, systems, or other units of analysis are substitutable, meaning they are capable of satisfying functional requirements in the event of disruption, degradation, or loss of functionality, is referred to as redundancy. Water drainage within a roadway structure is thought to be accomplished by a "free draining" base course placed on a crowned subgrade, typically constructed with a 2% to 3% crossfall. Ideally, this approach is sufficient to ensure a roadway's longevity. What happens if the subgrade is not strong enough to support the structure? Water may accumulate in the subgrade ruts, exacerbating the problem. Similar issues can arise in granular base/sub-base materials with fines contamination. Water will worsen the situation by interfering with free drainage. The inclusion of the ELDRG into such structures provides redundancy on two levels. First, the mechanical stabilisation benefits can compensate for the weaker supporting subgrade, reducing premature rutting. Second, the additional lateral drainage of the ELDRG provides water removal redundancy.

3.4 *Resourcefulness*

When conditions threaten to disrupt some element, system, or other unit of analysis, resourcefulness refers to the ability to identify problems, establish priorities, and mobilize resources. Moisture is the most common cause of premature roadway deterioration. It is easy to conclude that a system capable of removing excess water from such civil structures while also preventing rutting and surface cracking is an especially useful addition. The ELDRG is a particularly resourceful means that designers and owners can include in their roadway assets owing to its previously mentioned exceptional ability to remove moisture in both saturated and unsaturated conditions.

4 QUANTIFYING THE MECHANICAL AND HYDRAULIC BENEFITS OF THE ELDRG

Quantifying both the mechanical and hydraulic gains of the ELDRG in roadway design methodologies is important. The moisture content of unbound aggregate base has a significant impact on the material's resilient and permanent strains. Based on previous research, Lekarp *et al.* (2000) concluded that a high degree of saturation combined with low permeability results in high pore pressure and low effective stress, and thus low stiffness, strength, and deformation resistance.

4.1 *Flexible asphalt pavements*

One of most used design methods for flexible pavements in North America is the AASHTO Guide for Design of Pavement Structures (AASHTO 1993). A structural coefficient

incorporates the resilient modulus of the aggregate base, and a drainage coefficient considers the effect of moisture on the aggregate base within the methodology. Flexible pavement designs have included geosynthetics since the early 1980s. Lacina *et al.* (2015) evaluated high-modulus woven geotextiles in full-scale accelerated load frame pavement testing. The tests quantified the mechanical benefits provided by high-modulus woven geotextiles, including the ELRDG, in base reinforcement applications at various traffic levels and sub-grade conditions. This research yielded Geosynthetic Structural Coefficient (GSC) values that can be applied to the structural number of the granular layer directly overlying the geosynthetic. This approach also complies with AASHTO R50-09 (2009), which states that "because the benefits of geosynthetic reinforced pavement structures may not be derived theoretically, test sections are necessary to obtain benefit quantification."

Guo *et al.* (2017) investigated the hydraulic characteristics of the ELDRG through a series of demonstration, water tank removal, small box, and soil column tests. They also conducted six large-scale cyclic plate loading tests with rainfall simulations to assess the impact of the ELDRG on the permanent deformation of base courses and subgrades. This research provided design guidelines incorporating the ELDRG's water content reduction benefit, allowing for further modification of the 1993 AASHTO Pavement Design Guide. This work enables designers to generate a Hydraulic Improvement Factor (HIF) by incorporating local precipitation data for any geographical location in North America. It is determined by the following factors: (1) the frequency and duration of saturation rain events, (2) seasonal temperatures, (3) traffic load expectancy, and (4) the structural integrity of the granular layer overlying the ELDRG. Figure 5 depicts an example of HIF values for specific subgrade and traffic loading conditions in North America.

5 CONCLUSIONS

There is a growing need for more resilient construction practices. New ideas and innovative solutions must be developed and implemented to meet the limited natural and financial resources that various levels of government and owners face. The ELDRG is an example of looking at things differently. Designers now have a highly effective tool which removes water in unsaturated conditions. Lacina *et al.* (2015) showed that high-modulus woven geotextiles provide mechanical stabilization to soils having low bearing capacity. As a high-modulus woven geotextile, the ELDRG provides mechanical stabilization and, uniquely, it also

provides quantifiable hydraulic stabilization to roadway designs. The ELDRG has a decade plus proven history of solving moisture-related problems in expansive clays, frost-susceptible soils, areas with high-water tables and other applications where moisture can affect civil structures.

Sand-rubber mixtures under one-dimensional cyclic loading

S. Ozkan, E. Ibraim & A. Diambra
University of Bristol, Bristol, UK

ABSTRACT: The number of scrap tyres is growing all around the world due to increasing number of vehicles. This creates significant environmental and economic concerns. Recycling and reusing scrap tyres in engineering projects is an alternative way to deal with these concerns. Recycled tyres are commonly mixed with soils in different proportions. This paper presents a series of laboratory experiments on sand-rubber mixtures (tested with seven different volumetric rubber fractions ranging from 0% (pure sand) to 100% (pure rubber)) under one-dimensional cyclic loading at different stress levels. It is aimed to investigate the behaviour and response of mixture with increasing rubber fraction under different cycle loads. The results indicate that one-dimensional characteristics of mixtures depends on rubber fraction. The applied cycle load also affects the response of mixtures. The results of cyclic oedometer tests were analysed and the effect of applied vertical stress on the remanent deformation were discussed.

1   INTRODUCTION

Increasing number of scrap tyres causes significant environmental concerns globally. Recently, recycling scrap tyres through use in civil engineering projects has become an effective way to deal with their environmental effects. Additionally, the inclusion of scrap tyres in their shredded form into civil engineering materials creates alternative solutions to meet the demand for construction industry (Hazarika *et al.* 2010). As rubber is a soft, elastic material and has high damping properties, sand-rubber mixtures (SRM) are also used in playgrounds and sport facilities as a soft surface material and in railways, pavement and road embankments (Edil & Bosscher 1994; Edincliler *et al.* 2010). Rubber is also used in retaining walls as a lightweight backfill material (Lee *et al.*, 1999; Tweedie *et al.* 1998) and in structures to reduce the vibration (Feng & Sutter 2000). In geotechnical engineering, it has also been observed that mixing rubber particles obtained from scrap tyres with granular soils can help improving soil properties such as bearing capacity and settlement problems (Ahmed 1993; Tatlisoz *et al.* 1997). The engineering properties of SRM have extensively been studied in laboratory. most of the research has mainly focused on the characterization of the compressibility (Attom *et al.* 2007; Fu *et al.* 2014; Lee *et al.* 2007; Trouzine *et al.* 2012) and the monotonic strain-stress-strength behaviour of various combinations of soils, rubber types and particle size dimensions (Edil & Bosscher 1994; Rouhanifar *et al.* 2020; Sheikh *et al.* 2013; Zornberg *et al.* 2004). Rubber content, rubber particle size with respect to the size of the host granular soil and rubber particle shape have been found as key parameters in controlling the response of SRM (Kim & Santamarina 2008). A comprehensive summary of a range of experimental studies including the physical characteristics of the mixture materials used as well as the testing conditions and main outcomes is given by (Fu *et al.* 2017). However, the investigation of the cyclic behaviour of SRM is relatively limited (Mashiri 2014; Tsang *et al.* 2012; Uchimura *et al.* 2008). The undrained cyclic triaxial test results show

that the excess porewater pressure ratio decreases with increasing rubber content in the mixtures (Ahmed 1993) which also results in increasing liquefaction resistance with increasing volumetric fraction of tyre chips in the mixtures as observed from dynamic experimental work on sand-tyre chips mixtures (Tsang *et al.* 2012; Uchimura *et al.* 2008).

This paper presents the results obtained from laboratory-based research on the mechanical response of SRM under strain-controlled one-dimensional loading, including successive cyclic loading at different stress levels. The effect of the rubber content on the cyclic response of SRM is particularly investigated. The aim of this work is a fundamental investigation revealing insights into the internal interaction mechanisms between a rigid particle material, sand, and a soft particle material, rubber, to integrate into a constitutive model rather than optimising the amount of rubber content for engineering applications. In this respect, the particle size distribution of both sand and rubber materials are chosen to be identical. Test on pure sand and pure rubber complete the experimental programme.

2 MATERIALS AND METHODS

2.1 *Materials and sample fabrication*

Leighton Buzzard sand (D_{50} = 1.57, G_s = 2.65) is mixed with rubber material (G_s = 1.04, (Rouhanifar 2017)), both materials having the same particle size distributions (Figure 1) to remove any effect of sand/rubber particle size contrast as observed in the previous studies (Kim & Santamarina 2008; Lee *et al.* 2007). The rubber material was sieved, the particles separated and then remixed in such a way to obtain the same particle size distribution as that of the sand. Leighton Buzzard sand is mixed it with rubber material in seven different volumetric fractions (F_R):0 (pure sand), 10, 20, 30, 50, 70, and 100% (pure rubber). Volumetric fraction of rubber (F_R) is defined as the ratio of rubber volume to total solid volume of the mixtures as shown by the relation 1.

$$F_R = \frac{V_{Rubber}}{V_{Rubber} + V_{Sand}} \qquad (1)$$

where V_{Rubber} and V_{Sand} are volume of rubber and volume of sand, respectively.
Figure 1.   Particle size distribution for sand and rubber materials obtained from sieve analysis.

345

A steel cylinder (75 mm diameter and 60 mm height) was used for sample fabrication. Sand and rubber materials were initially mixed in dry conditions and then 10% water by the dry weight of sand only was added to all mixtures. Each sample was prepared in two volumetrically equal layers and compacted to required height to obtain a target fabrication void ratio of 0.64, except the sample at $F_R = 100\%$, for which this target void ratio was impractical to be reached in which case a single rubber layer was considered. The list of all the tests, including the sample characteristics like, F_R, initial height, the actual fabrication void ratio, e_f, and the axial displacement rate employed in this study are presented in Table 1. A study of the effect of the axial displacement rate conducted by the authors as part of this research showed that no discernible effect on the one-dimensional behaviour were observed for displacement rate ranges given in Table 1. In the name of the tests, the number represents the values of volumetric fraction of the rubber, F_R. When the sample fabrication process was completed, the top cap was carefully placed on top of the sample, and the one-dimensional test was ready to be conducted.

Table 1. Initial sample properties and testing conditions.

Sample	F_R%	Initial Height mm	Void Ratio (e_f)	Displacement Rate mm/min
SR0	0	57.93	0.644	0.1
SR10	10	57.84	0.642	0.5
SR20	20	57.94	0.644	0.5
SR30	30	57.85	0.642	1.0
SR50	50	57.98	0.645	1.0
SR70	70	58.17	0.651	1.0
SR100	100	34.27	0.881	1.0

2.2 *Experimental set-up*

A constant strain rate loading device was used for the cyclic oedometer tests. A load cell with 10 kN maximum load capacity was employed with a LVDT of 25 mm range for the axial displacement measurements. Three unload-reload cycles at different level of stress of approximately 200, 800 and 2400 (maximum load) kPa were applied for each sample. Once the reloading was applied for the third cycle, the samples were all fully unloaded.

3 EXPERIMENTAL RESULTS AND ANALYSIS

The results of the experimental work are presented in terms of void ratio-axial stress relationship (Figure 2). Making abstraction of the unload-reload cycles, the overall void ratio-axial stress Envelopes move further downwards as the rubber content is increased so the overall volumetric strains at a given stress level tend to increase with the addition of rubber. increasing rubber content induces further deformability and compressibility of the mixture (Kim & Santamarina 2008; Sheikh *et al*. 2013). As discussed by Fu *et al*. (2017) and Fonseca *et al*. (2019), the increased compressibility of the mixture is the result of the low shear modulus of the rubber, and it is the soft rubber distortion, not its compression, that increases the global volume change. As the stress level increases, the rubber particles deform further at the contacts with the rigid sand particles (or similar rubber particles) and, given the fact that the rubber is incompressible, a fraction of the porous space is filled by the deformed rubber particles, hence the increased reduction of the global void ratio, as also discussed by Platzer *et al*. (2018). For both the sand soil and the sand-rubber soil mixtures, unique normal compression lines can be defined especially the limits of the highest pressures. The values of

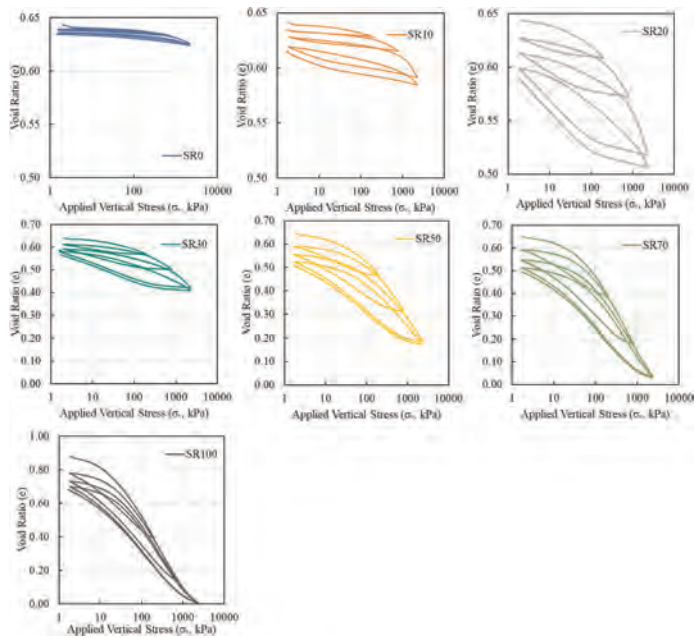
the compression indices, C_c, resulted from the estimation of the gradient of this normal compression lines function of the rubber fraction, F_R, are given in Figure 3. A steady increase of C_c values with the rubber fraction is recorded, although the increase rate seems to be slightly reduced for rubber contents lower than 20% or higher than 50%. However, at high rubber contents, over 50%, the one-dimensional compression path envelopes gently change into a convex curvature in the void ratio-vertical stress semi-logarithmic plane as similarly observed by Lee *et al.* (2010), Fu *et al.* (2014) and Fonseca *et al.* (2019). This is the effect of the saturation of the voids filled by the rubber grains and thus a clear sign of advanced levels of rubber distortion and rubber saturation of the void spaces.


Figure 2.   The void ratio-stress relationship for sand-rubber mixtures with different load cycles.
Figure 3.   Compression indexes against rubber fraction.

For the unloading-reloading cycles, the sand shows, as expected, low levels of strain recovery, although the recovery of axial strain is marginally higher for higher axial stress, though not visible at the y-axis scale shown in Figure 2 (SR0). However, the effect of rubber contents on the unloading-reloading cycles is very pronounced. For the sample with 10% rubber content, the unload-reload cycles appear linear for the first two cycles while for the cycle at the highest stress level, 2.4MPa, the unloading shows two distinct linear parts with different slopes, one up to an unloading axial stress of 50kPa and one with a higher gradient up to the full removal of the loading. The last cycle for the SR10 sample shows development of hysteresis. Hysteresis loops are further observed for all sand-rubber mixtures irrespective of the level of axial stress from which the cycles are conducted. Qualitatively, the energy dissipation estimation based on simple visual observation of the hysteresis loops shows that the energy dissipation increases with both the axial stress level, for a given rubber content, and with the rubber content, for a given unloading stress level. The bi-linear unloading paths observed in the semi-logarithmic axes are much more discernible for SR20 and SR30 specimens, while the samples with higher rubber contents, over 50%, the swelling paths have a distinct S-shape.

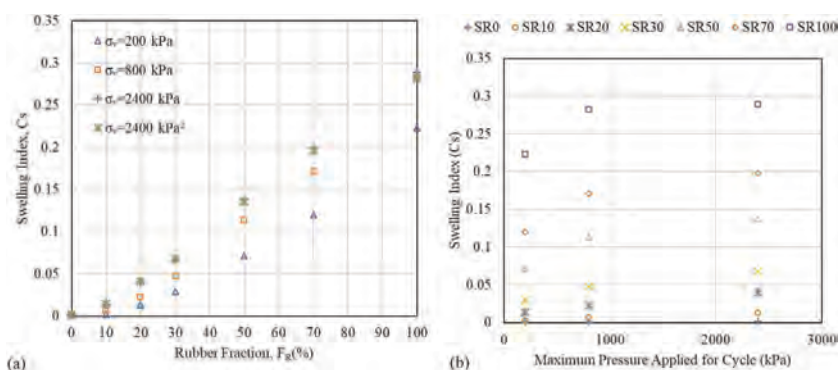
The effects of adding rubber and for one rubber content the effect of stress level from which the unloading is executed on the cyclic response can be compared by means of swelling index, C_s, Figures 4a and b, respectively. For the sand-rubber mixtures, the C_s values were chosen for the straight part of the swelling curve at the highest gradient. C_s increases with the rubber content, but the variation is linear for both swelling at 2.4MPa and non-linear for the cycles at 200 and 800 kPa (Figure 4a). The C_s variation with the stress level seems to be linear for rubber contents up to 20%, but non-linear for higher F_R values wheat higher increase gradients for pressures up to 800kPa and slower rate of increase for the pressure ranges up to 2.4MPa (Figure 4b). Overall, and based on the values of the void ratio at the end of the unloading cycle, it seems that the sand-rubber structure exhibits higher particle re-arrangements during the initial stage of the loading. As the pressure and the contact area between rubber-rubber and rubber-sand particle increases, the ability of the particles to re-arrange is reduced hence the highest values of C_s indices. As observed by Fonseca et al. (2019), the energy dissipation by unloading at higher stresses can only be explained in terms of the changes of void ratio. Humphrey et al. (1993), Edil and Bosscher (1994) and Bosscher et al. (1997) also showed that rubber-soil mixtures develop substantial initial plastic defor-mations under one-dimensional compression loading, and once the mixture is loaded to a level of reduced void ratio, the behaviour is controlled more by the elastic properties. However, the permanent deformation at the end of each cycle increases with increasing rubber fraction which is in good agreement with previous research by Sheikh et al. (2013).


Figure 4. Swelling indexes for all samples plotted a) against rubber fraction for each stress level, and b) against stress at each cycle for rubber fractions.

4 CONCLUSIONS AND RECOMMENDATIONS

The main results of 1-D loading with different unloading-reloading cycles at different stress levels for sand and sand-rubber mixtures of different rubber contents can be summarised as follows:

− Trouble content is the dominant factor controlling both C_c and C_s indices and so the ratio of elastic to plastic strains in compression as well as in unloading.
− The plastic deformation at the end of unloading is related to the applied stress level and rubber fraction.
− The plastic strain seems to be higher following the first unloading, sign of particle rearrangement, and much more reduced for the subsequent cycles, sign of reduced ability of the particles to re-arrange.

Based on the results, it seems that a clear distinction can be made between sand-like behaviour and rubber-like behaviour of the sand-rubber mixtures, and this would correspond to a F_R value of about 20%. Further research is currently conducted for the development of a constitutive model which would include modelling features to reflect the interaction mechanisms revealed by the 1-D loading and unloading-reloading cycles.

The sustainable approach to design a noise bund: Paragon Park, Coventry, Warwickshire, UK

Luckeet Rathod*
Geosynthetics Ltd, UK
International Geosynthetics Society IGS
Design Engineer

ABSTRACT: The Paragon Park phase 3 project consisted of constructing a 9.5m high noise bund, 400m in length between a new housing development and a metal recycling facility located in Coventry, Stoney Stanton Road which is in a densely populated area. One challenging aspect of the project was the soil conditions and the fill material, where site won material was to be considered to reduce the overall cost therefore avoiding the use of imported material which would also reduce the disturbance to the local community and travelers during the day. The face of the bund was also a challenge as the client wanted an aesthetic face therefore, we had to consider what possible solutions could be installed on the 70-degree steep face. The bund was built on top of a well prepared and compacted started layer and the site won material was used for the build-up of the bund with multiple layers of geogrid at various length to reduce the material cost. Within the face a rivel mesh system was used to keep the topsoil soil retained at the face with the use of the erosion control mat wraparound and help achieve the 70 degrees as each layer was constructed to achieve the total height of 9.5m. The key elements used to construct the bund: Geotextile Ekotex (nonwoven) used for separation between the different soil materials used for the project, Geogrid Strata to strengthen each layer of the bund, Erosion Control Landlok to achieve a vegetated face and a rivel mesh system to help achieve a 70deg face throughout each layer of buildup.The project was designed using the programs of Reslope and Ressa following the British Standards BS8006:2010 internal stability, Partial Factors and Interaction Factors.

1 INTRODUCTION

1.1 Site description

The Paragon Park project (Phase 3) is a site located at Foleshill Road in Coventry, Warwickshire, United Kingdom. It covers approximately 22 hectares that includes four site landfills in the northeast, a metal recycling yard in the south close to the redevelopment proposal. The redevelopment proposal was to create a residential and commercial/ industrial development on top the landfill areas

The site is underlain by variable thicknesses of made ground that overlays weathered clay and mudstone. Sandstone is expected to be present at depths of 15–20m bgl. Site won material was proposed to be used to help reduce wastage and unnecessary engineering fill import.

*Corresponding Author: Luckeet@geosyn.co.uk

1.2 Project introduction

Phase 3 for the Paragon Park project was to develop a series of low-rise houses and flats in associated soft standing areas. The site formed was to be constructed primarily of cut and fill site won material. A reinforced soil acoustic bund was requested to be designed between a metal recycling facility and a new housing development so that it can provide a noise and visual barrier whilst also being visually aesthetic.

The reason of why geosynthetic material was used for this project was to reduce the overall cost, material and carbon footprint used for the bund's construction with the site won material.

Figure 1.   Cargo containers separating recycling facility & Housing development (prior to bund construction).

Design Considerations

1.3 Noise bund geometry

The geometry for the noise bund was to be designed following the considerations below:

- Maximum height = 9.5m
- Slope angle at face (towards the recycling facility) = 70°
- Slope angle behind the face = 1V:2H
- Running Length (approx.) = 400m

1.4 Soil parameters and surcharges

The surcharge considered due to the fence being installed on top of the reinforced noise bund was a static dead load of 10kPa (unfactored) over the crest, which expands 3m.

Table 1.   Soil properties used in calculations.

Soil Type	Soil Description	Soil Class	Friction Angle $\phi'(°)$	Unit Weight γ (kN/m³)	Cohesion C' (kpa)
Reinforced Fill	Site won material: Dark brown very clayey sandy Gravel and slightly gravelly Clay	Class 2A/2C (Stoney Cohesive Fill)	30	18	0
Backfill	site won material: Very clayey sandy Gravel and slightly gravelly Stoney Cohesive Fill	Class 2A/2C	30	18	0

(*continued*)

Table 1. Continued

Soil Type	Soil Description	Soil Class	Friction Angle $\phi'(°)$	Unit Weight γ (kN/m^3)	Cohesion C' (kpa)
Starter Layer	Prepared subgrade compacted selected granular material	Class 6F2/6F5	35	18	0
Foundation Soil	Existing soil Firm becoming stiff slightly silty slightly gravelly CLAY	Existing Soil	30	18	0

- Surcharge (landscape) = 10kPa
  In order to perform the calculations, we used the following properties for the soil:
- Groundwater: Has been recorded at shallow depth within 2m of ground level across the site, therefore a value of 0.1 has been used for the pore-water conditions Ru taken it into account for the slope stability analysis calculations.

1.5 Sustainable site won reinforced fill properties

One important aspect for this project was to use the existing cuts of the site won soil as the fill for the Reinforced Soil Bund instead of importing engineered fill. This is so that the carbon content can be reduced by less traffic within the densely populated area from construction vehicles travelling to site as site entrance is on a main road.

Materials

The table and pie chart displayed below show the total CO_2e emissions associated with materials purchased for the contract.

Materials, Transport, Energy and Waste Emissions

national highways

Figure 2. Option 1) carbon footprint calculation of the reinforced soil bund with geogrids.

Imported fill was also used for the construction of the bund of which 80,000m^3 was imported from other sites located close by. The hydrocarbon and heavy metal contaminated fill would be treated and graded on site prior to its re-use for the bund. This helped avoid the import of Engineered fill that would have been used for the bund, preventing the material to be processed, graded & transported from further away. With the material being site-won the cost of import engineered fill has been reduced which sped up the construction.

The re-use of the imported material that otherwise would have gone to waste has sustainability benefits as found from calculating the total CO_2e emissions associated with the materials used for the bund was performed using the National highways carbon tool (Figure 2 & 3), considering the principles of PAS 2080:2016 to quantify, promote and deliver a low carbon solution for the project.

The analysis compared the emissions of a conventional solution using imported granular Class 6I/6J fill material to a solution using the site won & re-used fill. The following results were found (*Geosynthetics* 2021):

- 10,990 lorry loads were saved versus an unreinforced solution
- 61% reduction in land required versus an unreinforced solution
- 4,527T (58%) reduction of CO_2e versus a traditional unreinforced solution

Figure 3.   Option 2) carbon footprint calculation of traditional reinforced soil bund without geogrids.

2 SUSTAINABLE NOISE BUND SOLUTION

2.1 *Design method and standards*

The design for the internal and external stability of the reinforced soil bund was in accordance with BS8006:2010 and the global stability was in accordance with Eurocode 7 (BS EN 1997-1) for the design approaches 1 and 2. The final design proposal consisted of uniaxial Stratagrids of 60kN/m and 40kN/m as primary reinforcement with the use of compacted site won stoney cohesive material Class 2C. The total running length of the noise bund is approximately 400m with a maximum height of 9.5m and a slope angle of 70 degrees facing towards the metal recycling facility and an angle of 26 degrees towards the new housing development.

Figure 4.   Aerial shot of the completed bund.

2.2 *Sustainable noise bund design*

Below shows the detail of the solution for the bund:

- Maximum height = 9.5m
- Slope angle at face (towards the recycling facility) = 70 deg
- Slope angle behind the face = 1V:2H
- Running Length (approx.) = 400m
- Surcharge (landscape) = 10kPa
- Geogrid Reinforcement (300/600mm spacing) = 23 layers
  - 6 Layers of Geogrid strata SG 60kN/m, spacing 500mm, length 7.10m + 1.32m (wrap around)
  - 5 Layers of Geogrid strata SG 60kN/m, spacing 600mm, length 6.10m + 1.63m (wrap around)
  - 7 Layers of Geogrid strata SG 40kN/m, spacing 600mm, length 4.70m + 1.63m (wrap around)
  - 1 Layers of Geogrid strata SG 40kN/m, spacing 600mm, length 3.70m + 1.63m (wrap around)

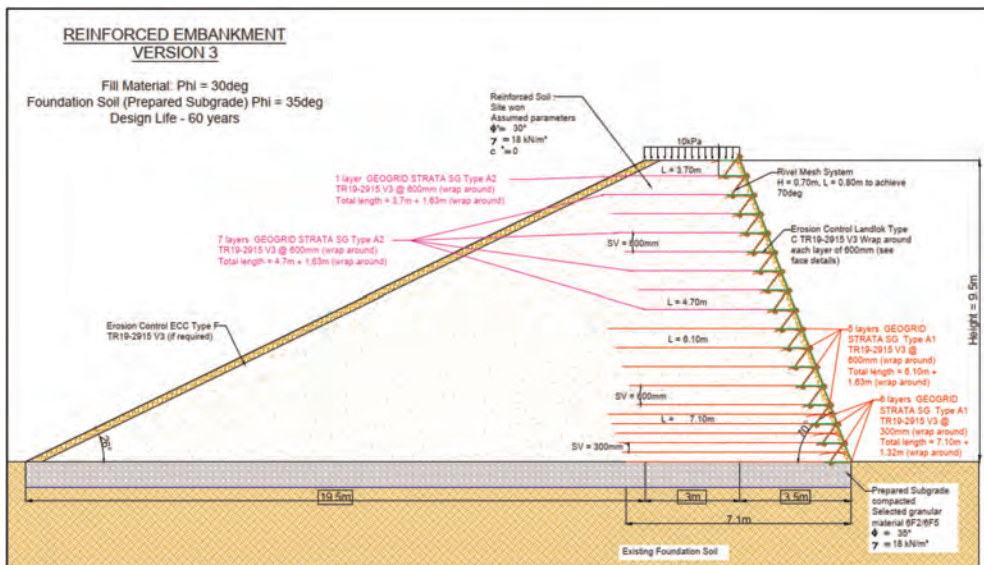
- 800mm starter layer compacted with selected granular material of class 6F2/6F5 with a layer of Geotextile wrapped around for separation.
- Reinforced fill material = Compacted site won soil class 2C (Stoney Cohesive Fill)
- Retained fill = Site won soil Class 2C (Stoney Cohesive Fill)
- Foundation soil = Made Ground Cu = 10 – 25 kPa
- Facing = each layer of 600mm compacted fill is covered with Landlok TRM (wrap around on the face) to protect the face from erosion and to avoid any wash-out of the fill material on the face.
- External Formwork = steel mesh A252, height = 700mm, length = 800mm to achieve a slope angle of 70deg


Figure 5.   Cross-section design of bund.

3   CONCLUSIONS

The use of Geogrids vastly helped in the reduction of CO_2 during construction of the bund using site won and locally imported material from other projects by reducing the time taken within the construction process, reducing on-site excavation, placement, importing fill material, testing of the material which was done on site and transportation. This resulted in less fuel consumption, travel and congestion within this area, which is densely populated, therefore reducing the emissions that would have been released into the atmosphere. As these were reduced it sped up the construction process due to not having to wait for material to be tested or being brought to site.

Geogrids helped use the existing material as they would help spread the load and make the poor soil become workable in compacted layers, instead of having been excavated and transported away whereas if Engineered fill was to be used, it would have to be imported from further locations and possibly multiple, depending on resources. Again, this would

have increased the duration of the project which consequently would have increased the CO_2 emissions emitted.

Reduction of aggregate usage, quarrying, dredging, extraction, transport, excavation, finance and waste take place when designing with a sustainable approach with the use of Geosynthetic material.

"Geosynthetics make infrastructure more sustainable. They extend the service life of roads, reduce the use of aggregates, conserve and protect water, minimize land disturbance and control soil erosion." For further research and evidence of the environmental impact and the sustainability of using geosynthetics in construction projects further supporting documents can be found (*IGS sustainability papers to feature at Italy Conference* 2022)

GRS retaining structure with paper industry waste as backfill material

S. Lenart, K. Fifer Bizjak & B. Likar
Slovenian National Building and Civil Engineering Institute (ZAG), Ljubljana, Slovenia

ABSTRACT: Deinking sludge ash (DSA) and deinking sludge (DS) represent the main waste from recycled deinking paper pulp production in a paper industry. Their mixtures were used in this research to develop a composite with the proper geomechanical properties for the backfill of GRS retaining structure. Several mixtures with different contents of DS and DSA were initially tested to develop an optimal composite. The chosen composite was used as a backfill material of the retaining wall structure built in the south part of Slovenia, near the railway line, for landslide stabilization. All laboratory and field tests confirmed the required physical characteristics are being reached.

1 INTRODUCTION

1.1 *Residues of the deinking paper industry*

Enormous amount of paper production result also in significant waste generation - 11 million tonnes of solid waste are generated per year in Europe (Garside *et al* 2019). Approximately 70% of this waste is from paper recycling, for example, deinking sludge (Monte *et al* 2009). Recycled paper residues are a potential material that could be substituted for virgin raw materials from a technical and economical point of view (Watkins *et al* 2012). Examples of pulp and paper industry residue implementation have been presented by other authors (Ferreira *et al* 2019; Gabriel *et al* 2017; Saeli *et al* 2019), but in general, most paper industry waste is burned in power plant boilers or landfilled. The production process with different fillers, pigments, and coagulates influences the type of paper ash. Also, the technology and temperature in the boilers have an effect (Fernandez *et al* 2010).

On the other hand, according to information published by the European Aggregate Association (UEPG 2018), the demand for European aggregates is 3 billion tonnes annually. About half of natural (virgin) material is consumed by the construction industry. Undoubtedly, virgin material that are used in various applications in the building sector in huge quantities, particularly for earthworks, can partially be substituted by other materials, such as recycled industrial material, including material made from paper industry waste. However, the mechanical and environment criteria for recycled materials according to the national legislation must be satisfied.

1.2 *Use of residues from deinking paper industry for construction purpose*

The existing published researches on the use of residues from deinking paper industry in construction works relates to laboratory testing. A mixture of sand, paper fly ash, paper sludge, and cement has been used in laboratory research (Wu *et al* 2018). The mixture reached a compressive strength of 0.8 MPa, which is high enough for use as a backfill material for a foundation structure, a structural fill, or a hydraulically bound layer in a road structure. Some published researches present also the field test results. For instance, a road

subgrade was stabilized in a length of 250 m with a mixture of paper sludge and cement in Portugal (Lisbona *et al* 2012). The installed mixture achieved an unconfined compressive strength of 4.5 MPa.

Paper sludge ash is also used in the cement industry as supplementary cementitious material in mortar (Sadique *et al* 2019; Vegas *et al* 2009), concrete manufacturing (Vashistha *et al* 2019), and the brick industry (Singh & Kumar 2017).

Practitioners find it difficult to decide to use recycled material in construction due to a lack of knowledge about the material, technology of installation, high cost of production, and often a negative attitude towards all new materials (UEPG 2018). Thus, the objective of the presented research was to develop a composite backfill material, consisted from the residue of paper industry production and test it in laboratory as well on the field with a pilot structure. A new composite should have high enough unconfined compressive strength and shear properties to be used as a backfill in geotechnical structures (e.g. retaining walls etc), but at the same time it should allow elastic deformation before cracking. Results published in the literature deal mostly with paper sludge ash and deinking sludge used in different mixtures with soil and other binders. It was an aim of a research also to evaluate the time effect upon the hydration process and the effectiveness of a material compaction in real environment. Geomechanical characteristics of the composite to be used as a backfill material were also evaluated in order to support future design of similar earth structures.

2 STABILITY PROBLEM TO BE SOLVED

There was an unstable slope near the railway line between Ljubljana and Novo mesto at a village Mirna Peč in Slovenia (Figure 1). Slope has been monitored for years and it was estimated that it presents a general danger to railway line. The instability of the slope was already evident during the geological-geomechanical mapping of the site. The existing telephone poles along the railway layout were unstable, the road above the slope is severely cracked and individual stone blocks are frequently unstable and inclined towards the railway line. Thus, the stabilization of slope was necessary. It was decided to construct a retaining wall along the railway line for that purpose.

Figure 1.   Unstable slope near railway line in Mirna Peč (Slovenia).

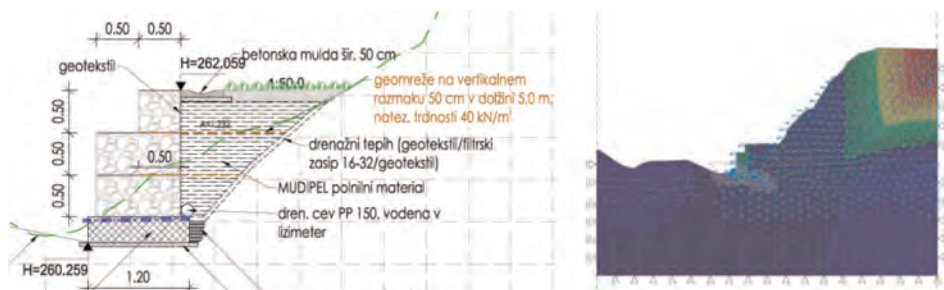
The landslide was stabilised with a retaining wall structure consisting from gabion facing and geosynthetic reinforced backfill of paper industry waste. Figure 2 presents the proposed solution with general results from FEM analysis. The input for the later are presented in the next section.


Figure 2. Proposed solution with retaining structure (left) and FE numerical model of structure (right).

3 MATERIALS

3.1 Deinking Sludge Ash (DSA) and Deinking Sludge (DS)

DSA and DS were two raw materials used in the research. They represent the main waste from recycled deinking paper pulp production at a paper industry company, VIPAP Videm Krško d.d., in Slovenia. The DSA is a combustion residue formed in a steam boiler during the incineration of DS. It consists of a mixture of bottom ash (approx. 90 wt %) and fly ash (approx. 10 wt %). VIPAP recycles around 600 tonnes of paper daily. Annually, 25,000 tonnes of DSA and 67,000 tonnes of DS are produced.

In order to design a backfill material for a retaining wall structure for the stabilization of a landslide near a railway line, several mixtures consisting of different ratios of DSA and DS were tested. Among them, two mixtures with sufficiently good geomechanical characteristics and suitable properties for compaction and installation were tested in the laboratory. Mixing proportions of the investigated mixture composites Mixtures were designated as D80/20 and D70/30, according to the composites dry mass mixing ratio DSA/DS in percentages.

3.2 Reinforcement geosynthetic

A polymer PET geogrid was used as a geosynthtetic used for reinforcing the backfill of retaining structure. The aperture size was 30 mm and tensile strength in two perpendicular directions was equal to 42 kN/m. The spacing between geosynthetic reinforcement was 50 cm.

4 TESTING

4.1 Laboratory testing of raw materials

The physical and mechanical properties of DSA and DS are presented in Table 1. DSA is a dry material, while the water content of DS ranges between 45% and 50%. In comparison with DS, the specific gravity of DSA was higher for about 20%. A standard Proctor test (SPP) showed that the optimal water content (w_{opt}) and maximal dry density ($\gamma_{d,max}$) were higher for DS. The unconfined compressive strength of DSA is between 300 and 500 kPa, which is in the range of very stiff soil according to the criteria for virgin materials. DS is a softer material in the range of stiff soil. Both materials are nonplastic.

Table 1. Physical and mechanical properties of raw materials.

Property	DSA	DS
Initial Moisture Content (w) (%)	0	45–50
Specific Gravity (γs) (Mg/m$_3$)	2.64	2.15
Optimum Water Content (wopt) (%)	51	56.5
Maximum Dry density ($\gamma_{d,max}$) (Mg/m$_3$)	0.99	0.89
Unconfined compressive strength after compaction (qu) (MPa)	0.3–0.5	0.22
Liquid Limit (LL) (%)		
Plastic Limit (PL) (%)	Nonplastic	Nonplastic
Particle Size Distribution		
Particle (>2.5 mm) (%)	0	–
Particle (0.063–2.5 mm) (%)	13.3	–
Particle (0.002–0.063 mm) (%)	75.59	–
Particle (<0.002 mm) (%)	11.11	–
D10 (mm)	0.002	–
D50 (mm)	0.02–0.06	–
D90 (mm)	0.4–0.8	–

4.2 Laboratory testing of composites

The components were mixed in a 20 L planetary mixer. Two kilograms were mixed for 2 min until a homogeneous mixture was obtained. Mixtures were compacted at the maximum dry density. In order to prevent evaporation, the composites were stored and cured in a climatic chamber at 90% RH and 22 °C. Compressive strength was tested immediately after compaction and after one, four, seven, 28, and 50 days of curing. The composite specimens were exposed to 12 cycles of freezing at −23 °C and thawing at 20 °C in a climate chamber during the freezing/thawing tests.

Similarly also the shear characteristics of the composites were tested directly after compaction and after seven days of curing. Additionally, the permeability of the composite was tested in a triaxial cell under a pressure of 50 kPa.

In order to investigate the impact of the transport time to the construction site, the time delay between mixing and compacting was taken into account. The tests were performed with two different testing procedures:

- The material was moistened to the maximum water content (w_{max}) and cured in the open air,
- The material was moistened to the optimal water content (w_{opt}) and cured in closed boxes.

After moistening and mixing, the mixtures were compacted in the following time intervals: immediately, and after 4, 8 and 24 h. After seven days, an unconfined compressive strength test was performed on each specimen.

Figure 3 left shows an increase of unconfined compressive strength with increasing of curing time. Furthermore, one can observe also a decrease of unconfined compressive strength, q_u with a higher quantity of DS in the composites. The tests performed immediately after compaction showed relatively similar values of qu (0.2–0.3 MPa), independent of the composition. After one day of curing, composites with higher percentages of DSA showed higher q_u values, accounting for the more intense hydration process in those composites.

The results (Figure 3 right) exhibit also a decrease of q_u with an increasing delay between mixing and compacting. Although a water content w_{max}, which is above the optimal one, w_{opt} causes lower q_u if specimen is compacted immediately after the mixing, the hydration process dries the mixtures and after 4 h resulted in a lower q_u for mixtures with a lower water content (w_{opt}). After 24 h, almost no difference could be observed in qu. Based on the results,

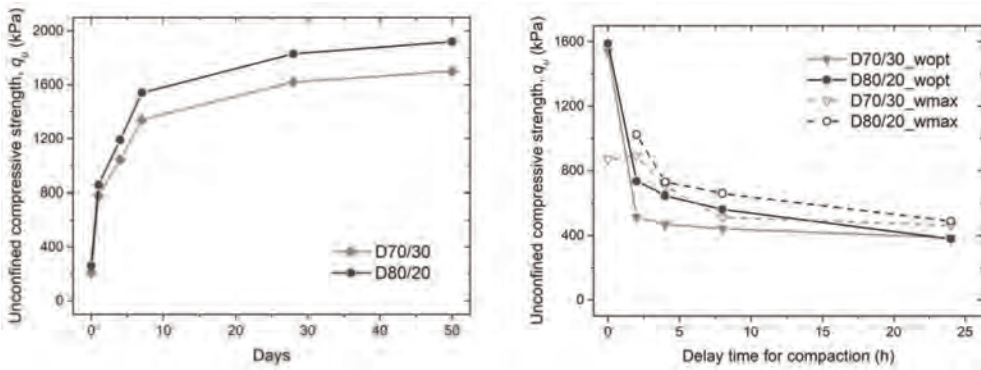
it can be concluded that the mixture compacted immediately must be moistened to the w_{opt}. For a mixture that will be compacted after 4 h due to transport, it is more appropriate to moisten it to the w_{max}.


Figure 3. Uniaxial compressive tests results for two composites with curing time (left) and with delay in compaction time (right).

The results of these tests are essential to determine the methods of mixing, transport, and installation of the mixture on the construction site and to assess the maximum distance between the composite production site and the composite construction site.

5 RETAINING STRUCTURE

5.1 *Construction*

A 50 m long retaining structure was built with the use of paper industry waste as backfill material in the south part of Slovenia. The composite D70/30 was used. Construction works were executed in August 2018. Retaining structure consisted gabion facing made from iron mesh and recycled gravel material (reused ballast material) and geosynthetic reinforced paper industry waste composite as a backfill. The structure with inclinometer measurements after completion of all construction works is presented in the Figure 4.

Figure 4. Retaining structure after completion (left) and horizontal displacements in borehole above the retaining wall (right).

5.2 *Field test and monitoring results*

The compaction tests of the installed composite D70/30 were performed at every installed layer (Figure 6). Results shows that only the first three layers were compacted below 95% $\gamma_{d,max}$. The reason for the lower compactness in the first layers is a low compaction of ground under the composite. In all other layers, a higher compaction degree was measured. Measurements confirmed that the composite can be installed according the requirements of the technical specifications.
Figure 6.   Results of the measurements with the neutron probe.

Results of shear tests of the samples taken from the composite at the construction site are presented in Table 2. They are similar to the results from the preliminary laboratory investigation and exhibit significant improvements due to hydration with time.

Table 2.   Shear properties of the compacted composite.

ShearProp.	Laboratory Results		Demo Field		
	Immediately	After 7 Days	Immediately	After 7 Days	After 28 Days
F (°)	44	45	37	40	45
c (kPa)	12	42	35	45	200

6   CONCLUSION

The geosynthetic reinforced retaining structure made of gabion facing and backfill from waste materials from the paper industry represents a successful practical example of the use of residues of the deinking paper industry. Development of composite for backfill material was supported by extensive laboratory testing, which enables use of proper composition of waste materials to achieve desired deformation properties. Furthermore, it gave also required information regarding proper composite mixing and installation, which were finally confirmed by field quality control tests.

Analysis of the generation of plastic debris and microplastics from geosynthetics

F. Fontana
Geosynthetics Consultant, Valbrenta, Italy

P. Rimoldi
Civil Engineering Consultant, Milan, Italy

M. Scotto & M. Vicari
Officine Maccaferri Spa, Bologna, Italy

ABSTRACT: The uncontrolled generation and dispersion of plastic debris and microplastics in the environment and particularly in the oceans has become a global problem. The present paper intends to critically analyse the source and quantities of microplastic debris produced by geosynthetics vs the environmental benefits afforded by geosynthetics. The paper considers the environmental innovation in the geosynthetics industry. Some fake news which associate geosynthetics to detrimental effects like the generation of plastic debris and microplastics are critically analysed. It is shown that in reality the advantages of geosynthetics are much larger than disadvantages, while detrimental effects are absolutely minimal. The conclusions highlight the undisputable fact that the generation of plastic debris and microplastics from geosynthetics is very limited, and lower than the quantities of microplastics generated by alternative solutions.

1 INTRODUCTION

The uncontrolled generation and dispersion of plastic debris and microplastics in the environment and particularly in the oceans has become a global problem. On one hand, environmental associations, social media, government agencies are claiming more and more attention to this problem, which risks to compromise the flora and fauna of all oceans, seas, lakes and rivers in the world. On the other hand, the same stakeholders and even the scientific community produce everyday fake news and sometimes unreasonable alerts about the amount and toxicity of plastic debris in the oceans. Also geosynthetics are sometimes associated with the production of such plastic debris and microplastics. The present paper intends to critically analyse the source and quantities of plastic debris produced by geosynthetics vs the environmental benefits afforded by geosynthetics.

2 MICROPLASTICS IN GENERAL

2.1 *What are microplastics?*

At present there is no normative definition of microplastics (MP), while MP are generally considered as plastic particles of different polymer composition, the size of which is < 5 mm,

for two or three dimensions. Nowadays, the following classification is increasingly found in publications:

- Macroplastics: particles with size > 5 mm in at least 2 dimensions
- Large microplastics: particles with size of 1 mm – 5 mm
- Small microplastics: particles with size of 1 µm - 1 mm

  Microplastics can be classified into two categories (Ebbert *et al.* 2020):

- Primary MP: plastic particles whose size already meets the size criterion for microplastics (< 5 mm) during their production and deliberately introduced on the market (e.g. particles in the toothpaste or skin scrubbers), or involuntarily introduced into the environment (e.g. granules and pellets). This category is said to represent from 15 to 30% of MP in the oceans and are expected to increase at a rhythm from 0.8 to 2.5 millions tons per year. Figure 1 (from Heß *et al.* 2018) shows possible forms of primary microplastics.
- Secondary MP: particles produced by the progressive fragmentation of macroplastics, separated by mechanical processes (e.g. abrasion), chemical degradation or UV exposure. As it can be seen in Figure 2, Image C, fibres also fall under secondary microplastics. According to Heß *et al.* (2018), the fibres come mainly from synthetic textiles, nets or ropes. Beer *et al* (2018) has looked at the microplastic accumulation in the Baltic Sea over the past 30 years: the fibres found in this study also originate from the wash water and were mainly found near large cities.
Figure 1. Primary microplastics (a: microbeads; b: raw pellets compared to microbeads; c: comparison between round microbeads and primary microplastics from cosmetics production) (from Heß *et al.* 2018).
Figure 2. Secondary microplastics (a and b: decomposition products of larger plastic parts; c: textile fibers) (from Heß *et al.* 2018).

2.2 *Where do plastics in open waters come from?*

Independent data shows that most plastic waste entering the environment is a result of poor waste management. In contrast to many consumer plastics, geosynthetics do not normally degrade and can be fully recovered and recycled at the end of their service life.

Marine plastic waste is derived from a huge variety of different sources reflecting the widespread and diverse uses of plastics. The EC's own figures (NOC, 2021) estimate that the origin of microplastics has the following statistical distribution (Figure 3): tires consumption: 48%; pellets: 28%; naval paintings: 10%; textile fibres (fibres released during laundering): 8%, road markings: (7%). Single use consumer plastics such as carrier bags and plastic bottles also contribute. The distribution of microplastic lost to the environment is dominated by elastomers (likely derived from tires), while macroplastic losses correlate with polymers commonly used in packaging including LDPE, HDPE and PP, and those most commonly produced overall.

Heß *et al.* (2018) estimated that of the 117 g per head per year ascribed to German construction sites, 90 g is due to demolition work; 25 g due to on-site processing of plastics, and 1.7 g due to losses from insulating materials. Hence the amount of microplastics released on construction sites is 10 times smaller than the main emitter, tire abrasion. Geosynthetics are not even mentioned.
Figure 3.   Main MP in oceans: pellets, tires, naval paintings, textile fibres released during laundering.

WWF (2022) clearly identifies the pathways of macroplastics into the ocean: it has to be noted there is no indication of any source from coastal protection structures.

2.3   *How are microplastics in the ocean produced?*

The aging of plastic items and particles will significantly alter their behaviour and fate due, for example, to loss of plasticisers and other chemical additives, fragmentation and degradation, and biofouling. Loss of additives can lead to change in colour, altered shape and embrittlement of plastics, ultimately leading to their degradation. At near-ambient temperatures chemical degradation typically involves either oxidation (involving O_2) or hydrolysis (involving H_2O), both of which can be accelerated by microbial action, heat and light. There are three important processes that impact the extent and speed of marine plastic degradation:

1. Bacterial and other organism colonisation of the surface of plastic particles will both physically
2. degrade the particles and generate biofilms which may produce enzymes that erode the surface.
3. Abiotic hydrolysis of functional groups, like esters, carbonates, and amides, can sever the large macromolecules which make up polymers, reducing their molecular weight.
4. Exposure to UV radiation and oxygen causes photodegradation, also reducing molecular weight, causing cracking that produces microplastics. This process produces aldehydes and ketones, further encouraging the development of biofilms. Physical weathering will also enhance interactions with organic pollutants, potentially making them more hazardous.

Therefore, when examining marine plastic waste, it is crucial to understand not only the sources and pathways of plastics, but also the chemistry of the plastics involved. Furthermore, the sorption of pollutants onto plastic particles is not the same across different types of plastics.

2.4   *Need to distinguish the types of plastic*

There are thousands of types of plastics with different polymer compositions, additives and characteristics that may be classified in different ways, based on their chemical composition, application and thermosetting properties. The physical characteristics of plastics can broadly be divided into two categories: 1) thermoplastics (which can be remelted and remoulded) and 2) thermosets (which cannot return to their original state once set). Additives within plastics give them their inherent properties, but are not chemically bound to the polymer's chemical structure

and can thus leach out over time, changing the properties of the plastic as it ages. The more commonly used polymers are high density polyethylene (HDPE), polyvinyl chloride (PVC), low density polyethylene (LDPE), polypropylene (PP), polystyrene (PS), nylon (polyamide, PA), and polyethylene terephthalate (PET). The distinct physical and chemical properties of plastics play an important role in determining the extent and rate of transformations (e.g. fragmentation, degradation, aggregation) and interactions (biofouling, ingestion, sorption of other pollutants) for different plastics in the ocean, and thus their persistence and impact on the biota within it. The impacts on biota and the ecosystem will depend on their composition, concentration, routes and time of exposure, as well as the state of organisms exposed (e.g. age and level of nutrition), all of which require intensive in situ and laboratory-based assessments, as they are currently at the very early stage of being quantified and understood.

2.5 *How are microplastics measured?*

Two methods have been proposed to count and measure microplastics: 1) number of pieces; 2) by weight. The most common techniques to reliably identify MPs seem to be spectroscopic (infrared (IR) spectroscopy and micro-Raman spectroscopy (RM)) or thermal degradation methods.

While the mass-based thermo-analytical methods can determine the overall mass of different polymer types, the spectroscopic methods provide information on the polymer type, number, size and size distribution, and morphology for each analysed plastic particles and MPs in a sample. Spectroscopic methods seem particularly well suited for gathering these characteristics, because they permit a direct enumeration of potential MPs and in contrast with colorimetric methods (use of dye) or morphological methods (e.g., scanning electron microscopy, SEM) they should be capable of specifically determining their identity through a complete spectral pattern recognition.

Anyway JRC, Joint Research Centre of the European Government, organized two years of interlaboratory investigation with 98 labs involved all around the world, with comparison with contextual studies in Norway (34 labs) and America (40 labs); this research got discouraging results, since the z-scores show a very poor reliability and reproducibility of the current methods.

Hence standardisation and reliability of methods are still a long way to reach, and a challenging task for the international technical community.

3   MICROPLASTICS AND GEOSYNTHETICS

3.1 *Effects of microplastics from geosynthetics*

WWF (2022) found that 190 marine species out of 2788 show some effects of MP with different importance and depending on the type of polymers.

According to Scholz *et al* (2021), ecotoxicity tests were performed to evaluate the geosynthetic leachate ecotoxicity: a combination of bioassays was applied, where both acute and chronic tests and organisms representing two trophic levels were used. The loss of additives, such as plasticizers and antioxidants, during the ageing of geotextiles potentially can add to the concentrations of hazardous substances in the water. Another consideration is that the base structure forming polymers gradually degrades to microplastic particles, and as such can be ingested by heterotrophs or interfere with algal photosynthesis. However, ecotoxicological test results in this research did not show significant toxicity of geotextile leachates to water organisms. In case of microalgae, the test samples showed even nutritive properties, as an increase in microalgae concentration was observed during the 72 h of the test. Currently, there is limited research in the field of geosynthetic ecotoxicity, but a study evaluating the environmental safety of construction

products also found that geosynthetic PET multifilament yarns and polyamide mono-filament with Polypropylene fleece coating have low toxicity. A lethal concentration (LC50) was calculated only for specific amphipods. However, the LC50 at 83% and 89% concentrations can be considered as very low toxicity. As geosynthetics in hydraulic engineering are exposed to intensive water exchange, no toxic effects in the environment could be observed.

3.2 *Beware fake news*

The two article by Bai *et al* (2022.a and 2022.b) are a dramatic example of fake news about microplastics derived from geosynthetics, even presented as scientific data. Instead, these papers lack any scientific rigor where the authors wrongly evaluate that geotextiles are a high-volume source of ocean microplastics. In facts, the numerical values, assumptions made and conclusions drawn in the papers are seriously flawed (NOC, 2021) and result in unrealistic amounts (Dixon, 2017). A first element to support this statement is related with the assumptions made regarding the mass per unit area of geotextile and the lifetime of geotextiles. A second element is related to the amount of exposed geotextiles (to UV). Those statements are supported by the developments here presented.

1 - Mass per unit area of geotextiles

Bai *et al* (2022.b) mention the following assumptions:

- An amount of fibres released in the range 0.696 to 2.267×10^6 particles per square millimetre or 0.696 to 2.267×10^{12} particles per square meter
- A typical linear density of 0.03 mg per mm, thus 3×10^{-5} kg/m
- An assumed average fibre length of 100 nm per particle

Therefore, although not outlined in the paper, the author calculates a production rate, PR, in kg of microplastics per m^2 of geotextile due to exposure in the range:

$$0.696 \times 10^{12} \times 3 \times 10^{-5} \times 100 \times 10^{-9} \ \leq PR \leq 2.267 \times 10^{12} \times 3 \times 10^{-5} \times 100 \times 10^{-9} \quad (1)$$

$$\text{Thus}: \ 2.088 \leq PR \leq 6.801 \quad (2)$$

Those figures are unrealistic for two reasons:

- According to Eq. (2), each m^2 of geotextile would produce from 2 to 6.8 kg of MP! But most geotextiles manufactured are far less than 2 kg/m^2 (Heerten 2012) and therefore there is not enough geotextile mass available to produce this amount of microplastics.
- Even if the geotextiles were of sufficient mass, this calculation estimates that the entire mass of the geotextile would degrade to 100% microplastics within 1 year, which is totally unrealistic (Koerner 2012).

2 - Amount of geotextiles exposed to UV

The paper Bai *et al* (2022.b) states that, at present, the quantity of geotextiles used globally has reached 14 billions square meters, out of which only 2% are natural fibres. Due to different degradation mechanisms of various types of geotextiles, only the number of microfibers released by PET geotextiles under coastal reclamation was estimated. PET geotextile production is assumed to account for up to 5% of the total production of geotextiles worldwide. Geotextiles used for drainage in coastal reclamation areas are assumed to account for 17% of the global market share in 2019. Based on the assumptions mentioned above, the authors obtain an amount of PET geotextiles used globally and exposed equal to 116,620,000 m^2.

Combining with the previous estimates from Equations 2, the authors obtain a Global Microplastics Production discharged every year into the environment from PET geotextiles only as presented in Equation (3):

$$\frac{2.088 - 6.801 \text{kg}}{\text{m}^2}/\text{year} \times \frac{1 \text{ton}}{1000 \text{kg}} 116,620,000 \text{m}^2 = 0.24 - 0.79 \text{ million tons/year} \quad (3)$$

It is not possible to agree on those figures (Freedonia 2020). Indeed, to perform these calculations, the authors assume that all geotextiles used in drainage applications (17%), made of PET (5%), are used exposed and in coastal protection applications, degrading to 100% MP.

Instead, extremely small quantities of geotextile are used for drainage in coastal reclamation areas. A small quantity of geotextile is used in the applications of erosion control (Rimoldi2021) and other coastal protections (Boucher 2017). A vast majority of these materials are buried or otherwise protected by covering (Koerner 2012). The authors make an inadmissible error in both extending their research from one site with specific conditions to global quantities of emissions; moreover, the assumptions and claims made in the document are inconsistent and unacceptable.

As comparison, the correct figures can be derived from Ebbert *et al.* (2020): a total of around 360 million tons of plastic are produced worldwide every year. The proportion of technical textiles made from synthetic filament fibres is 34.5 million tons or 9.6%. The proportion of the quantities processed in the construction industry is again significantly lower at only 1.4%. In hydraulic engineering, physical decomposition processes can occur, e.g. in the case of products exposed to the free flow due to sediment carried along in the water. However, this still includes a large proportion of textiles used in building construction (75% of the 1.4%). This includes gardening and landscaping textiles and a fifth of total amount used in building construction. Accordingly, the actual share of geotextiles, industrial and agricultural textiles is less than 1 million tons.

These figures can help to clarify that the proportion of geotextiles in relation to the total amount of plastic produced is very small.

It is clear that Bai *et al* (2022.a and 2022.b) figures of the global production of MP from geosynthetics are dramatically wrong, being 1 million to 1 billion times bigger than the reality!

3.3 *Life cycle*

It is clear that the whole geosynthetics industry do not produce any primary MP.
The issue of secondary MP depends on two main factors:

- Time gap between physical life and service life
- Exposure, during the service, or at the end of the life, to the degradation factors: oxydation, UV, temperature, abrasion, chemicals.

3.4 *Benefits of geosynthetics*

From Scholz *et al* (2021): the application of geosynthetics in coastal protection has huge economic benefits, such as savings via substitutions of or reductions in selected soil materials, ease of installation, increased speed of construction, life cycle cost savings through improved performance (by increased longevity or reduction in maintenance), and improved sustainability in terms of conserving natural environments as compared to alternative designs. It is commonly accepted that geosynthetics which are adequately stabilized with antioxidants (e.g., sterically hindered amines) will last in underwater constructions with limited oxygen supply and temperatures at constantly low levels for at least 100 years.

When used to line containment units, geotextiles hold sand fill, which results in a stable mass-gravity unit that is erosion resistant and structurally sound. They answer the growing concern over the environment and the concomitant restrictions in mining and quarrying. In addition, by allowing the use of locally available natural materials, high transportation costs and the associated pollution are avoided, An interesting element is that artificial reefs and submerged breakwaters made from geotextile tubes, geobags, and geogrid-assembled marine mattresses units provide a safe, injury-free environment for humans in close proximity to populated beaches. Geotextile containers also attract an abundance of marine plants and life soon after construction, making such living breakwater a prime marine habitat (Phillips 2013, see Figure 5). Moreover, there are many cases where geosynthetic structures enable the preservation of endangered species: several studies have shown that geosynthetics provide new habitats, proving to be effective for future preservation activities and offering safe solutions that fully integrate into the surrounding environment. Geotextiles are placed on glaciers to protect the ice against high temperatures and solar radiation, thus reducing and retarding the melting rate of snow and ice (Figure 5). Geosynthetics reduce freshwater losses from irrigation canals in water-stressed regions and play a critical role in water and wastewater treatment plants. Compared to other construction materials, their carbon footprint is typically 65% lower. They protect lives and livelihoods by reinforcing slopes and underpinning vital infrastructure. Geosynthetics offer a durable, reliable and resource-light means to protect vulnerable coastal zones from erosion. They also help to contain millions of tons of plastics wastes stored in landfill every year.

Figure 5.   Examples of living breakwaters with geosynthetic (from Phillips, 2013) and of geotextiles for protecting glaciers.

As shown above, the major source of MP comes from tires: hence geosynthetics, being light and non-voluminous products requiring an average of 50 times less trucks for transport compared to granular materials, afford to save million tons of microplastics which would be generated by thousands of trucks of clay or gravel or concrete consuming the tires.

3.5   *Risk of microplastics release*

It is important to fully consider the entire lifecycle benefits of all products that use synthetic materials in their manufacture. It is inappropriate to compare single-use consumer plastics, which decompose rapidly and are often disposed of irresponsibly, with high-quality durable engineering products that deliver long-lasting benefits to entire communities. Geosynthetics present a negligible environmental risk, and where risk exists at all, it is a rare occurrence within the highly regulated disciplines of civil and environmental engineering. Potential examples such as the use of incorrectly specified products or misguided installation and

maintenance practices are addressed through high technical and professional standards in the industry.

Geosynthetics are destined to a service life cycle designed to be as long as their physical life.

They allow to reduce the use of materials destined to undetermined service lives, and extremely expensive in environmental terms (like concrete, gravel, sand)

It is evident that, for 99% of the applications, geosynthetics are installed underground or under water with limited or absent problems of oxygen, without UV, without high temperatures, and without heavy mechanical or chemical actions.

Geosynthetics are made with the best polymers for obtaining very high durability and very long service life, with UV protection additives and antioxidant additives.

In literature the reported cases of supposed or possible MP release from geosynthetics are very few and essentially related to wrong design or wrong choice of the products.

From Scholz *et al* (2021): only the improper installation of the geotextiles and the lack of service and maintenance after extreme weather events could cause the failure of the engineered structures and, as a result, the pollution of the environment by remnants of geosynthetic materials. The successful application of geosynthetics in coastal protection depends on the selection of suitable materials and proper installation and maintenance.

From Scholz *et al* (2021): the field study performed at the shore of Kaliningrad Oblast (Russia) demonstrated that remnants of geosynthetic materials that are used in coastal protection structures (geotextiles, geocells, geogrids, plastic coating from gabions, and geotextile big bags) were found in the environment and were the mostly visible litter on the beach.

But it has to be noted that litter is not, or not yet, microplastic!

It is evident that the found objects could be attributed to unsuitable material selection and improper waste management. Considering that any damage, even partial, of the coastal protective constructions using geosynthetic material could lead to the littering of the beach or the sea, specific attention is needed for the maintenance of such constructions.

The base structure forming polymers gradually degrades to microplastic particles, and as such can be ingested by heterotrophs or interfere with algal photosynthesis. However, ecotoxicological test results did not show significant toxicity of geotextile leachates to water organisms. In case of microalgae, the test samples showed even nutritive properties, as an increase in microalgae concentration was observed. Moreover, a study evaluating the environmental safety of construction products also found that geotextiles made of PET multifilament yarns and polyamide monofilament with PP fleece coating, have low toxicity.

All this means that for geosynthetics there is very low or even negligible environmental risks from microplastics release.

4 ENVIRONMENTAL INNOVATION IN THE GEOSYNTHETICS INDUSTRY

Innovative research has been focusing on biodegradable polymers of natural origin, like cellulose fibres, viscose fibres and others, including poly(lactic acid) or polylactide (PLA), to reduce the use of plastics. Among the fully biodegradable polymers, PLA seems to be one of the most promising. PLA is a thermoplastic, high-strength and high-modulus polymer that has already been used on large-scale production and commercialized for a wide range of fields.

Biopolymer ensures several advantages in terms of sustainability and eco-compatibility: (i) they derive from renewable agriculture-based resources; (ii) they decompose into non-toxic substances, as water, carbon dioxide and humus; (iii) they degrade quite slowly; (iv) they are recyclable and compostable. In addition, some biopolymer based products can be reinforced with a wide variety of natural fibers such as bamboo, coir, cotton, flax, hemp, jute, kenaf, ramie, sisal.

Geosynthetics from biopolymers are used at present for short term applications, but their use in combination with live plants, where the root system development initially supports and then gradually substitutes the biodegradable products in soil reinforcement. Moreover, biopolymer can be used as environmentally friendly coating for polymer coated wire products.

Another innovation is the use of recycled polymers: one of the largest applications is the production of woven geogrids and nonwoven geotextiles from shredded polyester (PET) bottles; billions PET cold drinks bottles are used annually to produce geosynthetics with recycled polymers.

Hence innovative companies are raising the bar on the use of recycled content in the manufacture of high-quality geosynthetic materials.

Other geosynthetic companies are implementing new methods to offset carbon emissions, while other companies are developing new techniques for the greener disposal of geosynthetics and withdrawal of the products at the end of the service life in case of temporary applications.

These initiatives are having a huge positive socio-economic impact, including lowering greenhouse gas emissions during construction, longer-lasting engineering solutions and more effective waste management.

5 CONCLUSIONS

Geosynthetics, like any material, have an impact on the environment, yet this impact is much smaller than the alternatives.

The examples and measures shown in the paper make it clear on one hand that the use of geosynthetics is accompanied by a saving in microplastic emissions and, on the other hand, that greenhouse gas emissions are significantly reduced. Geosynthetics are therefore not only advanced materials but also ecologically sustainable building materials, provided they are manufactured, correctly designed and installed, and recycled in a sustainable manner.

The paper considers the recent use of biopolymers and of recycled polymers, which represent an important step towards decarbonised geosynthetics and polymer coated wire products.

Fake news available even in scientific literature, reporting non-scientific and sometimes catastrophic data, have been critically analysed.

In conclusions we highlight the undisputable fact that the generation of plastic debris and microplastics from geosynthetics is negligible and surely not worth of any negative evaluation vs the technical and environmental advantages provided by these products.

Hence, Geosynthetics are a part of the solution and not of the problem: geosynthetics are convenient products that improve the ecological and economical future of our planet.

Some current topics regarding geomembrane liners and floating covers for water storage reservoirs

M.A. Sadlier*
Geosynthetic Consultants, Australia

ABSTRACT: Current issues in the renovation of water supply reservoirs by the replacement of old geomembrane liner and floating cover systems with new systems are discussed. Topics include sampling and testing, underdrain systems, material choices, floating cover access for maintenance and the impact of conductive geotextiles on leakage rates.

1   BACKGROUND

In Australia and New Zealand many water storages and service reservoirs were renovated around the year 2000 and were fitted with geomembrane liners and floating covers based on flexible polypropylene (fPP). These fPP materials whether reinforced or not reinforced have suffered greatly from degradation as a result of their exposure to solar radiation and exposure to chlorine compounds in the stored water.

As a result there has been a need to inspect, sample and evaluate these materials and their state of degradation. This has also generated a lot of work to renovate these reservoirs and fit them with new liners and floating cover systems.

Aspects of the work including material selections were discussed by Sadlier and Frobel (2018) and this paper discusses other contemporary aspects of these reservoir renovation works.

2   SAMPLING AND TESTING

The liners and cover materials are generally in operating clear water reservoirs containing treated and usually disinfected water. Because the aged fPP materials have become difficult to clean and seam properly there has been a reluctance to take larger samples that would require substantial repair that may affect the operation of the facility. Larger samples provide an opportunity for tensile, tear, puncture and other mechanical testing.

In many cases smaller and less obtrusive samples have been taken from weld flaps and under perimeter batten bar fixings (See Figures 1 and 2) and this has required the use of tests such as Oxidation Induction Time (OIT) and High Pressure Oxidation Induction Time (HPOIT). These analytical tests use small samples the size of a thumbnail to assess the remaining anti-oxidant capacity of the material and the OIT method is applicable to materials with mainly phenolic anti-oxidants and the lower temperature HPOIT is applicable to materials with mainly hindered amine anti-oxidants.

The fPP materials generally used hindered amine anti-oxidants and that makes the HPOIT test the appropriate method to use. Although not often specified at the time these

Figure 1.   A small cover material sample taken from a ballast tube partly under a batten bar.

Figure 2.   A small liner material sample taken from under a batten bar. This floating cover had many small marked holes which had been caused by embers from a grass fire.

fPP materials generally had HPOIT values in the order of 100 to 150 minutes when new and we often see values now of around 50 minutes in sheltered samples and less than 30 minutes in exposed samples. At these low HPOIT values it is clear that these fPP materials are close to the end of their useful life.

3 LINER UNDERDRAIN SYSTEMS

Many of these reservoirs were originally constructed in fairly rural settings on the periphery of cities and towns and as populations grow they are often being encroached upon by urban environments. This has driven a need for demonstrated control of water leakage and this has resulted in these renovations seeing more and more use of double liner systems for better leakage control.

In some cases an existing concrete liner might be utilised and in others the old liner might be sufficiently effective to function as a secondary liner. There have been other projects where a choice has been made to install a complete new double liner system. See example in Figure 3.

Figure 3. A reservoir with the old discoloured fPP liner being used as a secondary liner. The white material on the floor is a drainage geocomposite and the black material on the slopes and the floor is a conductive non-woven geotextile with a unit mass of about 350 gsm.

These double liner systems have an underdrain system based on a geonet or geocomposite drainage layer and will often make use of conductive materials such as special conductive geotextiles to facilitate electronic leak location surveys. When conductive geotextiles based on graphene coated needled non-woven geotextile fabrics are used and heavier grades are available, they may be adequate for drainage on slopes without the need for a geonet as well as providing the other protective cushioning benefits of a heavy non-woven geotextile.

Where a reservoir has an existing gravity underdrain pipe under the embankment that will be tested and utilised if effective. However, because of the difficulties involved with properly grouting the annulus around a pipe new under embankment bores are not used and a down the slope pipe with a bore pump installation is used instead. See Figure 4.

The conductive geotextiles based on needled non-woven geotextiles are quite robust and easily installed with overlaps seamed by a wedge welder. However, supply situations have occasionally made them unavailable, and a few projects have used a needle punched composite with a 150 gsm non-woven geotextile base and a thin conductive film of polyethylene. This has required a separate drainage layer and has been much less robust than the heavier conductive non-woven geotextile.

Figure 4. An underdrain water extraction system with a down the slope pipe with a bore pump.

Figure 5. Holes in a conductive composite made by workers walking on it. These required patching to ensure adequate conductivity.

4 GEOMEMBRANE LINER AND COVER MATERIALS

Whilst high density polyethylene (HDPE) might be expected to dominate as the liner material of choice due to its cost advantages there other materials being used such as 1.1 mm thick reinforced polyvinyl chloride with elvalloy plasticisers (PVC/Elvalloys). Bitumen geo-membranes and coated fabric geomembranes are being considered if a new secondary liner is required.

All of these materials lie a lot flatter on the underdrain or subgrade with less wrinkles than HDPE and this has a positive influence on the quality of the subsequent work on primary liners and floating covers. Sometimes on sites with tight access the narrower (2-3 m wide) rolls are helpful and larger panels can be fabricated if required.

For the floating covers the PVC/Elvalloys are often being used in a 1.5 mm thick grade and reinforced chlorosulphonated polyethylene (CSPE) is still preferred on occasions. The PVC/Elvalloy materials are formulated to be suitable for both potable water and direct sunlight exposure. There are other PVC materials for water reservoir floating covers that have different formulations for the top and bottom coating layers.

A detailed discussion of the available materials was given by Sadlier and Frobel (2018) and will not be repeated here.

The fPP materials have not been considered recently because of their poor performance in the past. However there is now some interest in the newer formulations of fPP driven partly by the cost advantages offered and partly by the availability now of extended accelerated UV testing by QUV of up to 40,000 hrs. This interest has so far only extended to putting some large sample materials out at existing reservoirs for both water and sunlight field exposure and evaluation.

5 FLOATING COVER ISSUES

Access onto covers for maintenance remains a concern. Access is needed for water sampling and to clear leaves and other debris from the pumps or foot valves in floating sumps. The anti-skid surfaces on the walkways are much better than previously but there is still a reluctance to have personnel working on the cover.

Although there are openings for surface water release the ponding of surface water can be clearly seen along with the associated collection of leaves and debris.

Figure 6 is an example of a cover with floats for tensioning each side of the ballast lines and additional floats for walkways. These often have openings in the float paths intended to allow surface water to move around and enter the ballasted trench area for collection and removal. Prevailing winds can cause the water to pond and windblown dirt and soil collect at those locations and make the ponding worse.

Figure 6.   A floating cover with foam floats for tensioning and other floats for access walkways.

Especially on older floating covers there is a reluctance for personnel to use the access walkways to remove the leaves, soil and debris. There is also a reluctance to empty the reservoirs in order to carry out necessary maintenance and cleaning. In Figure 7 it can be seen how this can lead to substantial growth of undesirable vegetation.

Figure 7. A 30 year old CSPE cover where a lack of maintenance has allowed vegetation to grow.

6 LEAKAGE RATES

Based on North American data Peggs and Giroud (2014) suggested a range of action leakage rates for water supply reservoirs which included a suggestion for an expectation of leakage of around 2600 litres/hectare/day for a water depth of about 5 m.

A collection of ten of the recent renovation projects in South East Australia discussed above have seen PVC/Elvalloy geomembrane liners installed over geocomposite drain systems with existing compacted clayey soils, concrete liner or old geomembrane retained as a reasonably effective form of secondary liner. In terms of surface area the reservoir sizes have ranged from 3000 sqm to 10,000 sqm with effective depths of in the range of 4 to 8 m.

The majority of them used a conductive geotextile to facilitate an electronic leak location survey by the Spark or Arc Method (ASTM D7240 or ASTM D7953 respectively) and others had water introduced to enable a dipole water puddle or water lance leak location survey (ASTM D7002 or ASTM D 7703 respectively). All had independent third party quality assurance inspections.

Due to privacy concerns, we are not able to publish exact details but observed leakage rates were all less than 150 litres/hectare/day and in about half the cases less than 100 litres/hectare/day. Whilst these adapted secondary liners might not have been perfect these leakage rates are indicative of what can be achieved with good quality control and a conductive geotextile to facilitate an electronic leak location survey.

Points of weakness for leakage in renovation of these old reservoirs are seen to be the old concrete structures and the geomembrane liner fixings to the old structures such as shown in Figure 8. The concrete can be cracked, porous and rough providing a poor surface for an underwater batten fixing. Sometimes surface grinding of the concrete is enough but on other structures a coating with something like a smooth sprayed polyurethane is required and there are other structures that are best replaced.
Figure 8.   An old concrete structure for a scour outlet.

7   CONCLUSIONS

This paper has discussed a number of contemporary issues in the renovation of existing water supply reservoirs by the installation of new geomembrane liners and floating covers. Topics have included:

- Sampling and evaluation of existing materials
- Underdrain systems and options for removal of leakage water
- Liner and cover materials
- Cover design, access and maintenance
- Conductive geotextiles and the impact on leakage rates

ABSTRACT: In the mining plant, it is usual to direct rainwater to the nearest water bodies to reduce the accumulation and infiltration of water into the mining structures. However, little is discussed to minimize turbidity in the generated effluent, using downstream dam structures, that stabilize and reduce the turbidity of this effluent. Due to the environmental incidents of recent years, environmental agencies are imposing restrictions on projects for new dam structures. Because of this, mining has sought other technologies to solve the problem of fine sediments in water bodies. In this context, turbidity curtains act as filters and deflectors of suspended sediments, favouring turbidity reduction. The objective of this study was to analyse the performance of two turbidity curtains, installed downstream of a waste rock dump at a phosphate mine in Alto Paranaiba, Brazil, to investigate the performance of these structures when subjected to high peak flows. The results obtained in this study confirmed the effectiveness of the curtains and will support the design of new structures for future sediment containments.

1   INTRODUCTION

The turbidity curtains are vertical, flexible structures that extend downward from the water surface to a specified water depth and are designed to contain or deflect suspended sediments or turbidity in the water column (Francingues & Palermo 2005). These structures are supposed to divert sediment-laden currents towards the bed, thereby reducing the time particles take to settle and the horizontal range of influence of the suspended sediment (Radermacher *et al.* 2016).

The present work evaluated the possibility of incorporating turbidity curtains into the drainage system of a waste rock dump, still in the construction phase, in a phosphate rock mine in Alto Paranaiba, in Minas Gerais, Brazil. The area has a rainfall distribution concentrated in a restricted period of the year (rainy period), with a high solid carrying potential. Not been able to construct a dam to contain the sediments at the site, the investigation of other engineering solutions capable of reducing turbidity of the effluent is necessary.

The present study aimed at reducing the turbidity of the effluent generated by the drainage system of the waste rock dump by installing turbidity curtains in the receiving pond of this effluent. A hypothetical deductive method is used to evaluate the performance of the curtains in reducing turbidity as well as if they will survive the adverse conditions of working with peak flows.

2 MATERIAL AND METHODS

2.1 *Materials*

2.1.1 *Curtains*

The irregular rainfall regime makes it very hard to control the input flow in the pond. Thus, it can be assumed that the main risk associated with the experiment is the possibility of the curtains to collapse, either by the rupture of the tension cable, rupture of the woven geotextile or detachment of the anchorages due to flow peaks resulting from heavy rainfall.

Peak effluent flow can promote currents with high speeds, causing an increase in the risk of rupture or failure of the installed devices. The curtains in the present case-history were installed in two parallel sections, with an angle of approximately 45° to the flow direction. The geometry was of a labyrinthine type to increase the probability of the installed curtain to resist to the mechanical effects of weather variations and strains during the rainy seasons of 2021-2022.

The labyrinth configuration of the curtains was adopted due to the risk of rupture of the structure. The mining company did not receive installation support from the curtain manufacturing company, which yielded to an installation in a more effective configuration as suggested in the literature (Francingues & Palermo 2005; Johanson 1978).

In places where the curtains can be exposed to high hydraulic loads, it is suggested to adopt a tension cable to dissipate the loads at the anchorage points. As this was one of the risks identified at the beginning of the project, it was decided to adopt an upper-tension cable anchored to the edges of the structure. The anchor points consist of 2.8 m long train tracks, with columns in the ground to a depth of 2.0 m (Francingues & Palermo 2005; Palermo 2006; Palermo *et al.* 2008)

The turbidity curtains are formed by panels 5000 mm long and 3000 mm high, composing the curtain skirt with a minimum free edge of 300 mm. The core of the curtain is composed of a woven geotextile, made of high tenacity polypropylene strips, high tensile strength, high permeability, low creep, and anti-UV treated. The fabric provides high permeability to liquids but with rather low apparent pore openings, yielding to high solids retention. On the upper part of the curtains, handles were installed to provide more agility and ease in its movement and launch, as well as greater ergonomic and operational safety for its operators. The ballast of the turbidity curtain is composed by a chain of links with a minimum diameter of 9.0 mm, hot-galvanized steel with a minimum breaking load of 25 kN. Standard ASTM naval aluminum connectors were used, connectable through a pin-lock system, shackle, upper handles, and ultralight floats of expanded polyethylene. The technical specifications of the curtains are listed in Table 1. Figure 1 shows a schematic drawing of the curtains used.

Table 1. Technical specifications of the woven geotextile.

Component	Properties	Technical specifications	Unit	Method
WOVEN GEOTEXTILE	Raw Material - Woven Geotextile	Ultra-stabilized PP anti-UV laminates

	Tensile strength - longitudinal and transverse	105	kN/m	NBR ISO 10.319
	Deformation at nominal strength	$\leq 10\%$	%	NBR ISO 10.319
	Hydraulic conductivity	2×10^{-3} m/s	m/s	NBR ISO 11.058
	Filtration opening size	0.24mm	mm	NBR ISO 12.956
	Permeability	20×10^{-3}	m/s	
	UV resistance (residual after 4,300h of exposure)	$> 80\%$	%	DIN EN 12.224
	Circumferential and bottom seams	Overlocked, six high tenacity polyester sewing threads		
	Edge seams	Prayer type, six rows of high tenacity polyester seams and a reinforced seam		
Figure 1. Schematic drawing of the curtains.

2.1.2 *Drainage system*

The waste rock dump of the mining facility has a surface area of 93.5 ha with little vegetation cover and it is currently in operation. The slope revegetation process is in its initial phase and covers less than 11.8% of the area. The surface drainage system conducts the water collected from the berms to the channels and to the hydraulic stairs. The effluents are conducted from the peripherical channels to an effluent containment structure, called "the pond", which is approximately 230 m long, 45 m wide in average, with a depth of 9 m and a 15 m wide spillway (Figure 2).
Figure 2. Grain size distribution curves of the soils.

The waste material is composed by a high amount of weather-resistant minerals, with reddish sand-clay characteristics, sometimes with the presence of peat or massive sand-clay materials, grading to levels of sand-clay granulation, orange or orange-red color, interspersed with altered levels of magnetite with medium to coarse grain sizes. The material is mechanically disposed in the waste rock dump, spread, and compacted without the addition of any kind of chemical product that may alter its physicochemical characteristics.

2.1.3 Sedimented material

During the dry season, the containment structure allowed the collection of samples of sedimented material from the last rainy season. So, four samples were collected for characterization tests, two collected in 2021, before the installation of the curtains, and another two samples in 2022, after the curtains have been installed, at the same location. Both samples were collected at the entrance of the sediment containment structure, upstream of the curtains, being the typical sediments in the effluent to be filtered of deflected by the curtains. Typical grain size distribution curves of the materials collected are presented in Figure 2, and the main particle diameters listed in Table 2.

Table 2. Main particle diameters.

Sample	D10 (mm)	D30 (mm)	D60 (mm)
AG-PDE-02-21	0.0011	0.16	0.70
AG-PDE-02-22	0.0019	0.20	0.70
AG-PDE-03-21	0.0010	0.08	0.43
AG-PDE-03-22	0.0010	0.01	0.40

To collect the samples, first the area was cleaned to avoid contamination with organic matter, such as leaves and roots. The collected samples were classified as disturbed because they did not preserve their original structure.

The granulometric curves obtained present a similar shape, however the samples collected in the east inlet flow present finer granulometry then the samples collected in the north flow inlet.

2.1.4 Effluent analysis

For each effluent specimen, the turbidity parameters were analyzed using the YSI Professional Plus PRO-DSS portable multi-parameter probe. This is a multi-parameter portable instrument for water quality and can measure several critical parameters, depending on the sensor installed, such as dissolved oxygen (optical), turbidity, pH, ORP, conductivity, specific conductivity, salinity, TDS, resistivity, ammonium, chloride, nitrate, depth, temperature, and it also has a GPS. In the present study, probes were used to determine the following parameters: turbidity (NTU); temperature (°C); dissolved oxygen (%); conductivity (μs/cm); total suspended solids (TSS-mg/L); pH; ORP.

Effluent turbidity analyses were carried out to evaluate the efficiency of the turbidity curtains. Three samples were collected weekly during the rainy season (Figure 3). One sample was collected upstream (point A) of the curtains, another between curtains (point B), and the third downstream of the curtains (point C), but all on the west bank and perpendicular to the main flow within the effluent containment structure (pond). The analysis was associated with rainfall parameters. After that, it was possible to calculate the efficiency of the barriers by the following equation 1 (Oliveira *et al*. 2018, 2020):

$$E_i = \frac{(T_b - T_a)}{T_a} \tag{1}$$

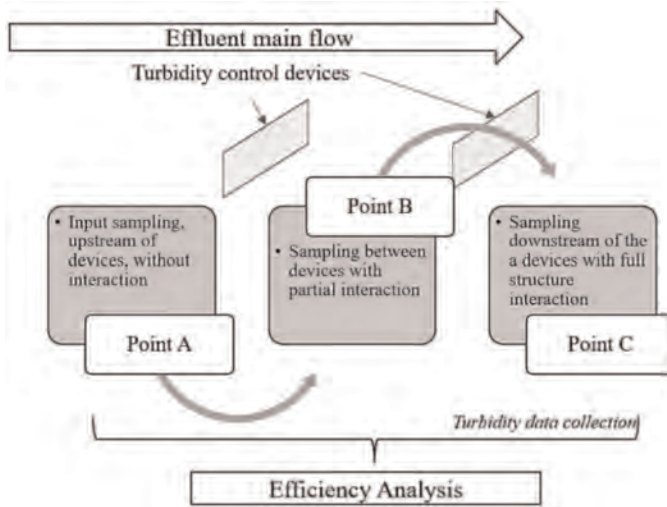
where E_i = efficiency at point i; T_b = turbidity before the point; T_a = turbidity after the point.


Figure 3. Flowchart of the project's data collection.

3 RESULTS AND DISCUSSION

Over the first 30 days of the experiment, it was possible to identify a significant reduction in the efficiency of the curtains. The curtains showed effectiveness above expectations for the designed conditions after the first month of the experiment with an efficiency of 92.19% (constant flow in a lotic environment). When the energy drops, the pond stops spilling, changing the flow regime to lentic. At this moment, the flow is governed by gravity, and the pond becomes exposed to external factors, like temperature and winds. These factors reduced the efficiency of the curtains, at the end of the first month to 60.83%. During the 2021-2022 rainy season, 148 turbidity samples were collected. The average efficiency obtained through out the study are summarized in Figure 4 as a function of the spillage process of the structure and sample location, either between the curtains or downstream of the curtains. The change of the flow direction caused by winds, associated with a maze configuration, favours the process of homogenization of the residual fluid in the pond, reducing the efficiency of the curtains. In these cases, the wind can suspend sediments, increasing the turbidity in the water body, besides imposing hydraulic loads from waves on the mooring cables and floats, which can cause structural failure (Francingues & Palermo 2005; Radermacher 2013).

386

4 CONCLUSIONS

This paper presented the results of an investigation on the use of curtains to reduce the turbidity of the effluent of the drainage system of a waste rock dump at a mining plant. The curtains resisted the rainy season, without damage and promoted satisfactory turbidity reductions of the effluent generated by the drainage system, which demonstrates the potential of this type of solution. However, the geometry used was a crucial factor in reducing the efficiency of the system with time and this study suggests the need for a change in the installation geometry of the curtains to a closed "U" geometry (Francingues & Thompson 2006; Johanson 1978; NYSDOT 1996; Pilarczyk 2000) before the 2022-2023 rainy season to increase the efficiency of the system.

Geosynthetics properties and testing

A comparison of particle motions in reinforced and unreinforced triaxial specimens of transparent sand

D.H. Marx, K. Kumar & J.G. Zornberg
The University of Texas at Austin, Austin, Texas, USA

ABSTRACT: This study investigated particle displacement and rotation (motion) in reinforced triaxial tests conducted on transparent sand. Individual particles were segmented from laser-illuminated sections through the specimens by using a neural network. State boundary lines between probable and improbable particle motions were drawn. The reinforced specimen was found to be stronger than the unreinforced, despite having a similar volumetric strain response. Measurement of the particle motions showed that the centre of the unreinforced specimen gradually shifted outwards under applied load. This applied an additional moment to the specimen. The reinforcement restricted the outwards movement of the specimen, resulting in a higher strength. These results also suggest that at a given applied axial strain, particle rotation increases with increasing lateral restraint.

1 INTRODUCTION

Conventional soil-geosynthetic interaction tests focuses on macro-scale behaviour. Pullout tests, direct shear tests and reinforced triaxial tests all measure the behaviour of the soil-geosynthetic composite, rather than the interaction of individual particles with the geosynthetic. However, it is only by studying the motions of individual particles that the mechanisms of soil-geosynthetic interaction can be fully understood.

Monotonic triaxial tests were done on transparent sand to investigate the effect of geosynthetic inclusions on the displacement and rotation (motions) of individual particles. The motions were compared at relatively large strains induced by monotonic loading. Thus, the mechanism of interaction was assumed to be similar to a geogrid providing reinforcement. The experimental setup, image analysis implemented to the track particles, and the mechanisms observed are discussed in the following sections.

2 METHODOLOGY

2.1 Experimental setup

The experimental setup shown in Figure 1 was used for the triaxial tests on transparent sand. The setup consists of an imaging frame attached to a regular triaxial cell, load frame and volume pumps. The pumps and loading frame are not shown in Figure 1. Two lasers with a wavelength of 638 nm, placed at 60° to each other, were used to illuminate sections through the specimens. Cameras fitted with 50 mm prime lenses captured images of the specimen every 0.02% axial strain. Oil was used both to saturate the specimens for transparency and as a confining fluid.
Figure 1. Experimental setup used to measure particle motions in triaxial tests on transparent sand (from Marx *et al*. 2023).

A custom, transparent silicone membrane was used for the tests. The frictional restraint of the platens was reduced by placing two layers of silicone lubricated with vacuum grease at either end. A drainage pipe protruded through silicone layers. Further discussions of the experimental setup can be found in Marx & Zornberg (2022b) and Marx *et al*. (2023).

2.2   *Materials*

The transparent sand tested in this study consisted of fused quartz saturated with a mixture of mineral oils. The fused quartz was uniformly graded with a D_{50} of 2.9 mm and compacted to its maximum density. A mixture of 52% Puretol 7 Special and 48% Paraflex HT4, both manufactured by Petro-Canada, was used to saturate the specimens (Peng & Zornberg 2019).

The honeycomb inclusion shown in Figure 2 was used to reinforce one of the specimens. The inclusion was water jet cut from a sheet of 3 mm thick polypropylene used in the manufacturing of integrally formed geogrids. A honeycomb shape was selected for the inclusions as it provides axisymmetric confinement, which is compatible with the stress state in a triaxial test. The ratio between aperture size and D_{50} was 4.7.

2.3   *Testing program*

Three groups of specimens were tested for this study: 1) two repeat unreinforced specimens consolidated to 25 kPa (U-25a and U-25b), used to validate the repeatability of the experimental setup, 2) a honeycomb-reinforced specimen consolidated to 25 kPa (H-25) and 3) an unreinforced specimen consolidated to 50 kPa effective stress (U-50). The U-50 specimen was used to compare the effect of reinforcement with that of increased confining stress.

All the specimens were back pressure saturated to 300 kPa before consolidation and had B-values of 0.99. The specimens were sheared at a rate of 6% axial strain per hour. This relatively slow rate of shear was necessitated by the constrained drainage through the lubricated platens and the slow shutter speed used to capture the images.

3 IMAGE ANALYSIS

The images of the laser-illuminated sections through the specimens were captured in a 14-bit raw format. Subsequently, the images were demosaiced, the dynamic range compressed and corrections for lens distortion and distortion by the triaxial cell was applied, as outlined in Marx & Zornberg (2022b) and Marx *et al.* (2023). A typical post-processed image from a section through the specimen in shown in Figure 3a.
Figure 2. Honeycomb inclusion used for reinforcement.
Figure 3. Typical result of image segmentation: a) original image and b) segmented particles.

A local measurement of axial strain was required as the global measurements included the compression of the lubricated platens. Digital Image Correlation (DIC) is an optical measurement technique that tracks regions of pixels (patches) from one image to another. By using the DIC software developed by Stanier *et al* (2016) it was possible to measure the displacement of the top and the bottom of the specimen and calculate the axial strain, as discussed in Marx & Zornberg (2022a).

The DIC measurements provides a continuum displacement field across the specimens. To investigate the motions of individual particles the images first had to be segmented. Analytical segmentation techniques failed due to inconsistent internal lightning, image noise and heterogeneous particle outlines. Consequently, a neural network was trained to segment the individual particles. The network, Cellpose (Stringer *et al.* 2021), was originally developed to segment biological tissue. By implementing transfer learning the network was able to segment fused quartz particles as shown in Figure 3b. The rotation and displacement, i.e. the motions, of the particles were subsequently tracked through successive images. The details of the image segmentation and particle tracking can be found in Marx *et al.* (2023).

4 STRESS-STRAIN RESULTS

The deviatoric stress-axial strain measurements for the four specimens are shown in Figure 4a. Standard area corrections (Head 2014) and membrane corrections (Ducan & Seed 1967) were applied.

The two unreinforced tests (U-25a and U-25b) show good correlation, illustrating the repeatability of the testing setup. Increasing the confining strength to 50 kPa (specimen U-50) resulted in a corresponding increase in strength. When reinforcing a specimen tested at 25 kPa confining stress its strength increased.

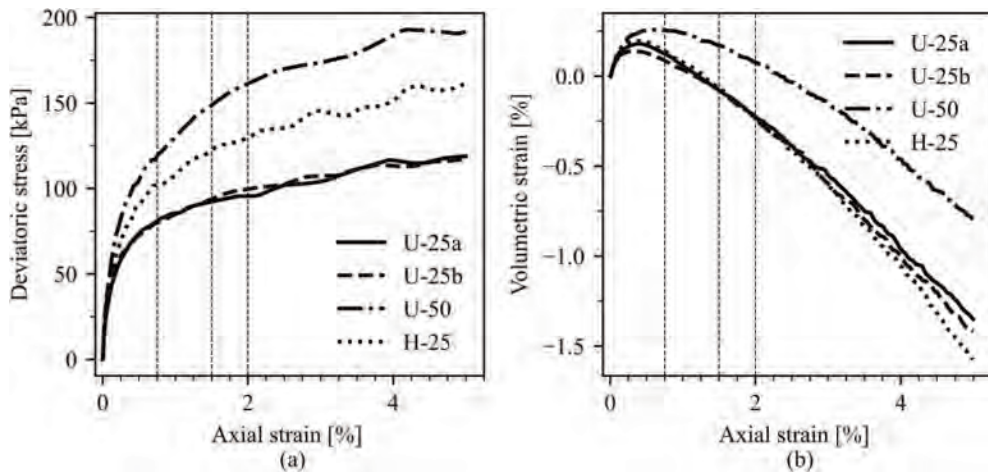
In Figure 4b the volumetric strain of the specimens is shown as a function of axial strain. All specimens contracted initially followed by dilation. Both the control specimens and the reinforced specimen tested at 25 kPa confining stress showed similar dilative behaviour up to


Figure 4.   Stress-strain results of the triaxial tests: a) deviatoric stress b) volumetric strain.

approximately 3% axial strain. Only when the confining stress was increased to 50 kPa did the rate of dilation decrease. In the following section the particle motions will be analysed to determine why the control specimens were weaker than the reinforced, despite displaying similar volumetric strain behaviour.

5   PARTICLE MOTIONS

5.1   Motions state boundary line

The particles in the centre 50 mm of one of the control specimens are shown in Figure 5a and b. In Figure 5a the particles are shaded by their horizontal displacement at 1.5% axial strain. In Figure 5b the particles are shaded by their absolute rotation. The displacement measurements clearly show the specimen expanding laterally. In contrast, the particle rotations are more haphazard in nature.

Marx et al. (2023) proposed that a boundary exists between probable and improbable particle states (i.e. displacement-rotation pairs). Under stable loading conditions a particle that displace significantly will not rotate significantly as well and vice versa. Consequently, when plotting all the absolute particle rotations against displacements in Figure 5c the state boundary follows the shape of a triangle.

The apex of the triangle was set at 2.5 MADs (Median of all Absolute Deviations from the median) away from the median rotation. Similarly, the base covers ±2.5 MAD from the median horizontal displacement. The MAD, a descriptor from the field of robust statistics (Rousseeuw & Hubert 2018), was used due to the large scatter in the rotation measurements. In addition, the median absolute rotation and median horizontal displacement is also indicated on the figure.

The median displacement is -0.12 mm indicating that in additional to expanding laterally the specimen is also moving towards the left at 1.5% axial strain. The maximum probable rotation is 6.5° and the range of probable displacements is [-0.46 mm, 0.22 mm] for a total range of 0.68 mm.

5.2   Comparison of probable motions across different levels of strain

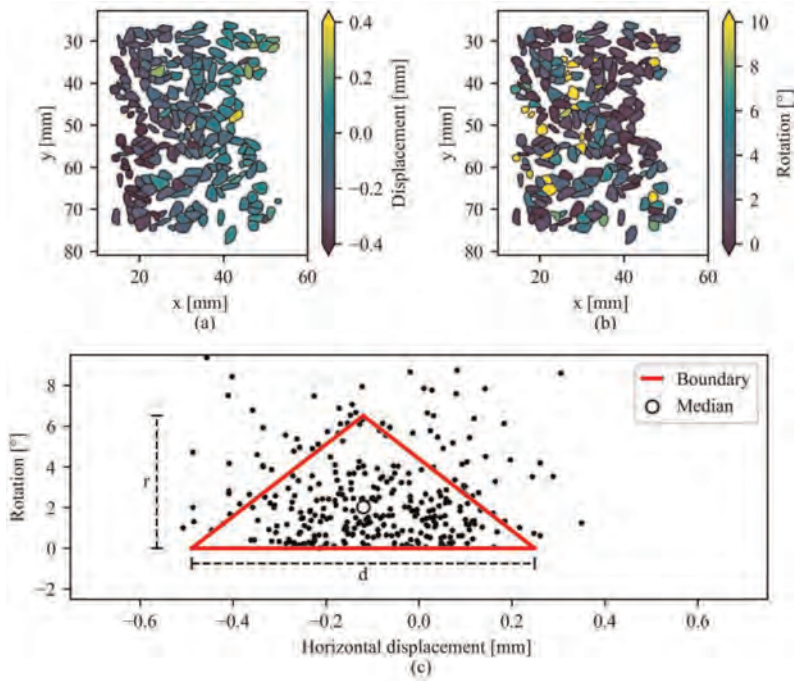
In Figure 6 the ranges of probable motions are compared across three levels of strain for the four specimens. Firstly, in Figure 6a the displacement range is compared. The greater


Figure 5. Particle motions for U-25b at 2% axial strain a) horizontal displacements, b) rotations and c) rotation-displacement pairs with state boundary and medians shown.
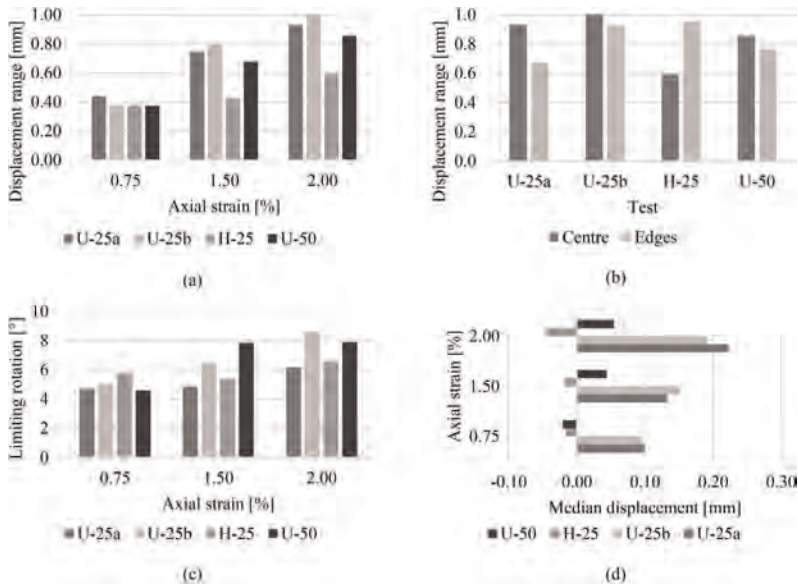

Figure 6. Summary for particle motion boundaries: a) horizontal displacement range (centre 50 mm), b) comparison between the horizontal displacement range at the centre of the specimens and their edges, c) maximum probable rotation (centre 50 mm), and d) median horizontal displacement (centre 50 mm).

confining stress of the U-50 specimen results in reduced lateral displacement compared to the U-25 specimens. Despite the similar volumetric strain response for U-25 and H-25 at a given axial strain, the H-25 specimen has a more limited displacement range. This is due the lateral deformation being distributed between the two halves of the reinforced specimen.

In Figure 6b the displacement range of the centre 50 mm of the specimen is compared with the displacement range of the outer two quarters. The extremities of the reinforced specimen displaced more than the centre, indicating that the lubricated platens were effective in preventing artificial restraint. In addition, the increased displacement at the ends balances the reduced displacement in the centre, to result in a net volumetric strain similar to the control specimens. However, the lubricated platens were not perfect as apparent from the reduced displacement at the edges of the control specimens when compared to the centre.

The resolution of the rotation measurements is coarse relative to the magnitude of the particle rotation. Thus, the difference in the limiting rotation between the specimens is less severe as shown in Figure 6c. However, in general the limiting rotation was greater for U-50 which has greater lateral restraint due to increased confining stress. When a fixed axial strain is applied to a specimen a particle can either move, compress, or crush. Both compression and crushing are unlikely for the stress considered in this study. For a specimen under low lateral restraint particles sliding apart provide the path of the least resistance. When particle displacement is restrained (e.g. by reinforcement) rotation of the particle may be a more efficient mechanism of deformation. Thus, the increase in particle rotation for the U-50 specimens when compared to the U-25 specimens, at the same level of axial strain.

Figure 6d reveals the mechanism producing the difference in strength between U-25 and H-25, despite both specimens having the same volumetric strain behaviour. The figure shows the median displacement for the centre 50 mm of particles each of the unreinforced specimens for three levels of axial strain. For the reinforced specimen the median displacement is shown for the centre 25 mm of upper half and the centre 25 mm of the lower half (i.e. a total of 50 mm of the specimen). The direction of the displacement is extraneous. However, the difference in magnitude is significant. The large median displacement of the two control specimens (U-25-a and b) indicates that the body of particles has shifted significantly away from the central axis the test setup. Thus, an additional moment was applied to the control specimens, which resulted in a lower strength. In the reinforced specimen the inclusion restricted this lateral shift.

The control specimen tested at 50 kPa confining stress also experienced a lateral shift. However, due to the increased confining stress along the length of the specimen U-50 remained stronger than the reinforced specimen tested at 25 kPa (H-25).

6 CONCLUSIONS

This study investigated some of the mechanisms of soil-geogrid interaction present in reinforced triaxial specimens of transparent sand. The effects of increased confinement, whether due to reinforcement or due to increased cell pressure, was measured in terms of the observed particles motions (displacement and rotation). Both the reinforced and unreinforced specimens tested at 25 kPa confining stress had the same volumetric response. However, the reinforced specimen was stronger. Investigation of the particle movements found that the difference in strength was due to a gradual lateral shift in the central axis of the control specimen. This shift resulted in an additional moment being applied to the specimen, and thus a lower strength was measured. Initial results indicate that when the lateral movement of the particles was constrained, particle rotation increased for a given applied axial strain.

Chemical characterization of geomembranes by mass spectrometry

Leonardo A. Valentin, Clever A. Valentin, Marcelo Kobelnik & Jefferson Lins da Silva
São Carlos School of Engineering (EESC), University of São Paulo (USP), São Carlos, Brazil

ABSTRACT: Geomembrane is a type of material used in civil engineering and environmental engineering works for the protection and recovery of environment. Five geomembranes commercially obtained from three Brazilian companies were chemically characterized in order to evaluate the chromatographic profile and differentiate them and the results contribute to create a database and evaluate the geomembranes after periods in different applications. The GC/MS technique and multivariate analysis tools were applied. 211 compounds were selected for SVOCs and 59 compounds for VOCs. Considering the 211 compounds, 159 met the p-value criterion < 0.05. For the 159 compounds 130 met the cut-off criterion of 2.0 for the fold change analysis and were considered in the study. Regarding VOCs compounds, of the 59 compounds considered, 25 met the p-value criteria < 0.05 and 15 for the cut-off 2.0 criteria for fold change analysis. The combination of chromatographic determination with multivariate analysis was applied and showed to be an excellent tool for chemical characterization and the differentiation between the five groups can be observed. This information can be useful for use of these techniques in routine for material quality control and for geosynthetics database.

1 INTRODUCTION

With the considerable advance of Chemistry and recent analytical instrumentation, a large number of substances became the target of investigations, making it possible to study their properties and classify them, according to their chemical structures (Hanton 2000; Korner *et al*. 1992). The classification of materials is very extensive and is related with concept of matter where any type of liquid or solid substance can be considered a material (Zarbin 2007).

Interest with composition and structure of materials soared that a new branch of chemistry studies was established, the "Materials Chemistry" (Zarbin 2007). The materials used in Civil Engineering, with emphasis on polymeric materials, are classified as geosynthetic and cover various types of polymers with functions in civil construction activity. A geosynthetic that stands out in works for environmental protection and recovery are geomembranes, especially those of polyethylene type, which are analyzed in this research.

The characterization of materials uses instrumental analysis techniques aimed at understanding different aspects related to composition (molecular mass, oxidation number, etc.) and structure (chemical bonds, crystalline phase, etc.) that are directly linked to chemical properties and physical, and these properties are linked to other properties such as mechanical, optical, catalytic, etc. (Skoog; Holler & Nieman 2009).

For geomembranes, regarding the most common instruments used, we can highlight spectroscopy in ultraviolet/visible (UV/Vis) region, infrared (IR) spectroscopy, X-ray diffraction, thermal analysis TG (thermogravimetric) and DTA (differential thermal analysis), DSC (differential scanning calorimetry) and DMA (dynamic mechanical analysis), chromatography and MS (Mass Spectrometry) (Ahari *et al*. 2019; Hanton 2000; Paiva *et al*. 2010; Valentin *et al*. 2018).

The characterization of different materials is found in literature using MS, being widely applied to biomaterials such as photoresins, polyphenols, PEGs, and others. The characterization of these materials by MS is used in order to elucidate the molecular mass through the identification of the molecular ion, in addition with information obtained by fragmentation (Figueiredo 2014).

Although several studies on geomembranes using instrumentation are found, most have focused on qualitative, quantitative determination or even focusing on standards such as international (ISO), German (DIN), French (AFNOR) and American (ASTM). For the characterization using chromatography with MS and mainly associated with the use of multivariate statistics, only few publications are found in literature.

Regarding multivariate analysis, we can reveal constituents that are important through various interferences and interactions (Wold *et al*. 2001). Multivariate, unlike classical statistics, considers several variables simultaneously. Although multivariate ANOVA (MANOVA) is available, other multivariate analytical methods have the advantage of being able to take collinearity into account (Gelad 2003; Naes et. al. 2002). Research with multivariate analysis covers a wide area with different methods that can be applied in different fields of science and technology (Naes et. al. 2002; Valentin *et al*. 2020).

In a previous study, four geomembranes were analyzed for TG, DTA, DSC and DMA (Valentin *et al* 2018). The different samples showed different thermogravimetric behavior. For the mechanical properties, it was observed that the density and carbon black data had compatible values between samples. The values obtained for tensile, tear and puncture tests are linked to material thickness and showed that commercial samples have values much higher than those recommended. With these results obtained, we realize the importance of chemical characterization of these materials (Valentin *et al*. 2018).

Therefore, the main objective of this study was to chemically characterize five geomembranes commercially obtained from three Brazilian companies, four of which have already been analyzed by Valentin *et al.* (2018) considering thermo-analytical analyses. The second point is to check if the results can contribute to create a database and evaluate the geomembranes after periods in different applications. The MS technique was used for these characterizations and multivariate analysis tools were applied to determine and process the results.

2 MATERIALS AND METHODS

2.1 *Materials*

The geomembrane samples were obtained from coils manufactured by three Brazilian companies, referred to A, B, C, D and E. Each of geomembranes has a different thickness being: A = 2.0 mm, B = 1.90 mm, C = 1.50 mm, D = 0.80 mm and E = 0.75 mm, all with smooth surface. The criterion for choice of samples were good reputation and representativeness of manufacturers, diversity of thicknesses and also the types of application for materials. Samples were collected directly on site and all of them are virgin samples. For the chromatographic determinations, specimens cut in format of tapes with length of 20 mm and thickness of 4 mm were used. The samples were used for determinations of volatile (VOC) and semi-volatile (SVOC) compounds in sufficient quantity for triplicate determinations. For both types of determinations, 22 mL vials with screw caps were used. The solvent used for this study was GC/MS grade Dichloromethane obtained from J T Baker Chemical Co (New Jersey, USA).

2.2 *Methods*

The chemical characterization for compounds was carried out in two steps. First, the samples were analyzed via headspace (HS) coupled to gas chromatograph with mass spectrometer (GC/MS) for volatile compounds. For the second stage, the same GC/MS was used

with liquid injection after extraction (sample preparation) of compounds for determination of semivolatiles.

2.2.1 *Determination of volatile compounds by HS-GC/MS*

Volatile compounds VOC were analyzed according to Castro, *et al.* (2014). For volatile compounds, samples (2 g) were transferred to 22 ml vials and sealed. After that, vials were taken to the CTC Combpal autosampler (CTC Analyticss, Zwinge, Switzerland) and analyzed in headspace (HS) mode by gas chromatograph coupled to mass spectrometer (GC/MS, model 7890) (Agilent Technologies, Inc., Palo Alto, USA) with S / SL inlet and MS single quadrupole model 5977A in scan mode (SCAN). The capillary column used was Agilent Technologies DB-5 (95% dimethylpolyixane and 5% phenyl, 30 m, 0.25 mm, 0.25 µm). The temperature ramp was 35 °C / 5 min, followed by 250 °C to 3 °C / min and holding 5 min at 250 °C. The inlet temperature was 250 °C throughout the run and the rate of carrier gas flow was 1.2 mL/min using helium. For mass spectrometer the source temperature was kept at 230 °C. The EI ionization source was kept at 70 eV. The mass range (m/z) used was 33-400. The parameters used for extraction of compounds in CTC were incubation oven temperature at 120 °C for 8 minutes and the syringe operating at the same temperature. The compounds were also deconvoluted using "Mass Hunter Qualitative" version B.10.00. Then the compounds were identified using the NIST library (National Institute of Standards and Technology) in ID Browser window, including mass and formula. The criteria used for comparison with the NIST library to identify compounds was a minimum score of 80%. All analyzes were performed in triplicate.

2.2.2 *Determination of semi-volatile compounds by GC/MS*

The semi-volatile compounds SVOC were analyzed according to Watanabe, *et al.*, (2007). For semi-volatile compounds, samples (2 g) were transferred to 22 ml vials, sealed and filled with 10 ml of dichloromethane. Then the samples were taken to ultrasound with heating at 60 ° C for 10 minutes. Then, a volume of 1 mL was transferred to vial and then taken to the CTC Combpal autosampler (CTC Analyticss, Zwinge, Switzerland) and analyzed using liquid injection mode by gas chromatograph coupled to mass spectrometer (GC /MS, model 7890) (Agilent Technologies, Inc., Palo Alto, USA) with S / SL inlet and MS model single quadrupole 5977A in scan mode (SCAN). The capillary column used was Agilent Technologies DB-5 (95% dimethylpolyixane and 5% phenyl, 30 m, 0.25 mm, 0.25 µm). The ramp temperature was 35 °C / 5 min, followed by 250 °C to 3 °C / min and holding 5 min at 250 °C. The inlet temperature was 250 °C throughout the run and the rate of carrier gas flow was 1.2 mL/min with a 1:10 split ratio using helium. For the mass spectrometer the source temperature was kept at 230 °C. The EI ionization source was kept at 70 eV. The mass range (m/z) used was 33-500. The compounds were also deconvoluted using "Mass Hunter Qualitative" version B.10.00. Then the compounds were identified using the NIST library (National Institute of Standards and Technology) in ID Browser window, including mass and formula. The criteria used for comparison with the NIST library to identify compounds was a minimum score of 80%. All analyzes were performed in triplicate.

2.2.3 *Statistic*

Initially, all identified compounds (VOCs and SVOCs) were evaluated in MassProfinder 10.0 software (Agilent Technologies, Inc., Palo Alto, USA) to verify the presence of false positives compounds and confirm the spectral fidelity among all samples. In Profinder we have some algorithms that allow find and confirm the identity of compounds. The algorithm used for VOCs and SVOCs was Batch Target Feature Extraction, where we initially selected the library and parameters to be used for identification. Then we define the tolerance percentage for identification followed by signal integrator, spectrum extraction and post-processing filters. Profinder also compare samples and blanks for verification of false positives. Finally, all data were converted to cef format and exported to Mass Profiler Professional MPP 15.1 software

(Agilent Technologies, Inc., Palo Alto, USA) where the statistical tools were applied. With MPP software, samples were separated in groups and analyzed using multivariate tools. In the first step, the significance analysis was performed, to verify if selected groups after defining a value of $p < 0.05$ to reject the null hypothesis. Principal Component Analysis (PCA) was used as a complementary technique to identify the variables and separate the geomembrane groups according to clusters. Fold change was also applied as measure to assess the change between the first group and the subsequent group with ratio between the two measures with variation of unfolding between the groups.

3   RESULTS

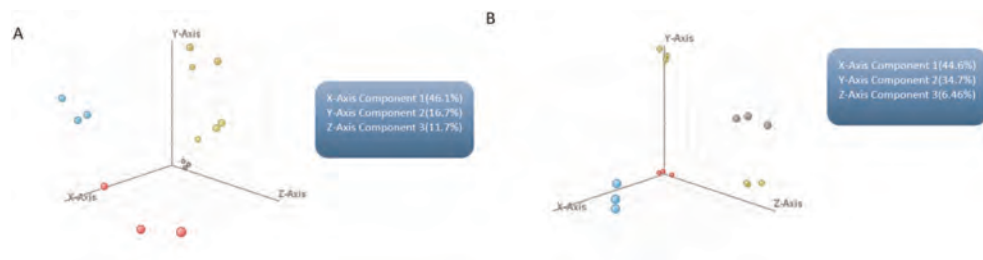
The results of chromatographic determinations for VOC and SVOC observed for five types of samples showed satisfactory results for significance analysis. After the interpretation performed using the massprofinder software and the application of criteria, 211 compounds were selected for SVOCs and 59 compounds for VOCs. For the 211 selected compounds, 159 met the p-value criterion < 0.05. For the 159 compounds 130 met the cut-off criterion of 2.0 for the fold change analysis and were considered. For the VOCs compounds, for the 59 compounds considered, 25 met the p-value criteria < 0.05 and only 15 for the cut-off 2.0 criteria for fold change analysis. Thus, the selected compounds were used for processing and plotted on 3D graph to first examine the values by PCA Figure 1. In the PCA graph we can clearly see the good separation of groups for five samples showing the difference obtained after applying the criteria for choosing compounds.


Figure 1.   3D representation for the PCA result in VOC (A) and SVOC (B).

4   DISCUSSION

The five commercial geomembranes samples with different thicknesses were chemically analyzed. The objective was identify the VOCs and SVOCs compounds that could characterize the samples using gas chromatograph instrument with mass spectrometer and multivariate tools (Costa *et al.* 2017; Crotty *et al.* 2016; Kusch P. & Knupp G 2002, 2004; Vilaplana *et al.* 2010). First, five samples were selected to complement a study carried out by our group considering other types of analysis. This first step was very interesting considering the type of information acquired in terms of chemical and physical characteristics for five samples studied. A second important aspect was obtain a chromatographic profile (Figures 2 and 3) for determinations in terms of VOCs and SVOCs compounds, which enables us to carry out future studies for other geomembranes in terms of degradation, aging, evaluation after pre-established times or even for quality control (Blanco *et al.* 2012).

For chromatograms shown above we can observe that for VOCs compounds (Figure 2), the difference between the five samples, mainly for general intensity of compounds. Other details are some peaks found around 7.5 min that are observed only for samples A, B and E. For samples of SVOCs (Figure 4), we can observe a very different profile around 19 min, where there are several candidates for markers. Another detail is the presence for sample D, compounds around 20.5 min, showing the real difference between the groups studied.
Figure 2.   Chromatograms generated for determination of VOCs compounds for five samples.

Another highlight for this study was being able to propose and develop analytical methodologies, since just few information for this subject is found in literature, mainly using instrumentation (GC/MS) combined with chemometric analysis. (Camacho W. & Karlsson S. 2000; Ciucanu *et al*. 2002)

For data analysis, the use of statistical tools such as PCA, cluster analysis, fold change, significance analysis, among others, were fundamental to determine which compounds could be considered in this study (Shenton *et al*. 2000). In the literature the compounds commonly identified by GC/MS in geomembranes for VOCs are Benzene, 1-1-(1,2-cyclobutanedkyl)bis, Styrene, Ethylbenzene, Candinene, Benzaldehyde, Isocumene, Tetradecane, Cumene, Diethylphthalate, Acetophenone, Diphenylether, tridecane, benzene, (1-methylpropyl), dodecane, nonanal, pentadecane, heptadecane, 1,3-dephenylpropane, benzene, 1-methyl-4-propyl, octadecane, octane, 1,1-oxybis, n-Heptadecanol-1, undecane, among others (Castro *et al*. 2014). For SVOCs, polymer or alloy, oil or plasticizers, carbon black, inorganics, antidegradants, sulfur, among others (Rolin & Rigo 1991).

The use of specific software such as massprofiler to create the criteria for acceptance of peaks found proved to be a fundamental step for this study. Often times, the use of only retention time or molecular ion can lead to use of false positives, which can generate inconsistent data about the actual characteristics of samples. The MPP software also deserves great attention in our study since, with the use of this tool, it was possible to practically and accurately use the data generated by instrument without the need for intermediate steps, such as the use of excel sheets, which they can generate errors and cause distortion of results. In addition to this issue, the possibility of analyzing all data with all

statistical tools proved to be very useful and complete allowing for an accurate interpretation of all compounds (Kumar *et al* 2014; Geladi 2003).

Regarding analytical instrumentation, the use of GC/MS technique was a powerful tool where we had an excellent chromatographic separation, the precise determination of masses and fragments for compounds, allowing the identification through comparison with NIST library (Garrigós *et al*. 2004). For determination of volatiles, the use of CTC with the headspace technique was extremely important where the sampler performed all the work of incubation, extraction and injection of volatilized sample (Wang *et al*. 2019). For SVOC compounds, through a simple sample preparation step, the liquid injection of solvent also brought complete information of entire profile called fingerprint.

The dichloromethane solvent presented a great extraction power for geomembranes where, combined with ultrasound and heating, it resulted in a powerful extraction for SVOC compounds (Smith, & Taylor 2002)

Finally, the combination of chromatographic techniques with chemometrics tools generated valuable results where compounds called markers were determined and selected and can be used in future studies for geomembranes, geosynthetics or related materials.

5   CONCLUSIONS

It was possible to identify a chemical profile to characterize the VOCs and SVOCs compounds using chromatographic techniques coupled with mass spectrometry. The combination of chromatographic determination with multivariate analysis proved to be an excellent tool for chemical characterization and the differentiation between groups could be observed. This information can be useful for use of these techniques in routine for material quality control and also for the creation of a specific database for geosynthetics in general.

Geomembrane integrity surveys of 30 liquid containment storages and their contribution to high quality installation outcomes

G. Fairhead
Fabtech, Adelaide, Australia

A. Bouazza
Monash University, Melbourne, Australia

ABSTRACT: There have been significant developments in the accuracy, speed and availability of integrity surveys over recent years. Geomembrane electrical integrity surveys have become a commonly used tool to assist in achieving low installed geomembrane defect rates and, accordingly, low seepage rates. This paper examines several recent projects where the correlation between defect rates, construction methods, and quality control strategies is reported. The database analysed includes a significant number of containment systems that were subjected to geomembrane integrity surveys quantifying the as-installed and post-survey quality levels. This data provides valuable insight into and contemporary benchmark for achievable defect rates in liquid containment storages.

1 INTRODUCTION

The use of geomembranes (GMBs) in lining systems has become a norm in modern waste containment facilities to cater for a large spectrum of waste, including municipal solid waste (MSW), hazardous waste (HW), mining waste, leachates from MSW and HW, liquors from mining and oil and gas industries and also in resource recovery such as heap leach pads. In typical liner configurations, the GMB is an excellent barrier to the migration of fluids, provided it is devoid of defects and free of wrinkles. However, defects in the geomembrane can occur, even with carefully controlled manufacture, and damage can be found even in sites where strict construction quality control (CQC) and construction quality assurance (CQA) programs have been put in place (e.g., Bouazza *et al.* 2002; Rowe 2005). Not surprisingly, tremendous efforts have been made in the past decade to implement various leak detection technologies to minimise leakages through geomembranes (Gilson-Beck 2019; Gilson 2021). This paper presents a short survey of leakage detection outcomes on leachate and liquors ponds lined with geomembranes as part of the lining systems.

2 ELECTRONIC LEAK DETECTION METHODS

There are a range of electrical leak location (ELL) methods available for conducting leak detection on geomembranes. ELL methods can be divided into two overarching categories: bare and covered geomembrane methods (Gilson-Beck 2019). Bare methods are conducted prior to covering the primary geomembrane. These include high voltage methods of Arc and Spark testing, as well as water-based methods such as water puddle and water lance techniques. Covered methods, such as dipole testing, are conducted during or after commissioning when the system is in operation. Both covered and uncovered methods are taken to

have relatively equal accuracy, however, Gilson-Beck (2019) warns that there is a greater risk of inaccuracy associated with the covered methods. The risk is introduced due to the sensitivity of the instrumentation and the greater reliance on operator skill and methodology. Despite this caveat, the present work assumes equal accuracy across the methods. The assumption is made, as the data was collected by highly skilled technicians, and there was an even distribution of techniques across the data set.

3 STUDY BACKGROUND

Various electrical leak location (ELL) methods were used in the current work. They included arc testing, water lance testing and dipole testing. These tests were conducted on thirty ponds of various sizes in Australia as part of a construction quality assurance program between 2012 and 2021. The ponds were constructed to store potable water, irrigation water, landfill leachate, minerals processing liquors, coal seam gas brines, petro-chemical liquors, and wastewater treatment liquids, respectively.

The lining system configurations and sizes of the ponds are given in Table 1, together with the type of ELL methods conducted on the geomembrane for each site. All the tests were conducted on the primary geomembrane except where indicated.

Table 1. Summary of liquid containment storages surveyed between 2012 and 2021.

4   RESULTS AND DISCUSSION

The survey on the detection of localised defects in geomembranes conducted in the current work indicated that most defects occurred during the installation phase, generally from construction activities. A total of 120 defects were recorded over 921888 m² of liner tested.

These defects included inadequate seams (18%), mechanical damage (61%) and animal damage caused by kangaroos (18%), as indicated in Figure 1. Interestingly, it was noted that relatively fewer defects were detected from 2017 through 2021 compared to 2012-2016, indicating improved installation methods and construction protocols.
Figure 1.   Cause and type of defects in geomembrane liners.

Another interesting aspect related to geomembrane defects is the leak density per liner area (i.e., the number of defects per hectare or m^2). The results of the survey shown in Figure 2 indicate that the frequency of defects is low (from 0 to 12 defects per hectare), with 24 sites experiencing only a frequency of defects ranging from 0 to 3 defects per hectare which confirms that the construction protocols adopted for these sites minimised the number of defects to the level that regulators consider acceptable. The average frequency for the 30 surveyed sites was 1.3 defects per hectare which is representative of the standard achievable with competent installation and thorough construction quality assurance.
Figure 2.   Variation of defect density versus area surveyed.

The above observations reinforce the fact that the application of a thorough quality assurance program substantially reduces the frequency of defects in a geomembrane liner. It is interesting to note that the density of leaks tended to decrease as the surveyed area increased. Colucci & Lavagnolo (1995) and Charpentier *et al.* (2016) pointed out that larger installations tend to have better construction quality programs aided further by the simplicity of the installation: whereas smaller sites have proportionally more complex features to deal with.

5   CONCLUSIONS

This paper examined the integrity of geomembrane liners used in 30 liquid containment storages using various electrical leak detection methods. The analysis of the database of the electrical integrity surveys conducted between 2012 and 2021 showed that the average frequency for the 30 surveyed sites was 1.3 defects per hectare. This indicates that a thorough quality assurance program substantially reduces the frequency of defects in a geomembrane liner. Furthermore, there were indications that fewer defects were detected from 2017 through 2021 compared to 2012-2016, indicating improved installation methods and construction protocols.

Triaxial compression tests on the stress-strain responses of geocell-reinforced normally-consolidated clay

Fei Song*, Wangsheng Chen* & Yawei Nie*

Institute of Geotechnical Engineering, School of Highway Engineering, Chang'an University, Xi'an, P.R. China

ABSTRACT: Experimental and theoretical investigations on the stress-strain responses of geocell-reinforced clay are very limited. In this paper, a series of conventional triaxial compression tests were conducted on the geocell-reinforced normally consolidated clay to investigate the reinforcement effects and validate the effectiveness of the proposed method. The study results show that the geocell-reinforced normally consolidated clay exhibits strain-hardening. The reinforcement effect on the clay increases with increase of the axial strain and the reduction of the confining pressure. The predicted stress-strain responses via the analytical method proposed in this study are in good agreement with those measured in the tests, showing the effectiveness of the proposed method.

1 INTRODUCTION

Geocell is a three-dimensional geosynthetic material which was originally developed in the late 1970s. Due to its excellent mechanical properties, geocell-reinforced soil has been widely used in engineering construction. Bathurst and Karpurapu (1993), Rajagopal *et al.* (1999), Madhavi Latha and Murthy (2007), Wu and Hong (2009), Chen *et al.* (2013), Chen *et al.* (2018), Xue *et al.* (2019), Song *et al.* (2019) performed triaxial compression tests to study the stress-strain responses of the geocell-reinforced soil and geotextile-encapsulated sand columns. Their research results show that the confining effect of the cell on the infilled soil can be equivalent to the increment of confining pressure, which can improve the strength and stiffness of the backfill. In addition, the cohesion of the infilled soil caused by the confinement of the cell is called apparent cohesion, while the internal friction angle of reinforced soil is basically the same as that of unreinforced soil. On the basis of the analysis of the test results, Song *et al.* (2020, 2022) proposed an analytical method for the stress-strain response of geocell reinforced soil by employing the soil response in the triaxial stress condition and the thin cylinder theories, and verified the validity of the analytical method via the common and large-scale triaxial compression test results of the reinforced soil. However, the infilled soil in the above experiments and theoretical studies are all sand and granular materials, and the analytical model of the stress-strain responses of geocell-reinforced clay is still not systematically studied.

In order to solve the above problems, a series of triaxial tests of unreinforced normally-consolidated clay and geocell reinforced normally consolidated clay were carried out by using GDS triaxial apparatus in this study. The stress-strain relationships under different confining pressures were measured. The differences between the unreinforced and the geocell-reinforced soil were compared, and the mechanism and influencing factors of geocell reinforcement for infilled clay soil were revealed and discussed. The validity of the proposed theoretical model for the geocell reinforced normally-consolidated clay was verified by the triaxial compression test results.

2 TRIAXIAL TEST OF REINFORCED NORMALLY CONSOLIDATED CLAY

2.1 *Test instruments and materials*

A static triaxial apparatus produced by the British GDS Company was employed in this study. The triaxial test system is composed of a microcomputer control system, a confining pressure chamber, two controllers (1MPa back pressure controller and 2MPa confining pressure controller), and a measurement system (axial load, confining pressure, axial deformation, pore pressure, and volume strain measurement devices). The basic physical properties of silty clay used in the test are shown in Table 1. In the tests, the silty clay was remolded to be two kinds of soil samples. One is with the moisture content of 21% and the natural density of 2.01g/cm^3, while the other is with the moisture content of 25% and the natural density of 1.94g/cm^3. The remolded clay sample was prepared by the moisture tamping method.

Table 1. Physical properties of the backfill used in the test.

Specific gravity, G_s	Liquid limit(%)	Plastic limit(%)	Optimum moisture content(%)	Maximum dry density(g/cm^3)
2.67	29.5	18.1	16.0	1.66

In this study with references to the research experiences of Madhavi Latha and Murthy (2007), and based on the similarity of strength and stiffness of geocell-reinforced soil, a circular model geocell is fabricated by using PE material, with a thickness of 0.12mm, a diameter of 39mm and a height of 26.6mm, as shown in Figure 1(a). The triaxial specimen has a diameter of about 39.1mm and a height of about 80mm, and it is composed of three circular geocells stacked along the height direction, as shown in Figure 1(b). The tensile stress-strain curve of the geocell strip was tested per ASTM D 882-12 (2012), as shown in Figure 2.

Figure 1. Geocell and the reinforced silty clay specimen.
Figure 2. Tensile load-strain curve of geocell sheet.

2.2 *Test scheme and results*

According to ASTM 4767-11(Reapproved 2020), the prepared remolded clay sample was saturated by the vacuum saturation method, so the saturation reached more than 95%.

Triaxial consolidated drained shear tests were carried out on unreinforced clay and geocell-reinforced clay. The axial shear strain rate is 0.012%/min. The measured stress-strain relationships of unreinforced and reinforced soil in the tests were shown in Figure 3.

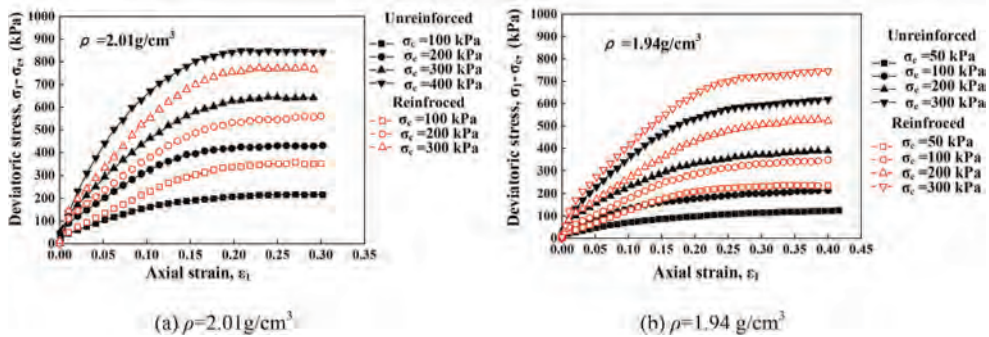
(a) ρ=2.01g/cm^3 (b) ρ=1.94 g/cm^3


Figure 3.   Stress-strain curves of unreinforced and reinforced clay specimens.

In order to study the increase in the stiffness of the infilled soil due to geocell reinforcement, the ratio of the secant modulus of the reinforced clay to that of the unreinforced clay is defined as the modulus enhancement coefficient η_E, expressed as:

$$\eta_E = \frac{E_{sr}}{E_{su}} \tag{1}$$

in which E_{sr} and E_{su} are the secant modulus of the reinforced clay and that of unreinforced clay, respectively.

According to Figure 3, the relationship between the modulus enhancement coefficient and the axial strain was calculated as shown in Figure 4. It can be seen from Figure 4 that when the axial strain is small, the modulus enhancement coefficient is close to 1, indicating that the cell reinforcement effect is not obvious, and the modulus enhancement coefficient increases gradually with the increase of the axial strain. For example, when the confining pressure is 100kPa, the modulus enhancement coefficient increases from 1.03 to 1.81 with the axial strain increasing from 0.05 to 0.3. The is probably because that with the increase of axial strain, the gradually increasing lateral strain of the infilled soil in the cell leads to the

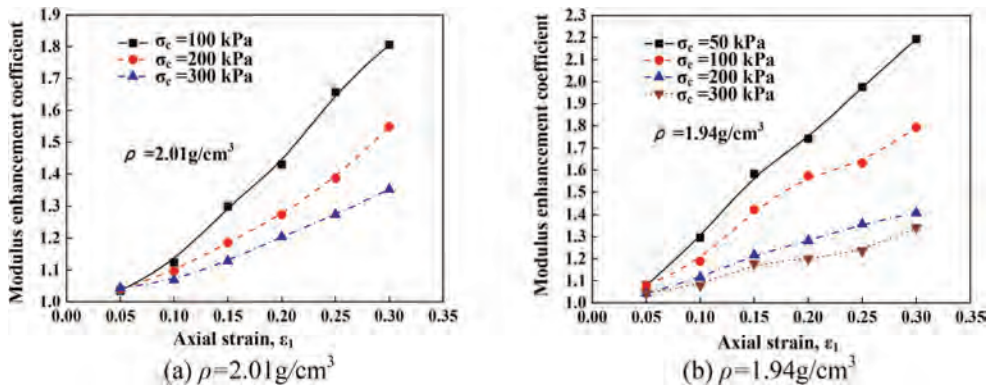
(a) ρ=2.01g/cm^3 (b) ρ=1.94g/cm^3


Figure 4.   Variation of modulus enhancement coefficient with the axial strain.

enlargement of the circumferential tensile strain and tensile force of the cell. Thus, the additional confining pressure provided by the cell to the filler will gradually increase with the increase of axial strain of the reinforced soil. In addition, for the same axial strain, the modulus enhancement coefficient decreases gradually with the increase of the confining pressure. For example, for $\varepsilon_1=0.3$，when the confining pressure increases from 100kPa to 300kPa, the modulus enhancement coefficient decreases from 1.81 to 1.35. This is because the volumetric contraction trend of the infilled soil is more obvious under high confining pressure, and its lateral strain is relatively smaller. Therefore, the tensile strain and stress of the geocell are smaller, resulting in smaller confining pressure provided by the cell under high confining pressure.

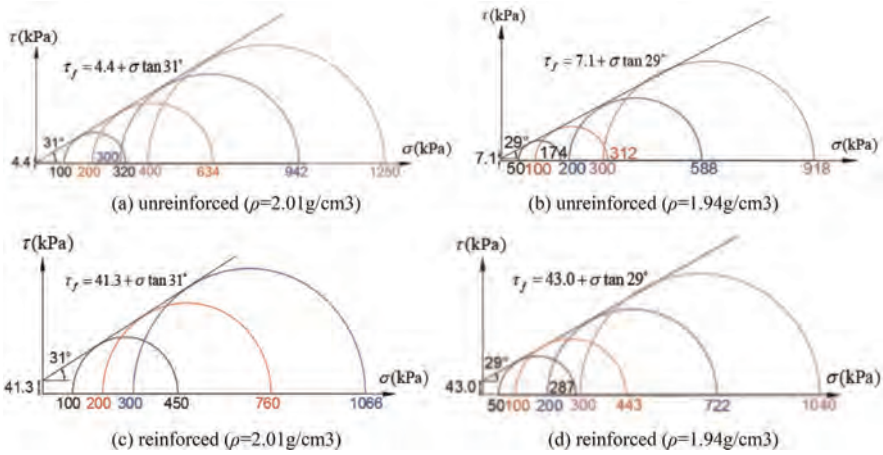
According to the peak deviator stress in Figure 3, the Mohr circle in Figure 5 can be obtained. It can be seen from Figure 5 that the failure envelope of normally-consolidated clay basically passes through the origin, and the apparent cohesion increases due to the confining pressure of the cell, but the internal friction angle remains basically unchanged. This is basically the same as that of cell-reinforced sand and gravel materials (Bathurst & Karpurapu 1993; Chen et al. 2013; Rajagopal et al. 1999; Song et al. 2019).


Figure 5.   Mohr circles of unreinforced and reinforced clay.

3   ANALYTICAL MODEL

An analytical method for predicting the stress-strain response of geocell-reinforced granular soil in the triaxial stress state was developed by Song et al. (2020, 2022). In their method, the relationship between the horizontal and vertical stress increments of the backfill can be expressed as:

$$d\sigma_1 = md\sigma_3 + E_t d\varepsilon_1 \qquad (2)$$

where σ_1 and σ_3 are the major and minor principal stresses of the infilled soil in the geocell, respectively, and ε_1 is the axial strain of the soil. $d\sigma_3 = d\sigma_g + d\sigma_c$, in which σ_g is the additional confining pressure provided by the geocell to the infilled soil and σ_c is the minor principal stress of the geocell-reinforced soil. m can be expressed as follows:

$$m = \dfrac{\dfrac{\partial f}{\partial q} - \dfrac{2}{3}\dfrac{\partial f}{\partial p}}{\dfrac{\partial f}{\partial q} + \dfrac{1}{3}\dfrac{\partial f}{\partial p}} \qquad (3)$$

413

in which p and q are the mean principal stress and deviatoric stress, which can be expressed as $p=(\sigma_1+2\sigma_3)/3$ and $q=\sigma_1-\sigma_3$, respectively, in the triaxial stress state. f is the yield function of the infilled soil. In this study, for the normally-consolidated clay, the modified Cam-clay yield function is adopted and then Eq. (3) can be expressed as:

$$m = \frac{1 - \frac{2\omega}{3}}{1 + \frac{\omega}{3}}$$ (4)

$$\omega = \frac{M^2 - \eta^2}{2\eta}$$ (5)

$$\eta = \frac{q}{p}$$ (6)

$$M = \frac{6 \sin \varphi_{cr}}{3 - \sin \varphi_{cr}}$$ (7)

in which φ_{cr} is the residual friction angle of the soil.

E_t in Eq. (2) is the tangent modulus in the nonlinear elastic stress-strain relationship (Duncan *et al.* 1980) and can be expressed as:

$$E_t = kp_a\left(\frac{\sigma_3}{p_a}\right)^n \left[1 - \frac{R_f(\sigma_1 - \sigma_3)(1 - \sin \varphi)}{2c \cos \varphi + 2\sigma_3 \sin \varphi}\right]^2$$ (8)

where k is the modulus number of the hyperbolic model, n is the modulus exponent, R_f is the failure ratio of the soil, and p_a is the atmospheric pressure. c and φ are the cohesion and friction angle of the soil, respectively.

The incremental expression of confining pressure formed by the confining constraint of the cell on the filler is as follows:

$$d\sigma_g = \frac{2M_t}{D_\varepsilon}\frac{d\varepsilon_c}{(1 - \varepsilon_1)}$$ (9)

where M_t is the tangent modulus of the geocell strip, ε_c is the circumferential strain of the cell when the geocell-reinforced soil reaches the axial strain ε_1, D_ε is the equivalent diameter of the geocell when the axial strain of the reinforced soil reaches ε_1. They are determined by equations (10) and (11) respectively (Chen *et al.* 2013):

$$\varepsilon_c = \sqrt{\frac{(1 - \varepsilon_v)}{(1 - \varepsilon_1)}} - 1$$ (10)

$$D_\varepsilon = D_0 \sqrt{\frac{(1 - \varepsilon_v)}{(1 - \varepsilon_1)}}$$ (11)

where D_0 is the original equivalent diameter of the geocell pocket and ε_v is the volume change of the filler. For the normally-consolidated clay, the volumetric change is contraction, which can be estimated via the modified Cam-clay stress-dilatancy relationship and expressed as (Roscoe & Burland 1968):

$$d\varepsilon_v = \frac{3(M^2 - \eta^2)}{M^2 - \eta(\eta - 6)}d\varepsilon_1$$ (12)

On the basis of the above derivation, the stress-strain responses of the geocell-reinforced clay can be obtained according to the procedure proposed by Song *et al.* (2020). In the analysis, the soil parameters include k, n, R_f, c, φ, and φ_{cr}, which can be determined by three conventional triaxial compression tests under different confining pressures. The parameters of geosynthetics include equivalent diameter, D_0, estimated by measuring the pocket size, and the tangent modulus, M_t, determined by tensile load tests.

4 VALIDATION OF THE MODEL

The validity of the proposed analytical method for predicting the stress-strain responses of geocell-reinforced normally-consolidated clay was verified via triaxial test results in this study. The parameters of the clay were calibrated from the triaxial test results and listed in Table 2. The comparison between the prediction results via the theoretical method based on the above parameters and the experimental ones is shown in Figure 6, and the agreement between the calculated curves and the measured ones proves the validity of the above parameters.

Table 2. Parameters of the clay in the analysis.

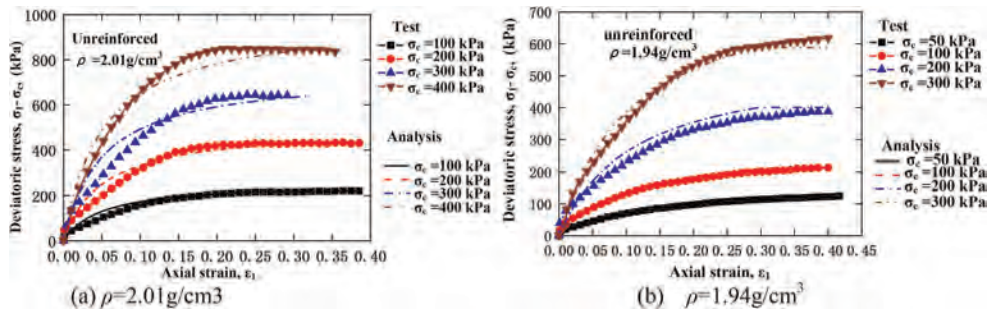
Density of clay, ρ, g/cm^3	k	n	R_f	c (kPa)	φ (°)	φ_{cr} (°)
2.01	52.2	0.970	0.890	4.4	31	31
1.94	25.6	0.953	0.729	7.1	29	29


Figure 6. Calibration of calculation parameters of unreinforced soil.

Based on the fitting of the tensile curve in Figure 2, the tangent modulus of the cell strip can be obtained as follows:

$$\frac{M_t}{M_{tref}} = 7G_0\varepsilon_c^6 + 6G_1\varepsilon_c^5 + 5G_2\varepsilon_c^4 + 4G_3\varepsilon_c^3 + 3G_4\varepsilon_c^2 + 2G_5\varepsilon_c + G_6 \qquad (13)$$

in which, G_0, G_1, G_2, G_3, G_4, G_5, and G_6 are 37605.76, -59332.02, 38152.04, -12991.258, 2575.89, -313.52, 24.06 and 0.00392. Since ε_c is dimensionless, the reference tangent modulus M_{tref} is defined here as 1kN/m. The initial equivalent circle diameter D_0 of the cell is 39mm.

The parameters of the above backfill and geocell were substituted into the analytical method proposed in this paper, and the incremental analysis was carried out to obtain the stress-strain responses of geocell-reinforced normally-consolidated clay under different confining pressures, as shown in Figure 7. In order to facilitate comparison, the experimental

results were also superimposed in the figure. The predicted stress-strain responses of reinforced soil were close to the experimentally measured results, which verifies the effectiveness and reliability of the proposed analytical method.

(a) $\rho = 2.01 \text{g/cm}^3$

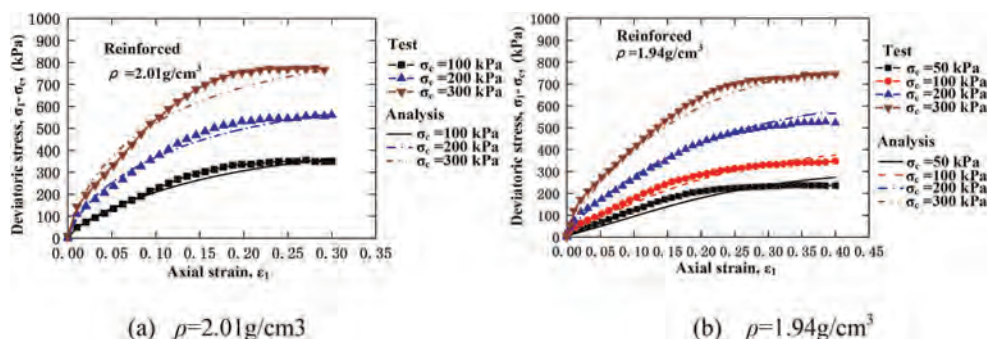
(b) $\rho = 1.94 \text{g/cm}^3$


Figure 7.   Validation of the proposed method via triaxial compression test results.

5   CONCLUSION

In this paper, a series of triaxial compression tests were conducted to investigate the stress-strain responses of geocell-reinforced normally consolidated clay. On the basis of the analysis of the test results and the theoretical derivation, the following preliminary conclusions were drawn:

(1) The stress-strain relationship of the geocell-reinforced normally consolidated clay was strain-hardening. Similar to the granular soil, the internal friction angle after reinforcement was basically unchanged, but the apparent cohesion can be improved significantly and the reinforcement effect increases gradually with the increase of axial strain.

(2) By employing the Duncan Chang hyperbolic model, modified Cam-clay yield function and dilatancy equation, an analytical method for predicting the stress-strain responses of geocell reinforced normally-consolidated clay was derived. The proposed method was theoretically rigorous, and the parameters of the geocell and soil required for the calculation have clear physical meanings and can be obtained through routine tests.

(3) The validity of the proposed analytical method was verified by the triaxial compression tests of geocell-reinforced normally consolidated clay in this study.

Soil-geosynthetic interface shear behaviour: Insights from inclined plane and direct shear tests

ABSTRACT: The assessment of soil-geosynthetic interface shear strength properties is essential for the safe design of geosynthetic-reinforced soil systems. In this study, a series of inclined plane and direct shear tests was carried out to evaluate the shear strength parameters of the interfaces between a residual soil from granite and two different geosynthetics: an extruded geogrid and a geocomposite reinforcement. The influence of soil moisture content was analysed under inclined plane and direct shear modes by compacting the soil at the optimum moisture content (w_{opt}) and 2% wet of the w_{opt}. The direct shear test results show that the increase in soil moisture content may lead to a considerable reduction in the apparent cohesion of the soil-geosynthetic interface. In general, higher shear stresses were reached at the interface involving the geocomposite reinforcement. Moreover, the interface shear strength parameters established from direct shear test results generally exceeded those obtained by inclined plane tests, particularly in terms of the apparent cohesion value.

1 INTRODUCTION

Understanding the shear behaviour of soil-geosynthetic interfaces is of the utmost relevance for the safe design of geosynthetic-reinforced systems. One of the major benefits from the use of geosynthetics as reinforcement elements in geotechnical structures is the possibility of using lower quality locally available backfill materials, such as cohesive and/or residual soils and recycled waste materials, particularly in cases where higher quality granular soils are not readily available. However, low quality soils are often more susceptible to the detrimental effects of moisture content increase, and thus the influence of moisture content on the behaviour of soil-geosynthetic interfaces involving these soils should be thoroughly evaluated (Ferreira *et al.* 2013, 2015).

The direct shear test is commonly used to investigate the shear strength properties of soil-geosynthetic interfaces subjected to relatively high normal stresses. The inclined plane test can alternatively be used to assess the interface shear strength under lower confining pressures. This method is particularly well suited to study the interaction between soils and geosynthetics when these materials are installed on inclined plane surfaces (e.g. erosion protection systems and landfill liner/cover systems), since it can more accurately reproduce the slippage that may occur on slopes (Ferreira *et al.* 2014; Lopes *et al.* 2014).

The main aim of the present study is to characterise the shear behaviour of the interfaces between a locally available residual soil from granite and two geosynthetics, specifically a

uniaxial extruded geogrid and a uniaxial geocomposite reinforcement, by using two distinct test methods (the inclined plane and the direct shear test), while establishing a comparison between the interface shear strength parameters estimated from both methods. Special care was taken to ensure that the specimen preparation was identical for both types of test to avoid any external factors that could hamper the comparison of results. The influence of soil moisture content and geosynthetic type on the soil-geosynthetic interface shear strength under inclined plane and direct shear modes is also evaluated and discussed in this paper.

2 MATERIALS AND METHODS

2.1 *Materials*

The soil used in this study was a locally available residual soil from granite with the particle size distribution curve presented in Figure 1a. This soil is classified as well-graded sand with silt and gravel (SW-SM) according to the Unified Soil Classification System. The maximum dry unit weight and optimum moisture content ($w = w_{opt}$) obtained from the Modified Proctor test (CEN 2010) are 18.9 kN/m^3 and 11.5%, respectively. The internal soil strength was evaluated by large-scale direct shear tests. For $w = w_{opt}$ and dry unit weight of 17.5 kN/m^3, the soil shear strength can be characterised by a friction angle of 42.4° and cohesion of 13.6 kPa.
Figure 1. (a) Particle size distribution curve of the residual soil from granite; (b) GGR; (c) GCR.

Two commercially-available geosynthetics were employed, specifically a uniaxial extruded geogrid (GGR) manufactured from high-density polyethylene, with a mean grid size of 22×235 mm (Figure 1b), and a uniaxial geocomposite reinforcement (GCR), consisting of a continuous filament nonwoven polypropylene geotextile reinforced with high modulus polyester yarns (Figure 1c). The tensile load-strain behaviour of the geosynthetics was assessed by wide-width tensile tests following the EN ISO 10319:2015 (CEN 2015). The average values of maximum tensile strength (T_{max}), strain at maximum load (ε_{Tmax}) and secant stiffness at 5% strain ($J_{5\%}$) for the geogrid (machine direction) were 52.2 kN/m, 12.4% and 509.8 kN/m, respectively. For the geocomposite, the corresponding values were 54.6 kN/m, 10.6% and 600.9 kN/m, respectively.

2.2 *Test devices and methods*

Two prototype test facilities were used to carry out the experimental programme: an inclined plane test device and a large-scale direct shear test device. The inclined plane device is

composed of a rigid lower box (510 mm × 350 mm in plan and 80 mm high), a rigid upper box (300 mm × 300 mm in plan and 80 mm high) and a rigid base (620 mm × 430 mm in plan and 10 mm high). According to the EN ISO 12957-2:2005 (CEN 2005), the test can be conducted by using a rigid support for the geosynthetic or with the lower box filled with soil. The tests reported herein were performed using the latter method. During the tests, the base plane was raised at a rate of 0.5°/min and the relative displacement between the upper box and the geosynthetic was monitored. The vertical force was applied by weights transmitted to a rigid steel plate installed over the soil specimen. To ensure that the vertical force approximately passed through the centre of gravity of the upper box, two wedges inclined 1:2 were placed on its front and back walls. The vertical stress (σ_v) was applied for 60 min prior to raising the base plane. Further details about the device, instrumentation and test procedures can be found elsewhere (Ferreira *et al.* 2014; Lopes *et al.* 2014).

The direct shear test device consists essentially of a steel shear box (including upper and lower boxes), a support structure, hydraulic actuators and respective power unit, an electric cabinet and a set of displacement and pressure transducers. The internal dimensions of the upper and lower boxes are 600 mm × 300 mm in plan and 50 mm height, and 800 mm × 340 mm in plan and 100 mm height, respectively. The tests may be performed according to the method of constant or reduced contact area. The present tests were conducted according to the latter method by placing a rigid ring inside the lower box, which enabled equally sized upper and lower halves to be filled with soil. Prior to shearing, the normal stress was applied to the specimens by a rigid metal plate for a period of 60 min. Following the EN ISO 12957-1:2018 (CEN 2018), a constant displacement rate of 1 mm/min was used. A detailed description of the test facility and procedures can be found in Vieira *et al.* (2013) and Ferreira *et al.* (2013, 2015).

2.3 *Test programme*

A series of inclined plane (IPT) and direct shear tests (DST) was carried out to estimate the shear strength parameters of the interfaces between the residual soil from granite and the geosynthetics. The IPT were performed under vertical stresses (σ_v) of 5, 10 and 25 kPa, as recommended by the EN ISO 12957-2:2005 (CEN 2005), and each test was carried out twice under identical conditions. The DST were conducted under normal stresses (σ_n) of 25, 50, 100 and 150 kPa. Soil dry unit weight was kept constant in all of the tests (17.5 kN/m³). The interface shear strength variation associated with an increase in soil moisture content (w), which may potentially occur under field conditions, was evaluated under inclined plane and direct shear modes by compacting the soil at the optimum moisture content (w_{opt} = 11.5%) and 2% wet of the w_{opt} (w =13.5%).

3 RESULTS AND DISCUSSION

3.1 *Influence of soil moisture content*

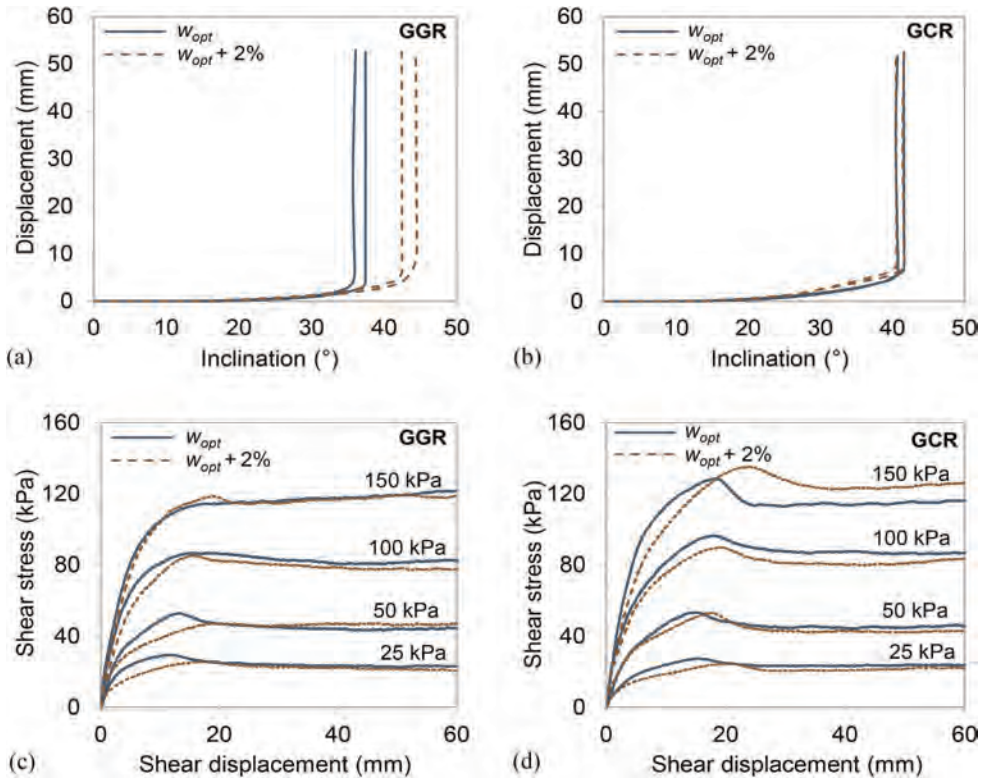
Figures 2a, b present the evolution of the upper box displacement with the inclination of the shear box from inclined plane tests on the soil-GGR and soil-GCR interfaces performed under σ_v =10 kPa and different soil moisture contents *(w_{opt} and w_{opt} + 2%)*. It can be observed that the influence of soil moisture content on the soil-geosynthetic interface shear strength under inclined plane mode was more significant when the geogrid was used (Figure 2a). For this interface, the slipping angle of the upper box (i.e. the inclination leading to the displacement of 50 mm) increased with the moisture content, implying that the moisture content increase (from w_{opt} to w_{opt} + *2%)* produced a beneficial effect on the interface shear strength. However, for the interface involving the geocomposite reinforcement (Figure 2b), the variation in soil moisture content did not significantly influence the slipping angle, and hence the interface shear strength. This is possibly associated with the structure and moisture absorption capacity of this geosynthetic.


Figure 2. Influence of soil moisture content on soil-geosynthetic interface behaviour: (a) inclined plane tests on soil-GGR interface (σ_v = 10kPa); (b) inclined plane tests on soil-GCR interface (σ_v = 10kPa); (c) direct shear tests on soil-GGR interface; (d) direct shear tests on soil-GCR interface.

Figures 2c, d compare the shear stress-shear displacement behaviour of the soil-GGR and soil-GCR interfaces obtained from direct shear tests carried out under different soil moisture conditions (w_{opt} and w_{opt} +2%). For the soil-GGR interface (Figure 2c), the increase in moisture content led to a considerable reduction in the maximum interface shear strength under lower normal stress values (by up to 11.5% for σ_n=25 kPa). When subjected to higher normal stresses (σ_n=100 and 150 kPa), the influence of soil moisture content on the maximum interface shear strength was almost negligible. Similarly, the maximum shear strength of the soil-GCR interface (Figure 2d) also tended to reduce with increasing moisture content (by up to 10.5% for σ_n=25 kPa).

3.2 Influence of geosynthetic type

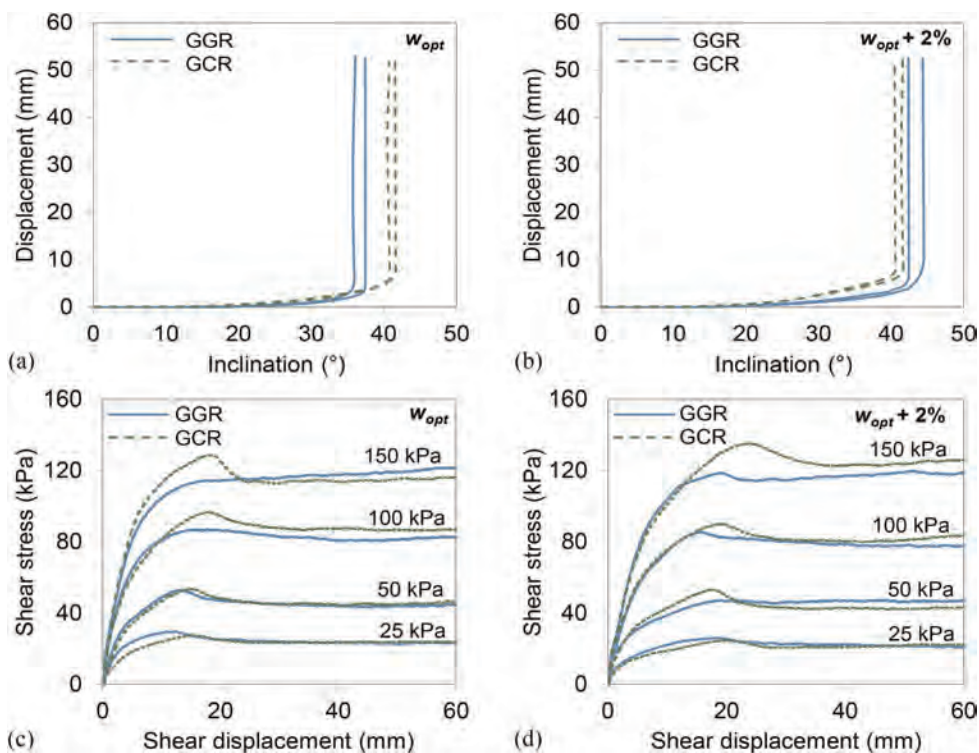
The influence of geosynthetic type on the soil-geosynthetic interface behaviour under inclined plane and direct shear modes is illustrated in Figure 3. It is noteworthy that the same type of support for the geosynthetic was used in all of the tests (i.e. lower box filled with soil) to enable the comparison of results. The inclined plane test data show that, when the soil moisture content is equal to w_{opt}, the slipping angles achieved at the interface involving the GCR were greater than those for the interface involving the GGR (Figure 3a). However, when the moisture content was increased (Figure 3b), the slipping angles were similar for both interfaces.


Figure 3. Influence of geosynthetic type on soil-geosynthetic interface behaviour: (a) inclined plane tests for $w = w_{opt}$ ($\sigma_v = 10$kPa); (b) inclined plane tests for $w = w_{opt} +2\%$ ($\sigma_v = 10$kPa); (c) direct shear tests for $w = w_{opt}$; (d) direct shear tests for $w = w_{opt} +2\%$.

The results from the direct shear tests, shown in Figures 3c, d indicate that the maximum shear stresses reached at the soil-GCR interface generally exceeded those at the soil-GGR interface, regardless of moisture content. In addition, the increase in the maximum interface shear strength attributed to the use of the geocomposite became more pronounced as the normal stress was progressively increased. The higher values of shear stress reached for the interface with the geocomposite may be associated with the higher surface roughness of this geosynthetic, comparatively with the geogrid, which promoted higher mobilisation of frictional resistance during shearing.

3.3 *Inclined plane test versus direct shear test*

Soil-geosynthetic interface shear strength parameters are generally estimated from direct shear tests by fitting a straight line through the plot of peak shear stress versus normal stress, which represents the interface shear strength envelope. Based on the Mohr-Coulomb failure criterion, the shear strength parameters, specifically the interface friction angle (δ) and apparent cohesion (c_a) are derived. A comparable analysis may be performed from the inclined plane test results, taking into account the shear stress and normal stress acting at the interface when failure occurs (i.e. at the base inclination leading to a relative displacement of 50 mm) (Ferreira *et al.* 2016).

Figure 4 compares the shear strength envelopes and associated shear strength parameters estimated from inclined plane and direct shear tests on the soil-GGR (Figures 4a, b) and soil-GCR (Figures 4c, d) interfaces under different soil moisture conditions (w_{opt} and $w_{opt} + 2\%$).

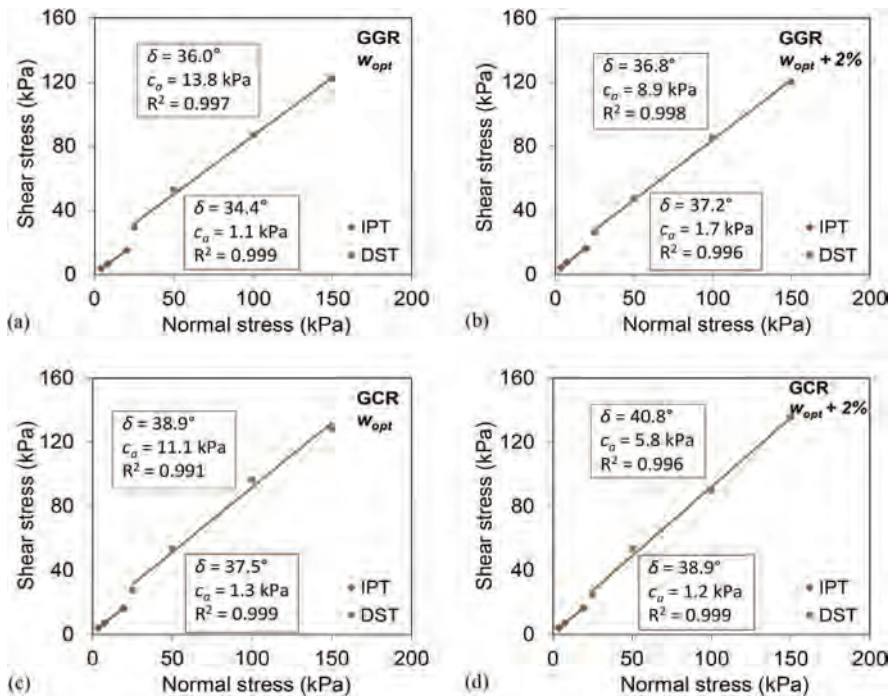
These results show that the shear strength parameters obtained from direct shear tests were generally higher than those estimated from inclined plane tests for a specific interface. The interface friction angles derived from the direct shear tests slightly exceeded those from the inclined plane tests (by up to 5%). On the other hand, the values of the interface apparent cohesion determined from the inclined plane tests did not exceed 1.7 kPa, whereas the values obtained from the direct shear tests were significantly higher. The above findings are consistent with previous studies on soil-geosynthetic (Izgin & Wasti 1998, Ferreira *et al.* 2016) and geosynthetic-geosynthetic interfaces (Girard *et al.* 1990; Wasti & Özdüzgün 2001), in which the interface shear strength parameters derived from direct shear tests exceeded those from inclined plane tests conducted on an identical interface. This indicates that the extrapolation of the linear interface shear strength envelope established from direct shear test results for normal stresses below the range over which the tests are conducted may be nonconservative. Therefore, in cases where the soil-geosynthetic interface is expected to be subjected to low normal loads during construction or throughout the service life of the structure (e.g. erosion protection systems and landfill liner/cover systems), the inclined plane test should be used for more accurate prediction of the soil-geosynthetic interface shear strength.


Figure 4. Comparison of soil-geosynthetic interface shear strength envelopes from inclined plane and direct shear tests: (a) soil-GGR interface ($w = w_{opt}$); (b) soil-GGR interface ($w = w_{opt} + 2\%$); (c) soil-GCR interface ($w = w_{opt}$); (d) soil-GCR interface ($w = w_{opt} + 2\%$).

4 CONCLUSIONS

A series of inclined plane and direct shear tests was conducted to investigate the effect of soil moisture content and geosynthetic type on the soil-geosynthetic interface shear strength and to compare the shear strength parameters estimated on the basis of the aforementioned test methods.

Under inclined plane shear mode, the increase in soil moisture content from w_{opt} to $w_{op} + 2\%$ did not induce any reduction in the soil-geosynthetic interface shear strength. However, under direct shear test conditions, the interface shear strength tended to reduce with increasing moisture content, particularly under lower normal stress values. Maximum shear strength reductions of 11.5% and 10.5% were obtained for the interfaces with the GGR and the GCR, respectively.

In general, higher shear stress values were reached at the interface involving the geocomposite reinforcement, regardless of soil moisture content, which may be attributed to the rougher surface of this geosynthetic, in comparison to that of the geogrid.

The interface shear strength parameters obtained from the direct shear tests generally exceeded those from the inclined plane tests conducted on the same interface. While the values of friction angle determined from the direct shear tests were only slightly higher (by up to 5%) than those estimated from the inclined plane tests, the apparent cohesion values were significantly greater when derived from the former method.

The effect of soil on the shear strength of geosynthetic interfaces

P. Pavanello & P. Carrubba
Dipartimento ICEA, Università degli Studi di Padova, Padova, Italy

ABSTRACT: In landfill cover systems, a geogrid or reinforced geomat is often used, placed just above the upper drainage geocomposite, to ensure the stability of the topsoil. In these cases, a specific interface occurs, which could be defined as a mixed interface, as there is a simultaneous contact between two geosynthetics and between the geosynthetics and the soil. The paper presents some preliminary results of a research on the interface shear strength of two interfaces of this type, corresponding to the contact between a drainage geocomposite and a geogrid or a reinforced geomat. A series of tests were carried out with a not standard direct shear device, operating at increased shear stress, to compare the response of the soil-less interface with that measured in the presence of the soil. The results showed how the presence of soil leads to an increase in the shear strength compared to the condition without soil and they also highlighted how the influence of soil on the behavior of the interface depends on the type of reinforcement used.

1 INTRODUCTION

In composite landfill cover systems, where geosynthetic materials are generally widely used, the problem of ensuring the stability of the topsoil frequently arises. To resolve this issue, a geogrid or a reinforced geomat is often inserted into the stratigraphy to reinforce and stabilize the upper layer of soil (Cortellazzo *et al.* 2022). Moreover, if the thickness of the soil is considerable or if the inclination of the slope is steep, it may be necessary to insert a further layer of reinforcement inside the soil, at half the thickness of the layer. For practical reasons, during the construction phase the first geogrid/geomat is generally placed immediately above the drainage geocomposite, which has the function of removing rainwater, and is subsequently covered with the soil. In these cases, among the various interfaces between geosynthetics that must be considered in stability analyses, there is also a unique interface corresponding to the contact between the geogrid/geomat and the draining geocomposite. The peculiarity of this interface is represented by the fact that it is a mixed type or hybrid interface, in which not only two different types of geosynthetic are in contact with each other but there is also the simultaneous presence of the soil. It is therefore neither a geosynthetic-geosynthetic interface, nor a geosynthetic-soil interface.

While many studies are available for both geosynthetic-geosynthetic (Carbone *et al.* 2015; Frost & Lee 2001; Pavanello *et al.* 2018; Stark *et al.* 2015) and geosynthetic-soil interfaces (Bacas *et al.* 2015; Moraci *et al.* 2014; Palmeira 2009), for these types of mixed contacts there is little information in the literature and the present study illustrates some preliminary results obtained at the geotechnical laboratory of the University of Padua by means of an experimental apparatus for shear tests at low confinement stress.

2 THE EXPERIMENTAL DEVICE

This study was carried out by means of an experimental device of new design, conceptually similar to a classical direct shear but with a different method of application of the shear stress and able to perform tests at very low normal stress (Pavanello *et al.* 2022).

The apparatus is composed of a steel box, having sides of 0.30 m × 0.30 m, which can slide over a horizontal surface. The first geosynthetic specimen is fixed to the base of the box, while the second is fixed over the horizontal plane. The box has no bottom and can be filled either with rigid steel plates or with soil. It is connected, via a steel cable, to a counterweight of variable weight (Figure 1): a load cell, placed between the box and the cable, allows to measure at any moment the value of the horizontal force acting on the mobile box.
Figure 1.   The direct shear apparatus: a) view from the top and b) sketch.

The instrumentation is completed by a linear variable displacement transducer (LVDT) which allows to detect the displacements of the box as a function of the applied shear stress. Indeed, during the test, the weight of the counterweight gradually increases over time, until the sliding box reaches a minimum displacement of 50 mm. The weight varies gradually by means of a simple mechanism, similar to an hourglass, which makes sand slide from an upper container into the counterweight at a constant speed. Under the hypothesis of a static condition, the mobilized friction angle can be evaluated, time by time, by means of the following simple equation:

$$\tan \varphi = \frac{H}{W} \qquad (1)$$

being H the measured horizontal force applied to the box and W its weight. In analogy with the standard direct shear, the interface friction is generally evaluated in correspondence to a displacement of 50 mm.

Referring to the differences with the standard direct shear test, it should be noted that in the standard device the displacement increases at a constant imposed speed of 1 mm/min while the response of the interface is detected in terms of opposing force, equal to the friction mobilized at the contact surface. Conversely, in the apparatus adopted in this research, the shear stress gradually increases, depending on the weight of the counterweight, while the

displacements of the interface are measured. In summary, in the first case a displacement is imposed and a stress is detected while in the second case a stress is imposed and a displacement is detected.

This latter approach is much closer to the real kinematics involved in the sliding of an interface over a slope and allows to highlight different behaviors of the interfaces that would not be so evident with the usual direct shear test (Pavanello *et al.* 2021).

3 TESTED MATERIALS AND SOIL

The experimental investigation examined the contact between a drainage geocomposite and a geogrid and the contact between the same drainage geocomposite with a reinforced geomat (Figure 2). The drainage geocomposite is formed by a three-dimensional high density polyethylene (HDPE) geonet coupled to two nonwoven geotextiles in polypropylene (PP). Its overall thickness at 2 kPa is equal to 6.4 mm and the tensile strength in the machine direction is 21.5 kN/m. The geogrid is made of polyethylene coated with pvc. It has meshes with a open size of 20x24 mm, mass per unit area of 367 g/m^2 and peak tensile strength of 85 kN/m in the longitudinal direction. Lastly, the reinforced geomat is a composite made by a woven geogrid from high tenacity polyester multifilament yarns protected by a polymeric coating and joined to a multifilamet polyolefin three-dimensional mat. The nominal thickness is of 7 mm and the mass per unit area is of 380 g/m^2; its tensile strength is equal to 25 kN/m in the machine direction.
Figure 2.   The geosynthetics involved in the experimentation.

Both the interfaces were previously tested without the soil and after with the soil (Figure 3). In the first case, the normal load was applied by means of steel plates placed inside the upper box. Conversely, in the case of test with soil, it was placed inside the box and a steel plate was added on the top of the layer of soil, to increase the confining stress. The tests were carried out under a normal stress of 5 kPa, for the condition without the soil, and of about 4 kPa in the case of presence of soil.
Figure 3.   Preparation of the box for the test a) without soil and b) with soil.

Referring to the selection of the soil, it must be considered that in general the material used to cover landfills does not have to meet very stringent requirements. For this reason, rather varied soils can be used, due to their availability in the area of the site, and consequently it is very difficult to identify a typical soil for these applications. In this research, a silty soil with traces of sand was used, as evidenced by the particle size distribution curve shown in Figure 4. The preliminary characterization tests indicated a liquid limit value of $W_L = 34\%$ and a plastic limit value of $W_P = 22\%$, while the standard Proctor test provided an optimum water content for the compaction of $W_{opt} = 14\%$.
Figure 4.   Particle size distribution of the tested soil.

Considering this data, the tests were performed with various water contents, ranging from approximately 9% up to 18%. In the preparation phase of each test, the dry soil was preliminarily hydrated. Subsequently, it was placed in the box, in three thin layers, and each layer was manually compacted by a variable number of blows, with a wooden pestle. In this way, tests with various densities and water content of the soil were performed.

4   RESULTS

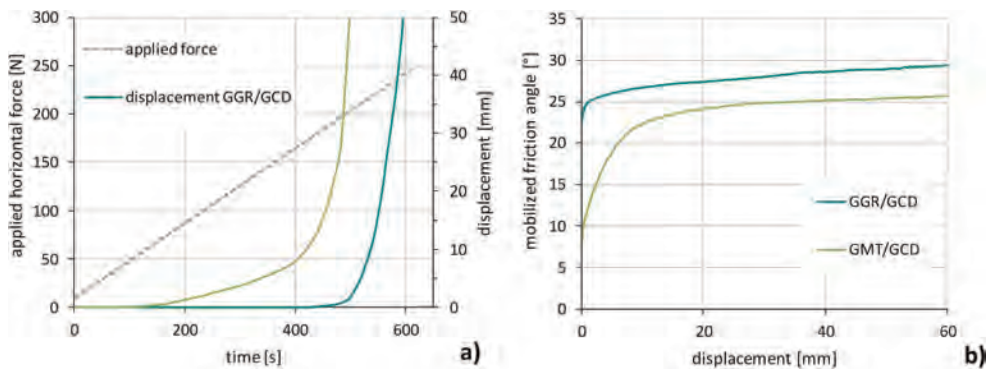
The first results relate to tests conducted on the interfaces without soil (Figure 5). In detail, Figure 5a shows an example of the increasing horizontal force, applied to the upper box, as a function of the time and the corresponding displacements of the two interfaces. Figure 5b shows the corresponding values of the mobilized angle of friction versus the displacement, as obtained by means of Equation 1. The two combinations of materials show a slightly different failure kinematics. It can be observed that the GMT/GCD contact is characterized by a very marked "gradual sliding" behavior (Pavanello et al. 2021): there is no a well-defined limit force value, beyond which the sliding is triggered and, on the contrary, the motion starts very slowly in correspondence with rather low force values and then gradually evolves as the applied shear stress increases. The behavior of the other interface, the GGR/GCD, albeit still characterized by a gradual sliding component, appears to have a much more restricted evolution range. As already highlighted in previous studies (Pavanello et al. 2021), the type of sliding behavior influences the criteria for defining the available static friction angle which in the case of "gradual" behavior, is more difficult to determine or in other words presents more uncertainty.


Figure 5. Results of the shear tests on the interfaces without soil: a) development of displacements as function of the time and of the applied horizontal force; b) mobilized friction angle versus displacement.

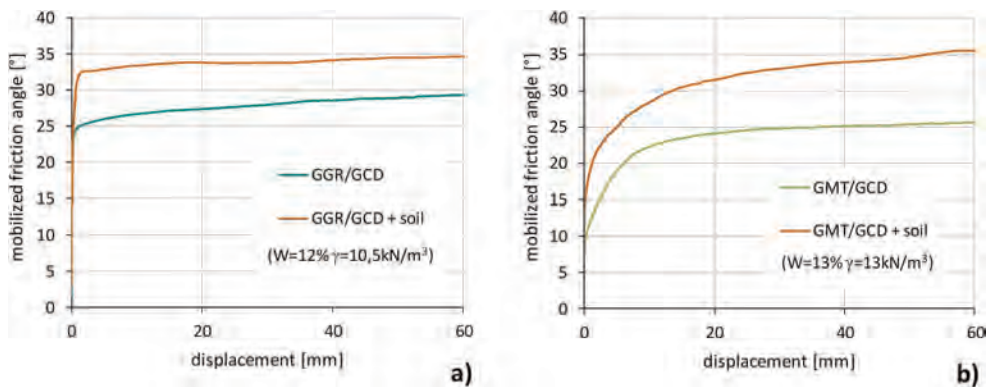
One of the aims of this research was to understand how much the presence of the soil can influence this type of interfaces, both in terms of the variation of the friction angle and in terms of the possible variation of the behaviour, i.e. the sliding mode. For this purpose, the shear tests were repeated also with the presence of soil at the interface and the related results are shown in Figure 6, compared to the results of the previous case without the soil. Figure 6a reports the case of the GGR/GCD contact, while the results for the interface GMT/GCD are shown in Figure 6b.


Figure 6. Comparison of the results of the shear tests for the interfaces with and without soil: a) GGR/GCD interface; b) GMT/GCD interface.

In both cases, a significant increase in the friction developed at the interface is observed thanks to the presence of soil particles. In the case of the first interface, GGR/GCD, the behavior evolves towards sudden sliding, with the sliding developing quite clearly when a limit value of the mobilized friction is reached. Differently, in the case of the GMT/GCD contact, the behavior remains of the "gradual sliding" type, with a wide range of friction values mobilized as a function of the displacement. To investigate the influence of soil properties on the interface shear strength, the tests were repeated with different values of water content and soil density. A graphical summary of the results obtained is shown in Figure 7 in terms of friction angle as a function of the wet density of the soil and of its water content. Given the gradual sliding behaviour of the GMT/GCD interface, the friction angle

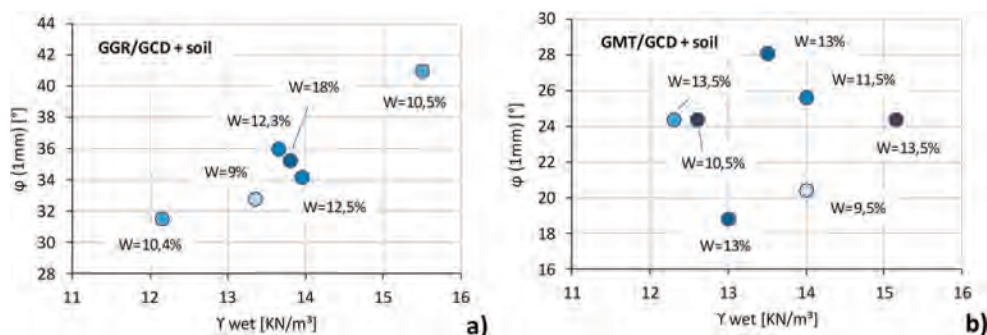
was evaluated at a displacement of 1 mm, instead of using the usual reference of 50 mm. The figure shows that there is no obvious correlation between water content and interface friction angle. Furthermore, regarding the influence of the compaction level, the two interfaces reveal a different behavior. In the case of contact with the geogrid, a certain dependence on the volume weight of the soil can be observed, with interface friction values increasing as the density of the soil increases (Figure 7a). On the contrary, in the case of contact with the geomat, the data show a relevant scattering and it is not possible to identify an analogous correlation between the values of the angle of friction and the degree of compaction (Figure 7b).


Figure 7.   Interface friction angle versus wet density and water content of the soil: a) GGR/GCD interface; b) GMT/GCD interface.

The set of data collected shows that for the interface with the geogrid, characterized by large openings between the meshes, the soil plays an important role in the formation of interface friction. In fact, not only does the shear resistance show an increase with respect to the case of an interface without soil, but the sliding kinematics itself changes, passing from a "gradual sliding" type behavior to a "sudden sliding" type one. Furthermore, precisely because of the extent of the contact between the soil and the geodrain, the interface shear strength depends on the mechanical properties of the soil and can be indirectly related to its level of compaction.

Conversely, in the case of the reinforced geomat, only a fraction of the soil can cross the geomat and come into contact with the drainage geocomposite. Consequently, while also in this case a general increase in the friction angle is observed, there is no modification of the sliding mechanism, which remains of the "gradual sliding" type even with the presence of the soil. Furthermore, the values of water content and soil compaction do not seem to significantly influence the results, probably due to the interaction with the geomat rather than with the interface.

5   CONCLUSION

The research analyzed the behavior of mixed interfaces, i.e. interfaces in which there is simultaneous contact between two geosynthetics and between the geosynthetics and the soil. Two interfaces were considered, generated by the contact between a drainage geocomposite and respectively a geogrid and a reinforced geomat. The results showed in both cases an increase in the interface shear strength between the test case with soil compared to the condition without soil. However, they also highlighted a different role played by the terrain at the two interfaces. In fact, while in the case of the geogrid the behavior changes passing from the case without soil to the one with soil, this does not happen for the interface with the reinforced geomat.

These investigations, although preliminary, allow some interesting conclusions to be drawn: the first is that in the absence of information on the soil that will be used on site, the tests conducted on geosynthetics without the soil are in any case a valid and certainly precautionary reference. The second observation is that the "gradual sliding" behavior observed for some interfaces without soil can remain so even in the presence of soil. This circumstance implies the need for a careful and prudent evaluation of the available friction in the design phase.

Response of diagonally enhanced geocells to significant planar tensile loads

K. Fakharian, M. Kashkooli & A. Pilban
Department of Civil & Environmental Engineering, Amirkabir University of Technology, Tehran, Iran

ABSTRACT: Geocells have been used as basal reinforcement in improvement of foundation soils, embankments and highway subgrades to increase bearing capacity and reduce total and differential settlements. Attempts have been made in engineering practice to somehow reduce the extensibility of the geocells whenever they are subjected to considerable tensile forces. This paper presents pullout test results on conventional (ordinary) and diagonally enhanced geocells under different surcharge pressures to evaluate feasibility of their applications when subjected to significant planar forces. Extensive pullout tests on scaled geocells embedded in silica sand are performed to investigate the effects of improvements on load-deformation response, strength and stiffness. Conventional web-shaped geocells are having a small stiffness when subjected to planar tension attributed to deformability of webs. Therefore, conventional geocells may not function properly when subjected to tensile forces along the main plane in service. A special geocell is fabricated in this study, similar to tendoned geocells, through adding diagonal members along the induced tensile load to overcome the shortcomings of conventional geocells. The test results have shown that both the stiffness and ultimate resistance of the diagonally enhanced geocells have significantly improved with respect to the conventional ones.

1 INTRODUCTION

A geocell is a three-dimensional cellular structure that can be filled with soil, gravel, or other materials and is made of high-density polyethylene (HDPE). Geocells have been used as basal reinforcement for improving the foundation soils, embankments and highway subgrades to increase bearing capacity and reduce total and differential settlements. Recent studies have presented the advantages of conventional diamond-web geocells with respect to planar reinforcements in certain applications (Fakher & Jones 2001; Tafreshi & Dawson 2010; Choudhary *et al.* 2020).

The reinforcement elements contribute to improving the soil characteristics including strength and stiffness on one hand, and their frictional interaction with soil on the other hand, to increase the stability and reducing the deformability of the soil structure system. Figure 1 shows typical examples of soil reinforcement under foundations and slope protection. The deformed geocell reinforced mattress of Figure 1a clearly shows the role of tensile load (T) along the geocell plane under a surcharge pressure and the shear stress transfer mechanism below and above the geocell. Figure 1b shows a steep soil slope protected with geocell from erosion. It is evident that both tensile stiffness and shear stress transfer are contributing to stability of the reinforced slope with geocells during the service life.

Attempts have been made in engineering practice to somehow reduce the extensibility of the geocells whenever they are subjected to considerable tensile forces. One example is nailing the geocell into ground to prevent sliding. Also, tendon type supports along the
Figure 1.   Example applications of geocells subjected to planar tensile forces: (a) Planar tensile forces (T) in a geocell mattress (Zhang et al 2012), (b) a Slope protected by geocell subjected to downward tensile.

tensile load plane have been added for anchoring the protected geocell layer to the crest of slope and also reducing the geocell longitudinal deformability (Senf 2010). The tendons are being installed diagonally after spreading the geocell in the field in every other web or one tendon per several webs.

The same idea of tendoned geocells and adding diagonal members is further studied here to expand the applications in engineering practice as well as identifying the interactive response with soil when subjected to tensile planar force. The main idea of modifying the common geocells was adding longitudinal members along the tensile load while they are connected at nodes, to enhance its load carrying capacity as wells as reducing the extensibility of geocells. The enhanced product does not function planar and still the multi-dimensional nature of geocell prevails while it is improved against the tensile loads.

A well-known testing apparatus capable of evaluating the tensile resistance/stiffness and interactive shear transfer mechanism is the large-scale pullout box. Most of the reported studies in literature using pullout box are limited to planar reinforcements such as geogrides and geotextiles. The reported data on pullout tests on 3D cellular reinforcement, however, are very limited. Khedkar & Mandal (2009) carried out pullout tests on 3D square webs with various heights and proved their advantages with respect to planar reinforcement, but their experiments were limited to using metal reinforcements. Han *et al.* (2013a,b) reported initial low stiffness and high deformability of diamond-web polymeric geocells. Their results indicated that pullout resistance increases with soil grain size and cell height. In their studies, however, the vertical surcharge was limited to the soil weight and no external pressure was applied onto the soil top.

The main objective of this study is to evaluate the tensile deformability and interaction response of conventional and diagonally enhanced geocells with soil using pullout tests. The longitudinal members are added to conventional diamond-web geocells to enhance their performance for applications in which tensile forces in service are considerable. Pullout behavior of "conventional" and "diagonally enhanced" geocells are carried out under various surcharges and then compared with similar pullout test results of geogrides.

2   TEST EQUIPMENT, MATERIALS, AND EXPERIMENTS

2.1   *Pullout apparatus*

The automated pullout box of Amirkabir University of Technology developed by Nayeri & Fakharian (2009, 2010) was used with some modifications, to carry out the experiments of this study. The schematics of the apparatus and more details are presented by Fakharian & Pilban (2021).

2.2 Soil

The soil used in this study was a crushed angular poorly graded silica sand (SP) with D_{50} of 1.15 mm, supplied from Firuzkuh mine located east of Tehran. Many studies have used different grades of this sand for research purposes and its properties have been well-documented. The sand was deposited through uniform pluviation from 20 cm elevation to obtain a relative density of 45%.

2.3 Conventional and diagonally enhanced geocells

Other than conventional geocells having diamond-shape cells, a special geocell was also fabricated for situations that planar longitudinal forces are significant. For this purpose, longitudinal members were embedded diagonally with the patterns shown in Figure 2. The special geocells are referred in this paper as "diagonally enhanced geocells". This is while diamond-shape webs are referred as "conventional geocells". The conventional geocells are named D25. Three types of diagonally enhanced geocells are fabricated with 3, 5 and 9 longitudinal members, named H25-3, H25-5 and T25, respectively, as shown in Figure 2. The height and length of all reinforcements are considered 25 mm and 720 mm, respectively.

The size of the fabricated geocell was reduced to fit in the common pullout boxes. Polypropylene strips with 1.5 mm thickness and having an ultimate tensile strength of 61 kN/m were adopted.

For comparison purposes of 3D reinforcements with planar reinforcements, extruded HDPE uniaxial Geogrids supplied by Tenax under names TT45 and TT120 were also used. The used Geogrids are having ultimate tensile strengths of 45 and 120 kN/m, respectively, referred to as GG1 and GG2 in this study.
Figure 2. Conventional diamond-shape geocell (D25) and diagonally enhanced geocells developed in this research having 3 (H25-3), 5 (H25-5) and 9 (T25) longitudinal members.

2.4 Sample preparation and test outline

Sample preparations and testing procedures are discussed in details by Fakharian & Pilban (2021). The maximum surcharge pressure used in this study was 33 kPa. With increase in surcharge, the strain hardening response prevails and hence the peak and post-peak of load-frontal displacement graphs cannot be reached within the 90 mm stroke of the apparatus. Pressures starting from zero up to 30 kPa with 10 kPa increments were specified.

3 PULLOUT TESTS RESULTS

The presented results include deformation and load distribution patterns as well as load-frontal displacement along different types of reinforcement at the end of test under different surcharges. Pullout behavior of reinforced elements is usually comprised of a strain-hardening portion first until reaching a peak load. If the displacement is continued, depending on reinforcement property, soil density and magnitude of normal pressure, post-peak softening may or may not be experienced until a steady state is reached. It is pointed out that the passive resistance is mobilized through relative displacement between side walls and soil inside the webs. In the following, the pullout test results are presented for conventional and diagonally enhanced geocells as well as planar geogrids and comparisons are made.

3.1 *Deformation and load transfer patterns*

The main objective of this study is evaluating the tensile response of a diagonally enhanced geocell when subjected to tensile forces along the geocell plane. Deformability of conventional and diagonally enhanced geocells at different stages of tensile force are schematically presented in Figure 3. The conventional geocells simply benefit their 3-Dimentional behavior (confinement and reduction of lateral movement of the soil inside the cells) that leads to an increase in bearing capacity of foundations and reduction of total and differential settlements. When conventional geocells are subjected to tension, however, the cells adjacent to the tensile force point at the front are deformed first and thus the displacements cannot distribute along the reinforcement, resulting in no interaction along the specimen with upper and lower soils. In other words, interactions only occur near the loading point and no extension is observed along the reinforcement. Therefore, both initial stiffness and pullout resistance become very small. To overcome this shortcoming, longitudinal members were added to webs aligned with tensile force direction. Deformation mode of the diagonally enhanced geocell compared to conventional geocell represents a rapid and simultaneous tensile load transfer mechanism between webs along the loading, as observed in Figure 3. The main difference in the conventional and enhanced geocells, is the extent of deformability and the load transfer mechanism between the cells.
Figure 3.   Plan view of deformation patterns and gradual mobilization of passive resistance during pullout: (a) along the typical diamond-shape (conventional); (b) along diagonally enhanced geocell.

3.2 *Load-frontal displacement and pullout force*

The load-frontal displacement and relative movements of the nodes of different geocells under different surcharge pressures 3, 13, 23 and 33 kPa are compared with each other. In general, according to the load-frontal displacement responses, as anticipated, the pullout resistance and stiffness have increased under higher surcharges.

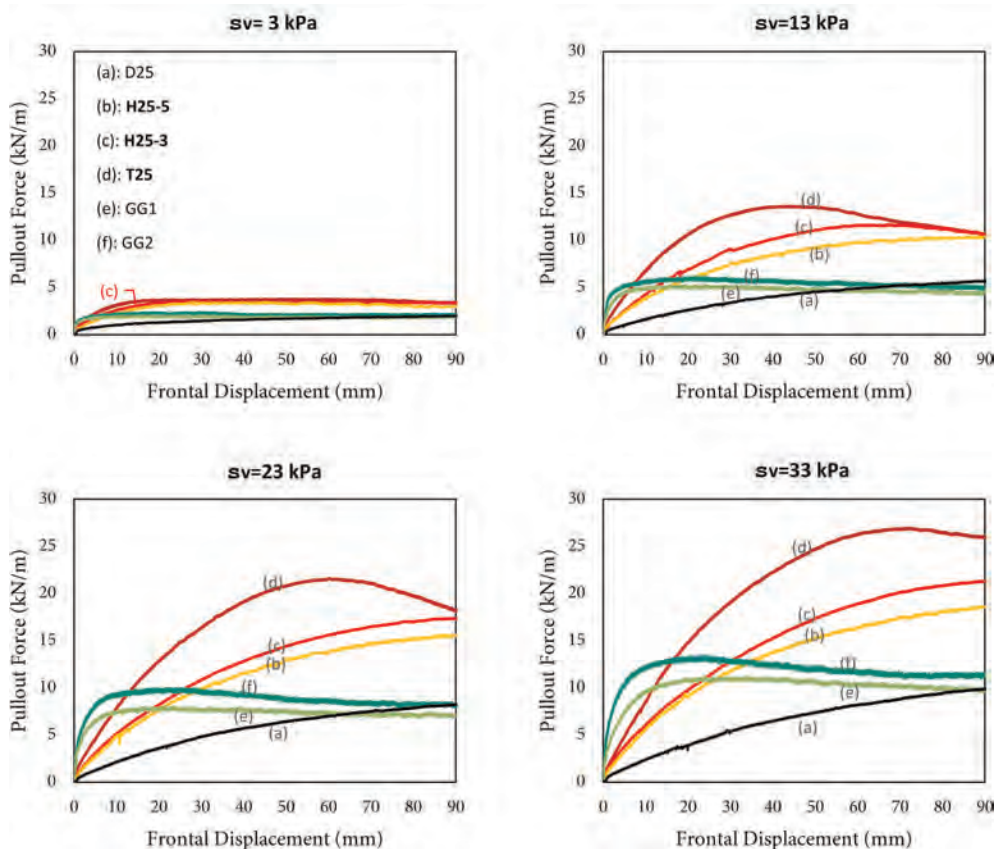
Figure 4 presents variations of pullout force versus frontal displacement along conventional geocells, diagonally enhanced geocells with 3, 5 and 11 longitudinal members—respectively


Figure 4. Pullout force versus frontal displacement for "geocells" (D25, H25-3, H25-5 and T25) and "geogrids" (GG1 and GG2) under different surcharges 3, 13, 23 and 33 kPa.

referred to as H25-3, H25-5 and T25—and two types of geogrids. The conventional geocells have shown initial low stiffness and strain-hardening response in such a way that up to the end of the test at 90 mm, no peak was observed. This is understood to be attributed to high extensibility of the diamond-shape conventional geocells. The results show that with increase in number of longitudinal members, the geocell has become stiffer, the relative movements along the specimen are shown to become more uniform and the pullout resistance has increased. The added longitudinal members are contributing to distribute the tensile force more evenly along the specimen and hence the entire geocell has contributed to increasing the interaction between soil and webs. In other words, the longitudinal members are transferring the frontal displacement to the end of the reinforcement (along the specimen) because of their tensile strength; then, the relative displacement between soil inside the cells and above/below leads to frictional and passive resistances along the entire length of reinforcement. (See Figure 3).

The pullout strength of all three types of diagonally enhanced geocells are greater than the geogrides. This is while the initial stiffness of both geogrides are greater than the diagonally enhanced geocells. The difference in strength is due to the fact that geocells are having a much higher passive resistance because of their height. But since the geocell webs are more deformable than extruded geogrides, their stiffness are smaller. The conventional geocell is having a much smaller stiffness than geogrides and diagonally enhanced geocells owing to its

much larger elongation subjected to tensile planar loads. The concept of the soil interaction mechanism inside the webs of geocells is not too different than contribution of the transverse ribs of geogrids. The passive resistance of the ribs is the result of the geogrid movement along the tensile load and the trapped soil inside reacts the movement of the passive rib as it is in frictional contact with the soil above and the soil below it. The thickness of the soil inside the geogrid is much smaller than the geocells though. Besides, geogrid webs are a kind of more rigid as compared to geocells in terms of compressive deformation during the pullout. That is why geogrids have exhibited initially stiffer response compared to (even) diagonally enhanced geocells (Figure 4).

Figure 5 presents the maximum pullout force variations with surcharge pressure for all the specimen types. It is noticed that the differences between pullout resistances of diagonally enhanced geocells with respect to geogrides have become more pronounced with increase in surcharge pressure. The maximum pullout resistance of conventional geocell is almost the same as geogrides, but a much higher deformation has been required to mobilize the pullout resistance.
Figure 5. Variations of maximum pullout force with surcharge pressure for different geocells and geogrids.

4 CONCLUSIONS

The most important findings of the study are summarized as follows.

The added longitudinal members in "diagonally enhanced geocells" contribute to transfer the tensile load towards the end of the specimen more evenly as compared to "conventional geocells". As the geocell moves relative to the soil along the specimen simultaneously, the interaction with soil is stronger resulting in higher strength and stiffness. The diagonally enhanced geocells are having higher pullout resistance.

With increase in number of added longitudinal members, the deformability reduces and pullout resistance increases, resulting in more efficient geocells whenever higher longitudinal loads are present in practice.

The extruded geogrids are having an initially stiffer response with respect to diagonally enhanced geocells. However, the pullout resistance of diagonally enhanced geocells are considerably higher than geogrids, providing slightly higher flexibility and hence damping properties when subjected to seismic excitations.

ABSTRACT: This article uses mathematical modeling to present a complementary approach for determining the failure over the geosynthetic's lifetime. Its relevance is in developing an exponential mathematical model to evaluate the durability of polypropylene woven geotextiles exposed in the field since exposure to the environment is of considerable complexity. It was found that the sum of resistance losses of the isolated periods cannot be considered equivalent to resistance loss for the total exposure period due to the accumulation of damages that the material subject. There was also a greater loss in the second exposure cycle compared to the first, justified by the damage that the polymer matrix structure had already accumulated during winter and spring. It was concluded that the durability of intact geosynthetics exposed to weathering factors presents itself differently due to different atmospheric dynamics since each period or season presented its peculiarities.

1 INTRODUCTION

Studies show that the world population is estimated at more than 7.4 billion people; among these, one in ten people does not have access to drinkable water, and one in three people does not have access to primary hygiene conditions. At the same time, natural disasters are recorded more frequently than in the past due to climate change. In this context, the United Nations (UN) in 2016, established a program to encourage sustainable development called Agenda 2030, which presents 17 sustainable development goals (SDGs) to assist and guide the decisions of nations (Dixon *et al.* 2017; Touze 2021).

Geosynthetics can be used in water treatment, food production, economic growth, fishing activities, and renewable energy production. In other words, such materials fulfillment of the 17 sustainable development goals established by the UN (Müller & Wohlecke 2017; Mirhaji *et al.* 2019).

Geosynthetics can be grouped into geotextiles, products related to geotextiles, geosynthetic barriers, and geocomposites (ISO TS 13434 2020). The increase in the use of these materials occurs due to multiple factors, such as the reduction in the environmental impact generated in the construction, operation, and service life of these works about conventional projects. Another factor is the easy installation, transport, and potential for emergency solutions. It makes these materials a reference for their technological appeal and for minimizing environmental damage (Blond *et al.* 2019; Chang *et al.* 2019; Chang & Feng 2021; Jahan *et al.* 2018).

The effects of the geosynthetic application environment on its design service life and, consequently, on its failure probability must be evaluated through appropriate tests, which require determining the material's primary functions and associated degradation processes (ASTM D5819 2022; Troost *et al.* 1994).

This paper presents a complementary approach to evaluate geosynthetics' durability. The present work proposes to evaluate the durability of polypropylene woven geotextiles in the field by submitting them to the weather. The results will be evaluated using statistical tools to validate modeling that considers damage accumulation in geotextiles exposed to the weather over time. This approach makes it possible to better understand the specific behavioral pattern of the material.

2 METHODOLOGY

The case study was the fundamental base for developing the mathematical modeling presented in this article. Two types of polypropylene woven geotextiles made for this research were used. Both were similar in their physical and mechanical characteristics but differing in the percentage of additive against UV radiation (HALS type). GLH (Geotextile with Lowest HALS) and GHH (Geotextile with Higher HALS) were analyzed. The UV radiation protection additive percentage in GHH was twice greater than in GLH, and both percentages were lower than 1%. Table 1 shows the physical and mechanical properties obtained by the GLH and GHH geotextiles.

Table 1. Properties of the polypropylene woven geotextiles (GLH and GHH).

Parameters	GLH**	GHH**
Mass per unit area (ISO 9864 2005)	273.0 g/m^2 (1.3%)	458.0 g/m^2 (0.8%)
Thickness (ISO 9863-1 2016)	0.96 mm (4.8 %)	1.62 mm (1.5 %)
Ultimate tensile strength (ASTM D 5035 2019)[*]	57.5 kN/m (1.7%)	55.8 kN/m (2.0%)

*Mechanical property in the machine direction (MD), **Confidence interval (CI), with 95% of confidence level.

The materials were submitted to weathering according to ISO 877-1 (2009a) and ISO 877-2 (2009b). The field was in the state of Minas Gerais, Brazil. Two exposure cycles were evaluated. The first started on December 21, 2016 (early summer) and ended on December 20, 2017 (late spring). The second was on June 21, 2018 (early winter) until June 20, 2019 (late autumn). GLH and GHH were exposed to the weather of each weather station individually and cumulatively.

The meteorological data from exposure periods was obtained through a meteorological station installed on field. An estimation of the 4.2% UV radiation of global solar radiation (UV/G) was adopted in the durability tests (Escobedo *et al.* 2009; Escobedo *et al.* 2011; Escobedo *et al.* 2014).

Graphs were developed based on the tensile strength data over the exposure time to validate a durability modeling, considering the aging until the degradation of the material, that is, the end of its service life. An exponential mathematical model, using the R^2 statistical analysis, was applied. The number of specimens allows for obtaining tensile strength results with an expected error of up to 1%.

3 RESULTS AND DISCUSSIONS

Table 2 presents the percentage loss of strength values for geotextiles exposed in the first cycle and Table 3 for geotextiles exposed in the second cycle. Confidence intervals were constructed for the aged geotextiles' strip tensile strength test results. This approach was based on the t-student statistical analysis, with a 95% confidence level, allowing the extrapolation of sample data for the population, with a 5% significance level (Tables 4 and 5).

After the first cycle, GHH showed less loss of tensile strength than GLH. It is in line with the percentages of additives against UV radiation used the in each geotextile. The confidence intervals explain that, for the first cycle, the percentage of the strength of geotextiles exposed to summer+autumn is only equivalent to the loss of material exposed to summer; that is,

Table 2. Percentage loss of strength values for geotextiles exposed in first cycle.

Period	GLH%	GHH%
Summer (Su.)	27.4	14.6
Autumn (Au.)	5.0	9.4
Winter (Wi.)	6.2	1.0
Spring (Sp.)	5.6	13.0

*LL: lower limit and **UL: upper limit.

autumn did not significantly affect geotextiles. The geotextiles also showed expected behavior in the second cycle, considering the accumulated time. GLH exhibited a greater loss of tensile strength when compared to GHH.

The distinct behavior of geotextiles in the face of both climatic cycles is highlighted. GLH and GHH, in the first cycle, showed a loss of strength in summer. However, analyzing the first cycle total exposure time, these losses were smaller than the second cycle losses. It is believed that the highest magnitude value occurred in the second cycle due to the polymer matrix structure accumulated damage during winter and spring. When these samples were exposed to atmospheric dynamics during the summer season, as part of their structure had already been compromised, the loss of strength was significantly higher than in the first cycle.

Table 5. Confidence intervals for the aged geotextiles' strip tensile strength in second cycle.

Period	GLH			GHH		
	LL* kN/m	Mean kN/m	UL** kN/m	LL* kN/m	Mean kN/m	UL** kN/m
Intact material	54.7	55.8	56.9	56.8	57.5	58.2
Summer (Su.)	45.6	46.8	48.0	45.8	47.5	49.1

Su.+Au.+Wi.+Sp	32.0	33.5	34.9	31.1	33.5	35.8

*LL: lower limit and **UL: upper limit.

Therefore, regarding the exposure to climatic seasons individually, it is noted that the greatest losses of tensile strength occurred after the summer and spring. In addition, it is noticed that the percentage of losses after total exposure is not equivalent to the sum of the losses in each climatic season. This fact is probably due to changes in the polymeric material structure that occur during exposure and directly influence its behavior. The polymer structure and behavior after exposure to one weather station differ when the material is exposed to other weather seasons, for example.

As expected, it was found that the durability of intact geosynthetics exposed to weathering factors presents itself differently if exposed to the same factors but with different atmospheric dynamics since each period or season presented its peculiarities.

Table 6 presents the estimated UV radiation incidence values and precipitation in the climatic seasons first cycle. Table 7 presents the estimated for the second cycle. It is observed that summer and spring presented high values of radiation and precipitation. This fact explains the higher percentage losses of geotextiles' tensile strength after exposure in these periods individually.

Table 6. Local UV radiation and precipitation values on first cycle.

Period	Number of days -	Estimated UV radiation MJ/m^2	Precipitation mm
Summer	90	76.0	342.4
Autumn	92	40.0	165.4
Winter	93	74.0	17.8
Spring	90	65.0	545.8
Total	365	255.0	1071.4

Table 7. Local UV radiation and precipitation values on second cycle.

Period	Number of days -	Estimated UV radiation MJ/m^2	Precipitation mm
Winter	90	64.0	169.0
Spring	92	63.0	412.2
Summer	93	65.0	504.9
Autumn	90	63.0	62.0
Total	365	255.0	1148.1

It is important to note that the percentage losses of strength were smaller in both cases, even in winter, presenting a similar UV radiation in summer and spring. The joint action of UV radiation and precipitation could be fundamental in the behavior of the exposed material. Therefore, Maxwell's model (2005) becomes less accurate in estimating the damage suffered since it only considers the action of UV radiation in isolation.

Another point to be noted is that during the winter and autumn seasons, days with little rain were predominant for both exposure cycles, thus creating a protective layer of dust on the exposed materials.

Graphs were obtained to validate a durability modeling, considering the degradation until its service life. As shown in Figures 1 and 2, the durability of geotextiles subject to weathering could be represented in terms of time versus tensile strength by an exponential mathematical model according to Equation 1.

$$R = Ke^{-(Y).X} \tag{1}$$

where R = tensile strength (kN/m); K = coefficient dependent on the strength characteristics of the intact material (kN/m), that is, the average value, within its lower and upper limits of the IC; X = exposure time (in days); Y = 10^{-4} to 10^{-3} (depending on the effect of weather, damage accumulation and protection level of material's polymer matrix-additives).
Figure 1.   Model considering the first cycle.   Figure 2.   Model considering the second cycle.
4   CONCLUSIONS

It was possible to verify a greater degradation of geotextiles in the summer climatic season compared to other seasons, even when the highest incidence of UV radiation did not occur in this season, as it was in the second cycle, where the highest incidence occurred in winter. This behavior is due to the sum between the weather, precipitation, and UV radiation.

In the first cycle, even with a greater volume of precipitation during the spring compared to summer, the incidence of UV irradiation was lower and, consequently, the loss of tensile strength. That is, the atmospheric dynamics of the field can directly influence the long-term geosynthetics' behavior in situations exposed to the weather.

GLH showed higher average values of tensile strength loss than GHH, probably due to the lower HALS-type additive concentration.

An exponential mathematical model could be determined to evaluate the geotextiles' durability, an adaptation of the exponential proposal of Maxwell (2005), which deals with the tensile strength in function only of UV radiation. The model proposed in this article seems promising, considering the atmospheric dynamics involved over exposure time. Therefore, the results are for research purposes and are not used in dimensioning parameters.

In order to improve the work developed in this paper, it is proposed to carry out more in-depth statistical analyses, such as, for example, adherence tests, since the R-squared coefficient could show greater adherence to the model.

Geosynthetics initial creep behavior parameters as a function of the load level applied in ramp and hold tests

ABSTRACT: Long-term analysis of geosynthetics is mandatory in the design phase. Once the performance of creep-rupture tests is too time-consuming, adopting temperature to accelerate the geosynthetics creep behavior is an attractive solution. The ASTM D 6992 provides guidelines to perform accelerated creep rupture tests in geosynthetics and recommends adopting ramp and hold tests to help assess the initial creep rupture behavior. Thus, this paper aims to assess the initial creep behavior of two geogrids and two non-woven geotextiles. A universal testing machine was used to perform ramp and hold tests. The specimens were loaded (at a similar load condition to the ones adopted in the accelerated creep rupture tests) to load levels ranging between 10% and 90 % of the geosynthetic ultimate tensile strength. Each load level was maintained for 3,600s and 10,800s for geogrids and non-woven geotextiles, in this order. Three specimens were tested for each load level and a best-fit equation was used to obtain the initial creep train rate and the initial axial strain of the mean curve obtained. The results revealed a higher development of creep strains for the non-woven geotextile than the geogrids. The effects of the non-woven geotextile mass per unit area, and the polymer type of the geogrids were pointed out. The results help to identify and compare the initial axial strain of these geosynthetics after the performance of the accelerated creep rupture tests.

1   INTRODUCTION

Once the service life of geosynthetic-reinforced soil structures can reach 100 years (Wu & Helwany 1996), assessing geosynthetics' long-term behavior is mandatory in the design phase (Allen & Bathurst 1996, 1994). Since the early 1980s, geosynthetics' elongation analysis under sustained axial load, which means the creep behavior, has been used to assess their long-term durability (Andrawes *et al.* 1984; Den Hoedt 1988; França & Bueno 2011; Greenwood 1990; Thornton *et al.* 1997; Zornberg *et al.* 2004). Under this condition, reinforcement reaches rupture under excessive elongation. However, to obtain the reduction factor for creep behavior used in the design, twelve specimens must show failure (rupture) at three (or more) load levels. To deal with these too time-consuming tests, Thornton *et al.* (1998) developed a test method (stepped isothermal method; SIM) that uses the temperature to catalyze geosynthetics' creep behavior.

ASTM D 6992 (2016) specifies the geosynthetic materials' accelerated creep and creep-rupture method using SIM. The standard recommends adopting a very short creep test (100 to 1000s; called ramp and hold (R+H) test) to complement the results obtained from SIM tests. This test can be used to i) estimate the initial parameters of creep curves (at load/strain

levels appropriate for the SIM results) and ii) establish the range of strains that the geosynthetics experience after a short response under a given load.

As non-woven geotextiles and geogrids can be adopted as reinforcement elements (Koerner 2005), this paper aims to report the results of R+H tests performed using four geosynthetics (two geogrids (GGR) and two non-woven needle-punched geotextile s (GTXnw)). R+H tests were performed at three specimens at each load level (ranging from 10 to 90% of the geosynthetics ultimate tensile strength, T_{ult}). This paper is part of a comprehensive study on the durability of geosynthetics, where accelerated creep rupture tests using SIM are being performed in undamaged and damaged samples to assess the synergisms between different degradation mechanisms. The results reported herein help to analyze the SIM test results performed in undamaged (virgin or as received by the manufacturers) specimens tested for the whole project.

2 MATERIALS AND METHODS

2.1 Geosynthetics

This study investigates four geosynthetics: two poly(ethylene) terephthalate (PET) non-woven needle-punched geotextiles (GTXnw1 and GTXnw2) and two woven geogrids (one made of PET yarns – GGR1, and the other one made of polyvinyl alcohol (PVA) fibers – GGR2). It should be mentioned that non-woven geotextiles are the most versatile geosynthetic materials that were used as reinforcement in Brazil's first geosynthetic reinforced soil structure. Moreover, Koerner (2005) highlighted the three reinforcement mechanisms (membrane, shear and anchorage) when geotextiles are used as reinforcement elements. Thus, both geogrids and geotextiles can be used in geosynthetics-reinforced soil structures. Table 1 shows some properties and characteristics of the materials according to the manufacturers' specifications. The study investigated two non-woven needle-punched geotextiles to assess the effect of the mass per unit area in the materials behavior.

Table 1. Characteristics and properties of the geosynthetics investigated.

Properties / Characteristics	Unit	GTXnw1	GTXnw2	GGR1	GGR2
Tensile strength MD*	kN/m	12.0	18.0	35.0	35.0
Elongation at break MD*	%	> 70%	> 70%	≤ 10	≤ 6
Mass per unit area	g/m^2	250	500	n.a**	n.a**
Open size	mm	n.a**	n.a**	20 x 20	20 x 30
Manufacturer	-	A	A	B	B

Notes: * Machine direction; ** not applicable

2.2 Test program

Tensile tests were performed in ten geogrids and geotextile specimens following the recommendation of ASTM D 6637 (2015) and ASTM D 4595 (2005), respectively. GGRs specimens (100 mm width – three longitudinal elements – x 500 mm wide) were tested using a load cell of 250 kN, roller clamp system, a strain rate of 10%/min and the strains were measured by a video-extensometer with infrared. GTXnws' specimens (200 mm width per 300 mm wide) were tested using a load cell of 30kN, pneumatic jaw clamps, a strain rate of 10%/min and the strains measured by displacing the upper clamp (the jaw clamp system adopted avoided the specimens slippage).

In the comprehensive project of the study, the SIM tests were performed using dead weights to apply the tensile loads to the specimens. The dead weights were applied to the specimens using an elevation table constructed for this application. Due to the equipment's limitation, the

specimens are loaded at a strain rate of 90mm/min. Thus, the geosynthetics specimens were also tested in the universal testing machines using the strain rate of 90mm/min.

The geosynthetics T_{ult} values obtained after tensile tests with the strain rate of 90mm/min were used as a reference value to calculate the loads adopted in the R+H tests. The tests were performed at 10% to 90% (load steps of 10%) of each geosynthetic's T_{ult} value. Three specimens were tested for each load level, and a mean curve was obtained. The time under sustained load was equal to 3600 s (1 hour) for geogrids, and 10,000 s (3 hours) for GTXnws – both periods were higher than the one recommended by ASTM D 6992 (2016). For the mean curve, a best-fit equation (Equation 1) was used to obtain the initial axial strain (ε_0) and the initial creep strain rate ($\dot{\varepsilon}_0$). This procedure was made just for the section under sustained axial tensile load, which means the loading section was not considered. This process was made for each geosynthetic and for the mean curve obtained by each load level applied.

$$e_t = \dot{\varepsilon}_0 . \ln(t) + e_0 \qquad (1)$$

where e_t is the total strain (percentual) at a given time t (in seconds).

3 RESULTS AND DISCUSSION

Figure 1 shows the results of the R+H tests performed in the geosynthetics. For non-woven geotextiles made of PET fibers, the increase in the material's T_ult value decreases the levels of strain experienced. The non-woven geotextile with a lower T_ult value (GTXnw1, Figure 1a)
Figure 1. Evolution of the short-term creep behavior for different load levels applied in a) GTXnw1, b) GTXnw2, c) GGR1 and d) GGR2.

shows higher strain levels in its short-term creep behavior than the one with the higher T_ult values (GTXnw2, Figure 1b). Figure 1b shows that GTXnw2 exhibits a gradual evolution of the initial creep behavior. However, GTXnw1 exhibits a very similar initial creep behavior for the load levels of 20% and 30%, 40% and 50%, and 60% and 70% (Figure 1a).

In the case of the geogrids investigated, the lower elongation at break of the geogrid manufactured with PVA filaments (GGR2; Table 1) can be pointed out as the reason for their lower strain levels experienced (Figure 1c) compared to the ones obtained by the PET geogrid (GGR1, Figure 1d). GGR1 exhibited a similar initial creep behavior when tested under the load levels of 30% and 40%, whereas the GGR2 experienced a negligible difference in the initial creep behavior for the load levels of 70% and 80% and a similar behavior at load levels of 50% and 60%.

Figure 1 also demonstrates that the geogrids are more susceptible to rupture under sustained axial load than the non-woven geotextiles. At the load level of 90% of T_{ult}, both geogrids reach rupture before 480s (eight minutes), whereas the non-woven geotextiles did not fail after 10,800 s (three days).

Figure 2 shows the parameters obtained from the geosynthetic's initial creep behavior as a function of the load level applied. Power model equations best fitted the geosynthetics results for the initial creep strain rate ($\dot{\epsilon}_0$; Figure 2a). The best-fit equations provided an excellent coefficient of determination (R^2) for the geotextile materials ($R^2 > 0.995$), but the geogrids show reasonable R^2 values (between 0.58 and 0.79). The geosynthetics results for the initial axial strain (e_0; Figure 2b) exhibited excellent R^2 values (higher than 0.94) for linear best-fit equations.

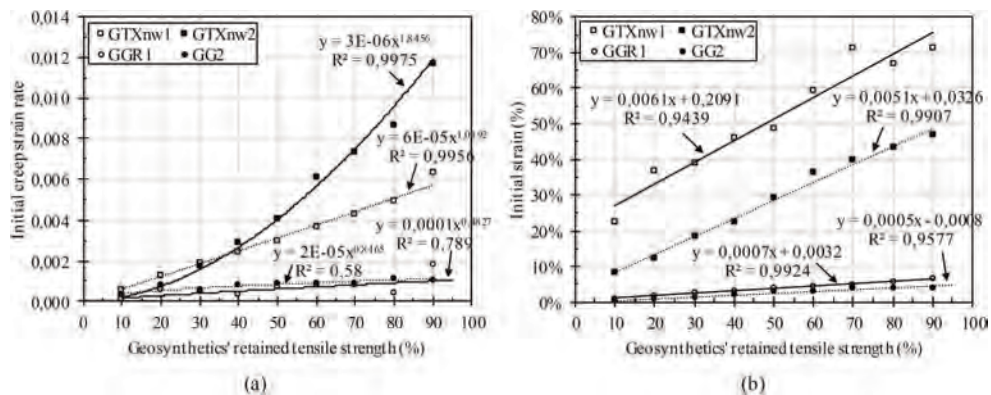
Although GTXnw2 exhibited lower e_0 values (Figure 1b) than GTXnw1, it demonstrated a significant increase in $\dot{\epsilon}_0$ values (Figure 2a) for load levels higher than 50% of T_{ult}. However, up to this load level (50% of T_{ult}) the geotextiles experienced similar $\dot{\epsilon}_0$ values. In terms of the geogrids results, the GGR1 had $\dot{\epsilon}_0$ and ε_0 values higher than GGR2. As previously mentioned, the lower strain values obtained for the GGR2 material compared to GGR1 are expected due to the lower elongation at the break of GGR2.


Figure 2. Evolution of the short-term creep behavior for different load levels applied in a) GTXnw1, b) GTXnw2, c) GGR1 and d) GGR2.

4 CONCLUSIONS

This paper assesses the initial creep behavior of four geosynthetics materials through the ramp and hold tests using load levels ranging from 10% to 90% of each geosynthetic ultimate tensile strength. The results reported in the study indicated that the non-woven geotextile with higher mass per unit area exhibited a lower initial strain. However, the initial creep strain rate was significantly higher than the non-woven geotextile with a lower mass per unit

area. Due to the PVA geogrid's lower elongation at break, it experienced lower initial axial strain and initial creep strain rates than the one made with PET fibers. Based on the geosynthetics' strain levels reported in this paper, the results of the first step of accelerated creep rupture tests performed in the same geosynthetics can be better assessed to obtain the material's creep rupture behavior with more reliability.

The impact of specimen preparation and ageing on oxidative induction time of HDPE geomembranes

G. Fairhead
Fabtech Australia, Adelaide, Australia

W.P. Hornsey
TRI Australasia, Gold Coast, Australia

ABSTRACT: The polyethylene geomembrane industry continues to evolve and enhance material formulations to meet the challenges of demanding containment systems. There is increasing interest in characterising these geomembranes when used in critical containment applications and this is often accompanied with increased quality assurance testing. A key test used to indicate the likely durability of a polyethylene geomembrane is to measure its Oxidative Induction Time (OIT) according to either ASTM D8117 for Standard OIT or ASTM D5885 for High Pressure OIT. These tests can be undertaken on new un-aged samples, materials that have been artificially laboratory aged, or specimens exhumed from the field. Particularly with more advanced polyethylene formulations the specimen preparation procedure for OIT testing can affect the measured OIT result, making the comparison of different geomembrane formulations and the comparison of new and aged test results problematic. This paper reports on a systematic examination of different specimen preparation procedures on the measured OIT result for several different geomembrane formulations, multi-layer geomembranes and aged geomembranes. Specimen preparation procedure was also observed to have a significant effect on OIT test repeatability. Results are analysed and suggestions made regarding specimen preparation procedures for advanced geomembranes.

1 INTRODUCTION

1.1 *Measurement of antioxidant levels*

High Density Polyethylene (HDPE) typically comprises a base polyethylene resin, carbon black to resist UV ageing, and additives primarily to resist oxidative ageing of the geomembrane (antioxidants). The presence and performance of antioxidants is measured according to ASTM D8117 (Standard-Oxidative Induction Time, S-OIT) and ASTM D5885 (High Pressure-Oxidative Induction Time, HP-OIT). Minimum requirements for OIT are set out in the industry reference standard published by the Geosynthetics Research Institute's standard GRI GM13. OIT measurements are also used to characterise the durability performance of Geomembranes by comparing OIT results for un-aged material and material that has been subjected to accelerated ageing in a laboratory, usually aged in air at elevated temperatures, UV exposure or synthetic liquors at elevated temperatures accelerating expected service conditions. Comparison of OIT results from in-service assets with their original as manufactured levels allows estimations of residual geomembrane life to be made.

OIT testing is widely used in material quality acceptance plans. It is therefore important that the test procedure correctly characterises the geomembrane properties to avoid incorrect acceptance or rejection of material. Also, when undertaking project specific testing to select a geomembrane material, predictions of geomembrane life will be less reliable if the sample preparation process is influencing the test results.

1.2 *Variability in results*

The ASTM D5885 estimates that precision of HP-OIT testing inter-laboratory reproducibility is 25% and repeatability is 6.5%. In this study of multi-layer geomembranes, repeatability has been observed to be significantly greater than 6.5%. Previous studies (Fairhead & Hornsey 2020) on monolayer homogeneous geomembranes have shown that test variables can be controlled and repeatability improved. Recently the ASTM standards for S-OIT (ASTM D8117) and HP-OIT (ASTM 5885) testing up-dated test protocols to mandate three replicates at zero and 90 days of ageing to improve the utility of OIT measurements, reflective of the issues explored in this paper.

Data from a continuous manufactured lot of geomembrane is summarised as a graph (HP-OIT minutes) in Figure 1. Eleven samples were taken as part of a quality acceptance programme and tested for HP-OIT in the un-aged condition and when air aged with tests at 30, 60 and 90 days in an oven at 85 deg C. Variability in results is evident in the results. When combining the results, a more consistent ageing characteristic is apparent. Relying on a limited data, which is more typical of industry quality acceptance standards and candidate material testing comparisons would not characterise this material well.
Figure 1.   Averaged HP-OIT results for eleven samples from a production lot when oven aged in air at 85 deg C.

1.3 *Multi-layer geomembranes*

Geomembrane manufacturing equipment can produce sheets from a single extruder and die or with multiple extruders allowing two or more layers of material within the sheet. If the same raw materials are used in multiple extruders a mono-layer geomembrane is produced, or by introducing different materials a multi-layer geomembrane is produced, with the capability to create unique properties. Conductive geomembranes have a thin outer skin containing a high percentage of carbon black. White geomembranes have a proportion of black material and a proportion of white, the ratio varies according to the manufacturing process and product performance requirements. The two layers have different additive packages, usually the white layer has a more highly fortified package than the black layer.

Table 1.   HP-OIT properties of a multi-layer black/white geomembrane.

Layer	HP-OIT [min.]
White	9646
Black	878
Full profile	3577

Multi-layer membranes are also designed to combine different properties such as chemically durable HDPE outer surfaces with a more flexible LLDPE core. An example of a multilayer geomembrane shown if Table 1 shows significantly different additive package performance for the black layer and the white layer as measured by HP-OIT testing.

1.4 *Plaquing of samples*

For both S-OIT & HP-OIT tests the relevant standards require the as-received specimens to be pressed into a thin sheet of 0.25mm ±0.015mm, for polyolefin geomembranes this requires the introduction of temperature and pressure to reduce the original thickness of between 1mm to 3mm.

1.5 *Homogenisation of aged samples*

With aged samples where the outer layers of the geomembrane may have lost a significant portion of the antioxidant package the interpretation of the results can become challenging as double exotherm reactions can occur as the outer layers burn off sooner than the core where the antioxidant package has remained relatively intact. It therefore becomes a subjective analysis of the results depending on how the technician or designer interprets the Heat Flow (W/g) graph. ASTM D5885 was updated to allow the homogenisation of aged samples in order to remove the double exotherm reaction. Three options for homogenisation are allowed namely, Torque Rheometer, Cryogenic Grinder and Two Roll mill. This paper reports on materials homogenised using the cryogenic grinding and mechanical grinding methods. Note while mechanical grinding method does not comply with the standard, many laboratories use this method due the equipment costs of the other methods.

When multilayer geomembrane (black/white) samples are not homogenised or plaqued adequately, two clearly recognisable exotherm peaks present in OIT testing. Industry does not have a uniform view on if the first or second peak is more useful to characterise the specimen and therefore should be reported. When a multi-layer sample is property homogenised, a single energy peak should present in OIT testing.

Additive loss occurs by diffusion, according to Fick's law, with a rate dependent on the crystalline structure of the geomembrane resin combined with the effectiveness of antioxidative additives resisting the oxidizing environment. HDPE geomembrane samples from a brine storage in Queensland, Australia, were tested after 8 years in service. UV exposed samples had been subjected to high UV loading and ambient temperatures while the brine exposed samples experienced moderate temperatures with a strong oxidizing alkaline environment. Samples were HP-OIT tested across the material section profile, at the top (exposed) surface, core, and bottom surface, Table 2. The UV exposed sample has the lowest HP-OIT values in the top surface which would have been exposed to UV and thermal degradation, while the remainder of the sheet would only be exposed to thermal degradation. The brine exposed sample would have experienced highly oxidative brine on the top surface. The lower surface would have limited thermal degradation and limited available oxygen. Degradation would be largely single sided; this is apparent from the measured HP-OIT values.

Table 2. HP-OIT measurements across the geomembrane profile for service aged geomembranes aged for 8 years in a brine storage containment.

Exposure		HP-OIT [min.]			
			Aged		
Duration	Type	Unaged	Top	Core	Bottom
8 Years	UV	600	334	474	392
8 Years	Brine	600	258	448	500

2 PLAQUING PROCESS

OIT test standards require samples to be compression molded (often referred to as plaquing) and test specimens extracted from these plaques. In the authors experience this aspect of the test standard is not uniformly adhered to by industry. The two test standards, ASTM D8117 and D5885 differ slightly in their requirements for the preparation of specimens. ASTM D8117 requires the samples compression molded at 160°C but does give a time period for which the sample should be exposed, the confining pressure under which it should be confined, or the how the specimens should be contained.

ASTM D5885 references ASTM D4703 Practice for compression molding thermoplastic materials into test Specimens, Plaques or Sheets states that the temperature for HDPE should be molded at between 155 &177°C under 5MPa pressure for a flash mold with a preheat time of 5 minutes and a full pressure time of 2 minutes.

2.1 Plaquing trials – Homogenous geomembranes

Process optimisation trials were undertaken seeking to improve OIT test repeatability. A series of plaquing tests were undertaken to assess the effect of temperature-time history on the measured OIT values, Figure 2. A compression mould consistent with ASTM D4703 was manufactured and a single geomembrane formulation tested to reduce test variables. Small quantities of un-aged geomembrane were compression moulded (plaqued) according to the standard.

Mould dwell time and mould temperature were varied and OIT measurements recorded. Mould dwell time was varied from 2 minutes to 8 minutes and mould temperature from 125 deg C to 177 deg C. From over 100 tests no coherent correlation was observed between mould dwell time or mould temperature and OIT measurements. It was expected that increasing temperature and time would accelerate oxidation of the geomembrane and therefore reduce measured values of OIT. This characteristic was not evident for the temperature-time histories examined and for this specific geomembrane formulation. The result may be formulation specific and a more significant relationship with temperature history with other geomembranes with different antioxidant packages.
Figure 2.   Compression mould temperature trials evaluating the effect on OIT measurements. Left S-OIT, Right HP-OIT.

2.2 Test consistency

A homogeneous geomembrane was subjected to an oven ageing study according to ASTM D5721. Consistent with previous studies (ASTM D3895 2019) multiple-frequency ageing tests were undertaken. The results were coherent, allowing the geomembrane ageing characteristic to be compared with the technical requirement or compared with other material formulations.

By comparison samples of a multilayer (black/white) geomembrane from two different rolls having been oven aged in air exhibited variable HP-OIT results, Figure 3. Test samples were
Figure 3. Oven ageing measurements for two samples of multi-layer geomembrane.

homogenised and plaqued prior to HP-OIT testing. All of the OIT exotherms generated were smooth with a single dominant exotherm peak. Variability between tests results at different ageing durations makes it difficult to determine the underlying ageing characteristic of this geomembrane formulation. These results confirm that it can be unreliable to rely on data from single test age points to characterise durability, multiple tests are beneficial.

2.3 Multi-layer geomembranes

In the case of multi-layer geomembranes simply plaquing the geomembrane is not possible due to the different melting point of the different layer will result in different ratios of layers within the plaque. This is not visible to the naked eye with a multi-layer black geomembrane; however, it is quite evident with a Black/White geomembranes, Figure 4 shows the distribution of the layers when plaquing without homogenisation.

Figure 4 clearly shows that simply plaquing a multilayer geomembrane is not acceptable as the ratio of each of the layers would not be representative of the actual product. In the case of multilayer geomembranes, they should be treated the same way as an aged sample requiring homogenisation prior to testing.
Figure 4. Plaqued Black/White geomembranes. Left: 80% Black–20% White, Right: 5% Black–95% White.

3 SAMPLE HOMOGINISATION

There are conflicting requirements when homogenising samples. A "coarsely" ground sample will have a lower surface area to volume ratio which, when the ground material is plaqued, will oxidise less than a "finely" ground sample. Conversely a finely ground sample will ensure homogenisation and repeatable results while a coarsely ground sample will not. Using the black/white geomembrane allowed two-dimensional uniformity of the homogenised and plaqued samples to be visually observed. Samples of a geomembrane with a profile of 70% black and 30% white material, were homogenised in a cryogenic impact grinding machine
Figure 5.   Visual homogenisation for different impact grind settings. Left to right, 300, 600, 1200, 2400 impacts.

and the ground material plaqued. The level of grinding was increased until a visually homogeneous plaque was produced, Figure 5.

For this grinding equipment the least amount of pulverisation that produced a visually homogenised sample was 2,400 impacts. HP-OIT repeatability with this sample preparation was approximately 4.5%. HP-OIT tests on samples with less than 2,400 impacts were less repeatable with values up to 20%. From visual observations reduced repeatability was directly related to unsatisfactory homogenisation of the two layers of material which had significantly different HP-OIT characteristics.

4   CONCLUSIONS

Geomembrane manufactures continual innovation to provide improved material performance challenge existing test procedures. Increasing use of multi-layer geomembranes in critical applications which usually have elevated levels of durability testing is increasing the importance of S-OIT and HP-OIT test repeatability. This study has examined the effects of sample preparation on S-OIT and HP-OIT test repeatability. Several different geomembranes formulations have been included in the study, results may be more or less significant for other geomembrane formulations. A single homogenisation procedure has been assessed, being low temperature impact grinding. From this work.

- Plaquing time/temperature history did not have a strong influence on measured OIT results for the geomembranes evaluated.
- Black/White multi-layer geomembranes allowed qualitative assessment of homogenisation.
- OIT measurements of samples with non-homogeneous structures are sensitive to the sample preparation procedure. This applies to multi-layer geomembranes, where the properties of layers are significantly different to aged material samples.
- An optimised sample preparation procedure has been developed which improved test repeatability.
- With multilayer geomembranes where one layer contains the bulk of the antioxidant package effective homogenisation must be carried out to obtain results which can be used to determine loss over time correlation.

At the limit of liner puncture resistance for high-capacity leach pads projects

A. León Saavedra
Axios Ingeniería SpA, Santiago, Chile
IGS Chilean Chapter, President 2022–2023

1 INTRODUCTION

The Liner system in leach pads projects is especially valuable and implies a considerable part of the capital expenditure for these types of projects. As well as the overliner material, sometimes represent a big challenge to find a nearby and adequate material source capacity. The overliner must meet specific geotechnical properties to provide drainage and liner protection, been critical a controlled maximum coarse size and sieve distribution to avoid puncture failure in the liner system and provide efficient drainage.

This paper includes the summary of two recent studies developed for one of the biggest copper leaching operations in Chile, consisting in an expansion of the secondary leaching process with more than 168 million tons capacity and 120 m maximum high of the leached ore deposit, and a Low-Grade Oxide dump leach expansion of 85 m high, with large surface of lining and high demand of overliner material where natural sources are almost unavailable.

2 METHODOLOGY

Large Scale Puncture test (ASTM D5514 Modified) were developed with the collaboration of Geo-logic Associates in USA. The objective consisted of studying the influence of the overliner materials and subgrade on a geomembrane by applying a normal load equivalent to the heap leach's maximum height.

The test configuration is shown in Figure 1(a) and its conditions are as follows:

- As a variation of the referred ASTM standard where a hydrostatic compression is applied, in this test the ore vertical load is simulated by a hydraulic pressure frame in a large scale direct shear test box. In that way it is possible to generate the liner contact effect in both sides under the load and, is closer to the specifics conditions in this type of projects.
- The test was carried out on a square hydraulic press of 12″x12″.
- Normal stress was applied at a speed of 70 kPa per minute for 48 hrs. up to the maximum specified load. For this test, the maximum load was 2400 kPa, which equivalent to 120 m ore height.
- The overliner material was placed under the middle of the test box at 1.85 ton/m3 of dry density (corresponding to 95% maximum dry density) and a moisture content of 3.0%.
- The subgrade was moisture conditioned near optimum moisture and compacted until no yielding was observed under pressure.
- Coarse material larger than 2″ were in contact with the geomembrane during the test.
- The textured side of the geomembrane is placed in contact with the subgrade material layer (Figure 1(b)).
Figure 1.   (a) Large scale puncture test configuration. (b) Subgrade material.

3   INCREASE IN OVERSIZE MATERIAL CONTENT

This analysis aims to verify the feasibility of using old leached crushed ore material as overliner on the geomembrane, by analyzing large scale puncture tests for loads equivalent to up to 120 m on an 80 mils (2 mm) HDPE geomembrane, considering an increase of coarse size overliner material between $2'' - 3''$. Previously, the project specified an overliner material with maximum particle size of 1 ½″ and coarse material over this size represent approximately 40% from the sources available, and a high cost of selection process.

3.1   *Overliner alternative sieve analysis*

The sample of the proposed material had a 5% of coarse size ($>2''$) and high fine content (16% under #200 sieve) according to the project specifications. Due to the major coarse content, the material may present a behavior that could generate puncture failures in the geomembrane. In addition, it could allow the migration of fine particles from the leached ore during the irrigation process. Figure 2 shows the leached ore sample used as overliner in the Large Scale Puncture test and Figure 3 shows its grain-size curve.

Figure 2.   Overliner used in puncture test (Leached ore sample).
Figure 3.   Overliner grain-size curve.

3.2 *Large scale puncture content test*

Figure 4 shows the 2 mm HDPE geomembrane after the large scale puncture test results, from which no puncture failures were observed in the geomembrane, showing only small yielding areas (plastic flow not recoverable after removal of the load). This is a normal response to the load level reached.
Figure 4.   2mm HDPE Geomembrane after puncture test.

4   PUNCTURE RESISTANCE VS LOAD INCREASE

Because of the lack of additional approved areas to stack more secondary leached ore, the current operation looked to reuse abandoned phases of the deposit to load additional fresh ore. Based on this, the objective was to determine the maximum height that the current Leached ore deposit can reach so as not to affect the integrity of the liner system and the drainage system due to the overload. The integrity of the liner material subjected to an

increase in load was analyzed by the performing different large scale puncture tests using an overliner material of 2″ maximum coarse size and normal stresses increments to up to 235 m ore height.

4.1 Large scale puncture test verification

4.1.1 Overliner sieve analysis

Same old leached ore material of previous test was used as overliner material (Figure 5), which complied with the grain-size specifications of the project. The sample's sieve analysis curve is shown in Figure 6.

Figure 5. Overliner material used in large scale puncture test.
Figure 6. Overliner materials sieve analysis curve.

4.1.2 Large scale puncture test results

The large-scale puncture tests results are shown in Figure 7 and summarized in Table 1. These show that, for heights lower than 180 m for 1.5 mm HDPE geomembranes and 185 m
Figure 7.   HDPE geomembranes after large scale puncture test.

Table 1.   Large scale puncture tests results.

Test ID	HDPE Geomembrane thickness (mm)	Equivalent Height (m)	Yielding	Puncture
4617B	1.5	140	Mild	Not observed
4617C	2.0	155	Mild	Not observed
4617D	2.5	165	Mild	Not observed
4617F	1.5	155	Moderated	Not observed
4617G	2.0	185	Mild	Not observed
4617H	1.5	180	Moderated	Not observed
4617I	2.0	235	Major	Not observed
4617J	1.5	225	Major	Not observed

for 2.0 mm, the geomembranes developed between mild and moderate yield, in addition to not generating puncture failure of the material.

On the other hand, tests 4617I and 4617J show major yielding for the 2.0 mm and 1.5 mm HDPE geomembranes when reaching equivalent heights of 235 m and 225 m respectively, which is expected due to the considerable increase in the applied normal load.

460

5 CONCLUSION

The current study assessed the feasibility of using granular materials with a maximum particle size greater than 2″ as overliner, as well as the viability of increasing the vertical load to which the liner is subjected. It is important to consider that these analyses were based solely on the integrity of the liner system under higher vertical loads and did not evaluate specific variables of each project that may affect its overall slopes stability.

Regarding the increase in the coarse material content in the overliner, the puncture test results verified that despite the major coarse size (2″ to 3″), the leached ore used as overliner did not generate punctures in the geomembrane. There was minor yielding in the contact side that generated observable amount of plastic flow which does not recover after removal of the pressure.

Therefore, it is concluded that the overliner material proposed with a maximum size of 3″ at an equivalent vertical load of 120 m would not generate punctures in the geomembrane currently considered in the dump leach project, since the portion of 3″ coarse size does not exceed 5% retained on 2″ sieve, the material must be well graded with sand and gravels content, and fine fraction under #200 sieve with maximum of 4%, to avoid migration of fine particles from the ore during the leaching process.

The puncture tests results showed that, for heights below 185 m for the 2.0 mm and 180 m for 1.5 mm HDPE geomembranes, respectively, also showed a mild to moderate yielding, in addition to not generating puncture failure.

On the other hand, tests equivalent to load heights of 235 m and 225 m showed a major yielding for 2.0 mm and 1.5 mm HDPE geomembranes respectively. From these results, it is determined that, although there is no puncture failure observed in the HDPE geomembranes considering these height increases, they are probably very close at the limit of the puncture failure with an increase in load or yielding over time.

It is important to note that the original project was developed 20 years ago, while the HDPE geomembranes tested for this study were of current manufacture, so it could be concluded that present HDPE geomembrane material developments are delivering a better performance.

Finally, it can be said that the tested HDPE geomembranes obtained high puncture resistant and low to moderate deformation for the 1.5 mm liner thickness cases up to 155 m total ore height equivalent load, as well as for the 2.0 mm up to 185 m. Comparing this results to the resistances and deformations that were obtained under theoretical calculations, the assessed HDPE geomembranes can offer better resistance than what was expected, demonstrating the improvement in technology and components that the materials used for their manufacture have had in the last years.

Designing and analysis of carbon fiber reinforced grid materials for application to seismic resistance improvement

H.Y. Jeon
Department of Chemical Engineering, Inha University, Incheon, South Korea

K.H. Nam
GSI-Korea, Incheon, South Korea

ABSTRACT: Carbon fiber geogrid usable as geosynthetics reinforcement was fabricated, and seismic resistance, which affects the stability of the soil structure when constructed on a soil structure, was analyzed through SIM (stepped isothermal test) creep test. Seismic resistance was tested by simulating seismic event circumstance at 40. 60. 80% of UTS (ultimate tensile strength) of carbon fiber geogrid, and it is seen that seismic simulated event has no effect on long-term property of carbon fiber geogrid.

1 INTRODUCTION

The geosynthetics reinforcement method is one of the seismic performance reinforcement methods, and has the advantage of being able to have various shapes depending on the weight of the material, the convenience of construction, and the fiber material and physical properties. Carbon fiber has properties such as high strength, high elasticity, light weight, excellent durability and construction method, and waterproof effect, so it can be used as an earthquake-resistant reinforcing material. The carbon fiber geogrid can be used as a one-way or two-way load member depending on the high strength and structure of the carbon fiber, so no additional process is required and equipment investment costs are reduced. In addition, carbon fiber geogrid can be applied to the manufacturing of concrete composite panels for construction depending on various factors such as optimization of weaving preparation process, composition of coating resin and coating conditions.

In this study, a creep test was conducted to examine the seismic resistance of carbon fiber geogrids to earthquakes that would occur when applied to underground structures. The SIM (stepped isothermal method) creep test method was applied, and the seismic resistance was explained by the creep behavior analysis by simulation considering the Effects of sudden loads that may occur in seismic situations.

2 EXPERIMENTAL

Carbon fiber for geogrid was made by the double covering process. To make carbon fiber geogrid, unidirectional design system was used and the specification of carbon fiber geogrid is shown in Table 1.

Table 2 shows the seismic simulated SIM creep test condition. Seismic resistance by the SIM creep test was used as a creep test. Five isothermal temperatures of 23, 37, 51, 65, 79 °C were applied to the SIM creep test procedure. The seismic simulation creep test is conducted

Table 1. Specification of carbon fiber geogrid.

Composition	Specification (Warp/weft) (Denier)	Ultimate tensile strength (UTS)(kN/m)	Tensile strain (%)
Carbon fiber	4000/573	87.8	1.2

Table 2. Seismic simulated SIM creep test condition.

Test Item	Test Condition
Temperature (°C)	23, 37, 51, 65, 79
Loading level (%) of UTS	40, 50, 60
Isothermal duration	1.5 hrs
Seismic simulated loading level (%) of UTS	80,90,100
Seismic simulated duration	1 min
Additional loading time	Midway through from 23°C to 79°C

for 1.5 hours by applying a creep load corresponding to 40 to 60% of the ultimate tensile strength (UTS) of the geogrid at the test temperature. Then, a creep test was conducted by applying a seismic condition sudden load (80 to 100% of the maximum tensile strength) for 1 minute, and then the overall creep behavior of the geogrid was analyzed. This test was carried out in 5 temperature ranges (23, 37, 51, 65, 79°C) respectively.

3 RESULTS AND DISCUSSION

Figure 1 shows the creep strain vs. log time at various stress conditions. The creep strain increases linearly with log time and creep rupture was detected at 70~100% of creep loads. After graphically showing the result of creep rupture with applied stress over rupture time,
Figure 1. Creep properties of carbon geogrid.

the applied stress at 106 hours of design term was obtained through regression analysis and the reduction factor was obtained by the comparison of this value with the UTS.

Creep strain exhibits an initial decrease at each elevated temperature step. The final strain was approximately 7.9%, similar value as that obtained from the application of the seismic load midway through 23°C temperature step. Creep strain decreased after seismic event cause of recovery force, after that strain increased again. After same condition of seismic event in different times, strain finally overlapped. Normally, seismic event has no effect on long-term property but in specific condition, a seismic event may reduce the creep property of carbon geogrid.
Figure 2.   Plot of applied stress vs. creep rupture time.

Figure 2 shows regression analysis diagram and it is observed that the data follows a linear trend and the reduction factor was 1.55.

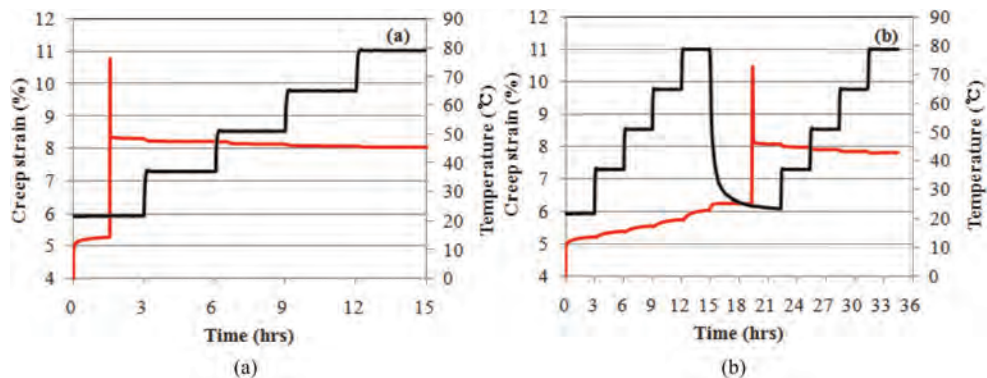
Creep response resulting from the application of the seismic load midway through the 23°C is shown in Figure 3 (a). Temperature was gradually increased from 23°C to 79°C and the seismic load produced an immediate strain of approximately 5.6% at initial stage. At this


Figure 3.   Creep strain vs. time curves for a seismic SIM creep test; (a) 100% of UTS applied for 1 min midway through the 23°C (b) 100% of UTS applied for 1 min after the 79°C.

moment, the strain recovery is 2.6% after removal the creep load. It is apparent that there is no effect on the creep response after 1.5 hour without regard to temperature till 79°C. The final strain was approximately 8%. The creep response of the application of the seismic load after the 79°C is shown in Figure 3 (b).

Creep strain exhibits an initial decrease at each elevated temperature step. The final strain was approximately 7.9%, similar value as that obtained from the application of the seismic load midway through 23°C. Creep strain slightly decreased at 40% of UTS until reaching the 65°C, after seismic event and began to increase after the 79°C. Creep strain rate is very slow after the seismic event, so the recovery force leads to long-term shrinkage. Creep strain slightly decreased at 50% of UTS until 103 hours, after which it increased. Creep strain rate at 50% UTS occurs at a greater rate than observed in the test at 40% of UTS after same seismic event. The time for shrinkage rebound for the test at 50% of UTS is shorter than that for the test at 40% of UTS. In contrast, creep strain increased at 101 hours for the test at 60% of UTS.

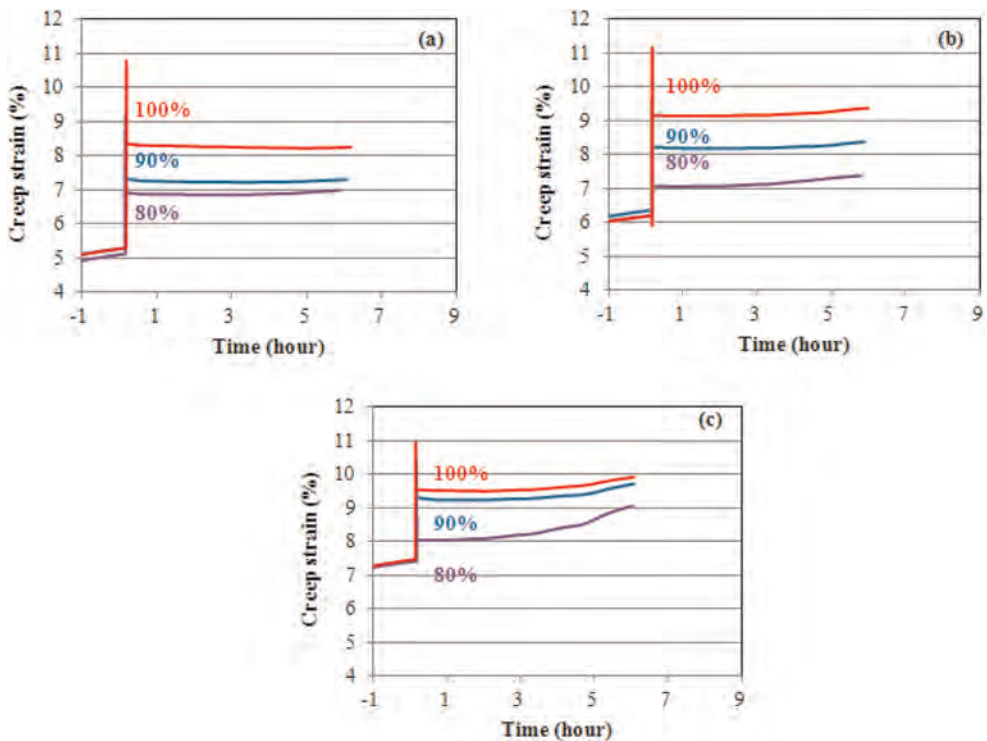
Figures 4 and 5 show the creep strain vs. log time curves for seismic SIM creep test, using a constant load of 40, 50% and 60% of UTS. It can be seen that the results of applying the seismic simulated loads corresponding to 80, 90, and 100% of UTS at 79°C for 1 minute are almost similar to those at 23°C as shown in Figure 3.


Figure 4.   Creep strain vs. log time curves for seismic SIM creep test; for creep load as (a) 40%, (b) 50%, (c) 60% of UTS and for simulated seismic load equivalent to 80, 90 and 100% of UTS for 1 min midway at 23°C.
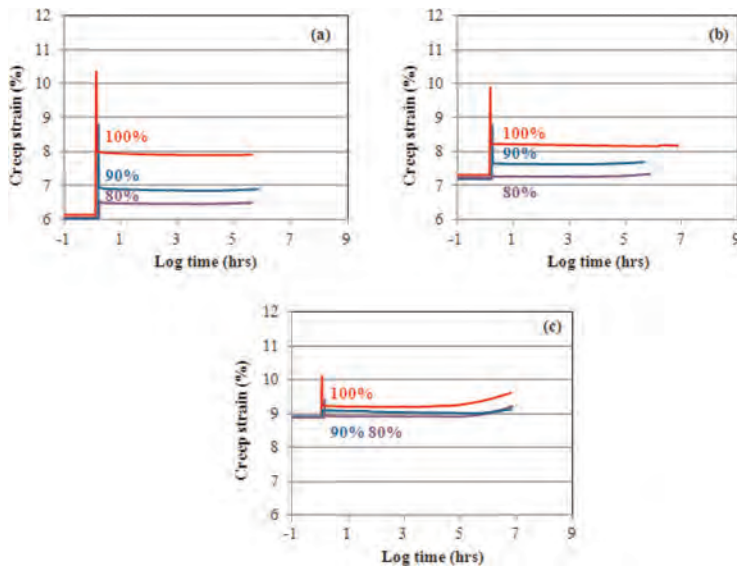

Figure 5. Creep strain vs. log time curves for seismic SIM creep test; for creep load as (a) 40%, (b) 50%, (c) 60% of UTS and for simulated seismic load equivalent to 80, 90 and 100% of UTS for 1 min midway at 79°C.

4 CONCLUSIONS

Creep properties of carbon fiber geogrid during a simulated seismic event were evaluated using the simulated SIM creep test method. Creep strain decreased after seismic event cause of recovery force, after that strain increased again. In general, seismic event has no effect on long-term property of carbon fiber geogrid in specific condition, a seismic event may reduce the creep property of a geogrid. Through the further study, we will make the hybrid carbon fiber geogrid to improve the seismic resistance, and evaluate the long-term performance and durability.

Geogrids in cold climates: Insights from in-isolation tensile tests at low temperatures

R.L.E. Desbrousses & M.A. Meguid
McGill University, Montreal, QC, Canada

ABSTRACT: Geogrids are used to reinforce ballasted railway embankments thanks to their high tensile strength and strong mechanical interlock with the granular material encountered in railway substructures. Railway tracks built in seasonally cold regions must also be designed to withstand harsh environmental conditions such as freezing and thawing cycles and the corresponding frost heave and thaw softening. In that context, it is crucial to understand how extreme temperature variations affect the performance of geogrids and their ability to fulfil their functions within a railway embankment. To do so, an experimental campaign is devised to assess how temperature changes in the range of -30°C to 20°C affect the tensile strength of a polymeric geogrid and a geogrid composite designed for use in ballasted railway tracks.

1 INTRODUCTION

Geogrids are sheets of polymeric material that consist of large openings called apertures bordered by longitudinal and transverse ribs (Desbrousses & Meguid 2021; Desbrousses *et al.* 2021; Koerner 2005). They are commonly used to reinforce earth structures such as retaining walls, slopes, embankments, paved and unpaved roads, railroad substructures, etc. owing to their ability to develop a strong mechanical bond with the soil in which they are placed (Desbrousses & Meguid 2021; Han & Jiang 2013; Jewell *et al.* 1984; Jewell 1988; Shokr *et al.* 2022). Because geogrids tend to be placed at a shallow depth below the ground surface, the temperature fluctuations associated with seasonal weather changes may cause variations in ground temperature and correspondingly impact the temperature of geogrid reinforcements, particularly since maximum ground temperature variations occur near the ground surface (Kim & Kim 2020; Segrestin & Jailloux 1988; Zarnani *et al.* 2011). Geogrids are typically made with polymeric materials called thermoplastics that exhibit temperature-dependent mechanical properties characterized by a brittle behavior at low temperatures and a ductile behavior at elevated temperatures, high-lighting the need to assess how temperature fluctuations affect the mechanical properties of geogrids.

Several studies have been devoted to examining the effect of temperature on the mechanical properties of polymeric geogrids. Kongkitkul *et al.* (2012), Chantachot *et al.* (2016, 2017), and Kasozi *et al.* (2014) investigated how elevated temperatures affect the tensile strength of polymeric geogrids and reported that a rise in temperature is usually followed by a reduction in the ultimate tensile strength and an increase in the ultimate strain of a polymeric geogrid, providing evidence that such materials become more ductile at high temperatures. On the other hand, Bonthron and Jonsson (2017) studied the impact of subjecting polymeric geogrids to low temperatures ranging from 20°C to -20°C on their tensile strength and concluded that polymeric geogrids tend to develop greater tensile forces at smaller strains as the temperature decreases. Shokr *et al.* (2022) examined the effect of

temperatures typical of seasonally cold climates ranging from -30°C to 40°C on the tensile strength of a fiberglass geogrid. Their findings demonstrated that the geogrid exhibited brittle and ductile responses to loading over the range of tested temperatures, emphasizing the influence temperature wields over the behaviour of geogrids.

Given that polymeric geosynthetics have temperature-dependent mechanical properties, this study seeks to examine the behavior of a biaxial polypropylene geogrid and a polymeric geocomposite in cold climates by performing in-isolation single rib tensile tests on the two materials at temperatures ranging from 20°C to -30°C. These two geosynthetics are designed and used to reinforce ballasted railway tracks resting on weak saturated sub-grades located in seasonally cold regions (Bhat & Tomas 2017).

2 METHODOLOGY

2.1 Testing program and experimental setup

This study seeks to investigate the effect of temperature on the tensile strength of a biaxial polymeric geogrid and a polymeric geocomposite. The tensile strength of the two geosynthetics is determined using single rib tensile tests as described in Method A of ASTM D6637. The tensile strength of the geogrid and geocomposite is determined at temperatures ranging from -30°C to 20°C in 10°C increments.

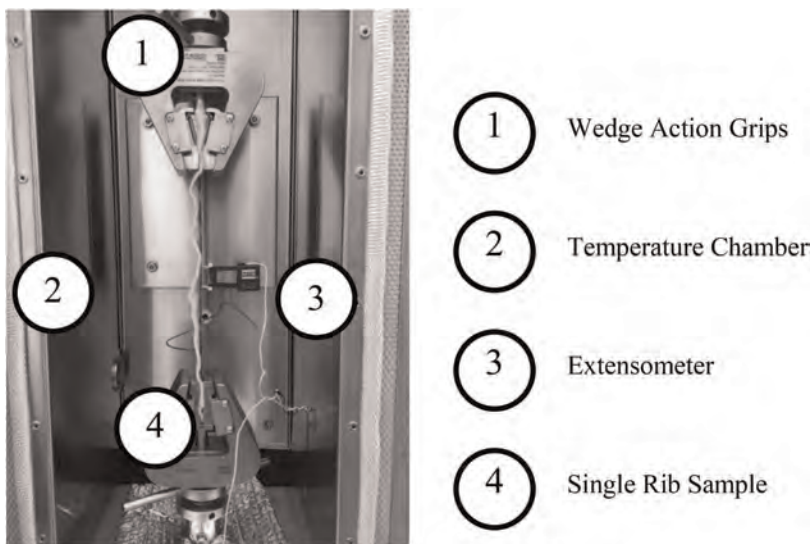
The tensile tests are performed in an MTS universal testing machine fitted with a 5kN load cell to monitor the tensile loads applied to the singe rib samples. The samples are held in place during the tests using two wedge action grips as shown in Figure 1. The elongation of the samples is recorded with a clip-on extensometer with a 25mm gauge length designed to operate at temperatures ranging from -100°C to 150°C. To perform experiments in a temperature-controlled environment, the testing machine is equipped with a temperature chamber with cooling and heating capabilities that completely encloses the wedge grips and the single rib sample being tested. The environmental chamber is connected to an analog temperature controller that regulates the opening and closing of a valve that links a tank of liquid nitrogen to the environmental chamber. Upon inputting a target temperature, e.g.


Figure 1. MTS testing machine and its temperature chamber.

-30°C, into the controller, an electrical signal is sent to the valve, triggering its opening and allowing liquid nitrogen to flow into the chamber. A thermocouple located within the environmental chamber monitors its temperature and sends a feedback signal to the controller to adjust the valve's opening and closing to maintain a steady temperature. The tensile test is initiated once the thermocouple detects that the environmental chamber's temperature has reached the desired setpoint.

2.2 Materials

The geosynthetics considered in this study are a biaxial polypropylene geogrid and a geo-composite composed of a biaxial polypropylene geogrid heat-bonded to a non-woven polyester geotextile manufactured by Titan Environmental (Titan Environmental Containment 2020, 2021). The mechanical properties of both materials as reported by the manufacturer are summarized in Table 1. It is noteworthy that both materials have identical properties in the machine and cross-machine directions. The two geosynthetics are shown in Figure 2.

Table 1. Material properties of the geogrid and geocomposite.

	Biaxial geogrid	Geocomposite
Material	Polypropylene	Polypropylene (Geogrid) Polyester (Geotextile)
Aperture size (mm)	57	38
Ultimate tensile strength (kN/m)	30	30
Tensile strength at 2% strain (kN/m)	11	12
Tensile strength at 5% strain (kN/m)	21	22
Figure 2. Biaxial geogrid (left) and geocomposite (right).

3 RESULTS

3.1 Biaxial geogrid

The average load-strain curves of the biaxial polypropylene geogrid at temperatures ranging from -30°C to 20°C are shown in Figure 3. The load-strain curve obtained at 20°C is used as a reference against which the other curves are compared given that it corresponds to the standard testing temperature given in ASTM D6637. The load-strain curves suggest that exposure to temperatures below 20°C translates into the geogrid exhibiting an increasing
Figure 3. Load-strain curves of the biaxial geogrid at temperatures ranging from -30°C to 20°C.

brittle behavior as the temperature decreases. Indeed, the curves show that as the testing temperature decreases, larger tensile forces are mobilized at a given strain. This is attributed to the geogrid being made from polypropylene, i.e., a thermoplastic polymer that exhibits a soft and ductile behavior at elevated temperatures and a stiff and brittle response to loading at low temperatures.

At failure, geogrid samples exposed to low temperatures develop an ultimate tensile strength that exceeds the one obtained at 20°C at a strain level that is smaller than at the reference temperature. The largest gains in ultimate tensile strength are recorded at -20°C and -30°C, with the tensile strengths being about 33% greater than at 20°C. Additionally, the biggest reduction in ultimate tensile strain also happens at -20°C and -30°C, with the ultimate strain at the two temperatures being about 28.5% smaller than at 20°C. It is noteworthy that the load-strain curves at -20°C and -30°C are very similar and contrast with the gradual stiffening of the load-strain response observed at 10°C, 0°C, and -10°C. This behavioral difference is caused by the testing temperature reaching and going below polypropylene's glass transition temperature.

3.2 Geocomposite

The geocomposite's average load-strain curves at temperatures ranging from -30°C to 20°C are plotted in Figure 4. The experimental data suggests that the geocomposite becomes increasingly brittle as testing temperatures drop below 20°C. Indeed, temperature drops to 10°C, 0°C, -10°C, -20°C, and -30°C result in ultimate strains that are 8.9%, 20.9%, 21.8%, 33.7%, and 32.2% smaller than the one at 20°C respectively. However, it is important to point out that the ultimate tensile strength appears to be relatively insensitive to temperature changes with a maximum increase in ultimate tensile strength of 3.4% being recorded at -30°C.

3.3 Comparison

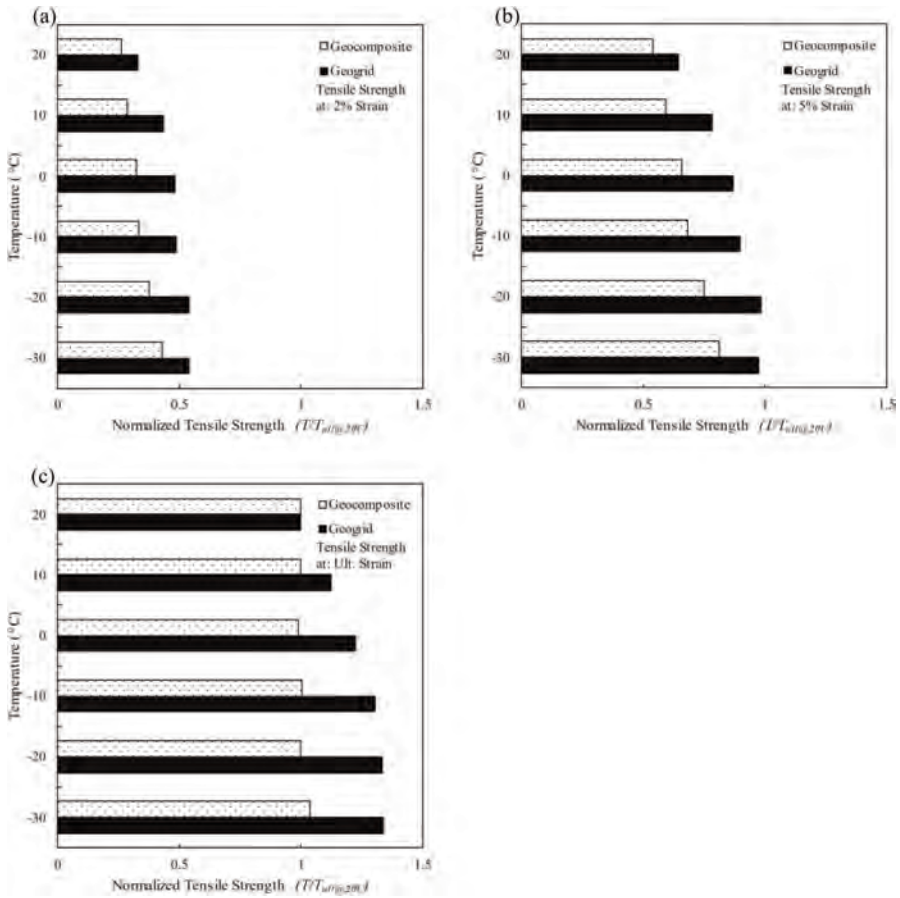
Figure 5 shows the normalized tensile strength of the geogrid and geocomposite at the 2%, 5%, and ultimate strain level. The tensile strength of each material is normalized by dividing its tensile strength (T) at the relevant strain level and temperature by its ultimate tensile strength at 20°C ($T_{ult@20°C}$). For example, at -30°C, the geogrid has a tensile strength of 17.99kN/m at 2% strain which, when divided by the geogrid's ultimate tensile strength of
Figure 4.   Load-strain curves of the geocomposite at temperatures ranging from -30°C to 20°C.


Figure 5.   Normalized tensile strength at (a) 2%, (b) 5%, and (c) ultimate strain for the geogrid and geocomposite.

33.55kN/m at 20°C, gives a normalized tensile strength of 0.54 at 2% strain. As shown in Figure 5a, the biaxial geogrid appears to be more sensitive to exposure to temperatures below 20°C than the geocomposite at 2% strain. Compared to the tensile strength obtained at 20°C at the 2% strain level, temperatures of 10°C and -30°C result in tensile strength increases of 32.6% and 63.4% in the geogrid against only 8.6% and 44.2% in the geocomposite. A similar trend is observed at 5% strain (Figure 5b) with exposure to temperatures of 10°C and -30°C leading to increases in tensile strength compared to that recorded at 20°C of 22.1% and 51.4% in the geogrid compared to 9.7% and 39.4% in the geocomposite. The trend observed at the 2% and 5% strain level is exacerbated at the ultimate strain level where the geocomposite appears to experience negligible fluctuations in its ultimate tensile strength as a result of temperature changes. This is in stark contrast with the considerable increases in ultimate tensile strength that occur in the geogrid across the range of temperatures shown in Figure 5c. While the ultimate tensile strength of the geocomposite only experiences a maximum increase of 3.4% at -30°C compared to that at 20°C, the geogrid exhibits tensile strengths at -20°C and -30°C that are about 33% greater than at 20°C.

4   CONCLUSIONS

This paper seeks to capture features of the behavior of geogrids in cold climates by performing in-isolation tensile tests on a biaxial polypropylene geogrid and a polymeric geocomposite at temperatures ranging from 20°C to -30°C. The key findings are as follows:

- The biaxial geogrid exhibits an increasingly brittle response to tensile loading when exposed to temperatures below 20°C characterized by higher tensile forces being mobilized at smaller strains
- The geogrid develops a maximum ultimate tensile strength at -20°C and -30°C that is about 33% greater than its ultimate strength at 20°C. This is accompanied by an ultimate strain that is 28.5% smaller than at the reference temperature
- The geocomposite becomes increasingly brittle when subjected to temperatures smaller than 20°C. However, while its ultimate strain decreases with decreasing temperature, its ultimate tensile strength appears to be insensitive to temperature changes
- The geogrid experiences more pronounced changes to its tensile load-strain response than the geocomposite as the testing temperature changes at 2%, 5%, and ultimate strain

ABSTRACT: This study investigates the resulting changes in the properties of a high-density polyethylene geomembrane (HDPE GMB) subjected to an accelerated UV (ultraviolet) ageing test. A commercially available GMB having a nominal thickness of 1.5 mm was exposed to UV radiation for varying durations for three years using an Atlas make UV weatherometer. Properties including thickness, density, melt flow index, tensile behaviour, oxidative induction time (OIT), crystallinity and microstructural changes using Fourier transform infrared (FTIR) spectroscopy were studied. The results showed that the thickness of GMB was not affected by UV radiation. However, density and melt flow index of the GMB showed a significant variation. At the end of 26095 hours of exposure, OIT was reduced by more than half the value of the initial OIT. The degradation by cross-linking was verified from FTIR spectra which showed an increased crystalline content against the ageing time.

1 INTRODUCTION

The high-density polyethylene geomembranes (HDPE GMBs) have become an integral part of the modern composite liner of engineered landfills. It has been the material of choice for most landfill liners because of its good physical, mechanical, and endurance properties (Rowe *et al.* 2010). In general, the durability of GMB mainly depends on the ageing rate of the liner material. Among all, the ageing of GMB is primarily governed by the exposure conditions pervading its service life. In landfill applications, the GMB may be exposed to different exposure conditions such as ultraviolet (UV) radiation, thermal, oxidative, and chemical exposures (Lavoie *et al.* 2020).

When the GMB is used as a basal and cover liner of a landfill, it may be exposed to UV radiation for short-term and long-term durations, respectively. Improper liner installation methods, delay in protecting GMB liner, and the formation of a whale/hippos may result in the exposure of GMB to UV radiation even for years (Anjana *et al.* 2023). It can trigger photodegradation and imparts discoloration, brittleness, and stress cracking in the liner material (Arnepalli & Rejoice 2012). This leads to damage to GMB and causes a reduction in the engineering properties of the material. The prolonged exposure to UV radiation may lead to the progressive degradation of polymeric liner material and alter its properties. These changes impair the geosynthetic material and eventually affect the service life of the GMB (Hsuan & Koerner 1995).

Ageing due to UV exposure is known to affect the physical and mechanical properties of the GMB (Arnepalli & Rejoice 2013a, b). Therefore, it is paramount to understand the behaviour of GMB under UV exposure conditions to ascertain its long-term performance in adequately providing the containment function. Given this, the present study aims to evaluate the effect of UV ageing on the depletion of properties of HDPE GMB subjected to

26095 hours (approximately three years) of exposure to UV radiation using a UV weatherometer in the laboratory. The present study focuses on the variation in the physical, mechanical, and endurance attributes of the GMB, including thickness, density, melt flow index, tensile behaviour, oxidative induction time (OIT), crystallinity, and microstructural changes examined using Fourier transform infrared (FTIR) spectroscopy.

2 MATERIALS AND METHODS

2.1 Geomembranes

A black smooth 1.5 mm-thick HDPE GMB was used in this study. Table 1 shows the featured properties of the selected GMB (Anjana *et al*. 2023).

Table 1. Properties of GMB used in this study.

Properties	Reference method	Values (Unit)
Thickness	ASTM D5199	1.51 ± 0.01 (mm)
Density	-	0.961 ± 0.001 (g / cm^3)
Melt flow rate	ASTM D1238	0.145 ± 0.001 (g / 10 min)
Oxidative induction time	ASTM D3895	132 (min)
Crystallinity	ASTM E794	49 (%)

2.2 Accelerated UV ageing test

The GMB specimens were exposed to UV radiation in the laboratory using an Atlas make UV Weatherometer. The samples were exposed to fluorescent UV light using UVA-340 lamps under controlled environmental conditions, according to ASTM G154. The exposure cycles of eight-hour UV radiation at 0.89 W / m^2 and four-hour condensation were followed. To study the effect of long-term UV exposure on GMB properties, the samples were subjected to 26095 hours (nearly three years) of accelerated ageing. The GMB samples were retrieved at various time intervals of UV ageing and tested for their desired properties.

2.3 Thickness

The thickness of the GMB was determined using a thickness measurement device by following the guidelines presented in ASTM D5199. The thickness was measured after applying a pressure of 20 kPa for 5 seconds against the specimen by means of a presser foot. The value was recorded to the nearest 0.02 mm, and the average thickness of ten samples was reported.

2.4 Density

The helium gas pycnometer (Quantochrome, USA) was used to measure the density of the GMB. The pycnometer measures the solid volume of the sample by displacing it with helium gas. From the known weight and the solid volume of the sample, the density of the GMB was determined.

2.5 Melt flow index

A fully automated melt flow indexer was used to perform the test according to ASTM D1238. As per the codal provisions, procedure-A was used to determine the melt flow index of a thermoplastic material. The molten polymer of the GMB was extruded through an orifice under an applied load of 2.16 kg and 190 °C. The mass of molten polymer extruded in 10 minutes (in grams of material / 10 min) is expressed as the melt flow index.

2.6 Oxidative Induction Time (OIT)

The standard OIT test was carried out according to ASTM D3895 using a Netzsch DSC 200 differential scanning calorimeter (DSC). The known sample weight was initially heated to

200 °C from room temperature at 10 °C / min in an inert nitrogen atmosphere. The sample was then maintained at the isothermal condition for 5 minutes, following which oxygen was introduced at 35 kPa pressure. The test was terminated after an oxidative reaction peak was observed. The OIT was calculated as the time elapsed between introducing oxygen and the arrival of the oxidative reaction peak.

2.7 *Tensile strength test*

A tensile testing machine (ZwickRoell, Germany) equipped with pincer grips and a video extensometer was employed to assess the tensile properties of the GMB as per ASTM D6693. The dog bone specimens were cut from the GMB using a die cutter and tested at a strain rate of 50 mm / min. The variations in tensile properties such as yield strength, break strength, yield strain and break strain for various UV ageing durations were determined.

2.8 *Crystallinity of polymer*

The crystallinity of the polymer was determined as per ASTM E794 using a Netzsch DSC 200 differential scanning calorimeter (DSC). A known sample weight was heated to 200 °C at 10 °C / min in an inert nitrogen atmosphere to obtain the crystallization melt curve. The crystallinity of the polymer is defined as the ratio of heat of fusion of GMB specimen and the heat of fusion of 100% crystalline HDPE polymer. The heat of fusion of 100% crystalline HDPE polymer, i.e., 293 J / g (Brandrup *et al.* 1999), was used to calculate the percent crystallinity of the samples.

2.9 *Fourier transform infrared (FTIR) spectroscopy*

The FTIR analysis was performed using a Perkin Elmer Spectrum 100 in the spectral range from 4000 cm^{-1} to 400 cm^{-1}, 128 scans at 4 cm^{-1} resolution. The test was conducted on virgin and aged GMBs to study the surface-level molecular changes owing to UV radiation. Further, the spectrum was obtained on the UV irradiated side of the aged GMB, labelled as the exposed side, and the other side on which UV light was not exposed, labelled as the unexposed side.

3 RESULT AND DISCUSSIONS

3.1 *Thickness, density, melt flow index, oxidative induction time, and crystallinity*

The thickness of a GMB is one of the important properties since it significantly affects the service life of a GMB (Rowe *et al.* 2010). The thickness of the GMB was measured at various durations of UV exposure. The results indicated that the thickness of the aged GMB was invariable for the complete duration of UV testing. There was no considerable change in the GMB thickness with UV ageing time. This implies that exposure to UV radiation does not affect or have an insignificant effect on the GMB thickness.

A notable change was observed in the density of GMB upon UV exposure (Table 2). When the ageing duration increased, the density of GMB decreased. For instance, the density of GMB reduced from 0.961 to 0.945 at the end of 11200 hours of exposure. This decrease in density reflects the localized change in the crystallinity or extraction of additives or absorption of solvents (Anjana *et al.* 2023).

The melt flow index measures the rate of extrusion of molten GMB resin. It is a useful measure for assessing the change in molecular weight of the polymer (Park *et al.* 2013). The degradation caused by cross-linking results in an increase in molecular weight, and chain scission causes a decrease in molecular weight (Hsuan & Koerner 1995). Table 2 shows the variation of the melt flow index with respect to ageing time. The melt flow index reduced for up to 11200 hours of ageing time and then increased. These characteristic changes denote the degradation of polymer caused by both cross-linking and chain scission reactions due to UV exposure. Thus, it can be inferred that UV exposure can deplete the GMB properties by one or more of the degradative reactions depending on the extent of exposure time (Guillet 1972; Anjana *et al.* 2023).

Table 2. Variation of GMB properties at various UV ageing durations*.

Ageing time hours	Density g / cm³	Melt flow index g / 10 minutes	Oxidative induction time minutes	Crystallinity %
0	0.961	0.145	132	49
90	0.956	0.141	132	46
1000	0.95	0.139	111	52
3000	0.949	0.138	94.8	65
9000	0.95	0.132	80	54
11200	0.9447	0.130	–	51
13803	0.9577	0.137	65	51
26095	0.9533	0.138	55	56

*From (Anjana *et al.* 2023)

Oxidative induction time (OIT) indicates the amount of antioxidants in the GMB. From Table 2, OIT was found to reduce with the increase in UV ageing time. At the end of 26095 hours of UV exposure, the OIT was reduced by a factor of 0.42 from its initial value. The relationship between OIT and ageing time was linear, and the depletion of antioxidants followed a first-order exponential decay. Hence, the above trend of reducing OIT against ageing time confirms that antioxidant depletion is proportional to the level of deterioration caused due to UV exposure.

The role of crystallinity is essential in explaining the GMB behaviour upon UV exposure as it affects mechanical and chemical resistance. When the crystallinity of GMB is high, its stiffness and chemical resistance would be high (Scheirs 2009). The crystallinity determined using DSC denotes the overall crystallinity in the bulk of a material. It is clear from Table 2 that UV ageing has resulted in an overall increase in the crystallinity of the polymer. The crystallinity increase with the increasing ageing duration can be attributed to the post-crystallization of polymer molecules due to UV exposure (Anjana *et al.* 2023). This observation is similar to the melt flow index test results, where the cross-linking reactions led to an increased crystallinity of polymeric GMB.

3.2 *Tensile properties*

Table 3 shows the tensile properties of GMB in the machine direction as a function of UV exposure. The GMB did not exhibit a distinct trend in the increase or decrease of the tensile properties. However, the overall increase in the tensile properties can be attributed to the crystallinity changes in the polymer due to UV ageing. The increase in tensile strength and the decrease in yield strain indicates the occurrence of cross-linking and oxidative degradations (Anjana *et al.* 2023). Similar behaviour was noted for cross-machine direction as well.

Table 3. Variation of tensile properties with UV exposure*.

Ageing time hours	Yield strength kN / m	Break strength kN / m	Yield strain %	Break strain %
0	28.18	26.33	18	542
90	27.7	32.15	18	669
1000	27.1	30.1	17	649
3000	28	36	19	753
9000	29.98	44.35	16	913
11200	31.55	48.14	17	800
13803	32.09	37.59	14	869
26095	32.98	40.25	15	889

*From (Anjana *et al.* 2023)

3.3 *Fourier transform infrared (FTIR) spectroscopy*

FTIR analysis was performed on virgin and aged GMB in view of studying the molecular changes due to UV ageing. The methylene functional group peaks are the prominent features

of HDPE GMB and are found at wave numbers 2915, 2848, 1472, 1462, 729 and 719 cm^{-1}. The peaks at 1462 and 1472 cm^{-1} correspond to the methylene deformation vibrations in the amorphous and crystalline regions, respectively (Anjana *et al*. 2023). Figure 1 shows the spectra of virgin and aged GMBs of exposed sides.
Figure 1. FTIR spectra of virgin and aged GMBs at varying UV ageing durations.

With the increasing duration of UV ageing, the peak corresponding to crystalline content was increased and the amorphous content was decreased. The variation of peak intensity in this region reflects the crystallinity increase in the polymer due to cross-linking reactions. This finding supports the results obtained in other tests of GMB properties. Thus, quantifying crystalline content in polymer becomes essential to validate those observations. Hence, the method described by Zerbi *et al*. (1989) was used to determine the crystalline content as per Equation 1 below:

$$Crystalline\ content\ = \left\{ 100 - \frac{[1 - (I_a/I_b)]/1.233}{1 + (I_a/I_b)} \right\} \times 100 \qquad (1)$$

where I_a and I_b denote the peak intensities of bands at 1472 and 1462 cm^{-1}, respectively. The crystalline content determined using Equation 1 represents the surface-level modification. The spectra were collected on both exposed and unexposed sides of aged GMB and their corresponding crystalline content was calculated (Table 4). The values were found to be higher for the aged GMB relative to the virgin GMB. Further, the crystalline content on the exposed side was greater than that of the unexposed side in the aged GMB. There was a significant difference in the crystalline content of exposed and unexposed sides beyond 1000 hours of ageing. These results imply that with the increasing duration of UV ageing, there is an increase in the crystalline content. This shows the evidence for cross-linking reactions, as the same was also witnessed in the other tests (Anjana *et al*. 2023).

Table 4. Variation of crystalline content with UV exposure*.

Crystalline content (%)	Ageing time (hours)									
	0	48	90	400	1000	3000	9000	11200	13803	26095
Virgin GMB	88	88	88	88	88	88	88	88	88	88
Exposed side	90.05	91.03	91.91	91.66	91.98	93.41	94.4	95.48	95.55	95.8
Unexposed side	88.62	90.4	91.74	91.28	91.89	91.45	91.97	91.71	90.95	92.4

*From (Anjana *et al*. 2023)

4 CONCLUSIONS

The study investigated the effect of accelerated UV ageing on the properties of HDPE GMB exposed to UV radiation for three years. The variation of GMB properties such as thickness, density, melt flow index, tensile behaviour, OIT, crystallinity and FTIR spectra with varying exposure durations have been studied in detail. The results showed an inappreciable variation in the thickness of GMB with UV ageing time. However, the effect of UV degradation was considerable, as evidenced by the changes in density, melt index and tensile behaviour of GMB. The reduced density, increased tensile properties and reduced melt index values dictate the occurrence of cross-linking reactions. The standard OIT decreased significantly as the ageing duration increased. This can be attributed to antioxidant depletion owing to oxidative degradation. The FTIR spectra showed that the crystalline content measured at the exposed GMB surface increased with the increasing UV ageing duration. This suggests that due to UV ageing, the GMB is more prone to surface-level damage and the evidence for cross-linking reactions depicts superficial degradation. The reported findings are confined only to the tested exposure conditions, and based on the above findings, it can be concluded that the depletion of GMB properties depends on the severity and extent of UV ageing.

Prediction of the vertical permeability coefficient of needle-punched nonwoven geotextiles

K.Y. Li, X.W. Tang*, J.X. Liang, W.K. Lin, T.Q. Wang & Q.Q. Xiang
Research Center of Coastal and Urban Geotechnical Engineering, Zhejiang University, Hangzhou, P.R. China
Engineering Research Center of Urban Underground Space Development of Zhejiang Province, Hangzhou, P.R. China

ABSTRACT: The vertical permeability coefficient is an important hydraulic characteristic index of needle-punched nonwoven geotextiles. A theoretical model has been proposed to predict the vertical permeability coefficient of nonwoven geotextiles, considering the fiber orientation distribution characteristics. The permeability coefficient and parameters of four needle-punched nonwoven geotextiles were obtained from the literature and image analysis. By comparing the predicted results of the permeability model with the experimental results, it is confirmed that the permeability model proposed in this paper was validated with thicker nonwoven geotextiles.

1 INTRODUCTION

Geotextiles have been widely used as filtration materials in civil engineering, water conservancy, port and environment and other engineering construction (Lee & Douglas 2012; Touze-Foltz *et al.* 2016; Yang *et al.* 2019). The vertical permeability coefficient of nonwoven geotextiles is an important hydraulic parameter used in the design of road separations, the design of dam filter layers and the selection of drainage design (Fatema & Bhatia 2021; Zhang *et al.* 2013).

In the current standards, such as ASTM D4491M-15 (2015), BS 6906: Part 3 (1989), and GB/T 15789-2016 (2016), the vertical permeability coefficient of nonwoven geotextiles requires time and energy consumption. The number of samples to be tested should be at least five, and the samples should be soaked in the water container until saturated. Furthermore, the experimental vertical permeability test cannot help to understand the permeability mechanism of nonwoven geotextiles.

Therefore, accurate prediction of permeability of nonwoven geotextiles by understanding the relationship between the pore characteristic and permeability. This study proposed a theoretical model to predict the vertical permeability coefficient of nonwoven geotextiles, considering the influences of fiber orientation distribution. Four geotextiles from the literature were used to calculate their permeability to determine the validity of the model proposed in this study.

2 THEORETICAL MODEL

2.1 *Analytical solution of pore size distribution*

Nonwoven geotextile is a three-dimensional structure consisting of fibers arranged in a planar direction. The structure and morphology of the pores in nonwovens are very

---

complex. Some analytical models for predicting the pore size distribution of nonwoven geotextiles have been found in the literature (Faure *et al.* 1986, 1990; Lombard *et al.* 1989). Faure *et al.* (1986, 1990) proposed a cumulative probability expression of a polygon inscribed circle based on the Poisson polyhedra theory. Lombard *et al.* (1989) calculated the pore size distribution by extending the definition of the effective thickness of the analytical model by Faure *et al.* Rawal *et al.* (2010, 2011) developed an analytical model for predicting the pore size distribution of nonwoven geotextiles combining the effects of fiber orientation. The cumulative probability $F(r)$ of a particle with a diameter r passing through the layers of nonwoven geotextiles is shown below:

$$F(r) = 1 - \left[\left(1 + \omega r + \frac{\omega^2 r^2}{2} \right) e^{-\omega r} \right]^N \tag{1}$$

where

$$\omega = \frac{4 V_f K_\alpha}{\pi d_f} \tag{2}$$

$$V_f = \frac{\mu_g}{\rho_f T_g} \tag{3}$$

$$K_\alpha = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} |\cos \varphi| \chi(\varphi) d\varphi \tag{4}$$

$$N = \frac{T_g}{d_f} \tag{5}$$

where ω is the scale parameter; N is the number of layers; V_f is the volume fraction of fiber; K_α is the directional parameter; d_f is the fiber diameter; μ_g is the mass per unit area; ρ_f is the fiber density; T_g is the thickness of geotextile; and $\chi(\varphi)$ is the distribution function of fiber orientation (φ). The details of the parameters can be found in the literature (Rawal *et al.* 2010, 2011).

2.2 Permeability model of nonwoven geotextile

Nonwoven geotextiles can be seen as porous materials composed of a bundle of tortuous capillary tubes with variable cross-sectional areas. Therefore, the cumulative probability function proposed by Rawal *et al.* (2010, 2011) can well describe the distribution of the pore channels. The probability density function $f(r)$ can be obtained,

$$f(r) = F(r)' = \frac{1}{2} \omega^3 N r^2 (1 + \omega r + \frac{\omega^2 r^2}{2})^{N-1} \cdot e^{-\omega r N} \tag{6}$$

Based on the Hagen-Poiseian equation, the flow rate $q(r)$ of a single r pore-sized tube can be modified as follows (Denn 1980):

$$q(r) = \frac{\pi}{128} \frac{\Delta P}{L_t r} \frac{r^4}{\mu} \tag{7}$$

where $L_t(r)$ is the tortuous length of the pore channels, ΔP is the pressure gradient, and μ is the dynamic viscosity. Yu and Cheng (2002) reported that the tortuous length of the pore channels $L_t(r)$ can be expressed as the equation of the diameter and fractal dimension:

$$L_t(r) = L_0^{D_T} r^{1-D_T} \tag{8}$$

where L_0 is the straight length of pore channels, it can be assumed to equal to the thickness of geotextile T_g. D_T is the tortuosity fractal dimension. $1 < D_T < 2$ presents the tortuosity of flow through a porous media capillary tube. When $D_T = 1$, the capillary tube is straight and when $D_T = 2$, the capillary tube is too torturous to fill the whole surface.

The flow rate per unit area $v(r)$ of a single tube can be taken as:

$$v(r) = \frac{q(r)}{\frac{1}{4}\pi r^2} = \frac{\pi \Delta P r^4}{128 \cdot T_g^{D_T} r^{1-D_T} \mu} \cdot \frac{4}{\pi r^2} = \frac{\Delta P r^{1+D_T}}{32 T_g^{D_T} \cdot \mu} \tag{9}$$

The total flow Q is given by integrating the products of Equation (6) and (9),

$$Q = \phi_{eff} A \int_{r_{min}}^{r_{max}} v(r) f(r) dr$$

$$= \frac{\phi_{eff} \Delta P A \omega^3 N}{64 \cdot \mu \cdot T_g^{D_T}} \int_{r_{min}}^{r_{max}} r^{3+D_T} \cdot \left(1 + \omega r + \frac{\omega^2 r^2}{2}\right)^{N-1} \cdot e^{-\omega r N} dr \tag{10}$$

where A is the flow area, r_{max} is the maximum pore size, r_{min} is the minimum pore size, and ϕ_{eff} is the effective porosity of nonwoven geotextile which can be expressed as:

$$\phi_{eff} = 1 - \frac{\mu_g}{\rho_f T_g} \tag{11}$$

In nonwoven geotextiles, the ratio of r_{min} to r_{max} is usually less than 0.01, so the Equation (10) can be simplified accordingly,

$$Q = \frac{\phi_{eff} \Delta P A \omega^3 N}{64 \cdot \mu \cdot T_g^{D_T}} \int_0^{r_{max}} r^{3+D_T} \cdot \left(1 + \omega r + \frac{\omega^2 r^2}{2}\right)^{N-1} \cdot e^{-\omega r N} dr \tag{12}$$

Based on Equation (11) and Darcy's law (Yu and Cheng 2002), the permeability coefficient model of nonwoven geotextiles can be calculated,

$$k = \frac{\rho g Q T_g}{\Delta P A} = \frac{\phi_{eff} \omega^3 \rho g N}{64 \cdot \mu \cdot T_g^{D_T-1}} \int_0^{r_{max}} r^{3+D_T} \cdot \left(1 + \omega r + \frac{\omega^2 r^2}{2}\right)^{N-1} \cdot e^{-\omega r N} dr \tag{13}$$

where ρ is the density of water, g is the gravitational acceleration.

3   EXPERIMENTAL PROCEDURE

In Equation (12), the permeability coefficient of nonwoven geotextile is in terms of the maximum pore size r_{max}, directional parameter K_α, fiber diameter d_f, tortuosity fractal dimension D_T, the mass per unit area μ_g, fiber density ρ_f, and the thickness of geotextile T_g, that is $k = k$ (r_{max}, K_α, d_f, D_T, μ_g, ρ_f, T_g).

3.1   Digital image analysis

The digital image method has been used in several studies to measure pore and fiber characteristics of nonwoven geotextiles due to the advantages of fast processing speed, high accuracy, and not damaging the specimen (Aydilek et al. 2002; e Silva et al. 2019). Therefore, the pore size and fractal parameters of the nonwoven geotextiles sample were obtained using image analysis.

Images of the geotextiles were obtained using scanning electron microscopy (SEM). Firstly, to make the pores and fiber boundaries of geotextiles clear and easy to identify, the image brightness and contrast of the geotextiles were adjusted to ensure sufficient contrast between interests. The optimal threshold values were calculated using Otsu's method (Otsu 1979). The resulting images were then converted into a binary format, where the pore pixel intensity and fiber intensity were set to 1 (pure white) and 0 (pure black), respectively.

Lastly, several required parameters can be determined through statistical analysis, including maximum pore size r_{max}, directional parameter K_α, and fiber diameter d_f. The procedures were as follows:

(1) The equivalent hydraulic diameter of the nonwoven geotextile pore was obtained based on hydrodynamic theory by converting the pores of the geotextile into circular channels as follow:

$$r = \frac{4A_p}{S_p} \tag{13}$$

where A_p is the pore area, S_p is the pore perimeter. Thus, the maximum pore size r_{max} can be obtained.

(2) The edge of the fibers was smoothed using median filtering and erosion operation. Then, the orientation distribution of the fibers was obtained statistically by fitting the pore edges with the Hough transform. The directional parameter Kα can be calculated by the proportion of lines for 10° orientation angle interval with respect to machine direction.

(3) The fiber diameters df of nonwoven geotextiles were manually recognized by drawing lines on the fibers using FSCapture. More than 100 fibers were need in this statistical work.

3.2 Determination of pore tortuosity fractal dimension D_T

Several studies have tended to determine the pore tortuosity fractal dimension D_T. Shen *et al.* (2018) calculated the value of D_T using a theoretical equation. Liu *et al.* (2011) used the box-counting method to obtain the value of D_T of nonwoven geotextile. Here, the box-counting method was recommended to be applied in this study.

It is tough to obtain the actual vertical percolation path of nonwoven geotextiles by experiment. It was assumed that the nonwoven geotextiles have the same pore size distribution in two and three dimensions. Thus, surface morphology images of nonwoven geotextiles were used to present the actual pathway of the longitudinal capillary tubes. First, the digital image analysis mentioned above was performed to convert the image into binary. Then, the binary image is divided by numerous square boxes with side *a*. The number $N(a)$ of boxes required to cover the whole area is counted. The side of the square box *a* was changed, and the above operation was repeated. Finally, the slope of the linear fitted line on the double logarithmic plot of *log(a)* and *log N(a)* was obtained.

3.3 Determination of physical properties

The physical properties of the nonwoven geotextiles, the mass per unit area μ_g and the thickness of geotextile T_g, were determined according to ASTM D5261-10 (2018) and ASTM D5199-12 (2012), respectively. The data of fiber density ρ_f can be obtained from manufacturers.

4 RESULTS

The data of the needle-punched nonwoven geotextile samples were obtained from Liu *et al.* (2011). The physical and fractal properties of the samples are presented in Table 1. Comparations of theoretical and experimental values of the permeability coefficient of

Table 1. Properties of nonwoven geotextiles.

Samples	r_{max}* (μm)	K_α*	d_f (μm)	D_T	μ_g (mm)	ρ_f (kg/m^3)	T_g (mm)
Sample 1	148.4	0.6378	20.0	1.061	172.37	1380	1.499
Sample 2	339.2	0.6599	20.6	1.065	354.39	1380	3.966
Sample 3	283.2	0.6362	21.2	1.073	526.61	1380	5.781
Sample 4	447.0	0.6432	19.9	1.058	591.88	1380	5.833

*These two parameters were determined using the SEM images of nonwoven samples (Liu *et al.*, 2011) in this study.

Table 2. The theoretical and experimental value of permeability coefficient of nonwoven geotextiles.

Samples	Experimental value (cm/s)	Theoretical value (cm/s)	Relative error (%)
Sample 1	0.18	0.19	5.55
Sample 2	0.43	0.39	9.30
Sample 3	0.41	0.30	26.83
Sample 4	0.34	0.20	41.18

nonwoven geotextiles are shown in Table 2. The experimental values were obtained from Liu *et al.* (2011), while the predicted values were calculated using Equation (13) and the parameters specified in Table 1.

The values of the predicted permeability coefficient compared well with the experimental permeability coefficient. For sample 1 and sample 2, the error rates between the experimental and the calculated value are 5.55% and 9.30%, respectively. Nevertheless, sample 3 and sample 4 show some differences. The difference between the two values ranges from 26.83% to 41.18%.

This discrepancy may be due to the fact that nonwoven geotextiles are complex porous structures. SEM image analysis can only be carried out on the surface layer of the geotextile, not on the deep layer. The pores within the geotextile cannot be adequately analyzed. Furthermore, Giroud (2010) claimed that the reliability of a nonwoven geotextile filter is a function of the number of constrictions in the filtration path. Constriction means a "window" delimited by three or more fibers through which soil particles could migrate. The number of constrictions of thicker geotextiles is larger than those of thinner geotextiles, which are more unpredictable. Therefore, the model proposed in this study (i. e. Equation (13)) is less applicable for thick geotextiles sample 3 and sample 4, which are more suitable for nonwoven geotextiles with low thicknesses.

5 CONCLUSIONS

A permeability model has been proposed to predict the vertical permeability coefficient of needle-punched nonwoven geotextiles. The fiber orientation distribution characteristics are considered in this model. The model involves the maximum pore size r_{max}, directional parameter K_α, fiber diameter d_f, tortuosity fractal dimension D_T, the mass per unit area μ_g, fiber density ρ_f, and the thickness of geotextile T_g. The permeability coefficient and parameters of nonwoven geotextiles are determined from the literature. The tortuosity fractal dimension and directional parameter are calculated by image analysis in this study. Comparison between the experimental and theoretical results shows that the model was validated with thin geotextiles but not as well for thicker geotextiles.

The evolution of geosynthetic hydraulic performance measurement

S.R. Allen
The TRI Environmental Group, Austin, USA

ABSTRACT: The growth of geosynthetic hydraulic product types, structures, and associated performance has been impressive. Geosynthetics routinely replace traditional materials such as soil and stone layers to provide for important engineering functions including drainage, filtration and erosion and sediment control, all while providing greener engineering options resulting in lower carbon footprints. The growth of product structures and performance behaviors has challenged the standardization community to keep pace with measurement technologies appropriate to capture both short and long term product performance. Along the way, many testing tools and measurement procedures have been developed, and many more are in development.This paper reviews many of the geosynthetic hydraulic structures and their specific applications. The important work ISO TC221 and ASTM International Committee D35 to standardize measurement technologies will be presented, including selected summary descriptions for:

- ISO 18198, Determination of long-term flow of geosynthetic drains
- ISO 12958-1, Determination of water flow capacity in their plane - Part 1: Index test
- ISO 12958-2, Determination of water flow capacity in their plane - Part 2: Performance test
- ASTM D4716, Standard Test Method for Determining the (In-plane) Flow Rate per Unit Width and Hydraulic Transmissivity of a Geosynthetic Using a Constant Head
- ISO TC 18228-8, Design using geosynthetics - Part 8: Surface erosion control
- ASTM D6459, Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Hillslopes from Rainfall-Induced Erosion
- ASTM D 6460. Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Earthen Channels from Stormwater-Induced Erosion

Also discussed is the significance of test water management, the use of alternative permeants such as leachates and air, and the accelerated "aging" of drainage systems in an effort to predict long term performance.

1 INTRODUCTION

Geosynthetics that provide desired hydraulic performance comprise a variety of manufactured products that include geotextiles as well as several three-dimensional structures. While the primary function of most geotextiles in hydraulic drainage applications is filtration, the ability of geosynthetic porous structures to provide hydraulic performance is impressive, and include products such as geonets, cuspated cores, geomats, geospacers, multilinear drains and drainage liners.

The majority of planar geosynthetic drains are geocomposites with geotextiles laminated to a drainage core and it is common to consider the drainage behavior of the geocomposite as a whole rather than the behavior of the component parts in isolation. Examples of geosynthetic products are included in Figure 1.
Figure 1.   Examples of drainage cores (from ISOTS18198-08).

When geotextiles are used for surface erosion resistance and associated filtration, woven or nonwoven geotextiles are common for both vertical applications of soil retention and dewatering applications.

Figure 2.   Examples of vertical surface erosion control products.

Also included in the geosynthetic contributions to hydraulic performance is the very important application of surface erosion control. Three-dimensional product rolls can protect the soil against rainfall splash and runoff by keeping in place soil particles. Moreover, they can increase the shear resistance of the root system several times over. The synthetic structure of geosynthetics work quite well with a variety of natural or bio-material fills that can serve to encourage vegetative growth. The permanent geosynthetic erosion and revegetation materials then provide erosion control, and aid in vegetative growth, eventually becoming entangled with the vegetation to provide reinforcement to the root system and enhanced hydraulic shear resistance.

Finally, some geosynthetics can provide vertical flow in dewatering or targeted drainage applications. Prefabricated vertical drains (PVDs) are typically constructed of an accordion shaped core, or other channeled structure and wrapped in a geotextile filter. These products are used successfully to dewater and accelerate consolidation of wet or saturated soils. They have also been used successfully to drain perched pregnant solutions trapped in mining leach piles after chemical digestion. By piecing the ground, or leach pad, with special installation equipment, PVDs can be placed in specific locations for application success.

Cuspated core vertical drains are common in housing or industrial building construction to drain away subsurface waters from the foundation.

2 GEOSYNTHETIC PERFORMANCE MEASUREMENTS

The following sections will look at some of the very important geosynthetic hydraulic measurements specific to our industry and the contributions of resource standards and laboratory investigations.

2.1 Planar drainage

Throughout geosynthetic drainage product development, the evaluation of performance has been necessarily focused on flow capacity, resistance to short-term compression and collapse, characteristics of the filter, and long term behavior or the drainage system. Recently, key guidance documents have been standardized by the International Standards Organization (ISO) Technical Committeee (TC) 221 on geosynthetics that are relevant to geosynthetic drainage systems. They are as follows.

- SO/TR 18228-3, Design using geosynthetics — Part 3: Filtration
- ISO/DTR 18228-4, Design using geosynthetics — Part 4: Drainage

These documents provide great benefit to all those wanting a comprehensive summary of the specific parameters for using geosynthetic drains and their components (filters and cores). They each reference the relevant test procedures needed to characterize the hydraulic properties of geosynthetics. Of special importance is the measurement of planar flow properties outlined in two ISO standards,

- ISO 12958-1, Geotextiles and geotextile-related products — Determination of water flow capacity in their plane — Part 1: Index test
- ISO 12958-2, Geotextiles and geotextile-related products — Determination of water flow capacity in their plane — Part 2: Performance test

ASTM International has also standardized this measurement via ASTM D4716, *Standard Test Method for Determining the (In-plane) Flow Rate per Unit Width and Hydraulic Transmissivity of a Geosynthetic Using a Constant Head*. In all of these standards, the basic procedure involves the use of a flow box capable of holding a planar drainage sample under an applied normal compressive load. Hydraulic energy is established via an applied gradient by controlling the upstream water reservoir height relative to the downstream water height.
Figure 5.   Example of ISO 18228 and ASTM D4716 test apparatus.

The figure below shows a typical planar test apparatus.
The discharge capacity of the geosynthetic drain can be given in terms of:

- Specific flow rate = discharge per unit width in the geosynthetic drain, under a specified hydraulic gradient:

$$Q = q \quad \beta \tag{1}$$

Some users of flow tests desire to index the discharge rate per unit width to the applied hydraulic energy or hydraulic gradient at which flow is measured. In this case:
- Hydraulic transmissivity = discharge per unit width of the geocomposite and per unit of hydraulic gradient.

$$\theta = (q \quad \beta)/i \tag{2}$$

489

The concepts of transmissivity and flow capacity were developed specifically to avoid consideration of the thickness as it is often difficult to specifically define the thickness of a geosynthetic drain under load in application. Transmissivity is equal to flow rate only at a gradient of 1. Note also that the numerical value of transmissivity can be very different than the numerical value of the specific flow rate at small hydraulic gradients (e.g. at i = 0.1 transmissivity is 10 times the specific flow rate).

(a)

(b)

(c)

(d)
Figure 6. Example of time under load on discharge rate at (a) 1 hour, (b) 24 hours, (c) (48 hours), (d) 100 hours, for an 8.9 mm geocomposite under 172 kPa compressive stress and a gradient of 0.33.
Figure 7. Example of filter geotextile intrusion under various compressive loads (courtesy of the Geosynthetic Institute).

It is well established that geosynthetic drains under load have a reduced flow capacity relative to the unloaded condition related to both the magnitude of compressive loading as well as associated changes in the three-dimensional drainage core structure. This change in structure is related to compression of the core and intrusion of the filter geotextile. Further, in addition to short-term response to load, or ductile deformation, additional change is time-dependent. The available long-term flow related to these phenomena and the reductions of flow related to chemical and biological clogging of the drain can be determined per ISO/DTR 18228-4 as follows.

$$Q_a = Q_L \ / \ (RF_{in} \ \cdot \ RF_{cr-Q} \ \cdot \ RF_{cc} \ \cdot \ RF_{bc} \ \cdot \ RF_L) \qquad (3)$$

where,

Q_a is available long-term flow rate for the geocomposite;

Q_L is the short-term flow rate obtained from laboratory tests with the appropriate boundary

conditions;

RF_{in} is the Reduction Factor for the intrusion of filter geotextiles into the draining core due to tensile creep of the gtx, occurring after the short-term test;

RF_{cr-Q} is the Reduction Factor for the compressive creep of the geocomposite;

RF_{cc} is the Reduction Factor for chemical clogging of the draining core;

RF_{bc} is the Reduction Factor for biological clogging of the draining core;

RF_L is the Reduction Factor for overall uncertainties on laboratory data and field conditions.

As the time-dependent resistance to vertical deformation or compression of planar geo-synthetic drains is paramount to the understanding of RF_{cr} and the related long term flow capacity, there have been several efforts to accelerate this measurement to provide confidence in drainage design and reduce the time necessary to realize this long term deformation. Conveniently, a summary of the most common procedures is included in ISO 18198.

Significantly, one accelerated procedure using a combination of the Stepped Isothermal Method (SIM) and subsequent thickness-dependent hydraulic discharge capacity testing is referencd in ISO 18198 and now standardized in ASTM D4716. In this test SIM is used to measure and document the time-dependent thickness reduction of the geosynthetic drain using ASTM D7361 and then subsequent design flow testing at a specific thickness associated with the anticipated service life instead at a specific load representing the intended product application is carried out. As shown in Figure 10, this testing requires a vertical displacement driven compression control mechanism with LVDTs and a feedback loop for thickness control. This assembly also requires hydraulic testing apparatus capable of affecting the desired thicknesses of the geosynthetic drainage core during flow testing.

Another feature of this testing is the possibility of incorporating site-specific conditions into the test via the use of anticipated in-situ soils and other geosynthetic products. As the site-specific materials are represented in the test, geotextile intrusion and compressive creep are modelled and may not need to be applied during the determination of long-term flow capacity, although this should be confirmed on a given drain and geotextile filter configuration. In addition, because the flow testing is short-term in nature, measurements of flow at different loading conditions through the service life of the geosynthetic drain may be visited and numerous specimens may be measured to provide greater confidence in developed measurements.

2.2 *Air as a permeant*

Another interesting development in the ongoing effort to make drainage capacity measurements easier and more accurate is the use of air as a permeant. The use of air as a permeant has already been well established and standardized in ASTM International in the geotextile

Figure 8.   Example thickness-dependent flow test configuration.

filtration measurements of permeability normal to the plane, or permittivity, and also opening size measurements to identify the opening size at which 95% of particles are retained. The advantages of air are many including the lack of need for temperature correction factors as air is much faster and quicker to condition and maintain than the temperature of water, and the lack of need to battle water quality issues as sediment, air and other contaminants can interfere with flow measurements. While yet to be standardized for planar flow measurements, the use of air in planar flow measurements is actively being investigated as an enhanced measurement approach.

The typical test apparatus is fitted with an upstream source of air that is introduced into the reservoir. Air flow rate is captured as a function of time and converted to hydraulic flow results using the same principles as permittivity tests, that is, using the mass density and viscosity of water and air.

2.3   *Erosion control*

Very important in the development of erosion control information and technology resources is the recently published ISO TR18228-8, Surface Erosion Control. This resource document
Figure 9.   Example hydraulic discharge capacity flow apparatus using air as a permeant.

provides a summary of relevant geosynthetic products and their erosion control measurements. Significantly, it also provides several tables of related reference data such as design factors related to topography, rainfall intensity and other relevant information.

Fundamental to the understanding of the performance of many of our planar geomeshes, turf reinforcement mats and similar products is performance testing. An erosion control product can shield the underlying soil from raindrop impact energy, yes, but we also want to provide for vegetative germination and growth, thus we need porosity and some level of openness. A product can also absorb and retain rainwater to hold it in place and gradually release it thereby prohibiting its damage to the soil, but we may also not want the product or the sol underneath it to become too saturated as it may become too heavy with water creating internal or even surface instability.

Observation of hundreds of large-scale performance tests lead to an understanding that erosion control products appear to fall into one of three general categories of field performance:

- Those that encourage infiltration as the primary mechanism to limit erosion;
- Those that block rainfall impact but rely on their anchor pattern/frequency to reduce erosion inducing runoff;
- Those that armor the slope against both rainfall impact and infiltration, leading to high percentages of runoff.

These competing needs are what is designed for in each product, and provide the performance as observed during testing. Erosion control products that cause excessive amounts of precipitation to infiltrate and remain in the slope rather than running off the slope may cause the soil to become supersaturated and unable to hold itself onto the slope. This causes a "mass wasting" phenomenon.

These large- scale performance phenomenon require large-scale tests to measure. Two tests referenced in ISO TR 18228-8 are the following.

1. ASTM D6459,Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Hillslopes from Rainfall-Induced Erosion

493

2. ASTM D6460,Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Earthen Channels from Stormwater-Induced Erosion

The slope erosion test is performed on one bare soil control and three replicate geosynthetic protected soil slopes at 3H:1V slope. Rainfall is simulated at target intensities of 50, 100 and 150 mm per hour, which are applied in sequence for 20 minutes each. Runoff from each slope is collected and soil loss is measured. From this data, an appropriate C-factor (for use in the RUSLE equation) can be calculated by comparing the geosynthetic protected soil loss to the soil loss of the bare soil control. Rain intensity, test duration and test soil variables may be investigated as desired.

(a) (b)

Figure 10. (a) The standard plot is a 3 to 1 slope with a down slope length of 12.2 m and a width of 2.3 m, and (b) calibrated rain delivery system.

For channel erosion the test is conducted in a rectangular flume with at least four sequential increasing flows applied for 30 minutes each (unvegetated conditions) or 60 minutes each (vegetated conditions). Unvegetated geosynthetic protected channel testing is typically performed in a 10% slope flume. Vegetated geosynthetic protected channel tests are typically performed in a 20% slope flume. The limiting or permissible shear stress is defined as the shear stress necessary to cause an average of 13 mm of cumulative soil loss over the entire subject test area.

There has been discussion in erosion standardization working groups about tilting bed test facilities. This test equipment has the ability to quickly change and test different slope angles. The tilting bed slope test configuration has been successfully used to isolate the surface dynamics from surface-depth slope stability issues, and thus has been shown in this limited context to segregate between surface-treatment technologies. These slope testing protocols often employ tilting beds that allow for the soil layer to drain from below. This prevents the soil layer from becoming saturated under heavy rainfall simulations. This also creates a soil condition that cannot exist in the real world. In addition, testing protocols using test slopes that are shorter and narrower may have index utility, while limiting the extent to which natural erosion mechanisms can develop, such as rills, rivulets and grooves.

Global erosion phenomenon, including infiltration and associated hydraulic loading, warrant the use of large – real world slope tests, such as ASTM D 6459, for field performance investigations.

While tilting bed test apparatus have utility for kinetic energy related studies, there are many times when the primary indicator of differences in the erosion control treatments is whether mass wasting occurs or not. For this reason, most large-scale users, like transportation related authorities, specify using real world slope tests.

In ASTM D6460 testing a rectangular or trapezoidal cross section channel may be used; however, a rectangular channel is recommended for consistency of construction and explicit computation of shear stress. A rectangular cross section must be 0.61 m minimum in width. The test channels are a minimum of 12.2 m in length.

Figure 11.   Large-scale channel erosion testing facility.

Test plots are constructed and then channel flow is initiated gradually (over about 5 minutes) into the channel and, using a velocity meter, the flow is monitored until it becomes steady. This flow is allowed to continue for 30 minutes (unvegetated) or 1 hour (vegetated). Velocity and water surface measurements are taken at all cross-sections during the last 10 minutes. With the flow stopped and without stepping into the tested channel, new measurements to top-of-soil are made to establish erosion caused by the chosen test flow. The process is repeated at somewhat higher shear/flow levels until all required data is
Figure 12.   Example large-scale channel erosion testing results.

collected. If a vegetative component is incorporated into the testing, quantification of the vegetative stand density is performed using a count box. The time-of-growth, type of seed, seed density (i.e. # seeds/sm), and other related info is documented. Channels are prepared identically to unvegetated channels and serve as the basis for the testing.

Test variables such as test vegetation used, growth time, test flow time and depth, etc. may be modified as desired to investigate specific site conditions.

In the figure above, the hydraulic shear results are plotted with an equation fit applied. From this the shear stress associated with a 0.5 inches or 13 mm of soil loss is determined as the limiting shear stress. This same measurement exercise can be performed on unvegetated, partially vegetated or fully vegetated channels with geosynhetic root reinforcement benefits demonstrated.

3 CONCLUSIONS

The geosynthetic industry has responded impressively with the development of measurement tools and standardized procedures and guides to propel and support the wonderful contributions that geosynthetics deliver to drainage and erosion control applications. It is important for industry participants to know of these documents and resources and to assist our expanding community of design engineers familiar, and unfamiliar, with geosynthetic design.

ABSTRACT: Geotextile tube is a popular solution for dewatering applications. During the dewatering process, infill material is pumped into the geotextile tubes through the inlet port at high pressures, and thus significant amount of tension forces can be developed at the inlet port sleeve and connecting parts of the tube. Geotextile tearing could occur at these locations during high pressure pumping. Therefore, it is important to determine its resistance to tearing and the factors that affect its tearing strength. So far, only limited studies have been done on this aspect. Hence, a new tensile test setup was developed to simulate the application of tensile forces on the inlet port sleeve and surrounding geotextile material during slurry pumping. The setup consists of a housing to clamp a portion of the geotextile tube body, and a circular drum that connects to the inlet port sleeve. Strain gauges were installed on the critical locations on the geotextile test specimen both on body and inlet port sleeve. Several types of inlet port designs were tested, and the critical tearing strength of these inlet ports were analysed. Test results suggest that the seam design connecting the inlet sleeve and geotextile body is a key factor in deciding the critical tearing strength of an inlet port design.

1 INTRODUCTION

Geotextile tubes is a popular solution in dewatering applications (Lawson 2008). Infill material such as soft soil slurries and sludge material are pumped into the tube through the inlet port at high pressures and left to dewater (Figure 1). As a result of high-pressure pumping, significant amounts of tension could be developed on the inlet port sleeve and parts of the geotextile tube body. While the inlet port sleeve itself is usually made from high strength geotextile material, tensile force is exerted on the seam connection between the sleeve and geotextile body, and the area on the geotextile body around the inlet port during high pressure pumping. Hence, the inlet port becomes a possible area of failure (Figure 2). If
Figure 1. Geotextile tube being infilled on site.
Figure 2. Separation of yarns around seam observed on-site due to tensions during pumping.

significant tearing occurs, the leakage (or piping) of infill material could result in environmental contamination and wastage of materials. The resistance of various geotextile tube components during high pressure pumping is not widely studied. Thus, a laboratory testing setup was designed and constructed to investigate the tearing capacity of inlet port designs, and the key components that contribute to the tearing strength.

2 METHODOLOGY

2.1 *Test specimen and material properties*

The sample tested is a geotextile using high-tenacity polypropylene multifilament yarns, which are woven into a stable network such that the yarns retain their relative position. This is one of the high strength woven geotextile commonly used in the construction of geotextile tubes. This type of woven geotextile was used for both the body of the geotextile tube and the sleeve of the inlet port. A picture of the geotextile material is shown in Figure 3(a). There are 3 main components of the inlet port specimen: (1) Inlet port sleeve; (2) Geotextile tube body; and (3) Seam design connecting components 1 and 2. The properties of the geotextile material used to make the test specimen, expressed in Machine Direction (MD) and Cross Machine Direction (CD), are listed in Table 1. The inlet port sleeve used geotextile A and had lower strength, but higher flexibility, which was required for infilling operations. The geotextile tube body was made from geotextile B, which had higher strength. The design of inlet port sleeve and geotextile tube body can affect the tearing strength. Two different inlet port seam designs (i.e. J-Seam and Butterfly Seam) as illustrated in Figure 3(b) were tested. In total, 3 different configurations were tested to investigate the effect geotextile grades and seam designs on the resistance of the inlet port to tearing. The configurations of the specimen tested in this paper are presented in Table 2.
Figure 3. (a) Geotextile material; and (b) Seam designs.

Table 1. Geotextile properties.

Property	Units	Geotextile A (For Sleeve)	Geotextile B (For Body of Geotextile Tube)	Standard
Wide Width Tensile Strength (MD/CD)	kN/ m	130/130	200/200	ISO 10319
Strain at Break (MD/CD)	%	10/10	12/10	ISO 10319

Table 2. Test specimen configurations.

Test ID	Seam Design	Inlet Port Sleeve	Geotextile Tube Body	Inlet Port Diameter (mm)
T1	J-Seam	Geotextile A	Geotextile A	500
T2		Geotextile A	Geotextile B	
T3	Butterfly Seam	Geotextile A	Geotextile B	

2.2 Testing setup and procedure

A test apparatus capable of testing a full-scale inlet port was designed and constructed in the Geotechnical Laboratory at the National University of Singapore (NUS) (Eng & Chew 2014), shown in Figure 4. The test specimen was fixed at 2 points onto the test apparatus: (1) The geotextile tube body was fixed to a 1000 mm diameter circular steel frame using clamps, and (2) The 500 mm diameter inlet port sleeve was fixed around a hanging steel drum. A hydraulic piston, connected to the extension rod, was pushed downwards, exerting a downward force onto the hanging steel drum; thus, exerting a tensile force onto the sleeve of the inlet port specimen. As the maximum travel distance of the piston was 300 mm, multiple pushes may be done (with additions of extension rods) before the tearing conditions were observed.

While previous tests had focused on the ultimate seam strength of the inlet port (Eng & Chew 2014), this parameter may not be the most critical condition in the context of on-site
Figure 4. Illustration of inlet port strength test apparatus in NUS (adapted from Eng & Chew 2014).
Figure 5.   Critical tearing during inlet port loading test.
Figure 6.   Strain gauge layout on inlet port specimen when loaded onto test apparatus.

pumping of fine infill material, as any slight tear that occurs before total failure may result in leakage of infill material. Thus, in this paper the term "Critical Tearing Strength" (in kN/m) is introduced, and is defined as the force at which the following conditions were observed during the test: (1) Tearing of seam lines; and (2) Apparent separation of geotextile yarns around the seam area that will result in leakage of infill materials during pumping. An example of the conditions observed when critical tearing strength was reached is shown in Figure 5.

The test specimens were extensively instrumented with 18 strain gauges, using the strain gauge method proposed by Chew *et al.* (2000), with 9 gauges each on both the geotextile of the sleeve and body. Strain gauges were installed in the Machine Direction (MD), Cross Machine Direction (CD) and the Diagonal Direction (DD). Figure 6 shows the layout of strain gauges installed on the body and sleeve. A load cell was also attached to monitor the load applied on the geotextile specimen.

3   RESULTS AND ANALYSIS

Figures 7, 8 and 9 shows the load cell and geotextile strain gauge results for Tests T1, T2 and T3 respectively during the inlet port loading test. The readings from the strain gauges were converted to tensile force (kN/m) using the tensile force-strain relationship of the geotextiles
Figure 7. Results of inlet port test T1.
Figure 8. Results of inlet port test T2.

calibrated prior to the test. Key results from strain gauges were highlighted. Finally, the point where critical tearing was observed was also marked on the graphs. When downward pushing load was applied to the geotextile via the hydraulic piston, there was a corresponding increase in the strain gauge readings at various locations of the geotextile. This suggested that the loading force from the hydraulic piston was transferred to the inlet port specimen effectively. All three test results showed good agreement between the readings from the load cell and strain gauges.

For Test T1, "critical tearing" condition was observed when vertical load reached 47 kN. The pushing continued until a vertical load of about 62 kN. On the geotextile body, the
Figure 9. Results of inlet port test T3.

largest tension developed at the "critical tearing" stage was in the MD direction at 36 kN/m (28% of ultimate strength of the geotextile material). Strain gauges in other directions on the body registered maximum tensions between 25–35 kN/m at this "critical tearing" stage. On the sleeve portion, the strain gauges registered tensions between 2–22 kN/m (17% of ultimate strength of the geotextile material) at this "critical tearing" stage, with the largest tensions developing along both CD and MD directions.

"Critical tearing" conditions were observed at a vertical load of 43 kN for Test T2. At the point of "critical tearing", the largest tensile forces developed on the body was observed at MD direction at 80 kN/m (40% of ultimate strength of the geotextile material), and at the sleeve was in the CD and MD direction at around 42 kN/m (32% of ultimate strength of the geotextile material). Compared to Test T1, the range of tensions registered at "critical tearing" in Test T2 was much larger than that in Test T1, especially on the body geotextile with a range of 15–85 kN/m.

Finally, the "critical tearing" conditions of Test T3 were observed at a vertical load of 82 kN. On the geotextile body, the largest tension developed at this "critical tearing" stage was in MD direction at 64 kN/m (32% of ultimate strength of the geotextile material) and around 70 kN/m (54% of ultimate strength of the geotextile material) along CD and DD direction on the inlet port sleeve. The range of tensions observed on the geotextile body at "critical tearing" stage was relatively small, between 55–75 kN/m. Table 3 shows a summary of the test results on the 3 inlet port tests.

Table 3. Summary of inlet port loading test results.

Test ID	Seam Design	Geotextile Tube Body	Inlet Port Sleeve	Tearing force observed for 500mm Diameter Specimen (kN)	Critical Tearing Strength (kN/m)*
T1	J-Seam	A	A	47	30.0
T2		B	A	43	27.5
T3	Butterfly Seam	B	A	78	50.0

*Based on the circumference of the 500 mm diameter inlet port

Comparing the results of Test T1 and T2, "critical tearing strength" of Test T1 was slightly higher than Test T2, likely due to its more uniform distribution of tension as compared to Test T2. However, overall "critical tearing strengths" of both Test T1 and T2 were relatively close. The results from these 2 tests suggested that varying sleeve and body geotextile grade configurations in this manner had minimal effect on the "critical tearing strength" of the inlet port specimen.

On the other hand, comparing the results of Test T1 & T2 (J-Seam) to Test T3 (Butterfly Seam), it could be observed that Test T3 obviously had a much larger "critical tearing strength". This was likely due to the difference in the seam design. Furthermore, it was also observed in all three tests that tearing of the geotextile occurred only at the seam area, and not on the greater geotextile material elsewhere. This illustrated that this tearing was very localized, or at least at the "critical tearing stage", did not propagate to the whole geotextile piece.

4 CONCLUSION

Based on the inlet port tests conducted and analysed in this paper, key findings were:

1. The grade of geotextile material used for the inlet port sleeve and geotextile tube body as configured in the manner shown in this paper has minimal effect on the "critical tearing strength" of the inlet port.
2. The seam design had a more significant effect on the "critical tearing strength" of the inlet port.
3. The seam is the most critical component of the inlet port design. The failure of the inlet port specimen was limited only at the seam, and no failure of the geotextile material itself was observed. The critical tearing at the seams also did not propagate to other parts of the geotextile piece.

It should be noted that the result presented here are for the specific geotextile material tested.

PVC geomembrane seams: Influence of the testing speed on peel and shear test results

M. Barroso
Laboratório Nacional de Engenharia Civil, Lisbon, Portugal

M.G. Lopes
Instituto Superior de Engenharia de Lisboa, Lisbon, Portugal

ABSTRACT: The PVC geomembranes are the most commonly used in dams. The success of geomembranes as barrier depends on field seams quality. Seams have to be evaluated in terms of continuity and mechanical strength, the latter being assessed by peel and shear tests. These tests are generally carried out according to the ASTM D 6392, which, for PVC geomembranes, recommends a testing speed of 50 mm/min, for peel test, and 500 mm/min, for shear test. However, in field, sometimes it is not possible to attain the testing speed suggested for shear test. This raises questions about the acceptance of seams. To address this issue, two thermally bonded PVC geomembrane seams were tested to peel and shear strength at testing speeds ranging from 50 to 500 mm/min. The results showed that shear and peel strengths tend to increase with the testing speed.

1   INTRODUCTION

Geomembranes have been applied to dams since the 1950s. In the first applications, a wide variety of geomembranes were used. Then, based on experience acquired in early applications, as well as developments in research, testing and manufacturing, the best performing geomembranes have progressively become more popular (Cazzuffi *et al.* 2010). Currently, polyvinyl chloride (PVC) geomembranes are the most commonly used in dams (ICOLD 2010).

The performance of geomembranes as barriers in dams depends on field seams quality. PVC geomembrane field seams are typically made by thermal fusion (hot air or hot wedge). For that it is necessary to melt the polymer at the sheet surface using a heat source. The heat can be transferred to the sheets to be welded from hot air or a hot wedge. A hot air welder uses an air blower that blows heated air from an electrical element between the two sheets to be bonded by melting an interface strip. A hot wedge welder generates the heat energy necessary to melt the sheets at the interface by electrical elements placed directly between two sheets. Pressure is applied to the top and/or bottom sheets of the geomembrane, forcing together the two surfaces to form a continuous bond (Stark *et al.* 2004).

Dual-track and single-track seams can be made. Both types of seams allow destructive and non-destructive testing to assess seams quality in terms of continuity and mechanical strength.

Mechanical strength is typically evaluated based on peel and shear tests. For PVC geomembranes thicker than 1.5 mm, these tests are generally carried out according to ASTM D 6392 standard, which recommends a testing speed of 50 mm/min, for peel test, and 500 mm/min, for shear test. However, in field, sometimes it is not possible to attain the testing speed

suggested for shear test, mainly due to limitations of the testing machines routinely used. This raises questions about the acceptance of seams.

To address this issue, two thermal fusion seams were tested to peel and shear strength at testing speeds ranging from 50 to 550 mm/min, based on test procedure described in the ASTM 6392 standard.

The locus-of-break codes of the seams, according the same ASTM standard, were also addressed in order to discuss its usefulness within the acceptance criteria for PVC geomembranes.

2 EXPERMENTAL WORK

2.1 *Materials*

Two commercially available PVC geomembranes were used in this study, hereafter referred to as geomembrane A (1.5 mm thick) and geomembrane B (2.0 mm thick). Their main properties are summarized in Table 1, according to Technical Data Sheets provided by the supplier.

Table 1. Main geomembranes properties based on technical data sheets.

Property	Geomembrane A	Geomembrane B
Color (upper /down side)	orange/black	orange/black
Thickness (EN 1849-2)(mm)	1.5 (-5/+10%)	2.0 (-5/+10%)
Mass per unit area (EN 1849-2) (g/m^2)	2055 (-5/+10%)	2740 (-5/+10%)
Tensile strength at break (EN ISO 527-1 and 3, specimen type 5, 100mm/min) (kN/m^2)	$\geq 1.5\times10^4$	$\geq 1.5\times10^4$
Elongation at break (EN ISO 527-1 and 3, specimen type 5, 100 mm/min) (%)	≥ 250	≥ 250
Tear resistance (ISO 34, method B, 500mm/min) (kN/m)	≥ 45	≥ 45
Puncture resistance (EN ISO 12236) (kN)	2 ($\pm$0.25)	2.3 ($\pm$0.25)
Foldability at low temperature (EN 495-5)	Not failure at -25ºC	Not failure at -25ºC

Dual-track seam samples, welded by hot air, were made from geomembranes A and B. From each seam sample, specimens were cut such that the seams were perpendicular to the longer dimension of the strip sample. Specimens were die cut using a 25 mm wide by 150 mm long die. (Figure 1).
Figure 1. Dual-track geomembrane seam sample and seam specimen.

2.2 Testing procedure

Tests were carried out based on the ASTM D 6392, but at different testing speeds of besides the one indicated in this standard, 50 mm/min, for peel test, and 500 mm/min, for shear test.

The ASTM D 6392 standard was used rather than ASTM D 7408 since the latter covers just PVC geomembranes in thickness of 0.25 through 1.52 mm.

Testing speeds used were as follows: 50, 100, 150, 200, 250, 300, 350, 400, 450, 500 and 550 mm/min.

Although on ASTM standard recommends to test five specimens to peel and five specimens to shear, in this study, for each testing speed, twenty specimens were tested to shear and ten specimens were tested to peel. A smaller number of specimens were tested to peel because the length of the sample did not allow to cut a larger number of specimens.

Specimens were pulled out as shown in Figure 2, for peel and shear test, respectively. In peel test, inner and outer welds were tested from outside towards the air channel.
Figure 2.   Scheme of the peel and shear test.

In total, 880 tests were carried out: 440 peel (10 specimens×11 testing speeds×2 welds×2 geomembranes) and 440 shear tests (20 specimens×11 testing speeds×2 geomembranes).

Minimum values of peel strength and shear strength of 2.6 kN/m and 20kN/m, respectively, are typically required for field seams of PVC geomembranes up to 1.5 mm thick (FGI 2017). For thicker geomembranes, to the best of the authors' knowledge, there are no general acceptance criteria.

In addition to peel and shear strengths, locus-of-break codes, as per their description in ASTM D 6392 (Figure 3), were recorded. Typically, AD and AD BRK break > 25% codes are unacceptable, in peel and shear modes.
Figure 3.   Locus-of-break codes for seam strength in shear and peel modes (ASTM D 6392).

3 RESULTS AND DISCUSSION

3.1 *Influence of the testing speed on shear strength*

Figures 4 and 5 present the results of shear strength as function of testing speed, for geomembranes A and B. The shear strength values correspond to the average of the 20 test specimens tested, per each testing speed.

Graphs contain error bars corresponding to the standard error. The standard error value was calculated from the standard deviation expanded to a confidence level of 95%, using the t-Student distribution. In the discussion presented below, it is assumed that differences in tests results are only significant when they are higher than the standard errors associated with the measurements.

Results depicted in Figures 4 and 5 show that shear strength tends to increase as testing speed increases from 50 to 550 mm/min. The increase was 3.2 kN/m, for geomembrane A, and 3.3 kN/m, for geomembrane B.

Results obtained in this study are consistent with the results reported by Lopes & Barroso (2022). These authors tested a PVC geomembrane seam (2.5 mm thick) at testing speeds of
Figure 4.   Geomembrane A (1.5 mm): Effect of testing speed on seam shear strength.
Figure 5.   Geomembrane B (2.0 mm): Effect of testing speed on seam shear strength.

100 mm/min and 500 mm/min. They tested 40 specimens, 20 at a testing speed of 100 mm/min and 20 at a testing speed of 500 mm/min, using a constant machine cross head speed. They found that shear strength was, approximately, 3.0 kN/m higher for testing speeds of 500 mm/min.

For geomembrane A, shear strength of dual-track seam ranged from 11.8 kN/m and 15.0 kN/m. These values are significantly lower than the minimum of 20.0 kN/m suggested on acceptance criteria by FGI (2017), raising questions about the seam quality.

For geomembrane B, shear strength ranged from 16.3 and 19.6 kN/m. These values are not compared with acceptance criteria proposed by FGI (2017), as they include only geomembranes up to 1.5 mm thick.

3.2 Influence of the testing speed on peel strength

Regarding peel strength, Figures 6 and 7 present the effect of testing speed obtained for the seams of geomembranes A and B, respectively. The peel strength values correspond to the average of the 10 test specimens tested, per each testing speed. As for shear strength, graphs also include the error bars corresponding to the standard error.

Peel strength shows a slight increase with the increase of the testing speed from 50 to 550 mm/min, for geomembranes A and B. This happens for both welds (inner and outer).

Geomembrane A shows systematically higher peel strength in the outer weld than in inner weld. This trend does not occur for geomembrane B, inner and outer welds presented similar strengths.
Figure 6.   Geomembrane A (1.5 mm): Effect of testing speed on seam peel strength.
Figure 7.   Geomembrane B (2.0 mm): Effect of testing speed on peel shear strength.

Taking into account the standard error estimated, results obtained suggest that testing speed has a small influence on peel strength.

For geomembrane A, results obtained for peel strength of dual-track seam ranged from 7.1 kN/m and 8.9 kN/m, for inner weld, and ranged from 8.0 kN/m and 9.6 kN/m, for outer weld. These values are significantly higher than the minimum of 2.6 kN/m suggested on acceptance criteria of FGI (2017), which raises questions about the suitability of the value required as a minimum.

For geomembrane B, peel strength ranged from 8.6 kN/m and 11.1 kN/m, for inner weld, and ranged from 8.5 kN/m and 11.6 kN/m, for outer weld. Minimum values for geomembranes thicker than 1.5 mm are not included in criteria by FGI (2017).

3.3 *Locus-of-break codes for the peel and shear modes*

Locus-of-break codes for the peel (inner and outer welds) and shear modes as per their description in ASTM D 6392 (see Figure 3), were recorded for each specimens.

Table 2 summarizes the results obtained in peel test. In shear test, all specimens exhibited SE break. This means that the 440 tested specimens exhibited SE break.

As can be seen in Table 2, most of the breaks were type SE (break in outer or in inner edge of the seam). A large number of AD breaks were also obtained. Regarding the SIP breaks, it was found that the separation occurred at the interface between the two layers that comprise the geomembrane, distinguished by different colors (orange and black).

Table 2. Locus-of-break codes for seam strength peel mode (based on ASTM D 6392).

Locus-of-break codes	Geomembrane A*		Geomembrane B*	
	inner weld	outer weld	inner weld	outer weld
AD	34	–	51	11
BRK	–	–	–	–
SE1	73	107	54	80
SE2	–	–	–	–
AD-BRK	–	–	–	–
SIP	3	–	5	–

* For some specimens it was impossible to fully grip them across its width. For geomembrane A, 217 of 220 specimens were tested; for geomembrane B, 201 of 220 specimens were tested.

The usefulness of break type analysis for PVC geomembranes has been questioned by several authors. For example, Rohe (2011) refer that an important difference between PVC and high density polyethylene (HDPE) seam testing is that failure does not have to occur in the PVC sheet on either side of the seam (FTB). FTB is the requirement that the bond of the seam is stronger than the parent film and the film itself fails before the seam fails. This requirement applies to HDPE films because they have such a small window of functional elongation. When the HDPE material only elongates 50% before it breaks, it is very important that the seam never comes apart. PVC geomembrane has a completely different molecular structure, which gives it excellent elongation properties. While the PVC material does thin out as it is elongated, it does not exhibit any yield point typical with polyethylene. At 200% elongation the 1.0 mm PVC geomembrane did not exhibit any failures in peel or shear mode. PVC only requires that the shear and peel strengths exceed a minimum specified value.

Results obtained in this study tend to confirm that the type of rupture does not provide additional useful information about the quality of seams. Thus, its usefulness raises some doubts. However, due to the limited number of PVC geomembranes tested, more research is necessary to confirm this judgment.

4 CONCLUSIONS

In this work, the influence of testing speed on peel and shear strength of PVC geomembrane seams was studied. This issue is important because, in field, it is not always possible to carry out these tests at the standard testing speed, raising questions on their acceptance.

The results showed that shear and peel strengths tend to increase with the testing speed. However, the increase of testing speed has higher impact on shear strength than on peel strength. More research seems to be necessary to confirm this trend.

ABSTRACT: A series of large-scale direct shear tests and cyclic shear tests were conducted on the staggered stacking soilbags. The influences of the number of cyclic shears, vertical stress, and amplitude of shear displacement during the cyclic shearing process on the dynamic deformation characteristics and shear strength of the staggered stacked geotechnical bags were explored. The results show that the shear failure of the interface between the soilbags before and after the cyclic shear basically conforms to the Mohr-Coulomb failure criterion. Under low vertical stress condition, the dynamic parameters of the interface between the soilbags change slightly as the number of cycles increases. As the vertical stress increases, the dynamic shear modulus of the interface between the soilbags increases, while the damping ratio remains unchanged. As the amplitude of horizontal shear displacement increases, the damping ratio of the interface between soilbags gradually goes up, and the dynamic shear modulus decreases. After the cyclic shear test, the increase in the shear strength of the interface between the soilbags increases with the rise of the vertical stress.

1 GENERAL INSTRUCTIONS

Soilbag is a kind of reinforced soil material widely used in building foundation (Matsuoka & Liu 2003, 2006), highway subgrade (Liu 2017), embankment (Martinelli *et al*. 2011), channel (Li *et al*. 2014), slope (Huang *et al*. 2008; Liu *et al*. 2015), retaining wall (Liu *et al*. 2018a, 2018b, 2020; Wang *et al*. 2015) and other projects. It has the characteristics of high compressive strength, local materials, energy conservation, environmental protection, economy and practicality. As a flexible foundation reinforcement material, soilbags not only have high compressive strength, but also have significant seismic isolation effect (Jia *et al*. 2020; Liu *et al*. 2014, 2015; Wang *et al*. 2014). In order to improve the overall stability of soilbag assemblies, staggered stacking is usually used in engineering field. Many scholars have studied the shear characteristics of the interface between layers of soilbags under static condition: Liu *et al*. (2016) conducted direct shear tests of soilbags with four different arrangements using a large indoor direct shear apparatus, and found that the arrangement of horizontal and vertical interlacing can significantly improve the equivalent friction coefficient between layers of soilbags. Fan *et al*. (2020) studied the interlayer friction characteristics of vertically staggered soilbags under different vertical loads through a series of direct shear tests.

The soilbags structure not only bears permanent loads, but also may be subjected to seismic and traffic loads. Therefore, the dynamic characteristics of soilbags have gradually attracted the attention of the academic community. In order to study the damping effect of soilbags, Wang *et al.* (2011, 2019) carried out a series of shaking table tests on soilbags and their materials by using electric shaking table tests, explored the damping effect of soilbags under different input frequencies and different vibration accelerations. They found that the greater the frequency and acceleration, the better the damping effect of soilbags. And this mechanism of soilbag is also researched by using discrete element method. Li *et al.* (2015) carried out a series of vertical stacked soilbag cyclic shear tests using a large cyclic shear tester to study the impact of different bag filling materials on the damping and energy dissipation effect of soilbags, and found that the particle size and grading had little impact on the damping and energy dissipation effect of soilbags. However, the current research on the dynamic characteristics of soilbags mainly focuses on the vertical layered soilbags, which cannot reflect the stacking situation of soilbags in actual projects. Therefore, it is important to study the dynamic characteristics of staggered soilbags and the interlaminar shear strength characteristics before and after cyclic loading to explore the seismic isolation effect of soilbags.

In this paper, a series of cyclic shear tests were carried out on staggered stacked soilbags by using a large cyclic shear system to explore the effects of different vertical stresses, different shear displacements and other factors on the cyclic shear characteristics of the interface between staggered stacked soilbags. The direct shear test was conducted immediately after the completion of the cyclic shear test to obtain the variation law of the interlaminar shear strength of staggered stacked soilbags before and after cyclic shear. It is expected to provide reference for the design of soilbag foundation, retaining wall and other projects.

2 TEST APPARATUS AND TEST MATERIALS

2.2 *Test apparatus*

The instrument used in the test is a large cyclic shear test system developed by Hohai University. The test system is mainly composed of three parts: loading system, measurement system and acquisition system, as shown in Figure 1. The horizontal loading system is composed of screws and flexible chains driven by motors on both sides, and the motor provides a horizontal movement rate of 2mm/min. The vertical loading system applies the vertical load by placing a certain number of weights on the loading plate. The mass of each weight is 50 kg. The measuring system consists of LTR-1 tension-compression sensor installed on the horizontal loading system and DTH-A-100 displacement sensor installed on the loading plate. The acquisition system is the UCAM-60B static data acquisition instrument. The tension-compression sensor and displacement sensor are connected to the static data acquisition instrument for synchronous data acquisition.

In this test, in order to ensure the continuity of horizontal shear force and the stability of vertical load during horizontal loading, as well as avoid the impact of shear and volume deformation in the upper soilbag on the interface characteristics (Chen *et al.* 2020), a "π" shaped
Figure 1. Cyclic shear test device for soilbags.

loading plate as shown in Figure 1 was designed. The width of the loading plate is slightly larger than that of the soilbag, which is convenient for stacking weights and installing connecting buckles. Both ends of the loading plate are connected with the horizontal loading system through flexible chains, so that the stably applied horizontal load can be obtained. Two vertical baffles with the same width as the soilbag are installed at the lower part of the loading plate. During the loading process, both sides of the soilbag are close to the vertical baffle, which can continuously and stably transfer the horizontal load on the loading plate to the lower soilbag.

2.2 Test material

The geotextile woven bag used in the test is a black polypropylene (PP) woven bag with a size of 80cm × 55cm and weight of 108g/m². The ultimate tensile strength in warp and weft is 19.46kN/m and 18.55kN/m respectively, and the ultimate elongation in warp and weft is 20.15% and 19.17% respectively. The filling volume is about 35kg, with a size of 52cm*48cm*12cm.

3 TEST SCHEME

The study is focused on the influence of cyclic shear number, vertical stress, shear displacement amplitude and other factors on the dynamic characteristics of staggered stacked soilbags, as well as the change rule of the interlayer shear strength of the soilbags before and after cyclic shear. The direct shear test and cyclic shear test of staggered stacked soilbags were carried out respectively, and the direct shear test was carried out immediately after the cyclic shear test. Firstly, the direct shear tests of staggered stacked soilbags under four different vertical stresses are carried out, and the reasonable range of the ultimate shear displacement amplitude of soilbags during the cyclic shear test is determined according to the test results. Then, the control variable method is used to carry out the cyclic shear test of staggered stacked soilbags under different cyclic shear times, different shear displacement amplitudes and different vertical stresses. The direct shear test is carried out on the samples immediately after the completion of the cyclic shear test, so as to obtain the change rule of the interfacial shear strength of staggered stacked soilbags before and after the cyclic shear. Table 2 shows the working condition setting of shear test. During the test, in order to ensure

the continuous and stable shear process and reduce the influence of stress and strain rate on the test results (Cen *et al.* 2019; Xu *et al.* 2013), the direct shear rate and cyclic shear rate are both set to 2 mm/min. The loading process of cyclic shear displacement is shown in Figure 3.
Figure 3. Loading process of the cyclic-shear tests.

4 TEST RESULTS AND ANALYSIS

The dynamic shear modulus G and damping ratio λ are two key parameters in the dynamic design of soilbag structures. According to the peak shear stress and corresponding shear displacement amplitude in Figure 4, the dynamic shear modulus and damping ratio of the soilbag assembly can be calculated by the following formula:

$$G = \frac{\tau_c}{\gamma_c} \tag{1}$$

$$\lambda = \frac{A_L}{\pi S_{\triangle abc}} \tag{2}$$

where τ_c and γ_c are the shear stress and shear strain at the top of the hysteresis loop, respectively; A_L is the area of hysteresis loop, $S_{\triangle abc}$ is the area of $\triangle abc$.
Figure 4. Schematic diagram of ideal hysteresis loop in cyclic shear test.

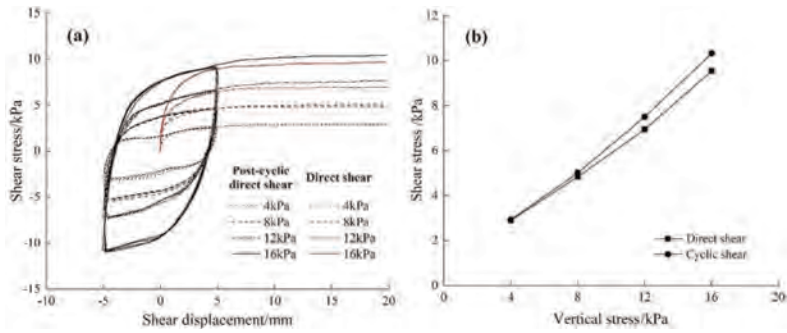
Figure 5 shows the comparison of the results of the direct shear test and the direct shear test after cyclic shear of staggered stacked soilbags under different vertical stresses when the


Figure 5. Results of direct shear tests and post-cyclic direct shear tests under different vertical stresses: (a) shear stress versus shear displacement; (b) shear stress versus vertical stress.

horizontal shear displacement amplitude is 5 mm and the number of cycles is 4. In the cyclic shear test stage, after the first cyclic shear is completed, the interfacial shear strength of soilbags increases significantly. In the second and subsequent cyclic shear processes, the interfacial strength basically does not increase, and gradually tends to be stable. In addition, it can be found from the figure that the relationship curve between shear stress and shear displacement is basically consistent with the direct shear test in the first quarter of the shear cycle before the cyclic shear test.

Under different vertical stresses, during the direct shear test after cyclic shear and direct shear test, the peak shear stress of the interface between layers of the soilbag increases with the increase of the vertical stress, and basically presents a positive correlation trend, indicating that the interface between layers of the soilbag basically conforms to the Mohr Coulomb failure criterion under the process of the cyclic shear test. With the increase of vertical stress, the difference between the peak shear strength of direct shear test after cyclic shear and that of direct shear test also grows gradually. It shows that after cyclic shear, the shear strength of the interface between staggered stacking soilbags gradually goes up, and the greater the vertical stress, the greater the increase of the shear strength of the interface between layers of soilbags. This is mainly due to the strengthening of the embedding effect between the staggered stacked soilbags during the cyclic shear process.

Figure 6 shows the direct shear test results of staggered stacked soilbags after cyclic shear under different horizontal shear displacement amplitudes when the vertical stress is 12kPa
Figure 6. Shear stress-shear displacement relation of post-cyclic direct shear tests under different shear displacement amplitudes.

515

and the number of cycles is 4. Under the same vertical stress, the apex of the hysteresis loop with smaller shear displacement amplitude falls on the path of the hysteresis loop with larger shear displacement amplitude, which indicates that the amplitude of the horizontal shear displacement has little effect on the peak shear strength of the interface between staggered stacked soilbags. This is mainly because there is always a good anchoring effect between the upper and lower soilbags during the cyclic shear process, this further shows that the staggered stacking soilbag composite structure has good recoverability in the shear process. It can also be found that the peak shear strength of interlaminar interface of staggered soilbags after cyclic shear is little affected by the amplitude of horizontal shear displacement.

5 CONCLUSIONS

In this paper, the direct shear test, cyclic shear test and direct shear test after cyclic shear are carried out for staggered stacked soilbags by using a large indoor cyclic shear tester. The shear characteristics of the interface between layers of soilbags under different vertical stresses, cyclic shear displacement amplitudes and other conditions are studied. The main conclusions are as follows:

(1) Before and after cyclic shear, the interlaminar shear stress increases with the increase of vertical stress.
(2) The shear strength of the soilbag assembly increases greatly after the first cyclic shear, and the interlaminar shear strength of the soilbag increases little after the cyclic shear continues.
(3) The greater the vertical stress is, the greater the difference between the direct shear strength after cyclic shear and the direct shear test strength is, and the two basically show a positive correlation trend. The increment of direct shear strength after cyclic shear mainly depends on the increment of shear strength after the first cycle.

Designing with geosynthetic cementitious composite mats – the importance of managing risk by using ASTM D8364-21 'standard specification for GCCM materials'

L. Church
Concrete Canvas Ltd, UK

N. Brusa
Tailor Engineering, Italy

ABSTRACT: Geosynthetic Cementitious Composite Mats (GCCMs) are factory-assembled geosynthetic composites consisting of a cementitious material contained within layers of geosynthetics that becomes hardened when hydrated, and are primarily used to replace conventional concrete for erosion control and weed suppression applications. GCCMs are unique geosynthetic materials as their properties change from flexible to rigid once cured and in service. The cured cementitious layer also provides inherent physical properties to the GCCM including its compressive strength, initial (1st crack) flexural strength and abrasion resistance. Assessing the performance of the cementitious layer within a GCCM typically falls outside the scope of conventional geosynthetic test standards. Similarly, testing of GCCM cementitious materials to conventional concrete standards at optimum water/cement ratios can also be unrealistic of in service GCCM performance, as the water applied in hydration is not controlled and GCCMs often cure in immersed conditions, increasing the water/cement ratio and decreasing the compressive strength of the cementitious layer. If a designer does not understand the test conditions that GCCM manufacturers have used to report their physical properties, there is a risk that they can specify an unsuitable GCCM material for their project. ASTM D8364 'Standard Specification for GCCM Materials' was published in March 2021 and provides assurance to designers of GCCM applications. This paper provides an assessment of ASTM D8364, reviewing the GCCM performance properties listed in the Classifications for GCCMs table and the importance of testing to the specified standards. Particular focus is given to why all GCCMs specimens should be cured by hydration by full immersion to ADTM D8030 and why the compressive strength should be determined to the GCCM specific test methodology in ASTM D8329. By specifying GCCM Classification Types to ASTM D8364, designers can protect themselves from using GCCM test data that may not be representative of in field GCCM performance.

1 INTRODUCTION

Geosynthetic Cementitious Composite Mats (GCCMs) are a relatively unique geosynthetic material, as unlike most geosynthetics their properties change from flexible in deployment, to rigid once hydrated and cured as illustrated in Figure 1. Many GCCMs consist of top and bottom geosynthetic layers, which are connected to constrain a cementitious material within. GCCMs are supplied in roll format, installed, and then hydrated in-situ. The cementitious material cures to form a thin, rigid cementitious layer. GCCMs are typically used to replace conventional poured, precast, and sprayed concretes for surface erosion control applications, including channel lining, slope protection, berm lining, culvert lining and concrete remediation, providing a robust and low-maintenance surface erosion control solution.
Figure 1. The change of GCCM properties on curing from flexible to rigid means that when assessing GCCM properties, appropriate test methods should be used to determine the cured, in-service GCCM cementitious layer performance.

GCCMs are therefore a composite construction product, combining both geosynthetic and cementitious materials, both of which possess very different physical properties. Geosynthetics are typically buried and their performance is often assessed according to their tensile performance, whereas hardened cementitious materials are often exposed and their performance is typically assessed by their compressive strength, which is typically correlated with durability characteristics such as abrasion resistance, freeze thaw resistance and resistance to chemical attack.

GCCMs are the only geosynthetic to contain cementitious material so traditional geosynthetic test standards do not include methods for understanding the performance of the cementitious material contained within a GCCM, such as compressive strength. It is important therefore to test the properties of the cured cementitious material so that the behaviour of the GCCM as a hardened composite can be understood. It is also necessary to ensure the cementitious material is cured at a water/cement ratio that is representative of field (in-service) hydration and not controlled in the laboratory to an artificially low ratio. If a design relies on performance property data determined under artificially controlled laboratory conditions, the engineer is potentially at risk of under designing their GCCM structure which could potentially lead to in-service failure.

Both the uncured (pre-set, soft and flexible) and cured (post-set, hardened and rigid) properties need to be reported to understand the realistic GCCM capabilities in both deployment and in-service respectively.

2 GCCM SPECIFIC STANDARD DEVELOPMENT

ASTM International Standards Organisation and its D35 Geosynthetics Committee has recognised GCCMs as a geosynthetic product, defining them in ASTM D4439 'Standard Terminology for Geosynthetics' as: a factory-assembled geosynthetic composite consisting of a cementitious material contained within a layer or layers of geosynthetic materials that becomes hardened when hydrated. To address the shortfalls in testing GCCMs using pre-existing geosynthetic or concrete standards, since 2015 the ASTM International Standards Organisation has published several standards specifically for GCCMs. They include (in order of publication):

- ASTM D8030 'Standard Practice for Sample Preparation for GCCM'
- ASTM D8058 'Standard Test Method for Determining the Flexural Strength of a GCCM Using the Three-Point Bending Test'
- ASTM D8329 'Standard Test Method for Determination of Water/Cementitious Materials Ratio for GCCMs and Measurement of the Compressive Strength of the Cementitious Material Contained Within'
- ASTM D8364 'Standard Specification for GCCM materials'

These standards have been created to ensure that repeatable testing and reporting of GCCM properties is conducted on specimens that have been prepared in a manner that is consistent with their use in the field, so the test results are representative of GCCMs installed in real-world operating conditions. Note there are currently no GCCM specific EN or ISO standards for sample preparation or physical property testing.

3 ASTM D8364 – STANDARD SPECIFICATION FOR GCCM MATERIALS

In March 2021, ASTM International published ASTM D8364/D8364M-21: 'Standard Specification for Geosynthetic Cementitious Composite Mat (GCCM) Materials'. ASTM D8364 is currently the only internationally recognised standard for specifying GCCMs and lists typical GCCM erosion control applications by three Classification Types: Type I, Type II, and Type III.

Type I GCCMs are described as being typically used to control wind and rain erosion, not used in constant water flow, and therefore have the lowest requirements for abrasion, wear and loading of the classes. They are installed over supporting subgrades such as concrete or rock. The most common Type I uses are for slope protection, berm lining and weed suppression applications.

Type II GCCMs are described as being typically used to provide erosion protection to hydraulic structures and therefore have greater requirements for abrasion, wear, and loading. They can be installed over medium dense subgrades such as clays or compacted soils. The most common Type II uses are for channel lining, culvert lining and armouring of hydraulic structure applications.

Type III GCCMs are described as being typically used on loose subgrades where additional flexural strength is required. They can be specified to provide greater durability and resistance to abrasion, wear, impact, and loading compared to Type I and Type II GCCMs when used in the same application.

The required physical properties for each type of GCCM is presented in Table 1 of ASTM D8364. The table lists the required minimum mean average performance values of each GCCM Type, based wherever possible on GCCM specific standard test methods, or by using modified geosynthetic or concrete tests methodologies in order to represent in-field performance of a GCCM product when used in typical erosion control applications.

The typical dimensional properties such as thickness, mass per unit area and density are listed first. Importantly, GCCM Types are not differentiated by thickness as both Type II and Type III GCCMs are required to have a minimum thickness of 7mm. Therefore, a thicker GCCM may not necessarily provide superior durability to a thinner GCCM when used in the same application. In Table 1 the cured, in-service performance of each GCCM Type is differentiated based on the flexural strength (initial breaking load), compressive strength, pyramid puncture resistance and tensile strength. The use of ASTM D8364 can therefore help ensure the quality and performance of a GCCM is suitable for the intended application, helping protect against project failures.

It is important that the ASTM D8364 specified test methods are used, as other non-GCCM tests could potentially be manipulated to give artificially high results. An example of this is when testing for compressive strength by using ASTM C109, preparing cubes by using

an artificially low water/ cement ratio that is not representative of field hydration conditions, instead of using ASTM D8329 (specified in ASTM D8364), which was developed specifically for GCCM materials and discussed in detail in chapter 5.

To ensure the reported cured GCCM values are representative of the in-service GCCM product, ASTM D8364 specifies that the GCCM test specimens must be prepared in accordance with ASTM D8030 prior to performance testing.

4 ASTM D8030 – STANDARD PRACTICE FOR SAMPLE PREPARATION FOR GCCMS

In virtually all concrete based materials the water/cement ratio governs the final compressive strength of the cured product. This is discussed in BR331-Design of Normal Concrete Mixes: second edition: 'A major factor in providing durable concrete is the production of a dense, impermeable concrete, having an adequate cement content and low free-water/ cement ratio, which is fully compacted and properly cured'. Therefore, if the water/cement ratio is too high, the compressive strength of the cured concrete will be extremely weak.

It is therefore important to control the water/cement ratio of all concrete materials to ensure they cure to provide the required GCCM durability. For conventional concretes, the addition of water is carefully controlled when batching. This is not so simple for GCCMs, as by their ASTM D4439 definition they are supplied in a flexible, uncured state and only harden when hydrated, which can only take place once the GCCM has been installed.

This means the GCCM manufacturer cannot directly control the quantity of water used by the installer when hydrating and must rely on the quality and structure of the GCCM to consistently limit the water/cement ratio. GCCMs are often used to line channels and culverts that naturally contain horizontal or concave surfaces that will pool water, so it is therefore likely that even if hydrated by spraying, some parts of a GCCM will cure under fully immersed conditions as illustrated in Figure 2. Immersed curing results in the highest water/cement ratio the GCCMs will be subjected to, resulting in the lowest in-service compressive strength and (according to BR331) the poorest durability of the cementitious material. It is critical that the performance of a construction material is assessed based on the physical properties present at the weakest point in the structure, as a failure will usually occur at this location. It is therefore critical to understand the in-service performance of GCCMs that have been hydrated by full immersion.

Figure 2. GCCM hydrated by surface spraying resulting in pooling water in the invert. These parts of the GCCM structure cure in immersed conditions.

ASTM D8030 specifies the procedure for the hydration and curing of GCCM material for subsequent physical property testing. This standard specifies that GCCMs are hydrated by full immersion for 24 hours to represent in-field hydration conditions.

Hydration of GCCM test specimens by surface spraying is not permitted in ASTM D8030. Spraying using a limited quantity of water can produce misleading physical property test results, as the water/ cement ratio can be lower than in parts of the GCCM structure that will cure under the immersed conditions. Using ASTM D8030 will therefore provide cured test specimens that represent worst case in-service cementitious material properties, such as compressive strength.

5 CEMENTITIOUS MATERIAL PERFORMANCE – GCCM COMPRESSIVE STRENGTH TO ASTM D8329

Conventional concrete compressive strength testing (for example ASTM C109) is conducted by casting a cube of cementitious material (typically 50 or 100mm in size) and loading it to failure. Since GCCMs cannot be cast into cubes, the cementitious material must be removed from the GCCM and cast into a cube at the appropriate water/cement ratio prior to load testing.

ASTM C109 and other non-GCCM concrete standards are usually designed for mixed concretes using a pre-determined water/cement ratio, which can be significantly lower than the GCCMs exhibit in actual use, so test results to this standard may not represent real world GCCM performance.

When testing for GCCM compressive strength, it is essential that the water/cement ratio used in the cube testing is representative of the ratio achieved during hydration of the GCCM on site. ASTM D8329 is specific to GCCMs as it determines the representative water/ cementitious materials ratio of a GCCM when hydrated by immersion. This water/ cementitious materials ratio is then used to prepare cube specimens for compressive strength testing.

The water/cementitious materials ratio is not the same as the water/cement ratio of a GCCM. If the cementitious material contains a high percentage of sand, aggregate or other additives, a low water/cementitious material ratio obtained using ASTM D8329 may still result in a high water/cement ratio. It is therefore important when determining the compressive strength of a GCCM that the cementitious material is extracted directly from the unset GCCM test sample so that the formulation is representative of the actual product. Testing of a powder sample only may not be accurate.

ASTM D8364 specifies that when tested at a water/cementitious materials ratio determined to ASTM D8329, Type I, II and III GCCMs to have a minimum 28-day compressive strength of 40, 50 and 60MPa respectively.

6 GCCM TENSILE STRENGTH

The Ultimate Tensile Strength (UTS) of a GCCM is primarily governed by the geosynthetic components within the composite. As cementitious materials typically have lower tensile strength than geosynthetics, when testing the tensile strength of a cured GCCM, multiple cracks will typically form in the cementitious material at low strains, transferring loads to the reinforcing fibres until the UTS of the GCCM is reached.

ASTM D8364 requires three tensile strength properties to be reported. The first is the UTS, or final strength of the GCCM its uncured state. Uncured tensile strength at fast loading rates is required when installing the GCCM as it might be suspended, stressed, and dragged on the job site. Once the GCCM has cured and is in service, the material may be stressed at perimeter and intermediate anchors when resisting hydraulic shear forces or wind uplift, which would be at a slower rate of strain. Two cured tensile strength properties must be reported; the Initial Tensile Strength when the cementitious material first cracks, and the

Final Tensile Strength (UTS) of the GCCM. Note the cementitious material could have cracked and effectively failed long before reaching the UTS, so designers need to be mindful when using tensile strength values in their designs and Initial Tensile Strength values are typically recommended for anchorage design.

It should also be noted that the top geosynthetic layer in a GCCM may be exposed to degradation from abrasion, especially in watercourse lining applications with high levels of sedimentation or debris impact, and UV exposure (depending on the composition of the geo-synthetic layer). Several GCCM manufacturers describe their top surface geosynthetic layer to be sacrificial. It is therefore important that reported tensile strength values take account of the effects of environmental degradation, or top geosynthetic layer removal. At the time of writing, the ASTM International Standards Organisation is developing a GCCM specific tensile strength test methodology, which proposes to establish long-term Initial and Final Tensile Strength values by removing the top geosynthetic layer from the cured GCCM material prior to testing.

7 ABRASION RESISTANCE

Abrasive conditions typically occur in GCCM hydraulic applications (such as channelling works or culvert remediation) where the top surface of the lining is subject to a range of water flow velocities and bed loads of silt, sand or cobbles during storm events. These actions can wear the surface of the GCCM and abrasion resistance is therefore an essential property of cured GCCMs.

Since the major contributor to abrasion resistance in GCCMs is the cementitious layer, there are no relevant test methods from within the existing library of geosynthetic standards. GCCM abrasion resistance is therefore best characterised using ASTM C1353 "Test Method Using Taber Abraser for Abrasion Resistance", a simple abrasion test using a rotary plat-form abrader.

The GCCM test specimen is placed in the abrader, two grinding discs are loaded on the top surface of the specimen, which is spun for a defined number of cycles to abrade the GCCM surface. In ASTM D8364, ASTM C1353 is modified to record the depth of wear of the cementitious material after every 1,000 cycles. A low depth of wear represents good abrasion resistance; a higher depth of wear represents a lower resistance to abrasion, meaning over the same duration, more of the GCCM will be abraded away under the same sediment flow conditions. ASTM D8364 specifies that all GCCMs must have a maximum depth of wear of 0.3mm/1000 cycles when tested to ASTM C1353 (modified).

8 SCPECIFICATION OF GCCMS

ASTM D8364 provides a simple way to specify GCCMs for erosion control applications. Using this standard ensures appropriate performance levels are defined and helps to protect Clients, Designers, and Installers against project failures, particularly given the typical life-span of GCCM surface erosion control projects and the likelihood of significant storm events. Designers can specify a GCCM classification Type in accordance with ASTM D8364, and insist that manufacturers provide independent test data showing that their material meets the minimum performance properties when tested to the specified test stan-dards. By using Table 1 of ASTM D8364 Engineers can have the confidence that the design values they are using are representative of in-service GCCM performance.

Where necessary, customers can conduct their own GCCM material testing either them-selves or by engaging test houses to verify properties to GCCM standards, such as ASTM D8058 1-day Flexural Strength and ASTM D8329 28-day Compressive Strength. When engaging a test laboratory, testing should always begin with samples of soft (uncured) material so that the test house can cure the material in accordance with ASTM D8030.

9 CONCLUSIONS

ASTM D8364 is an essential tool for all GCCMs users because it is simple. ASTM D8364 makes specifying the right product easier for the designer whilst ensuring they meet minimum performance requirements, helping to prevent project failures. It is safe, as specifying GCCM Classification Types to ASTM D8364 protects specifiers from designing with GCCM test data that may not be representative of in field GCCM performance, helping ensure the GCCM is suitable for the intended application. And finally, it is secure, as purchasing GCCM's that comply with ASTM D8364 protects contractors and clients from being misled by performance data using inappropriate non-GCCM specific standards that may not represent the performance that can be achieved in the field.

Aero Aggregates of North America, LLC, Eddystone, PA, USA

ABSTRACT: Ultra-lightweight foamed glass aggregate (UL-FGA) is a lightweight and insulating fill material used in the construction of retaining structures, embankments and general grade-raising fill, bridge abutments, and foundation slabs throughout Europe as well as in North America. UL-FGA is granular material that has dry bulk densities ranging from 180–240 kg/m^3 and a closed cell structure which provides good insulation properties and minimal water absorption. This sustainable material has a favorable carbon footprint in part because it is manufactured using recycled glass cullet. Most UL-FGA applications require a separation geotextile fabric to be installed in conjunction with the UL-FGA as the geotextile is critical in maintaining the UL-FGA layer's ultra-lightweight and highly insulating properties over the design life of the project. Additionally, there are UL-FGA applications where the UL-FGA layer is providing water storage and thus the filtration characteristics of the geotextile need to be understood. This paper summarizes the characteristics of geotextiles serving the separation and/or filtration functions in various UL-FGA applications over the design life of the project.

1 INTRODUCTION

Ultra-lightweight foamed glass aggregate (UL-FGA) has been a commercially manufactured product since the 1990s. The primary raw material used for production of UL-FGA is recycled glass. Closed-cell UL-FGA is used as an insulation or lightweight fill layer on infrastructure, commercial, and residential construction projects. It is also utilized as retaining wall or bridge abutment backfill where the low density and high friction angle (40-55 degrees) [Auvinen 2013; Arulrajah *et al.* 2015; Loux *et al.* 2019b; Swan *et al.* 2016] reduce lateral earth pressures significantly compared to normal weight fill. While the direct material cost of UL-FGA per unit volume is generally higher than mined aggregates in most of the U.S., it is competitive with other types of lightweight or insulating fill (e.g. expanded shale, clay, or slate, cellular concrete, and expanded or extruded polystyrene). Details regarding the history, manufacturing of closed-cell foamed glass aggregate via the dry-process of foaming, and applications are documented in the literature (e.g., Aabøe *et al.* 2005; Loux *et al.* 2019a; Zegowitz 2010).

The low density of UL-FGA permits large single truckload quantities of approximately 75 m^3 per load in North America (Loux *et al.* 2019a) and up to 120 m^3 per load in Europe. This is a major advantage compared to shipping in dump trucks that typically hold between 8 and 12 m^3 per load, decreasing the amount of truck traffic at the project site (Auvinen *et al.* 2013), and it makes UL-FGA an economically feasible option even for project locations that are a significant distance from the manufacturing plant (Loux *et al.* 2019a).

UL-FGA is placed and compacted according to a method specification. While the exact recommendations vary by supplier, typical procedures recommend compaction with tracked equipment (having between 30 to 50 kPa ground pressure) at 0.6 to 1 m thick lifts or with a vibratory plate compactor (50 to 200 kg) at 0.3 to 0.5 m thick lifts (Loux et al. 2019a). A roller is not used to compact UL-FGA in most applications. The compaction factor, defined as the ratio of bulk to in-place volume, for dry-process UL-FGA, will vary slightly based on the placement and compaction procedures. McGuire et al. (2021) reports a compaction factor of 1.08 to 1.20, excluding the effects of compaction due to leveling each lift, and Aabøe et al. (2005) reports values between 1.2 and 1.3. Therefore, an average compaction factor of approximately 1.25 is reasonable for estimating purposes.

2 UL-FGA PROPERTIES

2.1 Density

The low density of UL-FGA drives many of the uses and application for the product. Most dry-process UL-FGA has bulk densities between approximately 180 and 240 kg/m^3. Once the 1.25:1 compaction factor and moisture content of approximately 25% by mass, or 6% by volume, is accounted for, the in-place density falls between approximately 281 and 375 kg/m^3. (Auvinen et al. 2013; Arulrajah 2015; Loux et al. 2019a).

2.2 Gradation

As manufactured, UL-FGA has nominal particle sizes between approximately 10 and 60 mm with up to 15% by mass allowed under or over these limits. Some crushing occurs when the UL-FGA layer is placed and compacted resulting in an overall decrease in particle size; however, this particle breakage does not typically generate significant fines and any fines that are created are nonplastic. Typically, both the pre- and post-compaction gradation yields a GP classification per the Unified Soil Classification System criteria (Arulrajah 2015; Loux et al. 2019a).

2.3 Particle shape

Immediately after production, UL-FGA has sharp edges and may have a blocky particle shape. However, due to material handling and the temperature equalization process, delivered material will have rounded edges and is frequently more subangular in shape. The placement and compaction process tends to increase angularity due to the particle breakage of the blockier pieces that occurs as the material is seated. There is no evidence that changes to particle shape during handling, placement, and compaction elevate the potential for damage to geotextiles, which the authors speculate is due to the offsetting effects of increased angularity by particle fracture and decreased angularity from crushing of particle corners.

2.4 Permeability

Constant head permeability testing on UL-FGA indicates a permeability on the order of 1 cm/sec (Loux et al. 2019a) and accessible porosity for flow is approximately 38% or higher (Loux and Filshill 2021). This permeability result aligns with other similarly classified coarse aggregates (U.S. Department of Agriculture 1984).

2.5 pH

The chemical composition of UL-FGA is derived from the container (soda-lime) glass that is used in manufacturing. As such, there is a significant amount of sodium (an alkali element) ions in the internal structure of UL-FGA. pH testing methods for soils and aggregates subject samples to a liquid water bath for a given amount of time. Typical pH testing results

on powdered UL-FGA is between 10-11 (Arulrajah 2015); however, modified test methods that maintain the in-service gradation yield results closer to 9 (Loux *et al.* 2019b). The reason for this difference is the significant role that particle surface area plays in the dealkalization process that is occurring in the glass during a pH test.

3 GEOTEXTILES

3.1 *Definition and functions*

ASTM D4439 defines a geotextiles as "a permeable geosynthetic comprised solely of textiles." Geotextiles are used with foundation, soil, rock, earth, or any other geotechnical engineering-related material as an integral part of a human-made product, structure, or system. The original use of geotextiles was as a replacement for granular filters; thus, their early moniker of "filter fabrics" was born. In recent years, approximately 95% of geotextiles are manufactured from the polymer polypropylene (Koerner 2016). Geotextiles may be described by their fiber type (monofilament, multifilament, staple fiber yarn, slit-film monofilament, or slit-film multifilament) and method of fabric construction (most commonly woven or nonwoven for geosynthetics). Koerner (2016) provides a thorough discussion of geotextile manufacturing methods and types.

The major functions that geotextiles may serve include separation, filtration, drainage, and reinforcement. The separation function involves keeping dissimilar materials from mixing and can be seen when geotextiles are used between subgrade and stone bases in paved/unpaved roadways. When placing a coarse aggregate on fine-grained soils without a fabric, there are two mechanisms that occur over time. First, the finer soil particles enter the voids of the coarse aggregate and decrease its permeability. Secondly, the coarse aggregate intrudes into the finer soil, thereby decreasing the strength of the coarse aggregate (Koerner 2016).

The filtration function allows for cross-plane flow and the use of geotextiles in lieu of granular filters is a primary example. In this function, there is a balance between allowing adequate flow rates across the plane of the geotextile while limiting the migration of the finer soil across the plane of the geotextile and into the coarse aggregate. There are many approaches to soil-retention design. Most methods compare the soil particle sizes to the O_{95} value (the 95% opening size) for the geotextile. ASTM D4751 employs a dry-sieving process to determine the O_{95}, referred to as the apparent opening size (AOS) in this testing. While the O_{95} and AOS refer to the same pore size, the O_{95} is the corresponding sieve opening in millimeters while the AOS is the U.S. Standard sieve number. Outside of the U.S., wet or hydrodynamic sieving is commonly used to determine the O_{95}, referred to as the filtration opening size (FOS) in these tests (Koerner 2016).

The drainage function represents supporting in-plane flow and an example use may be as a drainage blanket beneath a surcharge fill or railroad ballast. Lastly, the reinforcement function serves to enhance the strength of weak soils or other materials. Geotextile-reinforced walls and slopes are an example of geotextiles serving this function (Koerner 2016). This paper limits discussion to the first two functions, separation and filtration, in applications where geotextiles will be in contact with UL-FGA.

3.2 *Design and construction considerations*

3.2.1 *Abrasion/installation damage*

Polypropylene fibers have been shown to have good abrasion resistance compared to other polymers (Galanti 1964). For applications of geotextiles in contact with UL-FGA, the installation damage caused by the placement of UL-FGA compared to a mined coarse aggregate, such as AASHTO #57 stone, is decreased for most geotextiles and geogrids (Koerner *et al.* 2023).

3.2.2 Clogging

The simplified design procedure proposed by AASHTO for filtration design considers the percentage of soil passing the No. 200 sieve (0.074 mm opening size). If the fine-grained soil has ≤ 50% passing the No. 200 sieve, then the required O_{95} for the fabric is < 0.60 mm. If the fine-grained soil has > 50% passing the No. 200 sieve, then the required O_{95} for the fabric is < 0.30 mm (Koerner 2016). After handling, placement, and compaction, the percentage of UL-FGA passing the No. 200 sieve is far below 50%, therefore, the O_{95} sizing is expected to be controlled by the subgrade soil.

3.2.3 Chemical compatibility/ UV degradation

The most popular polymer for geotextile production, polypropylene, is exceptionally chemically resistant (Galanti 1964) and is stable within a pH range of 2 through 13. Since UL-FGA is expected to exhibit an in-service pH between 9-10, insignificant impacts on chemical degradation of the polymer are expected due to contact with the UL-FGA. Most polypropylene geotextiles are produced with a UV stabilization package that is proprietary and specific to the manufacturer (Koerner 2016). However, even with this additional protection from UV degradation, there will be practical limits to the UV exposure for the geotextile. In particular, nonwoven geotextiles, because of the very small fiber sizes, uncovered exposure time is generally limited to 14 days. Contact between UL-FGA and the geotextile is not expected to pose unique impacts to UV resistance as compared with mined aggregates.

3.2.4 Overlap/seaming

Most UL-FGA applications require a separation geotextile fabric to be installed to completely surround the UL-FGA where it is in contact with another granular material. The geotextile is critical in maintaining the UL-FGA layer's ultra-light weight and high insulating properties over the design life of the project. In order to construct the geotextile so that it is a continuous wrap around the UL-FGA layer, the roll edges may be either overlapped or seamed together. A standard overlap distance of 0.3 m is sufficient in most cases. If significant movement is expected, as with soft subgrade soil, the overlap distance may be increased to ensure continuous coverage at the geotextile-UL-FGA interface.

3.2.5 Cover soil

UL-FGA is typically covered in service to ensure that the layer remains intact during the design life of the project. As such, the top and sides of the UL-FGA layer usually have cover soil or rip rap placed on the geotextile wrap of the UL-FGA. It is important to evaluate the veneer stability of the cover soil based on the steepness of the slope and the properties of the proposed cover material.

3.2.6 Design by specification

A common specification used in the U.S. for geotextiles on highway projects is AASHTO M 288. This specification is intended to ensure good long-term performance of geotextiles in the applications of subsurface drainage, separation, stabilization, erosion control, temporary silt fence, and paving fabrics. Suitable geotextiles must meet requirements for material quality and be able to withstand installation without excessive damage.

This specification sets forth general requirements for three geotextile classes – Class 1, Class 2, and Class 3; Class 1 geotextiles have the highest strength requirements and Class 3 geotextiles have the lowest strength requirements. High-strength geotextiles, e.g. those belonging to Class 1, can survive harsh installation conditions better than low-strength geotextiles, e.g. those belonging to Class 3. Thus, as the requirements for survivability decrease, a higher Class of geotextile, by number, may be used. The survivability requirements of the geotextile are a function of the subgrade conditions, the ground pressure from construction equipment, and the lift thickness as shown in Table 1. As subgrade conditions improve and lower ground pressure equipment is used, the survivability requirements for the

Table 1. Required degree of survivability as a function of subgrade conditions, construction equipment ground pressure, and lift thickness (Class 1, 2, and 3 properties are given in Table 2; Class 1+ properties are higher than Class 1, but not defined here and, if used, must be specified by the purchaser)[a] (adapted from AASHTO M 288).

	Low Ground-Pressure Equipment ≤25 kPa (3.6 psi)	Medium Ground-Pressure Equipment > 25 to ≤50 kPa (>3.6 to ≤7.3 psi)	High Ground-Pressure Equipment >50 kPa (>7.3 psi)
Subgrade has been cleared of all obstacles except grass, weeds, leaves, and fine wood debris. Surface is smooth and level so that any shallow depressions and humps do not exceed 450 mm (18 in.) in depth or height. All larger depressions are filled. Alternatively, a smooth working table may be placed.	Low (Class 3)	Moderate (Class 2)	High (Class 1)
Subgrade has been cleared of obstacles larger than small to moderate-sized tree limbs and rocks. Tree trunks and stumps should be removed or covered with a partial working table. Depressions and humps should not exceed 450 mm (18 in.) in depth or height. Larger depressions should be filled.	Moderate (Class 2)	High (Class 1)	Very High (Class 1+)
Minimal site preparation is required. Trees may be felled, delimbed, and left in place. Stumps should be cut to project not more than ±150 mm (±6 in.) above subgrade. Geotextile may be draped directly over the tree trunks, stumps, large depressions and humps, holes, stream channels, and large boulders. Items should be removed only if placing the geotextile and cover material over them will distort the finished road surface.	High (Class 1)	Very High (Class 1+)	Not Recommended

[a]Recommendations are for 150 to 300 mm (6 to 12 in.) initial lift thickness. For other initial lift thicknesses:
1. >300 to 450 mm (12 to 18 in.): reduce survivability requirement one level (i.e., increase Class number by one level);
2. >450 to 600 mm (18 to 24 in.): reduce survivability requirement two levels (i.e., increase Class number by two levels);
3. >600 mm (24 in.): reduce survivability requirement three levels (i.e., increase Class number by three levels). For special construction techniques such as prerutting, increase the geotextile survivability requirement one level. Placement of excessive initial cover material thickness may cause bearing failure of the soft subgrade.

geotextile are lessened. Similarly, greater initial lift thicknesses are expected to impart more uniform stresses to the geotextile during installation and lower the survivability/strength requirements. Table 2 lists the geotextile strength properties requirements for Class 1, 2, and 3 geotextiles.

The equipment commonly utilized for UL-FGA placement is within the "Medium Ground Pressure" category in Table 1. The survivability/ geotextile Class recommendations within Table 1 are based on a 150 to 300 mm initial lift thickness, and the footnote recommends a one-level reduction in the survivability requirement (thus, an increase in the Class number by one) for initial lift thicknesses >300 mm to 450 mm, a two-level reduction in the survivability requirement (thus, an increase in the Class number by two) for initial lift thicknesses >450 mm to 600 mm, and a three-level reduction in the survivability requirement

Table 2. Geotextile strength property requirements (AASHTO M 288).

	Test Methods	Units	Geotextile Class [a,b,f]					
			Class 1 (severe)		Class 2 (typical)		Class 3 (moderate)	
			woven[c]	nonwoven[c]	woven[c]	nonwoven[c]	woven[c]	nonwoven[c]
Grab strength	ASTM D4632	N	1400	900	1100	700	800	500
Sewn seam Strength [d]	ASTM D4632	N	1260	810	990	630	720	450
Tear strength	ASTM D4533	N	500	350	400[e]	250	300	180
Puncture strength	ASTM D6241	N	2750	1925	2200	1375	1650	990

[a]Required geotextile class is designated by the indicated application. The severity of installation conditions for the application generally dictates the required geotextile class. Class 1 is specified for more severe or harsh installation conditions where there is a greater potential for geotextile damage, and Classes 2 and 3 are specified for less severe conditions.
[b]All numeric values represent MARV (Minimum Average Roll Value) in the weaker principal direction.
[c]Woven corresponds to elongation <50% and nonwoven corresponds to elongation $\geq$ 50% as measured in accordance with ASTM D 4632.
[d]When sewn seams are required.
[e]The required MARV tear strength for woven monofilament geotextiles is 250 N.
[f]Minimum property values for permittivity, AOS, and UV stability are based on geotextile application.

(thus, an increase in the Class number by three) for initial lift thicknesses >600 mm. Also, it is noted the recommendations in Table 1 are based on the use of normal-weight mineral aggregates (e.g., AASHTO #57 stone) or fill as the initial lift materials. Given the unit weight and low installation damage expected from UL-FGA, the authors suggest that an additional one-level class reduction beyond the survivability requirements shown in Table 1, including the allowance for initial lift thickness, may be warranted for UL-FGA. For example, if subgrade conditions, installation equipment, and the initial lift thickness lead to the recommendation of a Class 2 geotextile based on mined aggregate or normal weight fill as the initial lift material, a Class 3 textile may be used when UL-FGA is the initial lift material and all other conditions remain unchanged.

Beyond the survivability requirements for the geotextile, other properties of the geotextile are relevant in the different applications covered within the AASHTO M 288 specification. For subsurface drainage and separation geotextiles, the authors do not recommend any deviation from the requirements in the AASHTO M288 specification when UL-FGA is used in lieu of mined aggregate or normal weight fill.

4 CONCLUSIONS

Ultra-lightweight foamed glass aggregate is manufactured from recycled glass and has a combination of physical and engineering properties that include low unit weight, high friction angle, high permeability, and high porosity. Both the pre- and post-compaction gradations yield a GP classification per the USCS criteria. Approximately 95% of geotextiles manufactured today use polypropylene fibers, which have been shown to have good abrasion resistance compared to other polymers and be stable within a pH range of 2 through 13. UL-FGA has an in-service service pH between 9-10, thus insignificant chemical degradation

is expected due to the UL-FGA. For applications of geotextiles in contact with UL-FGA, the installation damage caused by the placement of UL-FGA compared to a mined coarse aggregate, such as AASHTO #57 stone, is expected to decrease for most geotextiles. Accordingly, the authors recommend increasing the Class number by one level, i.e. lower the survivability requirement one level, for geotextiles when used with UL-FGA as the initial lift material.

ABSTRACT: Geosynthetic clay liners (GCLs) are factory-manufactured products used in various applications mainly for containment purposes. The type of construction, as well as the anticipated function determine the technical requirements that GCLs must fulfil. There are many laboratory test methods that can be used for the characterization of GCLs. Among other tests, the swell index test and the Enslin-Neff water-adsorption test are used for quality control in manufacturing and as performance indicators for the mineral component, i.e. bentonite clay. The paper presents the findings of within-laboratory evaluation of measurement uncertainty in bentonite swell index and water-adsorption testing, and the evaluation of some requirements of the standard test method, such as the influence of time and temperature of drying for the sample preparation phase or the influence of different observers. No statistically significant deviations from normality were found for the Enslin-Neff water-adsorption test. The F-test and t-test were performed to compare variances and means for the same observer at two drying temperatures, as well as for two observers at the same temperature, with some differences. The results of the detailed statistical analysis indicate that the assessment of the measurement uncertainty type A was properly estimated.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) are factory-manufactured assembled products consisting of geosynthetic and mineral components (usually natural sodium bentonites or sodium activated bentonites). They are increasingly used in geotechnical, hydrotechnical, mining and environmental applications as hydraulic barriers. The type of construction, as well as the anticipated function determine the technical requirements that GCLs as a composite material must fulfil. The mineral component that provides the sealing function continuously undergoes quality control, from the production and construction phase (MQC, MQA, CQC and CQA) to the end of its lifespan (long-term properties or durability).

The list of different testing methods for GCL components and the final product has been growing since 1990s. Within the framework of ASTM more than fifteen standards are active, covering mainly laboratory testing methods for the determination of physical, index, mechanical and hydraulic characteristics, but also guides and practices for storage, installation and quality control. The same trend of an increasing number of standard testing methods for GCLs can be found in the EU as well. With the given quality control measurements and standardization of testing methods the confidence among producers, designers and users can be properly established.

It is assumed that the exceptionally good swelling properties of the mineral component (bentonite) guarantee the sealing function and self-healing potential as well. There are many

laboratory test methods that can be used for the characterization of bentonites. It is common practice to perform chemical and mineralogical characterization of bentonites especially in the production phase. For practical civil engineering applications, physical and index testings of bentonites are more acceptable as they are used in everyday practice of geotechnical laboratories, are simple to perform and are relatively cheap. Besides, various correlations between index and other engineering properties are commonly used for the prediction of design parameters.

Among other tests, the swell index test (ASTM D5890) and Enslin-Neff water adsorption test (DIN 18132) are almost inevitably used for quality control in manufacturing and as the performance indicator for the mineral component i.e. bentonite clay. To assist the users of GCL products, ASTM developed two standards (ASTM D 5889 and ASTM D 6495), in which various properties are listed, together with the appropriate test methods and testing frequencies that should be applied as part of MQC and/or CQA.

Besides, the compatibility of the GCLs mineral component with various liquids or soils can be derived by performing swell index (ASTM D 5890) and fluid loss (ASTM D 5891) tests in accordance with ASTM D 6141. If the GCLs mineral component preserves its swelling properties when site-specific liquid or some other testing fluid is used instead of water, then it is assumed that it is chemically compatible. Otherwise, additional, more time-consuming and expensive testings may be warranted in order to prove its sealing properties (Erickson & Jasionek 2004).

In view of the above, index testing is inevitable and very often performed in the GCLs production phase, then during the construction phase until the end of the lifespan of its various structures. This paper presents the findings of the within-laboratory evaluation of measurement uncertainty in bentonite swell index and water-adsorption testing, and the evaluation of some requirements of the standard test methods, such as the influence of drying time and temperature in the sample preparation phase or the influence of different observers.

2 MATERIALS AND METHODS

Sodium activated bentonite, which is used as drilling mud in petroleum engineering and as a waterproof barrier in civil engineering applications, was chosen from a local producer. In order to evaluate the homogeneity of bentonite samples, Atterberg limits test were conducted on six representative samples from the same batch delivered by the producer in the same form as for commercial purposes i.e. in a bag (total mass of 30 kg). The range of obtained liquid limit values, w_L were between 380% and 391% with a standard deviation of 3.9%, and for the plastic limit, w_P were between 42% and 45% with a standard deviation of 0.9%, thus confirming the homogeneity of the tested samples.

The swell index test (ASTM D5890) and Enslin-Neff water adsorption test (DIN 18132) were performed on 120 samples in total for both methods (30 samples with the drying temperature of 60°C or 105°C each, and 30 samples by the first and the second observer each). The results for both methods with statistical analysis are presented in the next section. The ASTM D5890 standard test method appeared in a revised version in 2019 providing the expected precision for within- and inter-laboratory repeatability and reproducibility limits in terms of coefficients of variation. Previous research also showed that test results are mainly influenced by the careful addition of bentonite into the glass cylinder. In other words, the influence of the examiner seems to be the most important one (Olsta et al. 2004).

The water adsorption test was originally proposed by Enslin in 1933 and improved several times later on. Today it is mainly used in the clay industry, civil engineering and soil science under the name Enslin-Neff method (Kaufhold & Dohrmann 2008). In Germany this method is standardized (DIN 18132). Many authors have identified that the reproducibility of the Enslin-Neff method is strongly influenced by the laboratory ambient conditions, particularly temperature and relative humidity. This test is broadly accepted also as a quick method for the estimation of the mineral composition of clay materials, since

montmorillonites (bentonites) possess a large swelling capacity, as opposed to kaolinites or other clay minerals. For environmental applications, sodium bentonites or sodium activated bentonites are used for the production of GCLs as a hydraulic barrier. This test can, therefore, be used for the manufacturing quality control of the mineral component in the GCLs production stage, but also as a simple and quick method for construction quality control purposes or the estimation of long-term properties (DGGT 1993, 2002).

3 RESULTS AND STATISTICAL ANALYSES

According to the JCGM 100 "uncertainty (of measurement) is a parameter, associated with the result of a measurement, that characterizes the dispersion of the values that could reasonably be attributed to the measurand". In this paper, the type A evaluation of uncertainty is used which is based on the statistical analysis of laboratory data sets. The uncertainty in measurements is expressed using the arithmetic mean, standard deviation and coefficient of variation. The coefficient of variation as the relative standard deviation is a dimensionless measure of variability which enables comparing the precision of different methods.

As mentioned before, the swell index test (ASTM D5890) and Enslin-Neff water adsorption test (DIN 18132) were performed. Type III reagent water was used in all tests. The results of the measurement were determined on the basis of laboratory data sets obtained under repeatability conditions, r (the same: measurement procedure, observer, measuring instrument, conditions at the same location) and under reproducibility conditions, R (the changed parameter was the observer and drying temperature for the sample preparation).

The swell index test results are summarized in Table 1 for 120 tests in total, performed by two observers and by using two drying temperatures in the sample preparation phase.

Table 1. Swell index test results (in ml/2 g).

Statistical parameter*	Units	1st observer	2nd observer	1st observer	2nd observer
		Drying temperature for sample preparation			
		60°C		105°C	
min/max $value$	ml	22.5/24.5	24.0/25.0	24.0/24.5	24.0/24.5
$\overline{x}$	ml	23.7	24.5	24.4	24.3

$u_r = \frac{s_r}{\sqrt{n}}$	ml	0.11	0.06	0.06	0.04
$CV_r = \frac{s_r}{\overline{x}} \cdot 100$	%	2.49	1.25	1.37	0.99
$r = 2\sqrt{2}s_r$	ml	1.65	0.86	0.94	0.67
$\overline{x}$	ml	24.08		24.41	
$s_R = \left(\dfrac{\sum_{k=1}^{2n}(x_k-\overline{x})^2}{2n-1} \right)^{1/2}$	ml	0.64		0.30	
$u_R = \frac{s_R}{\sqrt{2n}}$	ml	0.08		0.04	
$CV_R = \frac{s_R}{\overline{x}} \cdot 100$	%	2.65		1.22	
$R = 2\sqrt{2}s_R$	ml	1.79		0.83	
$U_{rel} = \frac{u_R}{\overline{x}} \cdot 100$	%	0.34		0.16	

*NOTES: s - standard deviation, u - standard uncertainty, CV - coefficient of variation, U_{rel} - relative uncertainty, r - repeatability, R - reproducibility, n=30.

Table 2. Enslin-Neff water adsorption test results, w_A (in %).

Statistical parameter*	Units	1st observer	2nd observer	1st observer	2nd observer
		\multicolumn — Drying temperature for sample preparation			
		60°C		105°C	
min/max *value*	%	377.5/700.0	477.5/720.0	477.5/737.5	460.0/647.5
$\overline{x}$	%	540.1	569.0	586.4	559.9
$s_r = \left(\dfrac{\sum_{k=1}^{n}(x_k-\overline{x})^2}{n-1}\right)^{1/2}$	%	73.46	52.05	51.81	41.67
$u_r = \frac{s_r}{\sqrt{n}}$	%	13.41	9.50	9.46	7.61
$CV_r = \frac{s_r}{\overline{x}}\cdot 100$	%	13.60	9.15	8.84	7.44
$r = 2\sqrt{2}s_r$	%	205.69	145.74	145.07	116.68
$\overline{x}$	%	554.55		573.13	
$s_R = \left(\dfrac{\sum_{k=1}^{2n}(x_k-\overline{x})^2}{2n-1}\right)^{1/2}$	%	64.78		48.48	
$u_R = \frac{s_R}{\sqrt{2n}}$	%	8.36		6.26	
$CV_R = \frac{s_R}{\overline{x}}\cdot 100$	%	11.68		8.46	
$R = 2\sqrt{2}s_R$	%	181.39		135.75	
$U_{rel} = \frac{u_R}{\overline{x}}\cdot 100$	%	1.51		1.09	

*NOTES: s - standard deviation, u - standard uncertainty, CV - coefficient of variation, U_{rel} - relative uncertainty, r - repeatability, R - reproducibility, n=30.

An inter-laboratory study of the test was performed in 1999 (ASTM D5890) for seven clay samples and ten laboratories, showing the within-laboratory repeatability limit, CV_r % of 2-5%. The statistical analyses of our laboratory data sets showed a CV_r % from 1 to 2.5, which is in line with the ASTM D5890 precision requirement.

As the test results are presented according to the standard requirements to the nearest 0.5 ml, they do not follow the normal distribution, and it was impossible to perform the standard statistical analyses. Nevertheless, at the drying temperature of 60° the results obtained by the first observer are more dispersed (indicated by a greater standard deviation) compared to the results of the second observer, which also leads to a relatively high reproducibility; this difference between the two observers is smaller at the temperature of 105°. The results of the detailed statistical analysis indicate that the assessment of the measurement uncertainty type A was properly estimated. Also, the calculated relative uncertainty, U_{rel}, shows that the measurement uncertainty was reasonably estimated.

The water adsorption test results are summarized in Table 2 for 120 tests in total, performed under the same conditions as mentioned for the swell index testing.

Figure 1 summarizes all test results, for both observers and drying temperatures. Figures 2 and 3 show the comparison between two observers under the same drying temperature, 60°C or 105°C, respectively.

At both drying temperatures the results obtained by the first observer are slightly smaller and more dispersed compared to the results of the second observer; this difference between the two observers is slightly more visible at the temperature of 105°.

The Shapiro-Wilk test for normality was performed in the R programming language for the measurement results for each observer and each drying temperature, as well as the combined results for each temperature. No statistically significant deviations from normality
Figure 1. Water adsorption test results for two observers under two drying temperatures.
Figure 2. Water adsorption results for two observers and the drying temperature of 60°C.
Figure 3. Water adsorption results for two observers and the drying temperature of 105°C.

were found at significance level of 5% for all data sets. The F-test and t-test were performed in R to compare variances and means for the same observer at two drying temperatures, as well as for two observers at the same temperature. There were no significant differences found at 5% significance level, except for the first observer at two temperatures (the mean is smaller at 60°) and for two observers at the temperature of 105°C (the mean is larger for the first observer). A certain difference in variability between the two temperatures was observed by testing at the 5% significance level for combined results of the two observers (the variability is larger at 60°), while no statistically significant difference was found between their means.

As for the swell index test, the results of the detailed statistical analysis indicate that the assessment of the measurement uncertainty type A was properly estimated, giving a slightly

higher relative uncertainty, U_{rel}, which is probably due to the greater influence of the laboratory ambient conditions.

4 DISCUSSION AND CONCLUSION

The mineral component of GCL determines its hydraulic conductivity and sealing function. In the production stage, the clay mineral component (bentonite) can be obtained from various producers and deposits, with variable composition and quality. The swell index test (ASTM D5890) and water adsorption test (DIN 18132) are commonly used as simple and quick testing methods for the QC and QA in the production and construction stage, as well as for the control of the durability of GCLs in various structures and environments.

To examine the sensitivity of the swell index and water adsorption regarding variations in the test procedure, 120 tests were performed for both methods by two observers, using two temperatures ($60°C$ and $105°C$) in the sample preparation phase. All tests were performed in the same laboratory that was not conditioned (air temperature and relative humidity was changeable) intentionally to mimic the practice in many commercial laboratories.

Our test results and statistical analysis showed that statistically significant deviations from normality for all data sets were not found at the significance level of 5%. The F-test and t-test were performed in R to compare variances and means for the same observer at two drying temperatures, as well as for two observers at the same temperature. There were no significant differences found at the 5% significance level, except for the first observer at two temperatures; for two observers at the temperature of $105°C$, and between the two temperatures for combined results of the two observers.

The results of the detailed statistical analysis indicate that the assessment of the measurement uncertainty type A was properly estimated for both testing methods. Also, the calculated relative uncertainty, U_{rel} for the swell index test shows that the measurement uncertainty was reasonably estimated. A slightly higher relative uncertainty for the water adsorption test was probably caused by a greater influence of the laboratory ambient conditions. To conclude, our research showed that even in a non-conditioned laboratory, reproducibility and repeatability for the swell index and water adsorption test results can be obtained.

Shear strength prediction of fiber–reinforced soils based on direct shear test results

I.N. Markou, E.D. Evangelou & D.G. Chalkos
Democritus University of Thrace, Xanthi, Greece

ABSTRACT: The present study aims at the development of a model for the shear strength prediction of any type of soil reinforced with synthetic fibers of circular cross-section. A database was created from the available literature comprising experimental results of direct shear tests conducted in soils ranging from sands to clays, reinforced with polypropylene and nylon fibers. The shear stress at failure of fiber-reinforced soils was correlated to independent variables pertinent to the soil, fiber, and laboratory test by performing multivariable ordinary linear regression analyses of the experimental results with suitable statistical software. The model with the best performance exhibits a coefficient of multiple determination, R^2, equal to 0.96 and estimates successfully the experimental results used for model testing at a rate equal to 77%. The predictions of the shear strength parameters of fiber-reinforced soils, based on the proposed model, are in reasonable agreement with the measured values after applying appropriate reduction factors.

1 INTRODUCTION

Soil reinforcement with geogrids, geotextiles, metal strips, fibers etc. is an effective technique for increasing the strength and stability of the soil in various applications, including retaining structures, embankments, foundations, slopes and pavements. As the fiber inclusions bring several technical, economic and environmental benefits, in recent years, a great deal of interest has been created worldwide on the potential applications of fibers within the soils and other similar materials, such as coal ashes and mine tailings (Shukla 2017). Fibers are generally available in natural, synthetic and waste forms. Synthetic fibers made of polymers, such as polypropylene, polyester and polyethylene, are superior to natural fibers in terms of mechanical behavior, standardization and durability over time. Nevertheless, natural fibers emanating from various plants are used in countries where they are available in large amounts. Utilization of waste fibers in constructions can solve their disposal problems in a cost-effective and environmentally friendly manner.

Over the past 30–35 years, the laboratory and field research studies have shown that the use of fibers as a tension-resisting element and/or an admixture causes significant modification and improvement in the engineering properties (strength, stiffness, permeability, compressibility, etc.) of soils and other similar materials (Shukla 2017). The improvement of soil shear strength due to fiber reinforcement is investigated in the laboratory using mainly direct shear and triaxial compression tests (e.g. Anagnostopoulos *et al.* 2014; Atom & Al-Tamini 2010; Benziane *et al.* 2019; Chen 2010; Diab *et al.* 2016; Esna-Ashari & Asadi 2008; Falorca & Pinto 2011; Hejazi *et al.* 2014; Kar *et al.* 2010; Lirer *et al.* 2011; Mirzababaei *et al.* 2018; Pradhan *et al.* 2012; Santiago *et al.* 2013; Zaimoglu & Yetimoglu 2012). Test results have shown that the strength of fiber-reinforced soil depends on several factors such as: fiber content, fiber geometric characteristics, confining pressure or normal

stress and soil characteristics. The trustworthy prediction of the shear strength of fiber-reinforced soils can facilitate the reliable design and enhance the utilization of fiber-reinforced soils in civil engineering projects. As a result, attempts have been made to develop models for the estimation of the strength of fiber-reinforced soil, either by analytical solutions (Michalowski & Cermák 2003; Michalowski 2008; Shukla 2017; Zornberg & Li 2003) or by statistical processing (Dutta &Venkatappa 2007; Lirer *et al.* 2011; Maliakal & Thiyyakkandi 2013; Ranjan *et al.* 1996; Sivakumar Babu & Vasudevan 2008). In most cases, the development of these models was based solely on the experimental results of the same research effort and the produced models refer to specific type of soil, i.e. sand or clay. Also, some of these models cannot be applied easily as they employ parameters difficult to determine.

The abovementioned information indicates that a practical tool, applicable to any type of soil and based on simple parameters pertinent to the soil and fiber, could be an efficient means for shear strength prediction of fiber-reinforced soils. The study reported herein aims toward the development of a prediction tool having these characteristics. Accordingly, this presentation includes: (a) the database created for the purposes of this investigation, comprising shear strength measurements from direct shear tests conducted on various fiber-reinforced soils and found in the literature, (b) development of the new prediction model by performing multivariable ordinary (conventional) linear regression analyses of the obtained experimental results, and (c) documentation of model performance.

2 EXPERIMENTAL MEASUREMENTS

The first step for the development of the strength prediction model was the selection of the variables. The dependent variable should be quantified efficiently and the independent variables should represent factors affecting substantially the shear strength of fiber-reinforced soil. All variables should not hinge on specific materials and procedures. Accordingly, the shear stress at failure, $\tau_{f,r}$, determined by direct shear testing on fiber-reinforced soil was chosen as the dependent variable. Although the cohesion, c, and the friction angle, φ, are generally used for the quantification of shear strength, they were not used as dependent variables because their determination results from test series limiting in this way the number of the available measurements. The dependent variable was correlated to five independent variables pertinent to the soil, the fiber and the testing procedure.

The normal stress, σ_n, used in the direct shear tests was the first independent variable because it has been observed that its increase has a beneficial effect on the strength of fiber-reinforced soil (Qu *et al.* 2013). Due to the large number of factors affecting the behavior of soils, it was decided for simplicity reasons to use the shear stress at failure, $\tau_{f,u}$, of the unreinforced soil as the sole, independent variable representing the soil. The increase of the fiber content in the soil leads to an increase of shear strength up to a limit. Beyond this limit, further increase of fiber content causes an increase of the porosity of fiber-reinforced soil and, as a result, a decrease of its shear strength (Hoare 1979). The fiber cross-section and dimensions (e.g. diameter and length) are also important since they determine the contact surface of the fibers with the surrounding soil (Gray & Al-Refeai 1986). For that reason, the aspect ratio, A_r, (ratio of the fiber length to the fiber diameter) affects the shear strength of fiber-reinforced soil (Sadek *et al.* 2010). Another factor influencing the mechanism of soil reinforcement is the tensile strength of the fiber (Zornberg & Li 2003). Based on this information, the selected independent variables for the fibers are: the content, w_f, (percentage of fibers by weight of dry soil), the tensile strength, $\sigma_{y,f}$, and the aspect ratio, A_r.

For statistical processing, at least 20 measurements are needed for each independent variable used in the model (Coakes & Steed 1999; Field 2009; Harrel 2002). Taking into consideration that the cross-section type of the fiber affects the strength of fiber-reinforced soil, it was decided to use in this study the measurements obtained from direct shear tests

Table 1. Data of selected research studies based on direct shear tests.

				Fiber characteristics				Direct shear tests		
									Shear stress at failure	
				Aspect ratio	Tensile strength	Fiber content		Normal stress	Unreinforced soil	Reinforced soil

*P: Polypropylene, N: Nylon.

conducted on soil specimens reinforced with not crimped fibers of circular cross-section. This preference was dictated by the insufficient number of the available measurements obtained for fibers of other cross-section geometries. After an extensive literature review, the available for statistical analysis set of 219 measurements of the shear strength of fiber-reinforced soils, ranging from sands to clays and including values for all abovementioned independent variables, is presented in Table 1. These measurements were obtained from unconsolidated–undrained (UU), consolidated–undrained (CU) and consolidated–drained (CD) direct shear tests reported by Mirzababaei *et al.* 2018 [1], Anagnostopoulos *et al.* 2014 [2], Hejazi *et al.* 2014 [3], Falorca & Pinto 2011 [4], Pradhan *et al.* 2012 [5], Zaimoglu & Yetimoglu 2012 [6], Kar *et al.* 2010 [7], Atom & Al-Tamini 2010 [8] and Esna-Ashari & Asadi 2008 [9], and indicate shear strength increase of the soil due to fiber reinforcement. A percentage nearly equal to 80% (180 measurements) of the data presented in Table 1 was used for the generation of the model, whereas the remaining 39 measurements (≈20%) were used for the evaluation of the prediction efficiency of the model. This partitioning was made with extreme care in order to maintain the homogeneity and the representativeness of the two samples.

3 DEVELOPMENT AND EFFICIENCY OF MODEL

The preparation of the set of measurements and the selection of the dependent and independent variables were followed by the statistical analysis using the multivariable ordinary linear regression (MVOLR) method. A large number of analyses were performed using a special statistical software in an attempt to develop a model for predicting the value of the shear stress at failure of fiber-reinforced soil, $\tau_{f,r}$, based on the results of direct shear tests. A model developed by applying the multivariable ordinary linear regression method to a set of data, has the following form:

$$y = \alpha_0 + \alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n \tag{1}$$

where y is the dependent variable, $\alpha_0, \alpha_1, \ldots, \alpha_n$ are the partial coefficients and $x_1, x_2, \ldots, x_n$ are the independent variables.

For statistical purposes, the data must be checked for independence and regularity of observations, linearity between dependent and independent variables, equality of

dispersion as well as for the assumption of multi-collinearity and singularity (Norusis 2002). The verification of independence was carried out by using the Durbin – Watson index, which should attain values between 1.0 and 3.0 (Field 2009). The regularity, linearity and dispersion equality were checked using the relevant graphs provided by the software. The existence of multi-collinearity and singularity is not desirable in the analyses and was checked by using the eigenvalue of the covariance matrix, the condition index, the tolerance interval and the variance inflation factor. During the analyses, extreme and impact observations were checked with appropriate indicators. More specifically, the Mahanobis distance and the Leverage measure were used for extreme values, whereas the Cook distance, DfFits and DfBetas indicators were used for impact observations. Finally, the levels of statistical significance (p-value) for each variable as well as the value of t-statistics were checked in all analyses. The p-value must be lower than 5% and the absolute value of t-statistics must be greater than 2. Apart from the aforementioned statistical checks, the credibility of models was also attested by the high values of the coefficient of multiple determination, R^2.

The resulting models were also tested for their prediction efficiency utilizing, as stated above, a percentage approximately equal to 20% of the total set of measurements. The predicted values, $\tau_{f,r,predicted}$, of the shear stress at failure of fiber-reinforced soil were estimated by applying the models to these testing measurements. The deviation, Δ (%), of the predicted values from the experimental values, $\tau_{f,r,measured}$, was then calculated as follows:

$$\Delta\ (\%) = \frac{\tau_{f,r,measured} - \tau_{f,r,predicted}}{\tau_{f,r,measured}} \cdot 100 \tag{2}$$

The predicted values presenting deviation equal to or less than $\pm 20\%$ are considered acceptable. By finding the total number of acceptable values, the prediction efficiency of each model was obtained for the testing measurements as follows:

$$Efficiency\ (\%) = \frac{total\ number\ of\ acceptable\ values}{total\ number\ of\ measurements} \cdot 100 \tag{3}$$

The different combinations and variations of the aforementioned independent variables led to the examination of numerous models. Two types of analyses were performed, one including the constant term, α_0, (Equation 1) in the model and another one without the constant term so as to find the optimal equation. As a result, the model exhibiting the highest coefficient of multiple determination, R^2, the best statistical characteristics and the largest prediction efficiency is:

$$\left(\frac{\tau_{f,r}}{\sigma_n}\right) = 0.001 * \left(\frac{Ar}{\sigma_n}\right)^{1.75} - 3.958 * 10^{-5}\left(\frac{\sigma_{y,f}}{\sigma_n}\right)^{0.95} + 3.636 * \left(\frac{w_f}{\sigma_n}\right)^{0.75} + 1.462 * \left(\frac{\tau_{f,u}}{\sigma_n}\right)^{0.85} \tag{4}$$

This best model does not include constant term and is statistically acceptable as all p-values are lower than 5% and all absolute values of t-statistics are greater than 2. The model presents a value of the coefficient of multiple determination, R^2, equal to 0.96 indicating satisfactory conformity to the experimental measurements. The prediction efficiency of the model, computed with the Equations 2 and 3, is also satisfactory as it is equal to 77%. The performance of the proposed model is also depicted in Figure 1 where the estimated values of shear stress at failure of fiber-reinforced soil, $\tau_{f,r}$, are compared to those determined experimentally. It is confirmed that 30 (77%) of the 39 predicted values lie within the area set by the acceptable deviation of $\pm 20\%$ from the testing measurements.
Figure 1.   Performance of prediction model (testing data).

4   ESTIMATION OF SHEAR STRENGTH PARAMETERS

The shear strength of soil is generally used in the design of geotechnical engineering projects in terms of cohesion, c, and friction angle, φ. Therefore, it was decided to evaluate the effectiveness of the proposed model in the prediction of shear strength parameters of fiber-reinforced soil as well. For this purpose, the 74 cases of failure envelopes resulted from direct shear tests conducted on various fiber-reinforced soils were collected from the available literature and the corresponding values of shear strength parameters are summarized in Table 2. The numbering of references in Table 2 coincides with that of Table 1. Subsequently, estimated values of shear stress at failure, $\tau_{f,r}$, were obtained by applying Equation 4 to these 74 cases and were utilized for plotting the estimated linear failure envelopes and determining the predicted values of cohesion, c, and friction angle, φ, of the fiber-reinforced soils.

The predicted values of shear strength parameters are compared in Figure 2 to those determined experimentally. It is easily observed that the proposed model overestimates the friction angle values and the cohesion values up to 25 kPa (initial values in Figure 2).

Table 2.   Shear strength parameter values of fiber-reinforced soils.

Reference	Soil type	Fiber material	Test type	Number of failure envelopes	Shear strength parameters	
					Cohesion c (kPa)	Friction angle φ (°)

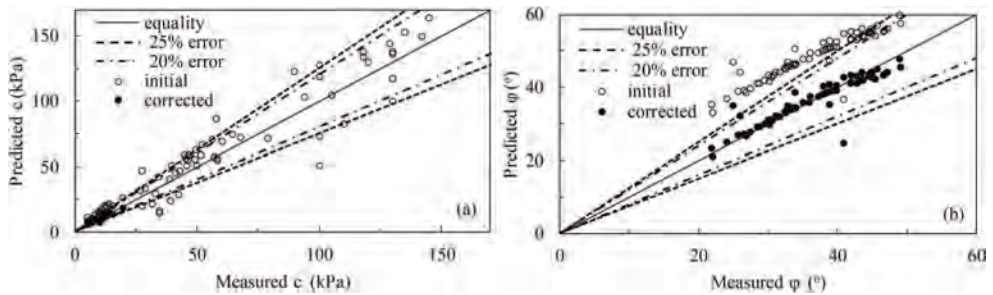

Figure 2. Comparison between predicted and measured values of shear strength parameters.

Consequently, the overestimated values of friction angle and cohesion were reduced by 12° and 30%, respectively, and the corrected values are also presented in Figure 2 in comparison with the measured values of shear strength parameters. It can be observed that, after correction, 49 (66%) cohesion values and 71 (96%) friction angle values lie within the area set by the acceptable deviation of ±20% from the measured values. In 48 (65%) of the 74 cases, the corrected values of both shear strength parameters lie simultaneously within the area set by the acceptable deviation of ±20% from the measured values. If the acceptable deviation from the measured values is increased to ±25%, 54 (73%) of the cohesion values, 72 (97%) of the friction angle values and 53 (72%) cases for both shear strength parameters are considered as estimated effectively by the proposed model.

5 CONCLUSIONS

Based on the results obtained in the investigation reported herein and within the limitations posed by the number of experimental measurements used, the following conclusions may be drawn:

- The model developed for the estimation of the shear stress at failure of fiber-reinforced soil using the multivariable ordinary linear regression method exhibits satisfactory performance as it presents value of the coefficient of multiple determination, R^2, equal to 0.96 and prediction efficiency equal to 77%. It is anticipated that this model can be further improved if the database of available measurements is enhanced with additional direct shear test results.
- The shear strength estimations of the proposed model lead to overestimated values of friction angle and of cohesion up to 25 kPa. By applying appropriate reduction factors to the overestimated values of shear strength parameters, the corrected values are in reasonable agreement with those determined experimentally.

ABSTRACT: To handle the sustainable construction required by the modern world, designers of geosynthetic reinforced soil structures should search for alternative backfill materials, such as recycled materials. Since installation damage is responsible for significant changes in geosynthetic stress-strain behavior, the ones caused by the recycled ones must be carefully assessed and quantified. This study aims to assess the damage to geosynthetics caused by the backfill material-dropping process. Four geosynthetics (two geogrids and two non-woven geotextiles) and five types of recycled aggregates (with different grain–size distributions) were tested. The experimental program consists of laying the geosynthetic on the area of the recycling plant and the individual launching of the tested backfill materials (using a backhoe loader) from two drop heights: 1.0 m and 2.0 m. The geosynthetic samples were then exhumed to obtain specimens, perform wide-width tensile tests, and assess their ultimate tensile strength. The geotextiles experienced reductions in the property of interest for all scenarios investigated. These reductions were higher than the ones experienced by the geogrids. Within some limitations, the results show that the damage increased as the maximum grain size of the backfill increased. Further investigations are required using sophisticated statistical analysis adopting a broader database.

1 INTRODUCTION

The geosynthetic properties along a structure lifetime must meet the ones established in the design phase. For geosynthetic reinforced soil (GRS) structures, three independent mechanisms that affect the durability of geosynthetics are required for design and have led to several investigations: i) installation damage (e.g., Austin 1997; Huang & Wang 2007; Hufenus et al. 2005; Lim & McCartney 2013; Paula et al. 2004; Pinho-Lopes et al. 2018; Richardson 1998), ii) creep behavior (e.g., (Andrawes et al. 1984; den Hoedt 1988; França & Bueno 2011; Greenwood 1990; Thornton et al. 1997; Zornberg et al. 2004), and iii) lifetime degradation (e.g., (Cassidy et al. 1992; Elias et al. 1998; Halse et al. 1988, 1987; Mathur et al. 1994)). However, one must consider specific work conditions to assess the geosynthetic durability.

According to Huffenus et al. (2005), the immediate reduction caused by the installation activities is the most relevant mechanism affecting the reinforcement element durability of a

GRS structure. The investigations into this mechanism encompass the damage caused by the backfill material drop and its posterior compaction. However, the influence of the backfill material drop process height has been addressed by a few studies, particularly when using recycled aggregates. Barbosa and Santos (2013) observed the visual damage caused by the drop of recycled construction and demolition waste (RCDW) from different heights (1.0 m and 2.0 m) on a PET geogrid and concluded that no visual damage occurred as the drop height increased. Fleury et al. (2019) reported a slight reduction in geogrid ultimate tensile strength due to the dropping process from 1.0 m and 2.0 m (maximum reduction factor – RF_{Drop} – equal to 1.11) and highlighted no direct association between the drop height and RF_{Drop} values. In another study, Barbosa et al. (2016) showed higher values of RF_{Drop} for the drop from 2.0 m (1.21) than from 1.0 m (1.11) for a non-woven geotextile.

These previous investigations have shown that the backfill material drop height may compromise the geosynthetic durability, and therefore must be investigated. This paper aims to assess the damage caused by different recycled aggregates (backfill material) on geosynthetic ultimate tensile strength. Moreover, this paper investigates if there is any correlation between the backfill grain size distribution and the reduction factor obtained.

2 MATERIALS AND METHODS

2.1 Geosynthetics

This study tested four poly(ethylene) terephthalate (PET) geosynthetics: two non-woven needle-punched geotextiles (GTXnw1 and GTXnw2) and two geogrids (GGR1 and GGR2). In Brazil, the geogrids are mainly used for the construction of reinforced soil structures. The non-woven geotextiles were chosen to quantify how the geotextiles' mass per unit area (M_A) influences the materials' survivability to the damage caused by the backfill drop. Table 1 shows some properties and characteristics of the materials according to their manufacturer's catalogues.

Table 1. Characteristics and properties of the geosynthetics investigated.

Properties / Characteristics	Unit	GTXnw1	GTXnw1	GGR1	GGR2
Tensile strength MD*	kN/m	6.0	14.0	35.0	55.0
Elongation at break MD*	%	>70	>70	≤10	≤10
Mass per unit area	g/m^2	130	300	n.a**	n.a**
Open size	mm	n.a**	n.a**	20 x 20	20 x 20
Manufacturer	–	A	A	B	B

Notes: * Machine direction; ** not applicable.

2.2 Backfill materials

Recycled construction and demolition waste (RCDW) was provided by a recycling plant located in Aparecida de Goiânia-GO, Brazil. After a sorting and doubled-stage crushing process (jaw crusher), the recycled aggregates were sieved to obtain materials classified according to their grain size (d) ranges: i) gravel A (GA; $d > 19$ mm), ii) gravel B (GB; 19 mm $< d < 9.5$ mm), iii) gravel C (GC; 9.5 mm $< d < 4.8$ mm) and iv) sand (SA; $d < 4.8$ mm). With the mixture of equal volumes of GA, GB, GC and SA, the recycling plant produced graded gravel (GG) material, which is the material most in demand nowadays. Figure 1 shows the grain size distribution curves of the materials investigated, and some characteristics are presented in Table 2.
Figure 1.   Grain size curves of RCDW.

Table 2.   Characteristics and properties of the RCDW.

Characteristic / Property	RCDW				
	GA	GB	GC	SA	GG
Fine grained specific unit weight (kN/m^3)	n.a[a]	n.a[a]	26.0	25.8	25.9
Coarse grained specific unit weight (kN/m^3)	n.t[b]	22.8	24.3	n.a[a]	23.1
Coefficient of curvature (C_C)	1.8	3.3	5.5	0.8	1.0
Coefficient of uniformity (C_U)	3.1	4.1	12.0	4.9	43.4
Classification (ASTM D 2487-06)	GP[c]	GP[c]	GP[c]	SP[d]	GW[e]
Shape index	n.t[b]	2.0	2.1	n.t[b]	2.1

Note: [a] not applicable; [b] not tested; [c] poorly-graded gravel; [d] poorly-graded sand; [e] well-graded gravel.

2.3   Damage simulation

The present study assesses the damage caused by the backfill drop, and does not consider the damage that could be due to the backfill compaction. The in-field tests were carried out near the recycling plant operation area. Firstly, loose gravel and strange materials (e.g., wood and metal) present on the surface (compacted RCDW) were removed manually. Afterward, geosynthetic samples (1.0 m long and 2.4 m wide) were laid over the flat surface. The backhoe loader was used to drop the backfill material (one at a time) from 1.0 m or 2.0 m height (considering the bottom part of the shell). After dropping the backfill over the whole area, the geosynthetics samples were exhumed carefully with a hoe and shovel – avoiding any additional damage.

After exhuming the samples, ten specimens were obtained from the damaged and undamaged samples (virgin condition as received from the manufacturers). The geotextile specimens (300 mm long and 200 mm wide) were tested accordingly to ASTM D 4595 (2005) using a universal testing machine with a load cell of 30 kN and pneumatic jaw clamps at a strain rate of 10%/min. The geogrid specimens (800 mm long and 200 mm wide) were tested following ASTM D 6637 (2015) using another universal testing machine with a load cell of 250 kN and roller clamps, at a strain rate of 10%/min. From the tests, the specimen ultimate tensile strength was obtained, which is the property of interest of this study. The laboratory test program comprises 240 samples.

The geosynthetic damage was quantified by reduction factors related to the drop process (RF_{Drop}; Equation 1), calculated as the rate between the geosynthetic undamaged ultimate tensile strength (T_{UND}; reference value) and its damaged ultimate tensile strength (T_{DAM}) for each backfill material investigated. RF lower than the unity (1.00) was considered 1.00 as these values should not be adopted for design purposes. This procedure is similar to the one adopted to quantify installation damage.

$$RF_{Drop} = \frac{T_{UND}}{T_{DAM}} \tag{1}$$

3 RESULTS AND DISCUSSION

Table 3 shows the mean ultimate tensile strength values obtained after ten tests performed in undamaged and damaged specimens. For both non-woven geotextiles tested (GTXnw1 and GTXnw2) and for GGR1, all damaged scenarios reduced the tensile strength reference value. The GGR2 shows unexpected results: the drop of the GG material from a 1.0 m height and the drop of GB, GC and SA materials from a 2.0 m height led to an increase in the tested material ultimate tensile strength compared to its undamaged value. Some authors (Huang & Chiou 2006; Paula et al. 2004) indicated that these increases result from fiber rearrangement due to the damage caused. However, no tests have been performed to validate this assumption, which requires further investigations to understand the increases reported.

In terms of RF_{Drop}, Figure 2 shows that the non-woven geotextiles exhibited RF_{Drop} values higher than 1.10 regardless of the drop height and backfill material dropped. On the other hand, the geogrids exhibited RF_{Drop} values lower than 1.10. Generally, this difference can be attributed to the materials' different structures. Due to the geogrid open area, their contact area with the material is smaller than the non-woven one leading to minor damage occurrences due to the backfill drop. However, further investigations are required to assess geotextiles and geogrids with a similar ultimate tensile strength to derive further conclusions. Except when the GC backfill was dropped, the GGR1 showed higher RF_{Drop} values than GGR2, indicating the geogrids with higher ultimate tensile strength may be more resistant to damage.

In general, GTXnw1 exhibited higher RF_{Drop} values than GTXnw2. This may indicate that the increase in the geotextile mass per unit area decreases the material sensitivity to the damage caused by the backfill drop. However, for GA and GG backfill materials, GTXnw2

Table 3.   Geosynthetic ultimate tensile strength for undamaged and damaged conditions.

Condition	Drop height	Backfill	GTXnw1	GTXnw2	GGR1	GGR2
Undamaged	n.a[a]	n.a[a]	3.91	17.83	29.74	44.54
Damaged	1.0m	GA	3.00	16.06	27.45	41.59
		GB	3.18	15.26	28.39	44.38
		GC	3.07	15.20	29.22	42.86
		SA	n.t[b]	16.30	27.68	44.03
		GG	3.37	14.06	27.42	47.70
	2.0m	GA	2.93	12.76	26.86	40.91
		GB	3.30	15.20	28.12	45.40
		GC	3.49	15.92	29.38	44.98
		SA	3.32	15.98	28.22	45,10
		GG	3.32	14.06	28.03	43.18

Note: [a] not applied; [b] not tested.

exhibited higher RF_{Drop} values than GTXnw1, which contradicts the previous information. Thus, it should be considered that the increase in the geotextile mass per unit area improved its resistance to mechanical damage caused by RCDW as previously reported by Palmeira (2018).

Figure 2 also indicates that the damage caused by the backfill material drop from a 2.0 m height was similar to those caused by a drop of 1.0 m height. This finding matches the results reported by Barbosa & Santos (2013) and Fleury et al. (2019).

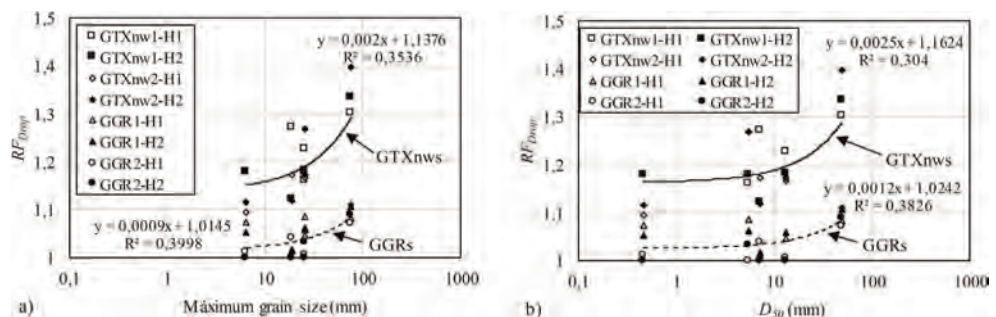
To verify possible relationship between the backfill grain size distribution and the RF_{Drop} values obtained, the RF_{Drop} values were plotted as a function of i) the maximum grain size (D_{max}; Figure 3a), ii) the grain size corresponding to 50% passing material (D_{50}; Figure 3b), iii) coefficient of curvature (C_c), and iv) coefficient of uniformity (C_u). The best-fit equations obtained from these plots are indicated in Figure 3. One must be aware that the figure joins the data obtained for different geogrids and different geotextiles in two groups: GGRs and GTXnws, respectively, which tries to join the data obtained from materials of the same type but different characteristics (mechanical and physical). Considering these limitations, Figure 3 shows that there is a tendency to increase the RF_{Drop} values as the D_{max} or the D_{50} increases but without a good coefficient of determination (R^2) –values remaining below 40% for all cases. However, despite these limitations, Figure 3 corroborates that the tested geogrids are more resistant to damage than the tested geotextiles.
Figure 2.   Reduction factors of each geosyntehtic related to the drop height and backfill material.


Figure 3.   Relationship between the reduction factor and a) the maximum grain size, and b) the grain size corresponding to 50% passing material.

4 CONCLUSIONS

This paper assesses the geosynthetic damage caused by the backfill material drop from an experimental in-field test. The results reported in the study indicated that the backfill drop should be considered in the design phase as it could be responsible for a decrease in the geosynthetic' ultimate tensile strength. The tested geogrids have shown to be more resistant to the damage caused by the drop height than non-woven geotextiles. Possibly, their different structure is responsible for the different results obtained. As expected, the increase in the geotextile's mass per unit area increases its survivability to the damage induced. On the other hand, as the geogrid ultimate tensile strength increased, they became more resistant to damage. Despite testing five different backfill materials, further studies are needed to validate any relationship between the grain size distribution of the backfill and the reduction factors. Even with a low coefficient of determination, it was observed that the damage tends to be higher as the RCDW maximum grain size increase, similar to conventional materials. Further investigations are required to assess and understand the factor that affects the damage caused by the backfill material drop, mainly when they consist of non-conventional materials. Investigations using sophisticated statistical analysis should be used considering a broader database.

ABSTRACT: Geomembranes can be produced with or without surface texture. This choice is generally driven by design requirements, in particular the slope stability, but also the safety of users and wildlife. Overall, a bit less than half of textured geomembranes worldwide are produced by coextrusion, a bit more than a third are embossed, and a bit less than a fifth are sprayed with polyethylene filaments. For coextruded textures, Blond & Elie (2006) have shown that there is a correlation between the height of the asperity, measured by ASTM D7466, and the shear-strength properties of the interface between the geomembrane and an adjacent material. Adesokan & Blond (2018) have shown that the density of asperity may also further influence the interface shear-strength properties. However, there is little information available on the performance of the two other texturing techniques frequently used for geomembranes, i.e., embossing the surface, or spraying it with polyethylene particles. Finally, there is a consensus on the limited performance of ASTM D7466 to adequately predict the performance of geomembranes with an embossed or a spray-on texture. In this document, the various techniques used to create a surface texture on a polyethylene geomembrane are described. The results of an experimental program aiming at measuring their shear-strength properties against a geotextile is presented. A new technique to qualify the performance of textured geomembranes is proposed, which can be used to generate an intrinsic property of the geomembrane, and which can also be used in manufacturing quality control to certify the geomembrane / geotextile interface friction angle.

1 INTRODUCTION

ISO 12957-1 and 12957-2 standards are used to characterize the behavior of interfaces including at least one geosynthetic. ISO 12957-2 is conducted using a tilt table, to model interfaces exposed to low normal stresses, to assess the interface friction properties at peak. ISO 12957-1 test is performed with a direct shear box under any normal stress to assess the interface friction properties at peak as well as at large deformation.

When specifying geosynthetics, a notable problem is the cumbersome nature of interface shear tests, which makes it very difficult to use them in construction quality assurance programs – as well as for manufacturing quality assurance. Current practice is to focus on an intrinsic property of the materials known to provide information which can be connected to the friction behavior of the interface. This approach is common practice for textures manufactured using blown film coextrusion process (Blond 2006), and recent attempts were

made for calendared textures (Adeleke 2020). Unfortunately these methods are only applicable to specific manufacturing technologies, and they remain indirect methods. In this project, a novel approach is proposed to assess the interface friction properties of any type of geomembrane, disregarding their structure and their manufacturing technique.

2 SURFACE CHARACTERISTICS OF TEXTURED GEOMEMBRANES

2.1 *State of the art*

The surface of polyethylene geomembranes can be textured to provide it with sufficient frictional properties. Figure 4 describes two types of texture commonly found on the market. The shear strength which can be developed between this surface and another material is thus influenced by a surface characteristic, i.e., by an intrinsic property of the geomembrane.

a) Cx Basic   b) Cx Rough   c) Cx Dense   d) Cx X-Rough   e) SO Standard   f) SO Dense
Figure 1.   Texture of polyethylene geomembranes (surface: 20 ×27 mm; Cx: coextruded, SO: Spray-on).

Blond & Elie (2006) have observed that for geomembranes with a texture produced by coextrusion in a blown film process (Figures 1-a, 1-b, 1-d), there is a relation between the shear strength and the asperity height, measured by the ASTM D7466 test (equivalent to the GRI GM12 test method referenced by Blond and Elie).

Adesokan and Blond (2018) have shown that in addition to asperity height, the density of asperities (Figure 1-c) also influences the shear strength of interfaces involving a geomembrane. Their study was focusing on the coextruded, blown film texturing process. However, no method for characterizing texture density is referenced by Adesokan.

Adeleke (2020) demonstrated that the height of the studs manufactured by calendaring as well as their density affect the maximum friction properties of calendared geomembranes. He also suggested that surface roughness may also impact the measured properties at large deformation. However, no standard test method is referenced by this author to characterize these properties. The height of the studs as well as their density are defined by the characteristics of the calendar roll used during manufacturing. Because of the relatively low density of the studs and the ease of visual identification, they can indeed be characterized using a ruler to measure their density, a caliper to measure their diameter, and the depth gauge described in ASTM D7466 to measure their height. However, surface roughness cannot be measured using a standard test method.

For geomembranes where the texture is sprayed on the surface of a smooth geomembrane (Figure 1-e, 1-f), experience shows that friction properties are influenced by the density of the texture, which also influences the height of 'asperities' as measured applying test method ASTM D7466, despite this test was developed for another type of manufacturing process. A more appropriate technique would be to determine the spray-on 'density', reflecting the quantity of filaments projected on the surface per unit area. This property is controlled during production by varying the quantity of polymer sprayed per unit area, using a proprietary process. However, there is no test method available to measure this characteristic once production is completed, and it would be difficult to assess in Construction Quality Control.

2.2 *Summary of relevant features of geomembrane textures*

Adeleke's findings are generally consistent with those of Adesokan, and they are consistent as well with field observations: the higher the asperity density and the asperity height: the 'rougher' the surface and the higher the shear strength developed at the interface.

Introducing the concept of 'roughness' (more than isolating or combining height or density) allows to extend this observation to spray-on textures: the rougher the spray-on texture, the higher friction properties can be developed at the interface.

However, it is not possible to determine a universal correlation between an indicative geometrical property of the surface texture, regardless of its morphology, and the shear strength that the geomembrane will exhibit against a given material. Furthermore, the morphology of the texture is not the only parameter that will affect shear strength: adhesion properties specific to each polymer – in particular the surface energy – will also affect the shear strength that can be developed against a given product.

Overall, it can be concluded that it is NOT possible to determine a physical property (such as asperity height) that could be measured on any type of texture (coextruded, calendared or sprayed), which could provide enough information to estimate even roughly the shear-strength performance of a textured geomembrane. The two methods currently available, based on asperity height measurement (ASTM D7466) or geometrical characterization of the texture (Adeleke's method), can only be used effectively on the material for which they were respectively developed, and cannot be extended to other manufacturing techniques.

3 NEW APPROACH FOR CHARACTERIZING THE SURFACE PROPERTIES OF GEOMEMBRANES

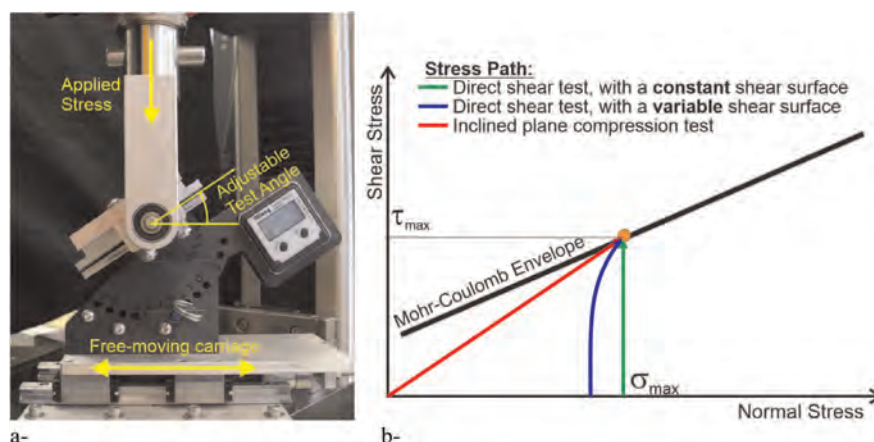
Blond (2022) provides more details on the development of the test developed to improve manufacturing quality control of spray-on texture, where the geomembrane is tested against itself. The general principle of the test is to replicate the conditions prevailing onsite by applying a vertical force (mimicking the gravity-controlled weight of a soil overburden) on the interface installed with a pre-set angle. The upper side of the tested interface is connected to a load cell, while the lower side rests on a carriage free to move horizontally (Figure 2-a).


Figure 2. Inclined plane compression test setup, stress paths reflecting the three methods which can be used to characterize friction properties of geomembrane interfaces.

With a fixed angle, the normal stress and the tangential stress increase proportionally as the vertical force increases. The maximum shear stress sustained by the interface 'τ_a' and the

corresponding normal stress 'σ_α' can be calculated using Equations 1, where 'α' is the (fixed) angle of the interface, 'F' the force applied, and 'S' the contact area:

$$\sigma_\alpha = \frac{F \cdot \cos \alpha}{S} \quad and \quad \tau_\alpha = \frac{F \cdot \cos \alpha}{S} \tag{1}$$

Practically, the 'Inclined Plane Compression Test' measures the vertical stress which must be applied on a given interface, installed at a given angle, to reach a failure, instead of looking for a maximum angle measured using an indirect method as with a direct shear test. With this approach, the modulus of the applied force 'F' is a value which directly reflects a gravity-controlled loading of the interface – such as the weight of an overburden soil. It can therefore be associated to a maximum service load which the interface at a given angle can carry before a failure is observed.

One of the most important conceptual differences between this test and direct shear tests such as ISO 12957-1 resides in the stress path followed by the interface until it reaches failure, which are illustrated in Figure 2-b:

- In a direct shear test with a constant shear surface (e.g., ASTM D5321 or ISO 12957-2), the normal stress is set and remains constant throughout the test. The shear stress increases until the Mohr-Coulomb failure envelope is reached. It is a displacement-controlled test, i.e. the rate of application of the shear stress is not controlled.
- If the direct shear test is performed using a variable shear surface, as for direct shear testing of soils (e.g., ASTM D3080), the normal stress increases throughout the test because of the reduction of shear surface. It is a displacement-controlled test as well, where the rate of increase of the shear stress is not controlled. the shear stress must be corrected to account for the reduction of the shear surface as the test progresses.
- With the proposed inclined plane compression test, both normal and shear stresses increase proportionally: the stress path follows an angle which is the same as the inclined plane angle. This stress path reflects the mechanism that would typically prevail onsite. A maximum force is achieved when the stress path reaches the Mohr Coulomb envelope of the interface. This mechanism cannot take place (i.e., an infinite force is reached) when the angle of the test (of the slope) is such that the stress path never reaches the Mohr-Coulomb envelope.

The details of device depicted on Figure 2-a will be revealed in a standard test method, to be published. However, the following details can be highlighted:

- Both platens are covered with an abrasive surface to exhibit a higher shear strength than the one being observed. No anchoring of the specimens should be necessary.
- The upper plate is articulated to ensure parallelism of the two surfaces. The rotation axis of the upper plate is in the same plane of the interface, to avoid the development of parasitic torque during the test.
- A magnet sets and restrains displacement carriage in a predefined location at the beginning of the test. Its force is adjusted to ensure the test surfaces are in contact with one another when the vertical force increases, eliminating parasitic effect of the curvature of the specimens.
- The speed of vertical displacement was set at 10 mm/min until a peak is observed or the capacity of the equipment is reached.
- Once a test is completed under a given angle, the test can be repeated using different angles, until a very high force is measured (when the angle is reduced) or a neglectable force is measured (when the angle is increased).

Testing one interface under a given angle requires up to 2 minutes per replicate (once specimens cut and the system calibrated), which was found an acceptable duration for Manufacturing Quality Control.
Figure 3. Idealized behavior of an interface during a series of inclined plane compression tests.

The idealized behavior of an interface is described on Figure 3. For each test angle, the stress path is a straight line starting from the origin and defined by the test angle, ending on the Mohr-Coulomb envelope of the interface, i.e., where slippage occurs. On Figure 3-a, the stress path is illustrated with a red arrow for the test angle '26°'.

The modulus of the vertical force 'F' required to reach failure is plotted against the test angle on Figure 3-b. This format is, in fact, simpler to report as it is the direct output from the dynamometer, and it can be set considering a friction angle which should be sustained by the interface (before any reduction factors are applied).

Blond (2022) reports a good correlation between results obtained using this novel procedure with those obtained using a direct shear box per ASTM D5321, when testing a medium-density, or a high-density spray-on texture against itself. This validation was however limited to 400 kPa, which is the capacity of the direct shear box used.

4 EVALUATION OF GEOTEXTILE / GEOMEMBRANE INTERFACES

Geotextile / geomembrane interfaces are frequently considered the critical part of a project with respect to interfaces stability. It was therefore decided to investigate if the Inclined Plane Compression Test can be used to assess the properties of such interfaces. Several geomembranes exhibiting different textures were tested against a non-woven, needle-punched continuous filament geotextile with a mass per unit area of 800 g/m^2. Both the IPCT and direct shear tests were used.

Figure 4 presents the (α, F) relation for these tests (i.e., using the presentation strategy exposed on Figure 3-b). Figure 5-a presents the Mohr-Coulomb envelopes obtained with both the IPCT and Direct Shear. Figure 5-b presents the angle for which a force of 3,000N or 8,000N can be applied on the tested interface without slippage, along with the tangent friction angle obtained using a direct shear test, and the asperity height, for each texture. The 3,000N and 8,000N values were selected looking at Figure 4 and choosing the region located immediately above what appears to be an inflexion of the 'Force versus Angle' curve, i.e., the limit where a reduction the test angle by just 1° leads to a significantly higher force.

Based on these observations, the inclined plane compression test appears as a promising technique to evaluate the geotextile / geomembrane interface friction properties. When using the shear surface used in this project (50 mm width x 120 mm length), it allows evaluation of the behavior of interfaces under very high normal loads, i.e., up to ~12 to 14 MPa using a 20kN load cell.

The stress path used to run the test mimics normal operating conditions of geosynthetic interface exposed to a vertical, static load, and the result can be expressed as a service load (i.e., weight of the overburden) under predetermined operating conditions. Hence, this test
Figure 4. Inclined plane test results, geomembrane tested against a geotextile.
Figure 5. Inclined plane test results, geomembrane tested against a geotextile.

could offer a better opportunity to quantify the serviceability of a structure using safety factors.

The simplicity and rapidity of the test makes it a good candidate for manufacturing quality control of geosynthetic interfaces, with geotextile / geomembrane friction properties becoming a feature that could be consistently assessed on a project-by-project basis as very low cost.

5 CONCLUSION

The proposed Inclined Plane Compression Test provides an opportunity to rapidly assess the surface friction properties of a geomembrane by testing the surface of the geomembrane against itself, as shown by Blond (2022). In addition, the test also offers the possibility to evaluate the behavior of geomembrane/geotextile interfaces. Under a similar normal stress, results were found to be comparable to those obtained using a direct shear box, per ISO 12957-2.

Moreover, the test allows characterization of the Mohr-Coulomb Envelope up to very high normal loads, much higher than the loads which can be reached using direct shear boxes currently available on the market.

This test offers the possibility to measure the stress necessary to reach the failure of an interface under a specific angle. This approach offers an opportunity to define a Safety Factor applicable to a service load for a given service condition = slope angle. This approach could improve the understanding of failure mechanisms and offer a new approach to define a safety factor applicable to the stability of an interface.

Chemico-osmotic efficiency of geosynthetic clay liners: Testing apparatus and preliminary results

D. Bernardo, J. Domizi, E. Fratalocchi & F. Mazzieri
Marche Technical University, Ancona, Italy

ABSTRACT: The membrane behaviour of conventional and enhanced Geosynthetic Clay Liners is regarded with interest for applications in barrier systems as the presence of chemical osmosis improves the GCL containment properties. With the purpose of assessing the existence and persistence of chemico-osmotic behavior in GCLs, an apparatus able to perform chemico-osmotic diffusion tests on GCLs and soils has been developed. The paper describes the main features of the systems and preliminary results obtained using conventional and polymer-amended GCLs and a 20 mM KCl solution. The measured osmotic efficiency and solute diffusion coefficients were close to results in the literature on similar GCL materials and similar testing conditions, proving the system reliability.

1 INTRODUCTION

The ability of bentonite-based geosynthetic clay liners (GCLs) to act as semipermeable membranes that is, inhibit the passage of ions while allowing the migration of water (chemical osmosis) is well recognized (Kang & Shackelford 2009; Malusis et al. 2001; Mazzieri et al. 2010). The restriction of solute transport is usually partial and the degree to which a soil inhibits the entry of ions into the pore has been traditionally quantified in terms of the chemico-osmotic efficiency coefficient, ω (Shackelford 20139. Chemico-osmotic diffusion tests have been widely used to determine the ω coefficient of soils and geosynthetic clay liners (GCLs). The most commonly adopted testing condition has been the closed-system approach (Malusis et al. 2001). which consists in generating a steady-state chemical gradient across a saturated specimen while preventing the hydraulic flow through the specimen. If the soil has semipermeable membrane properties, a differential pressure will arise across the specimen. The absence of volume change in closed-system chemico-osmotic testing is ensured by using rigid-wall cells and preventing the vertical swell by a locked-in-place rigid piston (Di Emidio 2010; Malusis et al. 2001). However, in rigid-wall cells, specimen shrinkage is possible, resulting in short-circuiting and destruction of membrane behavior (Bonhoff & Shackelford 2013; Scalia et al. 2018).

The paper presents a recently developed rigid-wall cell for diffusion and chemico-osmotic testing of GCLs or soils, with allows applying strain-controlled condition to the test specimen, either by a locked-in-place piston, similarly to the testing approach in Malusis et al. (2001), or by using a load cell, similarly to the testing approach described in Dominijanni et al. (2019). The latter setup enables monitoring the total vertical stress during the test and helps identify possible anomalies (e.g. vanishing total stress) yet allowing relatively small strains ($< 1\%$). The paper also reports the results of preliminary tests performed on two different GCLs materials with the purpose of comparison with literature data to check the system reliability and to highlight the possible influence of the testing approach on the determined membrane properties.

2 MATERIALS AND METHODS

2.1 *Chemo-osmotic diffusion apparatus and testing*

Figure 1 shows a drawing of the apparatus, conceptually similar to that described in Malusis et al. (2001). The principle of the test is to induce a steady-state chemical gradient across a saturated soil specimen, while preventing the hydraulic flow. The concentration gradient is induced by circulating equal volume rates of solutions of different concentrations at the specimen boundaries. This is obtained by equipping a double-syringe pump with two metallic cylinders. The syringe plunger separates the cylinder in two compartments, hydraulically connected to a porous disk lying on top or beneath the specimen in the testing cell, such that the solution is infused by the plunger displacement at one side of the porous plate and withdrawn at the other side.

The rigid-wall cell consists of a lower plexiglass mould housing the soil specimen and an upper plexiglass pressure chamber, hydraulically isolated from the specimen chamber by a sealed rigid piston. Plexiglass was preferred over stainless steel for being non-conductive. The specimen mould is 100 mm in diameter and 100 mm in height. The solutions are circulated through the porous stones by the two drainage lines connected to the cylinders, while a third drainage line connects the porous plates and a differential pressure transducer. The liquid pressures generated at specimens top and base during circulation are also monitored by means of in-line relative pressure transducers.

The rigid piston is free to move downwards or upwards under a given stress applied to the upper chamber, during the consolidation or swelling stage of the specimens. During the circulation stage the piston can be locked-in -place by blocking the rod against a rigid steel frame ("no-strain" condition). Alternatively, a stiff load-cell (LCM411-500-USBH Load Cell, AEP Transducers, Italy) can be interposed between the piston rod and the steel frame, which allows monitoring the total stress acting on the specimen during the chemico-osmotic test. As the load cell undergoes some deformation in measuring the applied load ($\approx$0.2 mm/KN), the volume
Figure 1. Schematic of the circulation apparatus and rigid-wall cell for chemico-osmotic diffusion tests.

change of the specimen is in principle not prevented for the latter testing condition ("small-strain" condition). A displacement transducer (LVDT) firmly attached to sliding rod of the piston allows monitoring any volume change during the preliminary consolidation or swelling phase of the specimen as well as during the chemico-osmotic diffusion stage.

A closed-system chemico-osmotic diffusion test consists in measuring the pressure difference induced across a soil or GCL specimen as a result of prohibiting the chemico-osmotic flux q of solution (Keijzer et al. 1999). The chemic-osmotic coefficient is determined as follows:

$$\omega = \left(\frac{\Delta P}{\Delta \pi}\right)_{q=0} \tag{1}$$

where ΔP = the liquid pressure difference across the specimen and $\Delta \pi$ = the theoretical pressure difference across an "ideal" semipermeable membrane separating dilute solutions of a single electrolyte, which can be computed using the van't Hoff Equation:

$$\Delta \pi = \nu RT \Delta C \tag{2}$$

where ν = the number of ions per molecule of the salt, R = the universal gas constant [8.314 J mol^{-1}°K^{-1}], T = the absolute temperature, ΔC = the concentration solute difference across the membrane.

As the restriction of solutes through the porous medium is usually partial, diffusive flux occurs in response to the induced concentration gradient until a steady-state diffusion condition is reached. Monitoring the outflow and inflow solute concentrations allows determining the solute steady-state diffusive molar mass flux J (Malusis et al. 2001) and the effective diffusion coefficient is experimentally determined as:

$$D^* = H \frac{J}{n(C_{t,av} - C_{b,av})} \tag{3}$$

where $C_{t,av}$ = the average solute concentration at top boundary, $C_{b,av}$ = the average solute concentration at the base boundary, H = the specimen thickness, and n = the total soil porosity. In case of a salt solutions and nil electrical current density, in the absence of membrane behaviour the measured diffusion coefficient at steady-state is the effective salt diffusion coefficient D_s^*. In the presence of membrane behavior the effective diffusion coefficient D^*, can be related to the salt diffusion coefficient, as follows (Manassero & Dominijanni 2003):

$$D^* = (1 - \omega)D_s^* = (1 - \omega)\tau_m D_{so} \tag{4}$$

where τ_m is the matrix (geometric) tortuosity and D_{so} is the salt diffusion coefficient in free solution.

2.2 Materials

Two different geosynthetic clay liner products (GCL-1 and GCL-2), previously used in other studies on chemico-osmotic behavior were used in this study to compare the results obtained with the testing apparatus with literature data. GCL-1 is a conventional needle-punched product (Bentomat®), consisting of a cover nonwoven polypropylene geotextile (0.3 kg/m^2) and a carrier woven polypropylene geotextile (0.2 kg/m^2), encapsulating a nominal unit mass of 4.2 kg/m^2 of granular natural sodium bentonite. Physical and chemical properties of GCL products with the same trade name are reported in Malusis & Shackelford (2002). GCL-2 is a product known as Dense Prehydrated (DPH) GCL

(Rawell, UK). The product type used in this study comprises a 4.6 mm thick layer of prehydrated and vacuum-extruded bentonite interposed between a perforated polyester geotextile (17 g/m^2) and a HDPE layer, that was removed before testing, as the bentonite core only was expected to exhibit chemico-osmotic behavior. The HDPE layer it is not firmly bonded to the bentonite layer and was easily peeled by hand. The bentonite of DPH GCLs is known to be amended with polymers (Na-Polyacrylate and Na-Carboxymethyl Cellulose) during manufacturing. Physical and chemical properties of the GCL are reported in Mazzieri & Di Emidio (2015).

2.3 Testing procedure and program

The liquids used in this study were distilled water (DW) and a 20 mM solution of potassium chloride (KCl). The salt solution was prepared by dissolving analytical grade KCl in DW. Circular GCL specimens (diameter =100 mm) were carefully cut from larger sheets and first permeated with DW to reduce the concentration of soluble salts, increase saturation and measure the initial hydraulic conductivity (k). Preliminary hydration and permeation were carried out in flexible-wall permeameters (FWP) under an average isotropic effective stress σ'_i=34.5 kPa (as per ASTM D5887); after 4-6 months of permeation, the specimen was transferred to the rigid-wall cell, paying attention to prevent gaps in the contact between the soil and the cell walls. Then, the GCL specimens were again permeated with DW (i=90-120) in the rigid-wall cell, primarily to check for sidewall leakage. After permeation, the piston was locked for the "no-strain" testing approach, whereas the load cell was interposed between the piston rod and the rigid steel frame for the "small-strain" approach. The upper cell was depressurized and DW was first circulated as input solution at both boundaries of the specimen to establish the baseline differential pressure. The circulation rate was set to 4.8×10^{-10} m^3/s in all tests to enable comparison with previous studies (Malusis & Shackelford 2002; Malusis & Danyarov 2016). After about 7 days of circulation with DW, the chemico-osmotic stage of the tests was initiated by circulating the 20 mM KCl solution as input solution at the top while continuing circulation of DW at the base. During circulation, the inflow and outflow solutions were collected with periodic refills (on average every 48 hours) to monitor the progress of electrical conductivity, EC, and for subsequent analysis of concentrations. At the end of chemico-osmotic testing, the GCLs specimens were permeated with the 20 mM KCl solution to check for specimen shrinkage and increase in k with respect to permeation with DW. Finally, the moisture content of the specimen was measured to check the final degree of saturation. Both GCLs were tested by adopting the two testing approaches and the 20 mM KCl source solution. In the case of the "small-strain" test on GCL-1 the source solution was subsequently increased (multi-stage test). The present paper reports on the first stage of testing only.

3 RESULTS AND DISCUSSION

3.1 Chemico-osmotic coefficient and diffusion coefficients

Figure 2 and Figure 3 show the differential pressured $\Delta P = (P_{top} - P_{base})$ during circulation of DW and of the 20 mM KCl solution for the tests performed adopting the conventional "no-strain" approach (Figure 2a and 3a) and the "small-strain" testing approach (Figure 2b and 3b) for GCL-1 and GCL-2 respectively.).

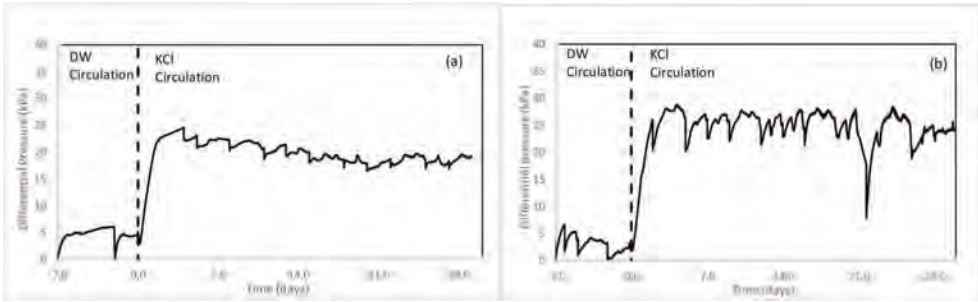
The average value of ΔP during circulation with DW was assumed as the baseline value, ΔP_{DW}. Input of 20 mM KCl solution in the top circulation loop determined in all tests an almost immediate increase in ΔP. The steady-state value of differential pressure during KCl circulation, ΔP_{KCl}, was estimated for each test considering the overall trend, as the


Figure 2. GCL-1. Differential pressure measured across the specimen: (a) with the conventional (no-strain) testing approach; (b) with the novel (small-strain) testing approach.
Figure 3. GCL-2. Differential pressure measured across the specimen: (a) under the conventional (no-strain) testing approach; (b) under the novel (small-strain) testing approach.

instantaneous ΔP values are affected by the sampling and refilling operations and to some extent by room temperature variations as well. The chemico-osmotic coefficient ω was the calculated as follows:

$$\omega = \frac{\Delta P_e}{\Delta \pi_{av}} = \frac{\Delta P_{KCl} - \Delta P_{DW}}{\Delta \pi_{av}} \tag{5}$$

Where ΔP_e= the effective differential pressure and $\Delta \pi_{av}$ = the theoretical averge osmotic pressure difference calculated with Equation. 2 from the average KCl concentration difference $\Delta C_{av}=C_{t,av}-C_{b,av}$ between the top and base boundary at steady-state, determined from concentration measurements (Table 1). In the case of GCL-1 (SS), the concentrations were estimated by correlation with the *EC*, as the chemical analyses are not yet available. Application of Equation. 3 to the calculated steady-state molar fluxes of the solutes gives the D^* values reported in Table 1.

The values of ω and D^* coefficients obtained in this study are for both GCLs in the range expected from the literature. For example, using the no-strain approach and GCL-1 at similar total porosity (n=0.79), Malusis et al. (2002) obtained ω=0.32 (vs. ω=0.16 obtained in this study). Malusis & Danyarov (2016) obtained ω=0.57 and D^*=0.45×10^{-10}m^2/s on a similar GCL-2 product (vs. ω=0.33 and D^*=0.59×10^{-10}m^2/s in this study). Therefore, while full reproducibility of literature data was not expected due to several influencing factors (e.g. difference in GCL properties over different production lots, details of testing procedure etc.) the capability of the apparatus of producing tests results reasonably close to literature data under similar conditions can be considered satisfactory. The ω and D^* values determined with the "no-strain" and the "small-strain" testing conditions are also relatively close;

*= estimated by EC; **= measured at the end of subsequent test stages (multistage test)

however, the available data do not allow identifying a systematic influence of the testing approach on the obtained results.

The total vertical stress acting on the specimen during the test, monitored with the "small-strain" testing option is shown in Figure 4a (GCL-1) and Figure 4b (GCL-2). Circulation of DW gradually reduced the content of soluble salt at the specimen boundaries, thus increasing the osmotic pressure difference between the internal pore water and the external bulk solution, which contributes to the increase in swelling pressure (Dominjanni et al. 2019). Conversely, circulation of 0.02 M KCl at the top boundary (and consequent migration of ions into the GCLs) determined a gradual decrease in total stress, associated with the reduction in double-layer repulsion and osmotic pressure difference. Indeed, the observed change in total stress with boundary concentrations can be related by physical modelling of chemico-osmotic phenomena in clays to intrinsic properties of the solid skeleton such as the fixed charge concentration (Guarena et al. 2022). Application of theoretical models to the interpretation of the obtained results is among the further objectives of this study.
Figure 4. Total vertical stress acting on the specimens during the chemico-osmotic tests with the "small-strain" approach: (a) GCL 1; (b) GCL-2.

4 CONCLUSIONS

Chemico-osmotic diffusion tests have been widely used to determine the chemico-osmotic coefficient (ω) geosynthetic clay liners (GCLs). The most common testing approach has utilized rigid-wall cells under no-strain conditions (testing specimens confined by a locked piston.) A modified rigid-wall cell has been recently developed, which allows conducting the test either under the no-strain condition or using a load cell, that allows monitoring the total stress during the test with relatively small strain of the test specimen ($<1\%$ in this study). Preliminary tests implementing the two testing approaches have been performed on

conventional and Dense Prehydrated GCLs. The values of chemico-osmotic coefficients obtained with the two testing approaches were for all tests in the range expected from the literature. Although the available data are still limited, the modified approach offers a more complete picture of the specimen behavior in response to chemical exposure and allows determining on the same specimen the relevant parameters for advanced theoretical modeling of chemico-osmotic phenomena in GCLs.

A practical isochronous stiffness model for analysis and design of reinforced soil structures

R.J. Bathurst
GeoEngineering Centre at Queen's-RMC, Royal Military College of Canada, Kingston, Canada

F.M. Naftchali
GeoEngineering Centre at Queen's-RMC, Queen's University Kingston, Canada

ABSTRACT: Geosynthetic reinforcement materials such as geogrids, geotextiles and polymer straps are rate-dependent materials which means that their mechanical tensile properties are most often time-, load- and strain-dependent. Nevertheless, analytical and numerical analyses of geosynthetic reinforced soil walls, slopes, thin fills and embankments under operational (serviceability) conditions are most often carried out using a single-value estimate of the reinforcement stiffness consistent with the notion of a single equivalent elastic modulus for the reinforcement material. This paper describes a two-component hyperbolic isochronous stiffness model that accounts for time-dependent changes in reinforcement stiffness due to creep. The model for the reinforcement can be used in numerical and analytical modelling of reinforced soil structures under operational (serviceability) conditions corresponding to low tensile loads and strains.

1 INTRODUCTION

Geosynthetic reinforcement materials are rate-dependent materials, which means they exhibit time- and strain-level-dependent behaviour under load to different degrees depending on the product. This introduces challenges for numerical and analytical models used to design reinforced soil structures where the reinforcement is most often assumed as a linear-elastic plastic material with constant stiffness. The first attempt to account for time-dependent strain (creep) under load is the seminal work of McGown et al. (1984a,b) who introduced the concept of isochronous load-strain curves deduced from constant load in-isolation tensile tests carried out on specimens of geosynthetic material. This paper describes a simple two-parameter isochronous tensile load-strain hyperbolic model for these materials that can be used to estimate the stiffness of the reinforcement at low tensile strain and load expected under operational conditions. The model has application to geosynthetic reinforced soil applications such as reinforced fills over voids, reinforced slopes and embankments, geosynthetic-reinforced pile-supported embankments, geosynthetic-encased columns, internal stability of geosynthetic mechanically stabilized earth (MSE) and the estimation of MSE wall deflections. The application of the model is limited to estimating the stiffness of the reinforcement at low tensile strain and load levels expected under operational (serviceability) conditions, as opposed to ultimate limit state conditions.

2 HYPERBOLIC MODEL FOR ISOCHRONOUS STIFFNESS

The procedure to construct isochronous stiffness curves is illustrated in Figure 1. Creep tests are first carried out at different constant loads as illustrated in Figure 1a. From these data,
Figure 1. Interpretation of load-strain-time data from: a) constant-load creep tests; b) isochronous load-strain curves showing secant stiffness, and; c) isochronous secant stiffness curves.

isochronous curves are constructed (Figure 1b). Finally, isochronous stiffness curves are plotted as shown in Figure 1c. Isochronous stiffness values can be used in analytical and numerical modelling to describe the tensile load in a polymeric reinforcement material using a single-value equivalent stiffness as follows:

$$T(\varepsilon, t) = J(\varepsilon, t) \times \varepsilon \qquad (1)$$

Here, $T(\varepsilon,t)$ is the strain-dependent tensile load at isochronous time t, ε is strain, and $J(\varepsilon,t)$ is the isochronous stiffness. Bathurst & Naftchali (2021) proposed the following two-parameter hyperbolic model to describe isochronous load-strain curves (Figure 1b):

$$T(\varepsilon, t) = \frac{\varepsilon}{\frac{1}{J_o(t)} + \frac{1}{\chi(t)}\varepsilon} \qquad (2)$$

from which the secant stiffness $J(\varepsilon,t)$ values shown in Figure 1c follow as:

$$J(\varepsilon, t) = \frac{1}{\frac{1}{J_o(t)} + \frac{1}{\chi(t)}\varepsilon} \qquad (3)$$

Here, $J_o(t)$ is the initial stiffness at zero strain for isochronous time t, and $\chi(t)$ is a parameter that captures the curvature of the isochronous curve. These parameters are determined by non-linear regression fitting to the curves in Figure 1c. Equation 3 can accommodate both linear elastic and non-linear (creep) stiffness behaviour. For instance, for steel grids and strips, $J_o(t) = E \times A$ where E is the elastic modulus of steel and A is the cross-section area per meter width of a continuous sheet of steel grid reinforcement or the width of a single strip, and $1/\chi(t) = 0$.

3 DATABASE OF CREEP TESTS

A total of 606 creep tests from 89 different products falling into seven different categories were collected by Bathurst & Naftchali (2021) from AASHTO National Transportation Product Evaluation Program (NTPEP) reports in the USA (see NTPEP 2019a, b) and from the research literature. Only data sets with a minimum of three creep curves at different low load levels were included in the database. A summary of the database appears in Table 1.

Table 1. Summary of reinforcement types in the database of Bathurst & Naftchali (2021).

Reinforcement type	Number of data groups (product lines)	Number of data sets (products in a product line)	Number of creep tests	Ultimate tensile strength, T_{ult} [a] (kN/ m) [b] or (kN/strap) [c]
HDPE punched and drawn geo-grid	9	19	148	38 – 177 [b]
PET woven and knitted geogrid	12	38	257	17 – 807 [b]
PP punched and drawn geogrid	5	7	37	12 – 39 [b]
PP woven geo-textile	3	4	22	51 – 155 [b]
PET woven geo-textile	3	8	56	53 – 1030 [b]
PET nonwoven geotextile	1	1	3	25 [b]
PET strap	4	12	83	28 – 156 [c]
$\sum$ =	37	89	606	12 – 1030 [b]

Notes: [a] Based on in-solation tensile test carried out at 10% strain per minute (ASTM D4595-17, ASTM D6637/D6637M-15). [b] T_{ult} values are reported as load/unit width of specimen (kN/m). [c] T_{ult} values reported as load/strap (kN/strap).

4 RESULTS

Figure 2a shows stiffness values for a typical HDPE geogrid used as soil reinforcement for MSE walls. The isochronous stiffness curves can be seen to converge with increasing time and strain. The data in Figure 2b are for a biaxial PP geogrid which is often used as secondary reinforcement in MSE walls and slopes, and to reinforce road base layers. This material has the same positive curvature as the HDPE geogrid but is less stiff. Figure 2c shows stiffness curves for a PET woven geotextile. This material has negative curvature which is ascribed to the macro-structure of the material tightening up during tensioning. A similar behaviour can be seen in Figure 2d for a PET strap material (geostrip) comprised of parallel-aligned bundles of PET filaments protected by a polyethylene sheath. The PET bundles also tighten up during tensioning. This material is used as soil reinforcement in MSE walls.

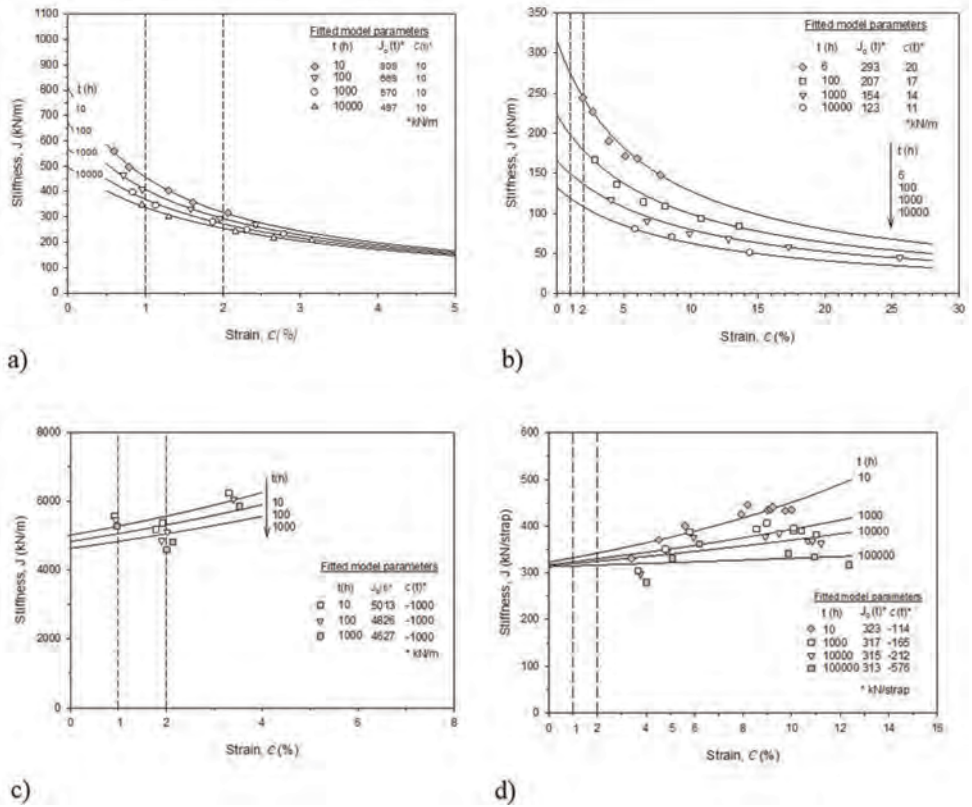
Product-specific isochronous curves such as those reproduced here can be used in numerical and analytical models for different reinforced soil applications. Most often, iso-chronous curves at 1000 h suffice for practical purposes because reinforced soil structures typically reach constant load equilibrium under operational conditions within this time frame. Isochronous curve approximations for a wide range of reinforcement products can be reproduced from tables of $J_o(t)$ and $\chi(t)$ values for different times and strain levels found in the supplemental material to the paper by Bathurst & Naftchali (2021). Values of $J_o(t)$ and $1/\chi(t)$ for different products are plotted against isochronous time in Figure 3. The data in Figure 3a show that with the exception of the PET strap material, $J_o(t)$ decreases with increasing isochronous time. The trend is reasonably well captured using a power function. The two HDPE geogrid products show the greatest sensitivity to isochronous time. From a practical point of view, values of $J_o(t)$ at 1000 hours are sufficiently accurate for design lives of 1000 h or greater for the reasons given earlier. The curvature of the isochronous curves expressed as $1/\chi(t)$ in Figure 3b can be seen to be sensibly constant with time, with the exception of the PP geogrid and PET woven geogrid.


Figure 2. Secant stiffness versus strain and isochronous time for: a) uniaxial HDPE geogrid product; b) biaxial PP geogrid product; c) PET woven geotextile product, and; d) PET strap product. Note: Negative $\chi(t)$ values have been capped at –1000 kN/m.

5 USEFUL APPROXIMATIONS

For many geosynthetic reinforcement products in use today, constant-load creep data are not available or, if creep tests have been performed, the data at low strains expected at operational conditions in the field were not recorded. Bathurst & Naftchali (2021) collected isochronous secant stiffness values and ultimate tensile strength (T_{ult}) values for each product in their data-base. Values of T_{ult} were determined in accordance with ASTM D4595-17 and ASTM D6637/D6637M-15 methods of test. The isochronous stiffness values for strains of 1%, 2% and 5% at 1000 h were found to be reasonably well represented by a simple linear function of the form:

$$J(\varepsilon, t) = R \times T_{ult} \tag{4}$$

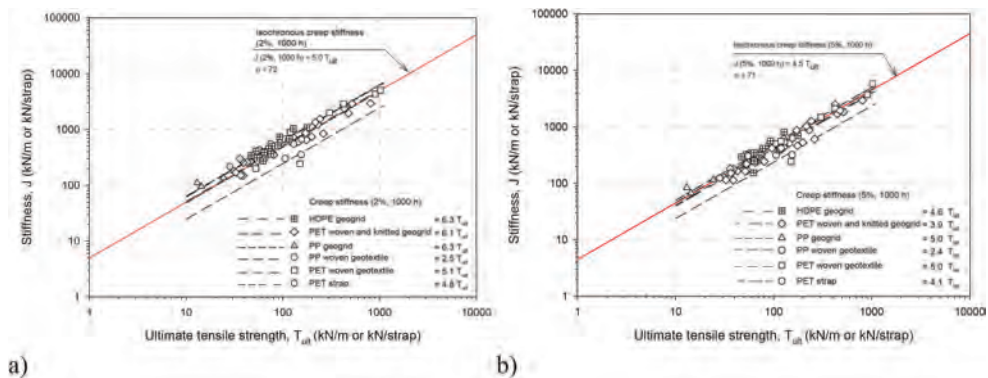
where, R is a dimensionless constant. This equation is in accordance with the observation that for products falling within the same product line, the stiffness of the reinforcement increases in direct proportion to its strength, which would appear to be reasonable. This relationship was observed to be true across product lines of similar type for practical purposes as shown in Figure 4.


Figure 4. 1000-h isochronous creep stiffness versus ultimate tensile strength for: a) ε = 2%, and; b) ε = 5%. Note: n = number of data points (data from Bathurst & Naftchali 2021).

The data are presented using logarithmic axes because of the wide range in magnitude of stiffness and strength values. Only product data from the six reinforcement categories with sufficient data points are presented. The plots show that average values of coefficient R = 5.0 and 4.5 for ε = 2% and 5%. However, within each plot the product type-specific R values vary widely as shown in the figure legends. The average R values shown here are useful for preliminary sensitivity analyses for different reinforced soil applications. As candidate solutions become more refined during design, the values for R based on product type can be used and finally, if available, product-specific isochronous stiffness data of the type shown earlier in Figure 1 can be used. The data in Figure 4 are also useful for numerical modelling purposes to ensure that the stiffness of the reinforcement used in calculations matches the expected strength of the material. This check is often missed in the numerical modelling research literature.

6 EXAMPLE

An unsurcharged vertical MSE wall of height H_w, constructed with layers of the same PET woven geogrid reinforcement having constant length and placed with uniform vertical

spacing (S_v) is illustrated in Figure 5a. The wall outward deformation Δh at layer depth z below the crest of the wall can be computed as (Jewell & Milligan 1989):

$$\Delta_h = \frac{K_a S_v \gamma z (H_w - z)}{3(\mathrm{J} \times S_r)} \left[\tan\left(45° - \frac{\psi}{2}\right) + 2\tan(90° - \phi) \right] \qquad (5)$$

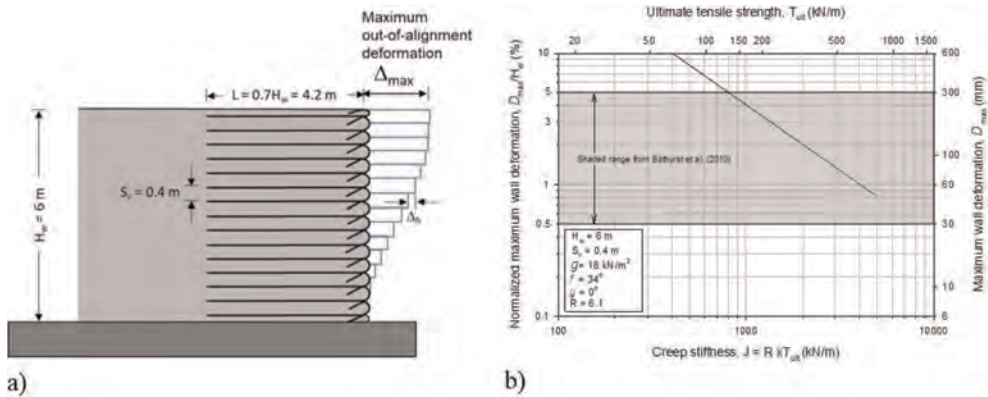
Here, Δh is the incremental wall displacement taken with respect to the time the layer is placed in the wall during construction. Hence, this moving datum displacement should not be confused with the wall final (end of construction) vertical out-of-alignment taken with respect to the toe of the wall. Other parameters are K_a = active earth pressure coefficient, S_r = reinforcement coverage ratio, γ = soil unit weight, ϕ = friction angle from direct shear tests, Ψ = dilatancy angle $\sim \phi - 30° \geq 0$, and J is the nominal reinforcement stiffness. For continuous sheet reinforcement $S_r = 1$, and for sheets of reinforcement placed with a gap or space between rolls, S_r is the fraction of the reinforcement layer that is continuous per unit length in the running wall direction. Figure 5b shows that the maximum outward deformation of the wall decreases with increasing stiffness of the reinforcement. The shaded range in the plot captures specified or anticipated values for well-constructed walls collected by Bathurst et al. (2010) from a survey of codes and design guidelines from different jurisdictions.


Figure 5.   a) Schematic of 6 m-high MSE wall with wrapped-face and 15 reinforcement layers, and; b) maximum horizontal wall deformation versus design isochronous secant stiffness [J(ε = 2%, 1000 h)] using Equation 4 with R = 6.1 for PET woven geogrid (Bathurst & Naftchali 2023).

7 CONCLUSIONS

This paper gives a brief review of a simple two-parameter hyperbolic isochronous tensile stiffness model developed by Bathurst & Naftchali (2021). The paper provides guidance to designers and researchers for the selection of constant stiffness values at different strain levels and elapsed time for use in analytical and numerical reinforced soil applications where: 1) the reinforcement is treated as a linear elastic-plastic material, and; 2) load levels are low enough that reinforcement strains are reasonably linear with logarithm of time, and creep to failure is not possible over the design life of the structure. The paper provides useful approximations for the magnitude of secant stiffness as a linear function of ultimate tensile strength, based on analysis of a large database of constant-load creep tests compiled by the authors. Finally, the reader is directed to the papers by Bathurst & Naftchali (2021, 2023) for a deeper treatment of the subject and other examples using the hyperbolic model for design of MSE walls and reinforced fills over a void.

Effect of welding quality from dual track wedge welding on post-weld geomembrane oxidative induction time

J.W.B. Silva & R. Kerry Rowe
GeoEngineering Centre at Queen's-RMC, Department of Civil Engineering, Queen's University, Canada

ABSTRACT: Geomembranes sheets used in fluid containment applications are welded together in situ using a dual track hot wedge welder or extrusion welding. In dual track wedge welding, overheating can occur in the weld and still meet typical acceptance standards based on peel and shear strength. However, this overheating depletes antioxidants and contribute to a potential reduction in the service life of the geomembrane in the heat-affected zone (HAZ) and junction zone (JZ) adjacent to the weld. This study examines the relationship between the welding quality and thickness on the production of the weld and any reduction in standard oxidative induction time (Std-OIT) for four HDPE geomembranes. The paper describes ageing tests being conducted on these different welds to evaluate the impact of ageing on the rate of antioxidants depletion during welding on the aging of the junction zone relative to the parent material.

1 INTRODUCTION

The composite liners using a geomembrane over a geosynthetic clay liner (GCL) are extensively used to minimize the migration of contaminants from solid waste landfill facilities (Abdelaal et al. 2019; Abdelaal & Rowe 2019; McWatters et al. 2020; Rowe 2005). However, the correct performance of the composite liners lies on the correct choice and installation of the materials with a service life that will need to exceed the contaminating lifespan (centuries). Previous studies have examined the degradation rates and service life of HDPE geomembranes for a wide variety of conditions (Abdelaal & Rowe 2019; Ewais et al. 2014; Li et al. 2021; McWatters et al. 2020; Morsy & Rowe 2020). Geomembranes are known to age at varying rates depending on the material, time, exposure medium, temperature, and strain, with brittle failure, or stress cracking, being the final failure mechanism. Researchers have examined the durability of HDPE geomembranes focusing on sheet durability. However, one of the essential processes involving the use of geomembranes as barriers, namely the welding of panels together, has been neglected in most studies. Available evidence suggests that the welds/seam are the most consistent weak point (Francey & Rowe 2021; Giroud 2005; Kavazanjian et al. 2017; Peggs et al. 2014; Rowe & Shoaib 2017, 2018; Zhang et al. 2017). Thus, this paper will follow on form the limited work to date by examining the effect of welding on the rate of antioxidant depletion in the junction zone (JZ) relative to the parent material for four different geomembrane thickness welded with two different sets of welding parameters. The junction zone (JZ) represents the intermediate area between the weld zone (WZ) and heat affected sheet zone (HAZ) as shown in Figure 1.

1.1 Seams

The wide use of HDPE geomembranes requires the application of weld techniques to construct a uniform barrier. There are different methods of geomembrane welding: extrusion fillet welding, extrusion flat welding, dual track wedge weld, and hot air welding. The current practices commonly use the dual track wedge and the extrusion welds due to the fast process and control. The dual track wedge welding consists of applying pressure to two parallel tracks of heated geomembrane and forming two welds with an air channel between the two. This air channel can be used to perform integrity tests after the welding process. During the welding process, the technician can change the machine's speed, temperature, and pressure based on environmental conditions and the thickness of geomembrane. These parameters should be validated using destructive tests and trial seams. If these welding parameters are not correctly defined, poor seams and localized defects can occur as the result of over or under-heating the weld itself (Elton & Peggs 2002; Müller 2007; Scheirs 2009; Zhang et al. 2017). The current definition of a good and bad geomembrane weld is based on the ASTM 6392 recommendations and German DVS 2225-4. However, while these guidelines are useful for construction monitoring, they have limited applicability with respect to the long-term performance of seams. There has been a paucity of studies examining the durability of HDPE seams, with a few notable exceptions. Rowe & Shoaib (2013, 2017) found that the heat-affected zone (HAZ) represents a critical location of the weld with respect to ageing, with faster antioxidant depletion. Kavazanjian et al. (2017) experimentally showed the level of strain concentration that occurs at seams. Francey & Rowe (2021) analyzed the stress crack resistance of HDPE seams exposed to synthetic leachate at 85°C and demonstrated that the stress crack resistance of seams is affected by the welding parameters and why these can make a weld the critical weaker point with respect to liner durability.

1.2 Ageing process and immersion tests

Oven immersion tests are commonly used to examine the stages of geomembrane degradation and to allow extrapolation of HDPE geomembrane behaviour at any site-specific temperature (Abdelaal et al. 2019; Abdelaal & Rowe 2019; Hsuan & Koerner 1998; McWatters et al. 2020; Morsy & Rowe 2020; Rowe et al. 2009, 2010a; Sangam & Rowe 2002). The exposure to elevated temperatures and synthetic MSW leachates reduce the time to chemical degradation of geomembranes. During these tests, three stages can be observed: (a) antioxidant depletion (Stage I), where antioxidants in the geomembrane have just depleted to a residual value; (b) induction period (Stage II), where additives have been fully depleted but mechanical degradation has not yet occurred; and (c) reduction in mechanical properties (Stage III), where thermo-oxidative degradation leads to a reduction in mechanical properties (Hsuan & Koerner 1998; Rowe & Sangam 2002). The life service of the geomembrane can be improved with either a change in the additives to increase Stage I or the resin to increase Stages II & III. However, the focus in both cases is on increasing the service life of the sheet. The portion of the sheet that is welded is subject to elevated temperatures to melt the geomembrane and produce the weld, with the normal wedge temperature ranging between 350-560°C; much higher than the effective temperature range of common antioxidants (Hsuan & Koener 1998). The implications of this are not well understood.

2 MATERIAL AND EXPERIMENTAL PROCEDURE

2.1 Geomembrane properties

Table 1 presents the initial properties of four HDPE geomembranes examined. These geomembranes were dual wedge-welded by an experienced technician at ambient temperature (20°C) using two different machines: DemTech ProWedge (DPW) and Leister G7 (G7). The welding parameters are presented in Table 2, following the guidelines of the welding machine

manufacturer and the qualification tests (peel and shear). "Good" and "Inferior" welds were prepared, changing the properties to produce rippling for the inferior welding quality.

Table 1.   Initial properties of HDPE geomembranes.

Index Property Geomembrane	Initial Value			
	MxC10	MxC15	MxC20	MxC24
Thickness (mm)	1.0	1.5	2.0	2.4
Std-OIT (min)	155	160	162	162
HLMI (g/10min)	17.3±0.6	15.3±0.2	15.7±0.7	16.3±1.1

Table 2.   Initial properties of HDPE seams.

Geomembrane Welding quality	MxC10		MxC15		MxC20		MxC24	
	Good	Inferior	Good	Inferior	Good	Inferior	Good	Inferior
Welding Speed (m/min)	3.0	1.8	5.5	3.7	5.0	2.6	3.2	1.6
Wedge Temperature (°C)	400	460	400	460	400	455	420	460
Welding Pressure (N)	-*	-*	1060	1060	1200	1200	1300	1300

Average Weld Thickness (mm)	1.90±0.07	1.69±0.09	2.40±0.05	2.03±0.12	3.35±0.17	2.93±0.12	3.90±0.07	3.11±0.06
Thickness reduction (mm)	0.1	0.31	0.6	0.97	0.65	1.07	0.9	1.69
Thickness reduction (T_R) limits (mm)		-	$0.6 \leq T_R \leq 0.8$		$0.4 \leq T_R \leq 0.8$		$0.4 \leq T_R \leq 0.8$	

*Welded with DPW which does not quantify pressure but has a number of specific settings.

2.2   Qualification tests

After the welding, the welds were tested following the current North American guideline (ASTM 6392). The criteria defined by ASTM D6392 require a specified value for peel and shear strength and elongation. For all four geomembranes and two welding qualities examined the seams passed the tests. Thus, seams welded considered to have inferior quality passed the usual quality control tests despite evidence of overheating in the form of rippling. Additionally, to the ASTM 6392 guidelines, the seams were evaluated by the DVS 2225-4 which has a thickness reduction criterion for the weld. The welds produced with inferior welding quality did not meet this criterion. For MxC10 it was not possible to produce a viable weld with a thickness reduction higher than 0.3.

2.3   Immersion test

After the welding process, qualification tests the four geomembranes were cut in coupons (190 ×95 mm) and immersed in synthetic leachate in 4-litre glass jars. The coupons were separated by 5 mm glass rods to ensure exposure to the fluid on both sides of geomembrane coupons. They were all incubated at 75°C and 85°C where chemical degradation requires a

short time. These samples were used to extract specimens for OIT tests at different times of ageing. The synthetic leachate solution used in this research is based on studies conducted by Rowe et al. (2009), Abdelaal et al. (2014b), and Rowe & Shoiab (2013, 2017). This solution is based on the chemical analyze conduct for the Keele Valley landfill, in Ontario, Canada (Rowe et al. 2009). Rowe and Shoiab (2017) conducted research using this leachate to examine the long-term durability of HDPE seams.

As a result of chemical degradation, there can be a loss of antioxidants or stabilizers from the geomembrane. To evaluate this change Std-OIT tests were performed using a TA instruments Q-200 series differential scanning calorimeter (DSC). The OIT specimens were taken at the three locations shown in Figure 1: (1) The Sheet Away from the Weld (SAW), where the geomembrane is unaffected by the welding process; (2) The Welded Zone (WZ) below the nip rollers which has experienced some thickness reduction (see Table 2); and (3) The Junction Zone (JZ) adjacent to the weld that includes some squeeze-out fused to and integral with the sheet on neither side by heat of the welding process and having a thickness greater than either the sheet or the Welded zone (WZ). This is the first study to examine the JZ; others have focused on the HAZ.
Figure 1.   Cross-section of typical HDPE dual track fusion weld (a) Schematic magnification of main zones, (b) Entire cross-section of the weld.

3   PRELIMINARY RESULTS

Std-OIT depletion was examined for four different geomembranes and two welding qualities, during the tests three different areas were analyzed for 16 weeks and two immersion temperatures (75°C and 85°C). Figure 2 presents Std-OIT results for MxC10 and MxC15 for both welding quality parameters with time, normalized by dividing the values by the initial (virgin) material values immediately after welding.

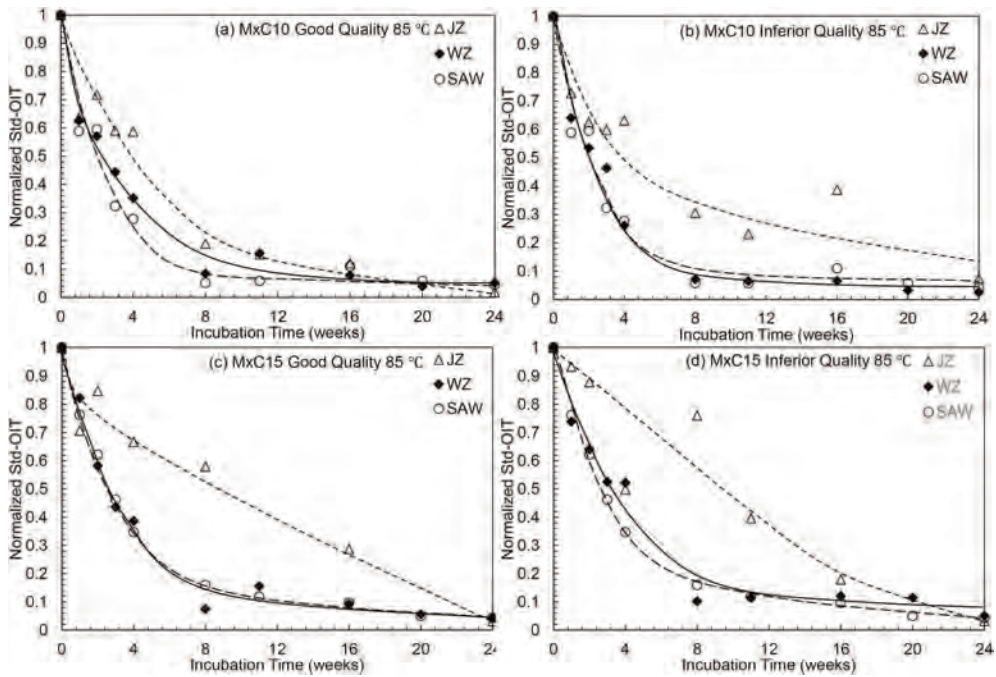
The observed results for MxC20 and MxC24 were similar to those shown in Figure 2 for thinner geomembranes. Based on these preliminary results the STD-OIT depletion of the antioxidants was fastest in SAW, next in the WZ and slowest in the JZ. This general trend was found for all the thicknesses for both sets of welding quality parameters and both immersion temperatures analyzed. The difference in welding quality is evident from faster Std-OIT depletion for the inferior welds than for the good welds. This effect decreased slightly with an increase in geomembrane thickness.


Figure 2. Normalized variation Std-OIT with incubation time at three locations immersed in leachate at 85 °C (a) MxC10-Good weld, (b) MxC10-Inferior weld, (c) MxC15-Good weld, and (d) MxC15-Inferior weld. Note: SAW is the same for good and poor for each GMB thickness and can be used as a reference curve.

The slower depletion of the junction zone (JZ) compared with weld (WZ) and the parental sheet (SAW) is attributed to the difference in geomembrane thickness at each location because an increase in thickness results in a longer path for the outward diffusion of anti-oxidants (Rowe et al. 2010, Rowe et al. 2014, Rowe & Ewais 2014). The fast depletion of SAW than WZ is in agreement with the findings of Rowe & Shoaib (2017) and Rowe & Shoaib (2018). Also, it is important to highlight that this study and Rowe & Shoaib (2017, 2018) used different HDPE geomembranes with different additives packages and properties. Longer incubation times are needed to more accurately compare the JZ and HAZ in terms of antioxidant depletion.

4 CONCLUSIONS

This paper has reported an examination of the effect of geomembrane thickness and welding quality on the Std-OIT depletion for three different regions of the weld. The preliminary results suggest the following conclusions for the four different geomembranes and two welding quality parameters examined in this paper.

- Std-OIT depletion was fastest for the SAW and WZ and slowest for JZ, showing that for the material and data analyzed to date, the JZ is not a critical zone with respect to antioxidant depletion.
- Welding quality appears to have a significative effect on the Std-OIT depletion rate for all the geomembrane and temperatures studied. The influence of welding quality on results appears to be reduced with increasing geomembrane thickness.

- The inferior welding quality that visibly presented some sign of overheating and rippling met typical QA/QC peel and shear test requirements.

These preliminary findings will be re-examined as more data becomes available.

Roughness based prediction of geofoam interfaces with concrete

P.G. Sreekantan
Geotechnical Engineering Division, CSIR-Central Road Research Institute, New Delhi, India

G.V. Ramana
Department of Civil Engineering, Indian Institute of Technology Delhi, Hauz Khas, New Delhi, India

ABSTRACT: Geofoam is a popular lightweight material block, used for the structural filling for the construction of vertical approach embankments of road bridges over soft subsoils. The design of such embankments is driven by the differential settlement, as the overall settlement of the geofoam blocks is lower than the fascia wall. Thus, the critical interface is the geofoam blocks with the concrete fascia wall. In the present study, an attempt has been made to determine the geofoam-concrete interface characteristics using a series of interface tests in a direct shear box. Geofoam with varying densities and concrete with varying roughness were utilised for the study. Based on the observed test results, a non-linear model for predicting interface friction angle with the roughness index was derived. This study can be utilised for the design and site quality assurance based on the roughness index of the concrete retaining wall cast at the site.

1 INTRODUCTION

Expanded Polystyrene blocks, also known as "Geofoam," are rigid cellular foam blocks used in various geotechnical engineering applications. Since these foams are typically 20-100 times lighter than soil (ASTM D6817, 2021), they are commonly used as lightweight fill. Since its first application by the Norwegian Public Roads Administration for preventing excessive settlement in 1972 (Aabøe et al. 2019), geofoams were popularly used for the construction of road embankments resting over soft soil. (Farnsworth et al. 2008; Puppala et al. 2019). In the past decade, it has also been used for the construction of vertical approach embankments for road bridges over soft subsoils as structural fill material (Bartlett et al. 2012; Stuedlein & Negussey 2013). However, the fascia wall of such embankments undergoes considerable elastic and consolidation settlement. This generates differential movement at the geofoam-concrete interface, leading to the development of interface shear stress. The estimation of this interface shear resistance is important for the accurate numerical modelling and design of such walls. Apart from this, to increase the stiffness of the geofoam subgrade, it is a common practice to provide a cast in situ load distribution slab over the geofoam blocks (Stark et al., 2004). In this case, the quantification of the geofoam-concrete interface is essential for the translational sliding failure analysis.

Various researchers (AbdelSalam & Azzam 2016; Khan & Meguid 2019; Özer & Akay 2022; Sheeley & Negussey 2000) have evaluated the interface shear behaviour between geofoam and concrete. Some have used cast-in-situ concrete, whereas others have used precast concrete. The reported interface friction values varied between 25° to 48°, whereas the friction coefficient varied from 0.5 to 2.3. This variation can be attributed to the variation in the roughness of concrete and geofoam (Özer & Akay 2022). However, none of these researchers quantified the roughness parameters of concrete blocks used in the testing. In the case of monolithic materials, the mechanism of friction is also influenced by the hardness of both sliding materials. Geofoam

and concrete being dissimilar materials, the difference in hardness influence the interface friction parameters. No research is available to date quantifying the friction parameters with respect to the roughness or hardness of geofoam and concrete. Such a study will give a generalized approach for evaluating and predicting such interface friction coefficients.

The main objective of this paper is to study the interface frictional behaviour of geofoam and concrete with varying roughness indexes and study the correlation between the friction parameters and the relative roughness values of the geofoam-concrete interface. Such a correlation, if established shall be useful for any concrete surface, irrespective of cast-in-situ or precast. The results obtained from the direct shear tests for the interface were used for arriving at this correlation. To obtain a generalized prediction model for the geofoam-concrete interface, the influence of the roughness of both materials is incorporated using a relative roughness (R') parameter. Additionally, to evaluate the mechanism of shearing, the relative hardness between the materials was also estimated.

2 MATERIALS AND TESTING METHOD

Expanded polystyrene (EPS) geofoam blocks manufactured by two Indian companies E-Pack Polymers Pvt. Ltd. and Shree Insupac Ltd., were used for the present study. Geofoam blocks namely 15D, 20D, 25D and 30D having respective nominal densities of 15 kg/m^3, 20 kg/m^3, 25 kg/m^3, and 30 kg/m^3, were collected. Cubical specimens of size 60 mm × 60 mm × 12.5mm were cut out from the blocks using a hot wire. The measured mechanical properties of various geofoam types are listed in Table 1. The surface roughness profiles of the geofoam specimens were measured using an advanced stylus profiler having an accuracy of 8 nm, as shown in Figure 1a. The roughness profile was measured at three locations of each specimen over an evaluation length of 12.5mm. The measuring force of the stylus needle was maintained at 4 mN throughout the measurement. A typical surface roughness profile for each type of geofoam is indicated in Figure 1b. The roughness profiles indicate that the maximum and the mean surface asperity decreases with the increase in geofoam density. This can be attributed to the decrease in bead size and the increase in bead density with increasing density. The arithmetic average and the root mean square of the difference between the peak and valleys of the surface profile is represented by average roughness, R_a and R_q respectively, which is indicated in Table 2.

Table 1. Mechanical properties of the geofoam.

Property		Test Method	Geofoam Type			
			15D	20D	25D	30D
Apparent Density, (kg/m^3)		ASTM D1622 (2020)	14.17-17.36	18.20-22.78	24.20-27.43	33.63-34.71
Avg. Density, γ (kg/m^3)			15.76	20.50	25.8	34.17
Compressive resistance (kPa) at strain	1% (σ_1)	ASTM D1621 (2016)	27	29	44	66
	Yield (σ_y)		72	105	126	167
	10% (σ_{10})		87	119	141	198
Elastic Modulus, E_i (MPa)			2.73	2.93	4.45	6.63
Monoblock cohesion, C_b (kPa)		ASTM D5321 (2021)	21.6	31.6	40.3	42.5
Monoblock internal friction, φ_b (°)			6.7	15.5	20.5	24.2

The different plain cement concrete blocks were cast using varying mix proportions of water, cement, fine aggregate and coarse aggregate to obtain different roughness. The roughness profiles of concrete blocks were measured using the sand patch method (ASTM E1845, 2015). Three different concrete blocks with average roughness ranging from 0.6 mm to 1.1 mm were cast and cured for 7 days before testing. The hardness of the materials was measured using Shore hardness durometers. Shore A tester was used for geofoam blocks, while Shore D tester was used for
Figure 1.   a) Roughness measurement using stylus profiler, b) Roughness profile of geofoam with varying density (kg/m^3).

	Shore D	–	–	–	–	55	77	81
Classification			Extra Soft		Soft		Extra Hard	

concrete blocks. The measured values are indicated in Table 2. Geofoam can be classified as extra soft to soft material, while all the concrete specimens are extra hard materials.

The interface shear tests were conducted in a direct shear testing equipment with concrete and geofoam blocks of size 60 mm × 60 mm ×12.5 mm each. Since both the concrete and geofoam are rigid blocks, the scale and edge effect of the shear box is not anticipated on the friction behaviour. This test has the advantage of maintaining the horizontal load application at the same level of interface, minimizing any eccentricity. The concrete blocks and geofoam blocks were placed at the bottom and top boxes respectively. This ensured maintaining the same horizontal interface throughout testing. Tests were performed at a strain rate of 1mm/min, under three different normal stresses (18 kPa, 28 kPa and 48 kPa), which are well within the elastic limits of the geofoam.

3   RESULTS AND DISCUSSIONS

3.1   *General response*

The typical variation of friction coefficient with respect to shear strain is indicated in Figure 2. It can be observed that with the increase in the normal stress, the friction coefficient reduces leading to the disappearance of the peak. This can be attributed to the flattening of micro-indentations of geofoam with the increase in normal stress. It can also be observed that with the increase in the roughness of concrete, the peak friction coefficient increases. Residual friction coefficient increases from 0.50 to 0.54, when the roughness of concrete increases from 0.6 mm to 1.0 mm. The local ploughing of geofoam strands leads to the formation of a peak friction coefficient and is more evident with increasing roughness of the concrete. After attaining peak stress, the geofoam strands undergo micro-cutting, which is
Figure 2. Variation of friction coefficient of 25D geofoam grade under different normal stress for varying concrete roughness (a) C_1 (b) C_2 (c) C_3; (d) Variation of friction coefficient with C_3 concrete and varying geofoam grades at 25kPa normal stress; Failure envelopes for varying (e) geofoam grades (f) concrete grades.

followed by sliding along the concrete surface. Thus, residual stress may be attributed to the sliding mechanism only.

From Figure 2d, it can be inferred that for the same concrete grade and normal stress, the friction coefficient increases with the geofoam density. This can be attributed to the increased yield strength of the strands with the increase in geofoam density. Increase in yield strength results in the increased effort by the concrete for ploughing the geofoam strands. The formation of peak friction coefficient is also evident with the increase in geofoam density, indicating the ploughing mechanism. The extent of ploughing is influenced by the relative hardness of the sliding materials. With the increase in geofoam density, hardness also increases leading to increased effort in shearing. However, at large strains, the friction coefficient attains a nearly constant value of 0.53 for all the geofoam grades. Even though the roughness of geofoam decreases with increasing density, its effect is not visible in the friction coefficient. It can be inferred that the effect of geofoam density is more than the roughness of geofoam, and the initial resisting force arises from the ploughing resistance of the geofoam rather than sliding.

Thus, the friction mechanism of the geofoam concrete interface can be classified into three distinctive phenomena namely, ploughing in the elastic range, micro-cutting during yielding and sliding during large strains. The main parameters governing the friction behaviour are

the roughness of concrete, normal stress and the geofoam density. Figure 2e and 2f indicate that the slope of the failure envelope increases with the increase in the geofoam density and roughness of the concrete respectively. The results obtained are lower than the other reported studies as indicated in Table 3. Some of the studies (Sheeley & Negussey 2000; Özer & Akay 2022) adopted two different sizes of top and bottom blocks. They also positioned the concrete blocks over the relatively larger-sized geofoam blocks. This might have resulted in the additional passive resistance from the uncompressed zone of the geofoam blocks while shearing, leading to a higher friction coefficient.

3.2 Prediction models

A generalized prediction model is developed based on non-dimensional parameters. The roughness and hardness of the materials were non-dimensionalised using relative roughness and relative hardness indexes as given in Equations 1 and 2. Since ploughing of the geofoam peaks is the major influencing factor on the friction behaviour, the roughness parameter which accurately quantifies the localized peaks of surface asperity needs to be utilized for developing prediction models. Consequently, the roughness parameter R_q of geofoam is chosen for deriving the relative roughness index. However, in the case of concrete, average roughness obtained from the sand patch method was utilized for the same.

$$R' = \frac{R_c}{R_{q_g}} \tag{1}$$

$$H' = \frac{H_c}{H_g} \tag{2}$$

where R_c and Rq_g indicate the roughness parameters of concrete and geofoam respectively. H_c and H_g indicate the hardness of concrete and geofoam respectively.

The variation of peak friction coefficient and friction angle with respect to relative roughness is indicated in Figure 3a. As expected, both the friction coefficient and friction angle increase with the increase in relative roughness. It follows an exponential pattern, and the empirical relationship is obtained as given in Equations 3 and 4. This expression shall be used for quick estimation of interface frictional parameters between geofoam and concrete.

$$\mu = 0.43 + 0.07 \quad e^{(R'-22.5)/18.5} \tag{3}$$
$$\varphi = 21 + 2.9 \quad e^{(R'-22.5)/13.9} \tag{4}$$

Additionally, to understand the effect of hardness on the ploughing behaviour, the variation of peak friction coefficient and friction angle with the relative hardness, is shown in Figure 3b. It can be observed that with the increase in relative hardness, both friction coefficient and friction angle reduce and follows a dose-response curve. When the relative hardness is more than 25, the friction coefficient and friction angle attain a minimum value of 0.53 and 14 respectively. However, additional tests for a wider range of relative hardness are required for developing an empirical equation with higher reliability.
Figure 3. Variation of friction coefficient and friction angle with (a) relative roughness; (b) relative hardness.

4 CONCLUSIONS

The following conclusions can be made for the present study.

– The friction mechanism of the geofoam concrete interface has three distinctive phenomena namely, ploughing in the elastic range, micro-cutting during yielding and sliding during large strains. The friction behaviour is governed by the roughness of the concrete, the normal stress, and the density of the geofoam.
– The peak friction coefficient reduces with the increase in the normal stress due to the flattening of micro-indentations of geofoam. Local ploughing of geofoam strands leads to an increase in the peak friction coefficient with an increase in the concrete roughness and an increase in geofoam density. The extent of ploughing is influenced by the relative hardness of the materials.
– Empirical correlations were developed for the quick estimation of friction parameters for geofoam-concrete interfaces. They indicate that the friction coefficient and friction angle increase exponentially with increasing relative roughness, while decrease with increasing relative hardness. When the relative hardness is more than 25, the friction coefficient and friction angle attain a minimum value of 0.53 and 14 respectively.

Estimate of the nonwoven geotextile mechanical characteristics starting from the fiber characteristics

Francesco Niccolai*

Ecofibre, Italy

ABSTRACT: The study in question is based on the specific industrial experience made on nonwoven lines consisting mainly of the following manufacturing phases: opening of the fiber, carding , pre-punching, needling 1, needling 2, folding, calandering.

The raw material considered is made of high tenacity polypropylene (PP) fiber. The study starts from the analysis of the fiber resistance trend in reference to the EN ISO 5079 toughness test, in order to characterize the behavior of a mixture of up to three types of fibers. The specific processing characteristic of the production line is represented by the specific mechanical tensile resistance values obtained on the nonwoven geotextiles with reference to EN ISO 10319. Subsequently, the loss of resistance of the mixture due to the different toughness and elongation of the three components of the mixture is determined. Moreover, the weighted resistance values of the individual components of the mixture are calculated in order to determine the toughness of the mixture itself. Starting from the toughness of the mixture, as estimated above, the resistance of the resulting nonwoven geotextiles is linearly obtained. In order to evaluate this model, the values of an historical series of production control tests have been processed.

1 INTRODUCTION

This study refers to the experience made on an industrial plant for the manufacturing of nonwoven needle-punched geotextiles consisting of the following phases:

– opening of the fiber, carding, folding, pre-punching, needling 1, needling 2, calandering
  This plant processes high tenacity polypropylene (PP) fiber starting from staple, that is fiber already cut to size. Hereafter some relevant characteristics of the fiber, i.e. fiber length, title, toughness, elongation, are reported.

Table 1. Some typical values of high tenacity polypropylene (PP) fiber.

Fiber length [mm]	Title [dtex]	Tenacity [cN[dtex]	Elongation [%]
70–90	4.4–6,7	4.8–5.6	70–100

The high tenacity polypropylene fiber is used for the production of nonwoven needle-punched geotextiles which are usually adopted in geotechnical works with different functions as separation, drainage, filtration and protection.

*Corresponding Author: f.niccolai@ecofibre.it

The nonwoven needle-punched geotextile is a technical product and is mainly characterized by its mechanical, hydraulic and durability characteristics.

The main mechanical characteristics, as illustrated by Cazzuffi (1996) and Corbet & Cazzuffi (2017), are the following:

– Wide-width tensile strength in reference to the EN ISO 10319 standard
– Static puncture resistance in reference to the EN ISO 12236 standard

The performance of the product on site could directly influence its applicability in specific geotechnical works.

The mechanical characteristics of the product are influenced by a series of factors, as:

– Type of fiber
– Mechanical characteristics of the fiber
– Type of machines used in the manufacturing processes and equipment of the machines
– Parameters used in the machine settings

The purpose of this study is to have a tool to predict the mechanical characteristics of the nonwoven geotextile starting from the tenacity and elongation characteristics of the fibers used in the blends for the realization of the nonwoven. In particular, the relationship between the characteristics of the original fibers and the mechanical characteristics obtained on the finished product, i.e. the nonwoven geotextile, is mainly investigated.

The approach takes into consideration the specific reference characteristics of the finished product, defined on the basis of experience, moreover it models the characteristics of the fiber, and the behavior of the blend in order to define a semi-empirical relationship between the main characteristics of the blend of fibers and the specific tensile strength of the nonwoven geotextile obtained in factory using this blend.

In particular, it is considered the common case that the production of nonwoven geotextile is carried out using fibers from two or three different suppliers, which necessarily have different mechanical characteristics, even if within the limits of acceptability imposed by the company's quality systems.

In order to characterize the performance of the finished product, the specific resistance will be considered: the specific resistance Rs is defined as the tensile strength (kN/m), obtained through EN ISO 10319 test, for every 100 grams per square meter of finished product (100 g/m^2).

Table 2. Abbreviations adopted for fiber parameters and nonwoven geotextile parameters.

Fiber parameters	Nonwoven geotextile parameters
Alfn [%]: Elongation of fiber nth in reference of ENISO10319	Ag [g/m^2]: Areic mass of nonwoven
Fibern [%]: Fiber nth quantity in blend	Rs [kN/m/(100g/m^2)]: Specific tensile strength reference
Tfn [cN/dtex]: Tenacity of fiber nth	Rnw [kN/m] = Ag·Rs/100:
Rt [cN/dtex]: Fiber reference tenacity	Reference tensile strength resistance of nonwoven
Ral [%]/[1% Elongation Difference]: Tenacity loss reference due elongation difference	Tnw [kN/m]: Estimated tensile strength resistance of non woven
RtLossn [%]:Fiber nth tenacity loss respect Rt	Rr [%] = Wrt/Rt: Nonwoven residual resistance respect Rnw
RaLossn [%]/[1% Elongation Difference]: Tenacity loss of fiber nth respect Ral	Rses [kN/m/(100g/m^2)]: Estimated specific tensile strength resistance
Rtfn [%]: Residual tenacity of fiber nth respect Rt	Rstest [kN/m/(100g/m^2)]: Tested specific tensile strength resistance
Wrtn[cN/dtex]: Weighed tenacity of fiber nth	
Wrt [cN/dtex]: Total tenacity of fibers blend	

Furthermore, based on experience, the tenacity Rt of the fiber required to obtain the Rs value will be defined.

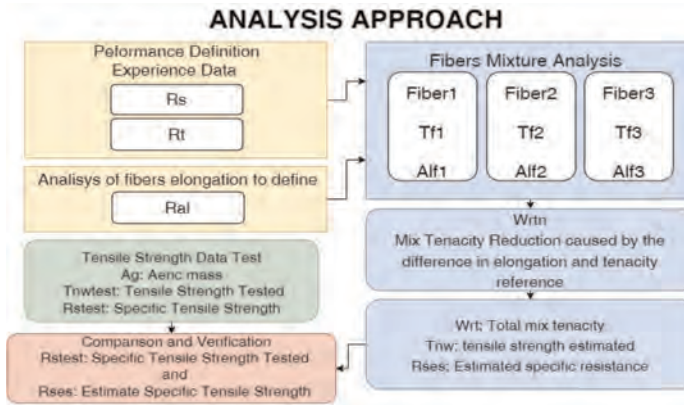
This approach makes it possible to avoid analyzing the complexity of the production process, the specific type of line and the particular set of industrial machinery adopted, as well as the specific mechanical, electrical and electronic parameters of each machine, considering only the ability to generate specific tensile strength resistance on the nonwoven geotextile (Figure 1).


Figure 1. Approach scheme.

2 CONSIDERATIONS ON THE POSSIBLE CORRELATION FIBRE – GEOTEXTILE

2.1 *Nonwoven geotextile*

The nonwoven geotextiles are formed by a set of mechanically bonded fibers and one of the main characteristics is the tensile strength, measured according to the EN ISO 10319 test. They are generally isotropic products, so in this analysis we will assume that the considered products are isotropic : in particular the average between machine and cross-machine direction resistance is adopted as the parameter of reference. In order to define a general and normalized parameter of performance of nonwoven geotextile, a specific tensile strength is defined in kN / m for every 100 g / m2 of nonwoven geotextile. This parameter would be defined considering the optimal processing and the use of fiber with optimal characteristics which will be defined respectively as Rt and Rs. These values are used to characterize the performance of a specific production line beyond any particular characteristic of the plant and of the machines, allowing for considerable simplification. These values may vary between different production plants and could allow for a general application of the estimation method in object.

Some basic assumptions:

– Nonwoven geotextile is an isotropic product
– The tensile strength of the nonwoven geotextile is linearly proportional to the tenacity of the blend of fibers used
– The tensile strength of the nonwoven geotextile is linearly proportional to the mass per unit area of the nonwoven geotextile itself

2.2 *Fiber tensile strength modelling*

Polypropylene fibers have a density of about 0.91g/cm^3; high tenacity fibers are defined fibers with tenacity generally higher than 4.8cN / dtex. The fiber tenacity test is performed

according to EN ISO 5079. The typical curve of a tensile strength test on the fibre is of the type:
Figure 2.   Fiber tenacity test result example.
Figure 3.   Fiber model example.

In order to simplify the calculations, the tenacity/elongation curve is modeled through two straight lines, one starting from zero up to the elastic limit and one, in the plastic part, which goes from the elastic limit to the tenacity and elongation at break, as illustrated in Figure 3.

In order to use only the tenacity and elongation data detected by the fiber control tests, the trend of the resistance of the fibers is modeled by setting the elastic limit at an elongation of 25% of the maximum elongation at break. In the same type of modelisation, the yield strength is set at 85% of the maximum detected tenacity.

This simplified approach allows to model the fibers tensile strength trend only by having the values of maximum tensile strength and elongation at break, which are the relevant values in the fiber control tests. This model simplifies the subsequent analysis of the tenacity and elongation characteristics of the blend of fibers consisting of a maximum of three types of fibers.

2.3   *Fibers blend considerations*

A blend of 3 fibers from different suppliers is considered, as it is common to select different types of fibers in this type of manufacturing of nonwoven geotextiles. A further assumption is that the strength of the nonwoven geotextile is linear with respect to the tenacity of the fiber and that the contribution to the total tenacity of the blend of fibers is linear with the percentage of quantity in to the blend of fibers.

To determine the tenacity of the blend of fibers, the following aspects are considered:

– The tenacity of the fibers blend is the sum of the tenacity of the single types of weighted fiber in relation to the quantity in the blend
– The difference in elongation at break between the three types of fibers generate a reducing of total tensile strength of fibers blend
– The difference in overall tenacity of the fibers blend will be compared with the optimal Rt reference value

In order to clarify the behavior of tensile strength resistance of blend of fibers we can make an example, of two fibers. Consider fiber F1 with 100 % of elongation at break and fiber F2 with 80% of elongation at break, we can consider overall tensile strength as the sum of single tensile strength until the fiber F2 arrive at breaking point. Subsequently of this point only the F1 tensile strength contribution remain. So the effect of difference of elongation at break of type of fibers is a decreasing of overall tenacity of fibers blend.
Figure 4.   Example of blend model.

2.4   *Analisys of influence of fibers elongation*

The difference in elongation at break of the fibers in a blend generates an inhomogeneity effect, which reduces the overall strength of the fibers blend, which we will evaluate as a percentage reduction due to the difference in elongation.

In order to calculate the reduction of the tenacity of the blend, we consider two fibers that have extreme characteristics in a typical range of polypropylene fibers, also considering that the fibers that detect greater tenacity generally detect a lower elongation:

– Fiber 1 (F1): tenacity 4.8cN/dtex, elongation 100 %
– Fiber 2 (F2): tenacity 5.6cN/dtex, elongation 70 %

To simplify calculation we propose to mediate the tenacity of F1 and F2 in the linear plastic part of the curve. Through a linear regression equation we can find a relationship that allows us to define the reduction in tenacity in relation of the elongation (Figure 4). Evaluating of angular coefficient of regression line of Av average trend line y = 1,28x + 4,16 we see that the tenacity reduction is 0.0128[cN/dtex] for 1[%] of elongation. In order to obtain a percentage value, we can refer this tenacity with respect of average Av trend line tenacity at 70[%] of elongation that is 5.056[cN/dtex], obtaining 0.0128/5.056 = 0.2532[%]/ [1% difference]. So we assume that the decreasing of tenacity with respect the 1[%] difference of fibers elongation is −0.2532[%]/ [1% difference], note that in hereinafter calculus we round the value Ral = −0.26[%]/ [1% difference]

This value mean that if we found a difference of 10% in elongation between two fibres, the fiber that has the higher elongation contribute to the fibers blend tenacity loosing 2.6 % of tenacity.

We consider the effect of reducing tenacity due to the difference in elongation at break, for the types of fibers contained in the blend calculating the tenacity loss for fiber nth with respect of the fiber that has the lowest elongation as following:

$$RalLoss_n = [Alf_n − min(Alf1, Alf2, Alf3)] \cdot Ral \ \ [\%] \tag{1}$$
Figure 5.   Fibers model with two fibers with limit characteristics.

For example, if we have fiber F1 with 100 % of elongation at break and fiber F2 with 80% of elongation at break, we obtain a value of reduction in tenacity of fiber F1, RalossF1 = Rt·(−5.2%)

We will obtain as results: RalLoss1, RalLoss2, RalLoss3 the reduction in tenacity due to the difference in elongation of each type of fiber compared to the one that has the lowest elongation.

2.5 *Analisys of influence of tenacity fibers difference with respect of the reference tenacity*

Let us now consider the percentage reduction effect of the tenacity of the blend of fibers, due to the difference between the tenacity of the three types of fibers with respect the reference tenacity detected by experience in reference of the fiber control tests and tensile strength test data on nowvoven geotextiles. Following fiber nth tenacity percentage respect of the reference tenacity Rt (Equation 2):

$$RtLossn \ [\%] = \frac{Tfn}{Rt} - 1 \tag{2}$$

We will get the reduction values for each fiber: RtLoss1, RtLoss2, RtLoss3.

2.6 *Estimation of nonwoven geotextile tensile strength*

In order to estimate tensile strength resistance of nonwoven geotextiles we consider RaLossn and RtLossn and we calculate the residual tenacity of the fiber nth, Rtfn:

$$Rtfn = 1 + (RaLossn + RtLossn) \ [\%] \tag{3}$$

Subsequently we'll calculate the weighted tenacity of fiber nth considering also the percentage quantity of fiber included in blend of fibers (Equation 4).

$$Wrtn = Rtfn \cdot Rt \cdot Fibern \ \ [cN/dtex] \tag{4}$$

And finally we can obtain total tenacity of blend of fibers as:

$$Wrt = Wrt1 + Wrt2 + Wrt3 \ \ [cN/dtex] \tag{5}$$

The total blend tenacity Wrt can be compared with Rt fiber reference tenacity, and remembering assumption:

"The tensile strength of the nonwoven geotextile is linearly proportional to the tenacity of the blend of fibers used" in Equation (6) it's possible to calculate the tensile strength of non woven geotextile making a proportion with blend of fibers tenacity and fiber tenacity reference, multiplied by reference tensile strength tenacity of non woven geotextile

$$Rnw = Ag \cdot Rs/100 \tag{6}$$

In this way we find the nonwoven tensile strength resistance in relation of tenacity of fibers blend.

$$Tnw = \frac{Wrt}{Rt} \cdot Rnw \ [kN/m] \tag{7}$$

So we arrive to find the estimated specific tensile strength resistance dividing by mass per unit area:

$$Rses = \frac{Tnw}{Ag} = \frac{1}{Ag} \frac{Wrt}{Rt} \quad Rnw = \frac{1}{Ag} \frac{Wrt}{Rt} \quad \frac{Ag}{100} \frac{Rs}{Rt} = \frac{Wrt}{Rt} \frac{Rs}{100} \ [kN/m]/[100g/m^2] \tag{8}$$

The specific tensile strength resistance Rses can be compared with reference specific tensile strength resistance Rs to understand if the process is in line with expectation or not.

Table 3. Resistance estimation example (with equation reference).

Parameters	Value			Blend Fibers			
Ag [g/m^2]	200			**Fiber 1**	**Fiber 2**	**Fiber 3**	**(Equation.)**
Rs [kN/m/(100g/m^2)]	8.0		Fibern [%]	35	32	33	
Rnw [kN/m]	16		Alfn [%]	90	80	70	
Rt [cN/dtex]	5.2		Tfn [cN/ dtex]	4.8	5.0	5.2	
Ral [%]/[1% DeltaE-long.]	−0.26		RaLossn [%]	−5.2	−2.6	−0.0	(1)
			RtLossn [%]	−7.69	−3.85	−0.0	(2)
			Rtfn [%]	87.1	93.6	100.0	(3)
			Wtrn	1.5854	1.5567	1.7160	(4)

Results	4.858	(5)	93.42	14.95	(7)	7.474	(8)

2.7 Statistical analisys

In order to test the model we made a statistical analisys on 105 tensile strength test results made by Ecofibre's internal laboratory. The analisys compares Rses, the specific tensile strength resistance of nonwoven estimated by this model and the specific tensile strength resistance of nonwoven calculated by tensile strength tests results Rstest.
Figure 6. Data of percentage difference between specific tensile strength estimated and tested.

Table 4. STATISTICAL PARAMETER of percentage difference between specific tensile strength comparison between estimated and tested values on 105 samples.

Rses[kN/m/(100g/m^2)] difference from expected	
Average	−1.036 [%]
Max	29.05 [%]
Min	−21.00 [%]
Dev.Standard	9.47 [%]
IC95[%]	1.31 [%]
IC99[%]	1.72 [%]
Figure 7. Percentage difference distribution.

Hereinafter the comparison of specific resistance distribution estimated by the model is given in Figure 8, while the actual values obtained by test results are illustrated in Figure 9.
Figure 8. Specific tensile strength by model.
Figure 9. Specific tensile strength by test results.

Table 5. STATISTICAL PARAMETERS in reference of distribution in (Figure 8) and (Figure 9) [kN/m/(100g/m^2].

Statistical Parameters Graph (Figure 8)		Statistical Parameters Graph (Figure 9)	
Average	7.40	Average	7.29
Max	8.93	Max	8.95
Min	6.19	Min	5.92
Dev.Standard	0.55	Dev.Standard	0.59
Kurtosis	0.73	Kurtosis	−0.13
IC95[%]	7.66 [%]	IC95[%]	8.19 [%]
IC99[%]	10.06 [%]	IC99[%]	10.76 [%]

We can see that the shape and frequencies of the distributions are very similar, so it could mean that the model is representative. Considering also that the reference of specific tensile strength is fixed as the optimized value obtainable from the process, we may think that the slightly greater dispersion of data of testing could be due to non-optimal processing.

An example of smartphone app in development is also reported in Figure 10.

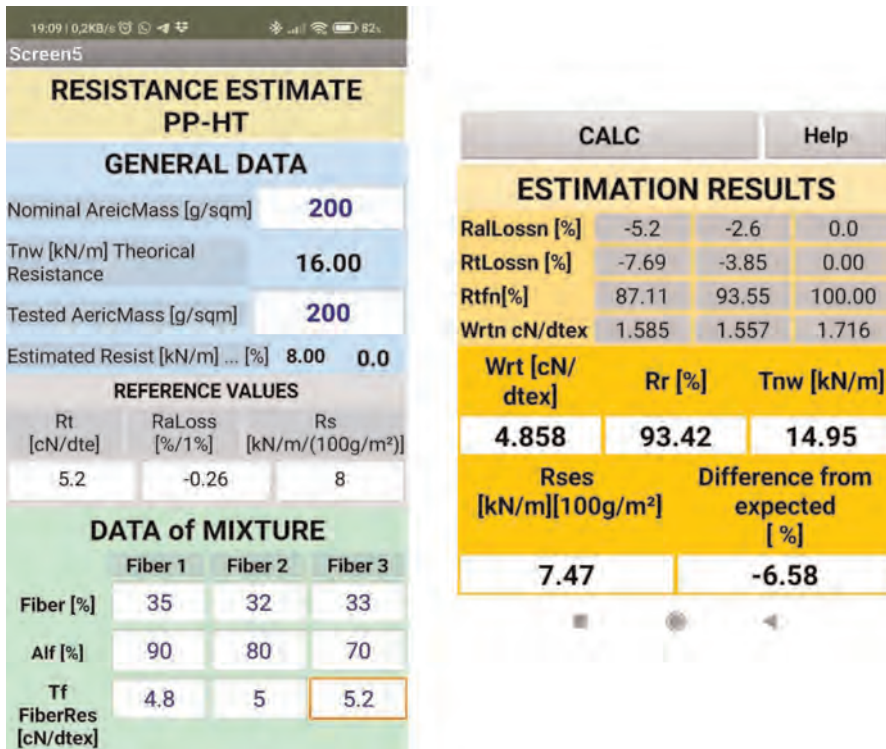
This simplified method could be implemented in app or other software to have a simple tool to be used to predict nonwoven tensile strength result in reference of fibers used to produce it, and it could permit also to optimize the selection of the original fibers. Also the


Figure 10. Screenshot of the smartphone app under development.

method could give indications about the efficiency of line of nonwoven production giving reference values to be compared with tested performance of nonwoven produced, in order to understand and continuously check the performance of the machinery setup.

Concluding we can say that this approach, that surely may be improved, could represent an interesting tool for people that work in nonwoven production plants – in particular for management and quality assurance phases – in order to estimate and verify the main results of process.

Soil-geosynthetic interaction

Experimental and numerical investigations on the pullout behaviour of coir geotextile

N. Kumar, M.S. Narayanan, S. Thasneem & R.K. Kandasami
Department of Civil Engineering, IIT Madras, Chennai, India

ABSTRACT: The pullout mechanism (typically due to friction and bearing) is influenced by the type of reinforcing material and the soil properties. To an extent, the interfacial behaviour of coir geotextiles with the surrounding matrix is affected by the low stiffness of the material. In this study, in order to quantify the soil-coir geotextile interaction, a series of pullout experiments were carried out with geotextiles having different mass density. For a particular normal stress, it was observed that geotextiles with higher mass density exhibit higher shear resistance during pullout. Further, for the coir geotextile having a specific mass density, a better shear mobilization was realized at a particular normal load. In order to predict the soil-coir geotextile interaction behaviour precisely, a three dimensional (3D) numerical model was developed in this study. Using an appropriate constitutive law for the geo-material and contact law for soil-geotextile interface, the numerical model was validated with the experimental results. This numerical model will be helpful in quantifying the extent of shear mobilization under different boundary conditions.

1 INTRODUCTION

Geotextiles are increasingly becoming an essential product for many geotechnical applications. Conventional forms of geotextiles are typically made of petrochemical derivatives such as polypropylene, polyethylene, polyester, and polyvinyl. These geosynthetic materials have good mechanical and durability characteristics however having high initial production cost and being unsustainable. With growing awareness towards utilization of sustainable materials in the construction sector, it is essential to explore alternate natural products (Rawal & Anandjiwala 2006). Natural fibres from plants such as coir, sisal, jute, hemp, flax, bagasse, abaca, bamboo, ramie, pine and many more are extensively available, especially in tropical and subtropical countries (Kumar *et al.* 2022). These natural fibre-based geotextiles have a great potential to substitute synthetic geo-materials owing to their comparable mechanical characteristics and abundant availability. It has been observed that some of the natural fibre-based geotextiles, in addition to being sustainable, exhibit high tensile strength and fracture modulus (Faruk *et al.* 2012). However, durability is the prime concern which inhibits its utilization in many construction projects. Among the various natural fibre-based geotextiles, coir geotextile is the most durable material (Vivek *et al.* 2020). The durability and strength can further be improved by performing physical and chemical treatments (Anggraini *et al.* 2016). Hence, before utilizing these geotextiles extensively in the field, it is important to quantify their suitability for specific applications. Existing studies showed that coir geotextiles could fulfil all the primary functions of synthetic geotextiles and have been successfully used as primary reinforcement layer in retaining walls, soil slopes, embankments of earthen dams, railways and highways and so forth (Lekha 2004). However, when used as a reinforcement, soil-geotextile interfaces act as a potential plane of failure especially during

shear due to pullout. Since the interfacial characteristics of coir geotextiles play a significant role in mobilizing the shear resistance between the reinforcement and the surrounding soil matrix, a comprehensive understanding of these interfaces is essential, especially in applications where the reinforcements are under tension, as shown in Figure 1a. The shear resistance provided by the geotextile is primarily due to two distinct mechanisms i.e., skin friction between the soil-geotextile interface and bearing resistance provided by the soil present in the aperture of the geotextile (Hussein & Meguid 2016). To quantify the interfacial characteristics under controlled conditions, a laboratory experimental technique such as the pullout test (Figure 1b) is widely adopted (Subaida *et al.* 2008). In this study, a suite of experiments was carried out on different grades (based on mass density) of coir geotextiles to quantify the pullout capacity of reinforced earth. Additionally, a three-dimensional numerical model of geotextiles with appropriate constitutive/ contact laws was developed to accurately analyze the interfacial behaviour of reinforced soil. Most numerical studies in the past have used simplified assumptions related to either geosynthetic geometry or the constitutive/contact model. Limited studies have been reported on the 3D numerical modelling of geosynthetics. A realistic three-dimensional modelling will help in accurately predicting the role of interface during the shear and pullout mechanism of geotextiles inside the soil. By using appropriate material and model parameters, the 3D numerical model used in this study was validated with the laboratory pullout experiments.

2   CHARACTERIZATION OF MATERIALS

2.1   *Coir geotextile*

Coir geotextiles having a mass per unit area of 400, 900, and 1600 g/m^2 were used for the laboratory pullout experiments. Before performing the pullout test, the coir geotextiles having different mass per unit area were characterized to determine the physical and mechanical properties. The summary of various properties of the geotextiles used in this study is shown in Table 1.

Table 1.   Various physical and mechanical properties of coir geotextiles.

Mass density (g/m^2)	1600		900		400	
Direction	Warp	Weft	Warp	Weft	Warp	Weft
Tensile strength* (kN/m)	32.75	30.90	14.25	12.90	6.89	5.26
Failure strain* (%)	30.82	28.38	25.80	23.95	20.62	19.40
Thickness (mm)	4.032 − 4.52		2.55 − 2.96		1.306 − 1.68	
Aperture size (mm)	12.35 × 4.05		17.4 × 9.5		24.5 × 16.5	
Fibres density (g/cm^3)	1.593		1.288		1.202	

*Average values.

2.2 *Tensile strength*

The tensile strength of the coir geotextile was determined as per ASTM D4595 standards. The variation of tensile force with the axial displacement in the warp direction for different mass densities of coir geotextiles is shown in Figure 2. The experimental results indicated that the tensile strength and failure strain of coir geotextile primarily depends on the geotextile's mass per unit area (GSM) and the number of yarns in both directions of geotextiles. Additionally, the geotextiles with higher GSM (mass per unit area) exhibited a higher failure strain and tensile strength compared to lower GSM geotextiles. Furthermore, the tensile strength and failure strain of the coir geotextile in the weft direction was comparatively lesser than in the warp direction.
Figure 2. Tensile characteristics of coir geotextiles having different mass density (GSM).

2.3 *Characterization of geo-materials*

The geo-material used in this study to carry out pullout experiments was dry river sand with a specific gravity of 2.69 and a uniformity coefficient of 2.86. The sand has a dry unit weight of 16.73 kN/m^3 and was compacted at a relative density of 80 % to perform the laboratory tests.

3 LABORATORY PULLOUT EXPERIMENTS

The experimental setup consisted of a steel box having a square cross-section of 300 × 300 mm and an overall depth of 230 mm, as shown in Figure 1b. The tangential loading unit consisted of a horizontal actuator and a load cell connected in series with the loading shaft, which was further attached to a clamp to hold the geotextile in a tangential direction. Additionally, the normal load (connected to a load cell having a capacity of 100 kN) was applied on the loading cap through a steel ball which spread the load uniformly over the soil surface. During specimen preparation, sand was pluviated into the box in four layers and compacted adequately to achieve a desired relative density of 80%. A coir geotextile having a width of 200 mm was placed in between the two halves of the box, and enough gap was provided to minimize friction between the steel box edges and the surface of coir geotextile. After carefully placing the geotextile inside the steel box, the gap between the box's upper and lower half was covered by a thick strap to avoid any soil loss from corners during the pullout loading. All the geotextiles were pulled tangentially to the steel box at a

rate of 1 mm/min under a constant normal load of 0.5 kN, 1 kN, 1.5 kN, and 2.0 kN. During the testing process, proper care was taken to make sure the tangential loading unit was coaxial with the geotextile for proper transmission of force along the shearing plane without causing any eccentricity.

3.1 *Results and discussion from laboratory pullout tests*

The shear stress mobilization during the pullout test depended on the geometrical and mechanical properties of coir geotextiles in addition to the boundary stresses. The pullout resistance of geotextile with very closely spaced yarns (1600 GSM) was nearly double that of the open mesh geotextile (400 GSM), as shown in Figure 3a. This pullout behaviour could be due to the high frictional resistance in geotextiles with closely spaced yarns which increases the surface area as well as adequate bearing resistance generated due to high lateral confinement of the soil present inside the apertures. The result shown in Figure 3a illustrates that the pullout resistance has a substantial correlation with the mass density, aperture size and thickness of geotextiles. Further, due to the higher stiffness of closely spaced yarns in geotextiles, the shear mobilization rate was higher than in open mesh/ lower GSM geotextiles. In addition, for any geotextile (irrespective of their mass per unit area), the maximum pullout resistance, shear displacement, and shear mobilization rate depended on the specific set of normal loads (Figure 3b). With the increase in normal load (up to a certain extent), the maximum pullout resistance increased while the corresponding displacement decreased. However, when geotextiles with low mass density were subjected to a very high normal load, only the coir geotextiles were stressed, leading to tearing failure before shear mobilization could occur. Experimental results for 900 GSM demonstrated that, at a very low normal load (0.5 kN), large displacement was observed before reaching the peak capacity; this could be due to lesser frictional resistance and lower confinement of soil inside the aperture of the coir geotextile, which allows the geotextiles to move in tangential direction without mobilizing peak shear resistance. Hence, an optimum normal load should be applied over the coir geotextile reinforced soil to mobilize their peak shear resistance within the permissible limit of displacement. This study showed that the maximum pullout resistance within the permissible displacement limit occurred at 1 kN of normal load (Figure 3b) for 900 GSM coir geotextiles. However, this observation needs to be validated with further laboratory experiments and field tests.
Figures 3   a, b. Pullout characteristics for different grades of coir geotextile at different normal loads.

4 FINITE ELEMENT MODELLING OF GEOTEXTILE REINFORCED SOIL BED

A three-dimensional finite element model was developed using ABAQUS (Figure 4) to simulate the pullout test for determining the interfacial characteristics. All the geometrical and mechanical parameters of the geotextile were fixed based on the experimental results obtained from the laboratory tests.
Figure 4.   Different loadings and boundary conditions in numerical model.

4.1   *Geometrical modelling and validation*

A coir geotextile of 900 GSM was used for simulating the pullout experiment. Due to the difficulties in meshing the realistic woven geometry of coir geotextiles, the geotextile geometry was modelled as a cuboidal structure with rigid joints while retaining the aperture size and dimensions. Both the soil and geotextile were discretized using eight-noded linear brick elements (C3D8). The model was simulated using 157,373 elements. The soil-geotextile interface was modelled using the ABAQUS inbuilt Master-Slave contact pair technique with surface-to-surface contact discretization. The part with the coarser mesh (i.e., soil) was considered the master surface, and the one with the finer mesh (i.e., geotextile) was considered the slave surface. The master-slave model incorporated both tangential and normal behaviour between the soil and geotextile. The tangential behaviour was based on the Coulomb friction law, which used two input parameters, friction coefficient ($\mu = 0.74$) and a tolerance parameter ($E_{slip} = 0.005$). The normal behaviour, based on the contact pressure-overclosure model, was incorporated using two models; the hard contact model and the linear softened contact model. The hard contact model, which does not allow the penetration of the geotextile into the soil, was used for both the horizontal sides of the geotextile as well as the vertical sides of longitudinal yarns. A linear softened contact model was used for the vertical sides of transverse yarns since the geotextile penetrates into the soil when subjected to pullout force. The boundary conditions of the model were defined such that the base is fixed, and the sides of the soil model are allowed to move only in the vertical direction (roller support). Initially, geostatic loading was applied to the whole model. Further, a normal pressure of 11 kPa (a total of 1 kN normal load) was applied at the top surface, followed by a velocity-controlled pullout load at the rate of 1 mm/min. The properties of the coir geotextile were obtained from the uniaxial tensile test performed in the laboratory. A non-linear elastic-plastic constitutive law based on the Von Mises failure criterion was used for the geotextile. The soil was modelled using the elastic-plastic Mohr-Coulomb model, which involves five input parameters, as shown in Table 2.

Table 2. Input parameters for validation of numerical model.

Density (kg/m^3)	E (MPa)	μ	Φ°	Ψ°	C (kPa)
1681	50	0.3	39.39	9.38	11.79

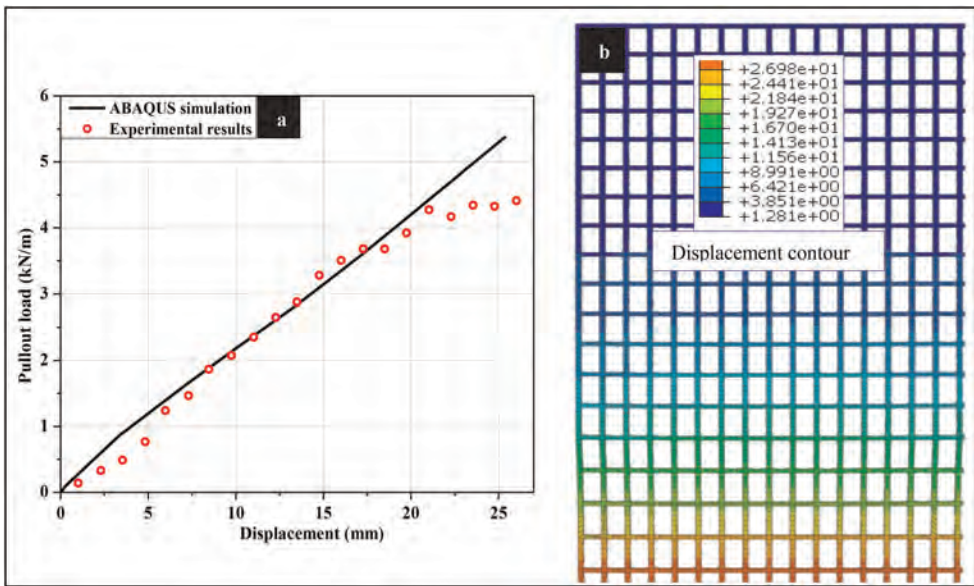
The numerical results were validated against the experimental data (Figure 5a) obtained from the laboratory pullout tests. From the displacement profile, the shear mobilization was observed for a considerable length of geotextile inside the soil box (Figure 5b). This model accurately predicted the pullout response until a certain displacement. The slight deviation in the pullout resistance at higher displacement can be attributed to the simplification of geotextile geometry, choice of joints in the numerical model, interface friction/contact parameters, as well as the low stiffness response of geotextiles. Additional studies are required to accurately quantify the pullout mechanism i.e., individual contribution of friction and bearing towards the pullout behaviour.


Figure 5 a. Validation of the simulation with the pullout experimental results, b. Displacement contours of the coir geotextile inside the soil during pullout.

5 CONCLUSIONS

- Pullout resistance of coir geotextiles was observed to be dependent on the mass density of the coir geotextile and the magnitude of normal load applied to it. Further, the extent of shear mobilization during pullout depended on the strength and stiffness of coir geotextiles
- Shear mobilization rate and maximum pullout resistance of coir geotextiles depended on the optimal normal load. A higher normal load led to maximum stretching of geotextile between the clamp and the face of the box during the pullout test without mobilizing the peak shear resistance in the soil

- The numerical model was successful in predicting the load-displacement response of coir geotextiles subjected to pullout until a displacement of 22 mm. Realistic geometry needs to be considered for predicting the pullout behaviour under large displacement.

ABSTRACT: The interface shear strength between geomembranes and other materials plays an important role in waste landfills and has been investigated over the years. Although prior investigations regarding different types of used materials, just a few publications were found concerning the geomembrane´s surface. This paper presents a study which shows several roughness parameters of one smooth and three textured geomembranes and tries to relate them to the interface shear strength. The results showed a great potential of these parameters to help understanding how the geomembrane surface contributes to the interface shear strength.

1 INTRODUCTION

Geomembranes have been used as impermeable material in geotechnical constructions such as waste landfills and water transportation canals and the shear strength between them and overlaying materials has a paramount function in order to avoid the sliding of the latter over the geomembrane. Laboratory tests can be performed to estimate interface friction angle (ϕ_i) and the adhesion (a) values of the interfaces. In this context, the direct shear test can overestimate the obtained values for low applied normal stresses. One technique which can be used to reduce this problem is the investigation of these interfaces by means of inclined ramp tests (Palmeira & Viana 2003; Pitanga et al. 2009). Large-scale experiments were conducted by Briançon et al. (2002) and the results were compared to ramp tests. The authors found close obtained values when comparing field and laboratory experiments, therefore showing satisfactory results for the ramp tests.

Besides the type of experiment, many factors can affect the obtained values such as the geomembrane asperity height, and polymer. Regarding the granular overlying material, the results can vary depending on the granular material density, particle shape and its grain size distribution (Abdelaal & Solanki 2021; Bacas et al. 2011; Palmeira & Viana 2003; Pitanga et al. 2009). In this context, the geomembrane surface has also a potential influence on the interface strength.

In the recent years, several investigations have shown that the geomembrane surface can also impact on the interface shear strength based on the micro and macroroughness distribution (Vangla & Gali 2016). Recently, the current devices that can measure roughness characteristics have been improved so that more parameters can be obtained.

This paper shows the results of inclined plane tests of four geomembranes (one smooth and three textured) in contact with sand. Additionally, several bidimensional roughness

---

parameters were evaluated to understand how they could influence on the interface shear strength. The results of the surface parameters were compared to the interface shear strength to imply which one has the best relation to the geomembrane-soil resistance.

2 ROUGHNESS PARAMETERS

Several surface parameters are specified by the ISO 4287 (1997). In this investigation, four parameters are associated to the surface height (Figure 1): (i) the Maximum Height of the Profile (R_z), (ii) the Total Height of the Profile (R_t), (iii) the Arithmetical Mean Deviation of the Assessed Profile (R_a) and (iv) the Mean Height of Profile Elements (R_c). It is important to point out that in the analysis there is a difference between the sampling length and the evaluation length: the first one is measured in each parallel line drawn in the surface and the evaluation length is defined as the sum of "n" sampling lengths. In this study, ten sampling lengths were used.

3 MATERIALS AND EQUIPMENTS USED

Four High Density Polyethylene (HDPE) geomembranes were used in the tests as impermeable material: one smooth, two blown film textured and one flat die textured and they are illustrated in Figure 2.

As overlying material, a 50-mm thick medium uniform sand was placed, lifted in two layers for compaction control. The material had angular grain sizes ranging from 0.16 mm to 2 mm and according to the Unified Soil Classification System (USCS -ASTM D2487-17e1 2017), it was classified as poorly graded (SP). For the experiments, a relative density (Dr) of 57% was adopted, which resulted in a peak friction angle of 39°. Table 1 summarizes the main properties of the used materials.

The used inclined plane apparatus was composed by a metal frame structure with a rigid base which has a hinge at one extremity and a hook at the other side (Figure 3a) with a large box (1.90 m long and 0.50 m wide) over it. Prior the tests, sandpaper was glued to the ramp surface to increase friction with the lower geomembrane face. Then, the geomembrane was

Notes: [1] ASTM D6913/ D6913M-17, [2] ASTM D3080/D3080M (2011), [3] ASTM D5261 – 10 (2018), [4] ASTM D4595 – 17 (2017), [5] ASTM D5199-12 (2019), [6] ASTM D7466-08 (2008), [7] ASTM D1505-18 (2018) and [8] ASTM D4885-01 (2018).

rested on the sandpaper. The tested side as interface was the outer side of geomembrane´s roll. This represents the typical situation of canal constructions for water supply, where the geomembrane is commonly in contact with a soil layer.

The test strain rate adopted to raise the plane was $3 \pm 0.5°$ / minute and the experiments were finished when the box displacement reached 50 mm (ISO 12957-2, 2005). Rollers underneath the ramp´s box were used to minimize the friction between it and the base of the ramp. Concrete blocks were used as surcharge to provide normal stresses of 1 kPa, 3 kPa and 5 kPa (Sánchez 2018). Two displacements transducers and one load cell were used to measure box displacement and the geomembrane tensile force. As sandpaper was used on the ramp base, measured forces were equal to zero.

In order to characterize the geomembranes surface, Olympus LEXT OLS4100 3D digital microscope was used. The apparatus has a high sensibility detector which can obtain the position and estimating the superficial height of this point, regardless of the surface texture (Figure 3b). Firstly, based on previous analysis, a 10x magnification was chosen as standard

for the surface survey, since it provided satisfactory results within a test duration of six hours. Then, the cutoff wavelength was defined following ISO 4287 (1997). The lateral borders of the specimens were removed in order to reduce the influence of handling and sample cutting implying in an initial specimen size of 20 mm. All the tests were performed using virgin samples.

In this investigation, the number of profiles used for the measurements in each sample is equal to ten. Over any of the ten profiles, each point has an abscissa x and an ordinate $Z(x)$, where $Z(x)$ refers to the point´s elevation or depression. For bidimensional measurements, the sample was divided into ten randomly chosen profiles to guarantee better statistical variability. Although the microscope can also obtain 3D surface distribution, this paper will discuss the results of 2D parameters only.
Figure 3.   Inclined plane tests: (a) overview and (b) Tridimensional image obtained by the microscope of a flat die manufactured geomembrane.

4   RESULTS

Figure 4a presents the results of inclined plane tests and it is possible to notice that the presence of the texture increases the interface shear strength. However, no further rises were observed when the asperity height increased from GM-T1 to GM-T3, which is probably due to the relation between the grain size and the asperity height Afzali-Nejad et al., (2017). The results may also be influenced by the soil density: it is expected that higher densities should have led to increases of the friction angle if the sand had a different relative density Dejong, Westgate (2005).

Figure 4b illustrates how the roughness parameters herein analyzed varied among the geomembranes analyzed. The Maximum Height of the Profile (R_z) showed an increasing for the external side regarding the asperity height. Nonetheless, this trend is not observed for the shear resistance. Therefore, this surface parameter is not considered adequate to predict the interface shear strength. On the other hand, the Total Height of the Profile (R_t) presented similar behavior, also not being considered satisfactory to be related to the interface shear resistance. For both R_t and R_z parameters, it is important to point out that they have their values defined locally and it not measured throughout the sample length. For this reason, average values are considered more adequate.

The Arithmetical Mean Deviation of the Assessed Profile (R_a) also indicated an increasing value with the asperity height rise. Nevertheless, when the asperity height raised from 0.32 mm (GM-T1) to 0.52 mm (GM-T2) no significant change in the R_a value was observed. This finding may be due to the observed variability of the topography concerning the two geomembranes (Figure 1) and the parameter calculation, which is based on the ordinate module. Furthermore, R_a presented the lowest values among the four parameters investigated and this is related to the way that it is calculated: only considering positive values as

shown in Figure 1c and therefore is not considering the presence of valleys. Due to the way that R_a is calculated, it is not considered adequate to related to the interface shear strength. Goodhand et al. (2015) examined different surfaces and concluded that they exhibited unsimilar topographies although they had the same value of R_a.

The Mean Height of Profile Elements (R_c) depicted similar trends comparing to R_a, with average values higher than R_a and lower than R_t and R_c. It is important to clarify that R_c is calculated based on an average value over the sampling length, which is different the way of R_t and R_z are calculated. Therefore, R_t and R_z might have measured values out of trend when comparing to the overall surface distribution leading to higher values. As R_c uses an average value which considers peaks and valleys, it may be used to applied to estimate the interface friction angle when considering other parameters Araujo et al., (2022). It also possible to observe that the smooth geomembrane exhibited larger values of R_z and R_t than R_a and R_c. This likely occurred due to existent indentations prior to the surface measurements that increased the first two cited roughness parameters, once they are estimated locally.
Figure 4.   Results obtained: (a) Interface friction angles and (b) Analyzed Roughness parameters.

5   CONCLUSIONS

In this investigation, ramp tests were performed in order to measure the interface shear strength between geomembranes and different materials for low normal stresses. Bidimensional roughness parameters were also measured to evaluate how they may interfere on the interface resistance. Based on the results, the following conclusions could be made:

- The ramp tests showed that, for the interfaces applying sand, providing asperities to the geomembrane increased the interface shear strength. However, increasing the asperities height does not raise this resistance significantly.
- Depending on the parameter analyzed, it is not possible to relate it to the interface shear strength and this is due to how the parameter is calculated.
- Among the four bidimensional roughness parameters investigated, the R_c average value was considered the most adequate to be related to the interface shear strength, once it had the tendency which could be more directly related to the interface resistance.

ABSTRACT: To predict the performance of engineered structures such as composite liner systems in landfills, constitutive modelling of soil–geosynthetic interfaces is required. This paper presents a numerical model that was developed to simulate the shear stress versus shear displacement responses of single and multi-layer soil-geosynthetic interfaces. A series of large direct shear tests were initially carried out to investigate the behaviour of the interface of a typical composite liner system made up of compacted clay and three geosynthetics: Geotextile (GTX), Geomembrane (GMB), and Geosynthetic Clay Liner (GCL). The numerical model developed in MATLAB R2022a was then utilised to simulate the behaviour of the soil-geosynthetic interfaces using the experimental data. The shear stress–displacement response of the soil-geosynthetic interfaces was modelled by dividing it into two parts: pre-peak and post-peak behaviour. The modelling parameters were then determined based on the results of the large direct shear tests performed on these interfaces. Subsequently, the shear stress–displacement response of the interfaces was evaluated and compared with the experimental results. For both single and multi-layer soil-geosynthetic interfaces, the predicted shear stress–displacement response was shown to be in good agreement with the experimental results.

1 INTRODUCTION

Multiple interfaces exist in geotechnical structures such as composite liner systems in landfills, which consist of compacted soil with low permeability and geosynthetic materials (Feng & Cheng 2014; Guler 2017). Therefore, several interface planes are introduced into the system, potentially causing instability along the slope, and eventually leading to failure. Shear strength between soils and geosynthetics has been identified as a significant challenge in landfill designs. The shear strength of each material layer and the different interfaces between contact layers in the system influences the stability of these liner systems (Feng & Cheng 2014; Stark et al. 2012). The interface shear behaviour of these components can be determined from various laboratory tests using direct shear, ring-shear, inclined plane and pull-out apparatus (Moraci et al. 2014). However, direct shear is frequently used to assess the interface shear behaviour between soils and geosynthetics (Lings & Dietz 2004).

A landfill liner system is made up of several interfaces that must be tested as a single system to fully comprehend the shear strength characteristics of the entire composite liner system (Adeleke et al. 2021; Sikwanda et al. 2019). Using a Large Direct Shear Apparatus (LDSA), two methods of determining the interface shear strengths can be employed, namely, single and multi-layer interface shear testing (Stark et al. 2015; Shenthan et al. 2019). The behaviour of geosynthetic reinforced structures such as landfills is strongly influenced by soil-geosynthetic interaction. For the theoretical and numerical analysis of soil-geosynthetic interaction problem, constitutive modelling of soil-geosynthetic interfaces plays a major role in geotechnical engineering. Thus, a series of direct shear tests using the LDSA were performed to numerically study the soil-geosynthetic interface shear behaviour of components of a typical liner system.

2 EXPERIMENTAL STUDY

2.1 Test materials

The soil used for this study was a reddish-brown clay, which was sourced from Durban, South Africa. The clay was consistent, and simple to work with, allowing the results obtained to be replicated. It was found to have a plasticity index of 30.2 % and based on the Unified Soil Classification System (USCS), it was characterized as a lean clay with sand (group symbol – CL). The clay's specific gravity was found to be 2.8, and its Maximum Dry Density (MDD) and Optimum Moisture Content (OMC) were reported to be 1.6 Mg/m^3 and 24.3% respectively.

Three types of geosynthetics, namely Geotextile (GTX), Geomembrane (GMB), and Geosynthetic Clay Liner (GCL), were used for this study. The 6.4 mm thick GTX had a mass per unit area of 1080 g/m^2, a static puncture strength of 11.7 kN, a permeability of 0.0026 m/s and 50 – 80 % of elongation at break. The GMB, on the other hand, was a 2 mm thick, 2.5% carbon black, Double Textured (DT) High Density Polyethylene (HDPE), with a formulated density of 0.94 g/cm^3. The reinforced GCL was composed of a white polypropylene non-woven GTX cover, a middle layer of light brown, dry sodium bentonite powder with 0% moisture content, and a bottom layer of polypropylene slit film woven GTX carrier. The Minimum Average Roll Value (MARV) was 200, 3700, and 110 g/m^2 for the cover, bentonite, and carrier layer, respectively.

2.2 Test procedures

The automated *ShearTrac-III* Large Direct Shear Apparatus (LDSA) was used in this work. The apparatus was composed of a top (static) shear box with plane dimensions of 305 × 305 mm and a depth of 100 mm and a lower (moving) shear box with plane dimensions of 460 × 355 mm and a depth of 100 mm. The procedures followed to perform both single and multi-layer interfaces tests are briefly summarized and discussed below. More detailed information on the test apparatus and procedures followed can be found in Muluti et al. (2023).

The geosynthetics were cut into rectangles with sizes of 300 × 420 mm and 300 × 520 mm to fit the top and bottom shear boxes of the LDSA, respectively, and placed parallel to the Machine Direction (MD) during testing. As shown in Figure 1(a), for single interface testing, the GTX was fixed to the bottom shear box using bolts and a clamping device. For multi-layer interface testing, on the other hand, one geosynthetic was fastened to the bottom shear box using bolts and a clamping device, and the other geosynthetics were laid on top of the clamped geosynthetic without being clamped, as can be seen in Figure 1(b) and (c). This was done to allow failure to occur at the weakest interface during interface shearing. Then, clay mixed with water quantity corresponding to the OMC, was placed in layers, and compacted to a density close to its MDD.
Figure 1. Single and multi-layer interface shear test configurations.

The tests were conducted at increasing normal stresses of 50, 100, 200, and 400 kPa, with a Shearing Displacement Rate (SDR) of 0.1 mm/min. These normal stresses were selected to simulate the increasing load of waste during the landfill design life. At the end of each test, the equipment automatically generated the variation of the shear stress against the shear displacement for each applied normal stress which was subsequently used during data processing and analysis.

2.3 Test results

The shear stress versus shear displacement curves from both the single-layer and multi-layer interface tests are shown in Figure 2. The measured shear stress responses were non-linear for all the interfaces. The CLAY-GTX-GMB interface showed a fast reduction in shear strength after the peak shear stress was reached for the fourth applied normal stress (400 kPa). This behaviour was again obtained when this test was repeated. This observation may possibly have been due to the transfer of the shear stress within the system. It was also observed that for the CLAY-GTX-GMB-GCL, there was a gradual decrease in shear stresses at applied stresses of 200 and 400 kPa, with continuous progress in horizontal displacement to approach the Large Displacement (LD). More detailed information on the results of the other geosynthetic-geosynthetic single interfaces (i.e. GTX-GMB and GMB-GCL) are available for comparison in Muluti et al. (2023). Moreover, the peak and LD strength envelopes for the three interfaces are shown in Figure 3. The peak secant friction angles for the CLAY-GTX interface were 37°, 36°, 35° and 32° for the corresponding applied normal stresses of 50, 100, 200 and 400 kPa. Similarly, they were 40°, 38°, 35° and 28° for the CLAY-GTX-GMB, and 36°, 35°, 33° and 29° for the CLAY-GTX-GMB-GCL interface respectively. On the other hand, LD secant friction angles for the CLAY-GTX interface were 32°, 31°, 29° and 25° for the applied normal stress 50, 100, 200 and 400 kPa respectively. Likewise, they were 39°, 36°, 30° and 16° for the CLAY-GTX-GMB, and 25°, 24°, 22° and 18° for the CLAY-GTX-GMB-GCL interface respectively. These values of peak and LD secant friction angles decreased generally with the increasing applied normal stresses.

3 MODELING OF INTERFACE SHEAR BEHAVIOR

The complete shear stress - displacement behaviour of the interfaces was considered and modelled by breaking it up into two segments, namely, a pre-peak and post-peak behaviour as illustrated in Figure 4. The numerical models developed by Anubhav and Basudhar (2010) and Aza-Gnandji et al. (2019) to account for the nonlinearity of the failure envelopes was utilized to simulate the shear stress-displacement behaviour of the single and multi-layer interfaces. In the simulations, the peak and LD (residual) shear stresses were computed from the nonlinear failure envelopes shown in Figure 3.
Figure 4. Generalized stress–displacement relationship for clay–geosynthetic interface.
Figure 5. Residual factor vs plastic displacement for CLAY-GTX-GMB-GCL interface.

3.1 Pre-peak behaviour

It can be seen from Figure 4 that the initial shear stiffness depends on the normal stress and the tangent shear modulus varies with the displacement. The approach suggested by Duncan and Chang (1970) and Duncan et al. (1980), which was modified by Anubhav and Basudhar (2010), was used to predict the pre-peak behaviour. Before shear stress reaches peak shear strength, the relationship between shear stress and shear displacement of the interface can typically be modelled by a hyperbolic equation:

$$\tau = \frac{\delta}{\frac{1}{E_i} + \frac{\delta}{\tau_{ult}}} \tag{1}$$

Where τ = shear stress; δ = horizontal displacement; E_i = initial tangent shear modulus; and τ_{ult} = ultimate shear stress.

For soil-geosynthetic interfaces, an increase in normal stress will result in steeper shear stress-relative displacement curves and a higher strength and thus, the values of E_i and τ_{ult}

increase with increasing normal stress. The following equation was used to express the variation of E_i with σ_n (Janbu 1963):

$$E_i = K \cdot P_a \left(\frac{\sigma_n}{P_a}\right)^n \tag{2}$$

Where σ_n = applied normal stress; K = modulus number (dimensionless number); n = modulus exponent (dimensionless number); and P_a = atmospheric pressure. The variation of the ultimate shear stress (τ_{ult}) with the normal stress was considered by relating it with the peak shear stress (τ_p) as follows:

$$\tau_p = R_f \cdot \tau_{ult} \tag{3}$$

Where R_f = failure ratio, which is always less than one (1) since τ_p is always smaller than τ_{ult}. To obtain the values of the coefficients K, n and R_f, the procedure explained in the research of Duncan et al. (1980) was followed for their determination.

3.2 Post-peak behaviour

The tested interfaces in this research showed a post-peak strain softening behaviour like the general curve shown in Figure 4. The strain-softening behaviour has been modelled using the method modified by Anubhav and Basudhar (2010) which accounts for the slow decrease of the shear strength in the initial stages after the peak. Initially, the relationship between the reduction factor (R) and the shear displacement (δ) is established. Then, the reduction factor (R) is defined by the post-peak reduction ($\tau_p - \tau$) in shear stress normalized by the shear stress reduction from peak to the LD or residual value ($\tau_p - \tau_{LD}$):

$$R = \frac{\tau_p - \tau}{\tau_p - \tau_{LD}} \tag{4}$$

Where τ_p = peak shear strength; τ_{LD} = LD/residual shear strength and τ = shear stress obtained after the peak shear stress is reached. From the experimental observation of clay–GTX interfaces, relationship between plastic shear displacement (δ_p) and residual factor (normalized shear strength degradation, R value ranging from 0 to 1) was proposed by Anubhav and Basudhar (2010) to be represented as follows:

$$R = 1 - \exp\left(-A \cdot \delta_p^z\right) \tag{5}$$

To simulate the post-peak behaviour, the two parameters, A and z, were obtained through a non-linear regression analysis using a code developed in MATLAB R2022a. This was achieved by first plotting the residual factors against experimental data as a function of the previously defined plastic shear displacement (δ_p). Then these residual factors were correlated with the fitted curves defined by Equation 5. Good fits were obtained during the analyses, as shown in Figure 5 for the CLAY–GTX-GMB-GCL interface data. Table 1 shows a summary of the model parameter values obtained.

Table 1. Values of model parameters for pre-peak and post-peak behaviour.

Interface	Pre-peak parameters			Post-peak parameters	
	K	R_f	n	A	z
CLAY – GTX	74.32	0.688	1.4	0.069	1.022
CLAY – GTX – GMB	103.83	0.759	0.8	0.081	0.974
CLAY – GTX – GMB – GCL	67.72	0.675	0.8	0.088	1.051

4 SIMULATION OF SHEAR DISPLACEMENT BEHAVIOR

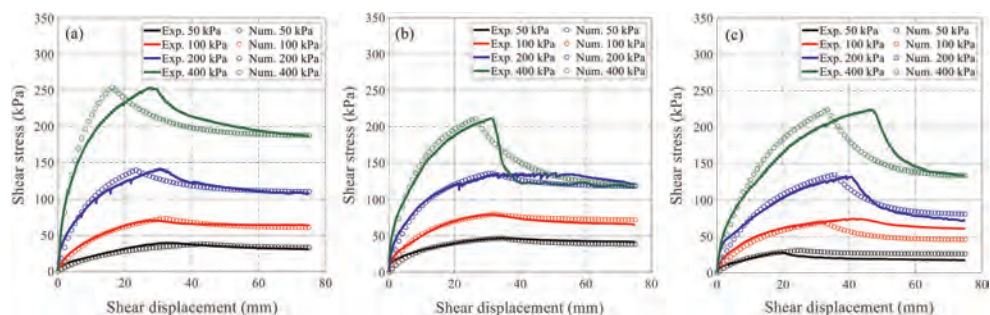
From Figure 6, it can be observed that the numerical data obtained through a back-fitting analysis performed in MATLAB R2022a, exhibited good agreement with the experimental results, although, they could not well fit them for the high normal stress 400 kPa. Nevertheless, the model was able to reproduce the shear behaviour of the soil–geosynthetic interfaces involving the clay and the three geosynthetics over the entire range of normal stresses used in the experiments. In addition, the numerical method that was originally developed for the analysis of sand-geotextile interfaces has demonstrated a good agreement of effectiveness in simulating the shear stress versus shear displacement responses of the interface between the tested single and multi-layer clay-geosynthetics considered in this work.


Figure 6. Experimental vs. numerical stress-displacement curves for: (a) CLAY-GTX, (b) CLAY-GTX-GMB, and (c) CLAY-GTX-GMB-GCL.

5 CONCLUSIONS

This study investigated the numerical modelling of single and multi-layer clay-geosynthetic interfaces. The results of the LDSA on the three interfaces revealed that the stress–displacement behaviour of the interfaces could be divided into two zones: pre-peak and post-peak behaviour. The shear displacement necessary to mobilize the peak shear strength increased with higher applied normal stress, and it was lower for the single interfaces compared to that of the muti-layer interfaces. Over the entire range of normal stresses used in the experiments, the stress-displacement response of the interfaces predicted using the proposed model exhibited good agreement with the experimental data. It is therefore possible to consider using this numerical approach for the analysis of interface behaviour along geosynthetic materials that may exhibit similar behaviour based on the results of this work.

Long-term pullout tests to analyse the soil-geogrid interaction

M. Pisano, G. Cardile & N. Moraci
Mediterranea University of Reggio Calabria, Italy

P. Recalcati
TENAX S.p.A., Italy

ABSTRACT: One of the most important aspects regarding the design of geosynthetic-reinforced soil structures is to predict the long-term behaviour of reinforcements and interfaces. The paper describes a new large-scale laboratory apparatus capable of investigating the behaviour under pullout conditions of a geosynthetic reinforcement embedded in a compacted granular soil, and subjected to sustained tensile loading. By using the long-term pullout test results, the writers suggest a procedure for the determination of the interface parameter necessary to design the length of the reinforcement in the anchorage zone that can take into account the viscous effects of the polymeric material arising under serviceability conditions during the design working life.

1 INTRODUCTION

The viscous nature of geosynthetics leads to a reduction of their tensile resistance due to the development of tensile creep strains in the reinforcements during the working life of the structure they are embedded into. Although both experimental measurements on full scale walls (Bathurst et al. 2005; Carrubba et al. 2000) and laboratory tests (Tatsuoka 2008) have shown that these tensile strains are limited when the reinforcement is placed in contact with soil, the viscous behaviour may reflect on the soil-geosynthetic interface response under serviceability conditions. In fact, since the stress-strain state of the reinforcement in the anchorage zone varies over time, the interface parameters currently obtained from standard pullout tests may be not conservative. As this aspect neither has yet been investigated in scientific literature nor considered in the design of civil and environmental engineering works, further in-depth research seems useful.

To this effect, the Authors designed and assembled a new large-scale prototype pullout apparatus capable of studying the variation over time of geosynthetic strains that occur under sustainable tensile loading due to interaction with soil. After describing the long-term pullout apparatus and the developed test procedure, the paper shows the preliminary results obtained from tests carried out on geogrids embedded in a compacted granular soil.

2 EXPERIMENTAL STUDY

2.1 *Apparatus*

In this research, the Authors (Cardile et al. 2021) have developed a large-scale prototype apparatus (Figure 1) equipped with a completely mechanical system for the application of a constant tensile load over time, capable of simulating the strain state variation that arises

due to the geosynthetic pullout mechanism in the anchorage zone of a geosynthetic-reinforced soil (GRS) structure (Bathurst & Ezzein 2015; Bergado et al. 1993; Cardile et al. 2014, 2017a, 2019, 2020; Di Filippo et al. 2019; Jewell 1990; Palmeira 2009; Pisano et al. 2018, 2019; Wang et al. 2016). The long-term pullout apparatus consists of: a large rigid steel box (625x400x1700 mm) to reduce scale effects (Moraci & Recalcati 2006; Moraci et al. 2017), with walls covered with Teflon films; a pair of metal sleeves (200 mm long) positioned in the slot on the front wall; an internal system to clamp the geosynthetic; a pneumatic system for the application of vertical loads (flexible rubber membrane filled with air); a reserve tank to compensate for lack of air in the case of suspension of the electricity supply; a mechanical system (Figure 2) for the application of the horizontal load (potential maximum force equal to 70 kN) made up of weights, gear wheels and pulleys (theoretical transmission ratio of 10:1); six rotary variable displacement transducers (RVDT) for the measurement of the geosynthetic displacements; and a system for data acquisition.

Figure 1.   Large-scale prototype apparatus for long-term pullout tests.
Figure 2.   Longitudinal (a) and transverse (b) cross-sections of the system for the application of pullout load. 1) Gear rack; 2) Main axles; 3) Axles in support of gear rack; 4) Gearwheel 1; 5) Gearwheel 2; 6) Gearwheel 3; 7) Pulley; 8) Bearing in support of gear rack; 9) Gear rack lateral supports; 10) Shock absorber for gear rack.

2.2   *Test materials and procedure*

The first long-term pullout tests on two twin apparatus were carried out on two identical specimens of geosynthetic (330x1200 mm) embedded within a compacted granular soil classified as SW and A1-b according to ASTM D2487 (2017) and UNI EN ISO 14688-1

(2018). The compaction of soil inside the pullout box was performed until reaching a dry unit weight value equal to 95% of the maximum dry unit weight obtained by AASHTO T 99 (2015) Standard Proctor compaction tests. The values of the soil peak shear-strength angle ϕ'_P were obtained by direct shear tests performed on compacted soil specimens ($\phi'_P = 52° \div 44°$ for $\sigma'_v = 10 \div 100$ kPa).

The geosynthetic used in the long-term pullout tests is a high-density polyethylene (HDPE) uniaxial extruded geogrid, whose geometric characteristics are listed in Table 1. Wide-width tensile tests (Cardile et al. 2016, 2017b) were carried out to investigate its mechanical behaviour according to UNI EN ISO 10319, 2015 (Table 2).

Table 1.   Geometric characteristics of the geogrid used in this research.

Geosynthetic			Uniaxial Extruded Geogrid High-Density Polyethylene
Polymer			(HDPE)
S	(mm)	*Spacing between two consecutive bearing members of geogrid*	240
W_T	(mm)	*Width of bar portion between two nodes*	4.4
B_T	(mm)	*Thickness of bar portion between two nodes*	4.5
W_R	(mm)	*Node width*	15.2
B_R	(mm)	*Node thickness*	6.8

Table 2.   Wide-width tensile test results of geogrid used in this research.

$T_{max\ (ISO)}$	(kN/m)	at $\varepsilon'=20\%$ per minute	159
$\varepsilon_{max\ (ISO)}$	(%)	at $\varepsilon'=20\%$ per minute	12.2
$J_{sec\ 2\%\ (ISO)}$	(kN/m)	at $\varepsilon'=20\%$ per minute	2454

A procedure to make the long-term pullout tests repeated, reproducible and without scale effects was developed. The first step consists of covering the internal walls of the pullout box with Teflon; then, the lower half of the pullout box is filled with the selected soil, which is compacted by layers of small thickness to the desired dry unit weight value; the geosynthetic specimen is clamped and positioned on the lower layer of the compacted soil; the upper half of the pullout box is filled and the soil compacted according to the procedure followed previously for the lower half; the flexible air-bag is put in place and the pullout box is closed using a rigid steel plate; the pneumatic system is connected to the air-bag; the desired confinement pressure is applied and the data acquisition software is set; the clamp system is connected to the horizontal force application device; and the test is launched.

The long-term pullout tests are carried out at controlled temperature and humidity conditions by applying a vertical effective stress equal to $\sigma'_v = 50$ kPa to both soil-geogrid specimens. The sustained pullout loads P applied on the two twin apparatus are equal to 50% and 70% of the peak pullout resistance P_R obtained by a pullout test performed, according to ASTM D6706–01 (2013), on the same interface at constant rate of displacement (CRD) equal to 1 mm per minute and at the same vertical effective stress.

3   ANALYSIS OF TEST RESULTS

The design of geosynthetic-reinforced soil walls and slopes is commonly performed using Limit Equilibrium methods for which it is necessary to determine the apparent coefficient of friction between soil and geosynthetic, $\mu_{s/GSY}$. This coefficient allows determining the

reinforcement length (and consequently the reinforced block size), and it is generally used considering its peak value (calculated from the peak pullout resistance P_R obtained by standard pullout tests). In light of the fact that creep/relaxation phenomena affect the deformation of geosynthetics over time, it is useful to analyse to what extent the apparent coefficient of friction mobilised at the interface should be reduced in order to take these phenomena into account. The coefficient is defined as follows:

$$\mu_{s/GSY} = \frac{P}{2 \cdot L_R \cdot \sigma'_v} \tag{1}$$

with P being the sustained pullout load and L_R the reinforcement length.

To investigate the influence of the viscous behaviour on the interface under serviceability conditions, isochronous curves on the $\mu_{s/GSY}$-ε_{conf} plane were built, where ε_{conf} are the strains calculated along the geogrid portion closer to the clamp, (i.e. in the most stressed segment, which goes from the first confined section to the first transverse bar). $\mu_{s/GSY}$ values starting from the two different levels of the sustained load investigated experimentally ($P = 50\% \ P_R$ and $70\% \ P_R$) were computed, in order to plot the isochrones. For each value, the ε_{conf} strains mobilised at set times (t=1 h, 10 h, 100 h, 1000 h, 10000 h) were also calculated. Thereafter, curve fitting was used on the pairs of $\mu_{s/GSY}$-ε_{conf} values thus obtained, leading to the isochronous trend shown in Figure 3. By looking at the trend in the figure, it can be stated that it is generally almost linear providing no local rupture phenomena or tertiary creep take place.
Figure 3. Isochronous interaction curves under long-term pullout conditions (modified from Cardile et al. 2021).

As might be expected, the graph shows that the reinforcement strains in the anchorage zone increase continuously just as the $\mu_{s/GSY}$ value that provides stability to the structure over time has been mobilised, and this applies to each reinforcement layer (therefore, for varying the vertical effective stress). While the tensile strains grow, it is important to check whether the final value achieved (i.e. at the design working life) is compatible with the serviceability of the structure.

Additionally, moving from one time in logarithmic scale to the next, the cumulative strains decrease significantly over time for a given coefficient of friction (i.e. P), with the exception of the isochrone at $t = 10000$ h. In this case a deviation from the trend can be noted. This different behaviour might be connected to local phenomena, such as a local damage caused by the clamping system or a local flaw in the material, leading to the rupture of one or more longitudinal ribs. In fact, by comparing the tensile strain increments obtained for the two different loading levels when time ranges from 1000 h to 10000 h, it can be seen that for tests carried out at $P = 50\% \ P_R$ the strain increment is nil, oppositely to what happens for tests carried out at $P = 70\% \ P_R$, where the strain increment is equal to 27%.

The construction of these curves, obtained for different vertical effective stresses, could help in design structure because they allow the designer to choose an apparent coefficient of friction that also considers the long-term behaviour of the geosynthetics. If design methods focusing on

the ultimate limit state are used (Cardile & Pisano 2020), the design parameter $\mu_{s/GSY}$ could be chosen through the $\mu_{s/GSY}$-ε_{conf} isochronous curves so as to also take into account the serviceability limit state. Specifically, the design procedure (Figure 4) would consist in entering in an isochronous $\mu_{s/GSY}$-ε_{conf} graph (plotted for a given vertical effective stress) with a horizontal segment representing the allowable strain value for a certain structure. When the segment touches both the curve of the strain occurring at the end of the selected design working life and that of the strain at the end of construction, the corresponding coefficient value in the vertical axis can be read (long-term creep apparent coefficient of friction $\mu^{LTC}_{s/GSY}$). The allowable strain could be obtained by evaluating the correlation between the strain of the most stressed segment of the reinforcement and the actual deformation of the structure (e.g. horizontal deformation of GRS wall facing) for each layer of reinforcement by means of numerical analyses and/or measurements on full-scale walls, thus determining threshold values to ensure that the most commonly used design methods investigating the ultimate limit state (e.g. Limit Equilibrium design) also take into account the serviceability limit state.
Figure 4.   Long-term apparent coefficient of friction assessed at a prescribed limiting value of post-construction strain in reinforcement by using isochronous curves (modified from Cardile et al. 2021).

4   CONCLUSIONS

The paper illustrates a new large-scale prototype apparatus capable of analysing the pullout behaviour of a soil-geogrid interface subjected to a tensile load kept constant over time.

The first results obtained allowed the Authors to build isochronous curves that link the apparent coefficient of friction mobilised at the interface under long-term pullout conditions to the geosynthetic confined strains occurring when a tensile load is kept constant over time. These isochronous curves demonstrate that the choice of the interface parameter currently being done could lead to tensile strains that are not compatible with the serviceability of the structure. Therefore, their construction could help the designer to choose an apparent coefficient of friction at the interface that also takes the long-term behaviour of the geosynthetics into account. For this purpose, the Authors propose a procedure to ensure that the limit equilibrium analysis (which investigates the ultimate limit state) could also bear in mind aspects regarding the serviceability limit state.

ABSTRACT: Geosynthetic-reinforced soil (GRS) structure has been received much attention recently due to its advantages of less over-excavation, ease of construction, cost-effective and excellent performance in practice. The backfill gradation may influence the bearing capacity of GRS mass. This paper conducts a series of model tests under plane strain condition using transparent soil to investigate the effect of backfill gradation on the bearing capacity of GRS mass. The particle image velocimetry (PIV) technique was adopted to monitor the deformation field change in the backfills during testing. The results showed that the maximum aggregate size of backfill affected the bearing capacity of the GRS mass, while the test with well-graded aggregates yielded larger bearing capacity than that with poor-graded aggregates although both backfill had the same maximum aggregate size. Moreover, the well-graded aggregates reduced the deformation of GRS mass.

1 INTRODUCTION

Geosynthetic Reinforced Soil (GRS) generally refers to densely reinforced soil with reinforcement, which behaves as a macroscopically uniform and anisotropic composite material (Adams & Nicks 2018). In practice, the reinforcement spacing is commonly less than or equal to 300 mm. Many studies have shown that RGS composite structure has high bearing capacity and coordinated deformation capacity (Barrett & Ruckman 2007), is easy to construct, and clearly offers both social and economic benefits (Aub-Farsakh et al. 2017; Sagherbfar et al. 2017).

The main factors influencing the bearing capacity of GRS composite include the reinforcement spacing, reinforcement strength, and backfill properties, as well as some external factors, such as the width of bearing plate and setback distance (Xiao et al. 2015). The FHWA design and construction guidelines for geosynthetic reinforced soil abutments and integrated bridge systems (Adams & Nicks 2018) considers the most internal influence factors in calculation of bearing capacity,

$$q_{ult} = (0.7^{(Sv/6d_{max})} \frac{Tf}{Sv}) Kp \tag{1}$$

where S_v is the reinforcement spacing; T_f is the ultimate tensile strength of reinforcement; K_p is the coefficient of Rankine passive earth pressure, and d_{max} is the maximum particle size of backfills. However, in terms of particle size of backfill, this method only considers d_{max} against the influence of bearing capacity.

Nicks and Adams (2013) found that the well-graded backfill is considerably stiffer than the poorly-graded backfill, although both backfills had the same maximum particle size. Nicks et al. (2016) further indicated that the load-bearing performance of GRS composite is not only affected by the maximum particle size of the backfill, but also by the gradation of backfill. This paper presents a series of plane strain model test to investigate the effect of backfill gradation on bearing capacity of a GRS mass. Transparent soil combined with particle image velocimetry (PIV) technique was used to monitor the load-bearing performance of GRS model as the applied load creased.

2 MODEL TEST

2.1 *Test setup and test plan*

Figure 1 shows the setup of the model test. The model box had the inside dimensions of model box are 700 mm (length) × 100 mm (width) × 650 mm (height). The model box was made of 20 mm-thick Plexiglas panel and fixed by steel frames. The Plexiglas panel allows visual observation and photogrammetry of the soil particle movements during the test.

This study considered a GRS mass under a plane strain condition, which had dimensions of 300 mm (length) × 100 mm (width) × 600 mm (height). Considering the size of the mode box, the size effect of $n = 3$ was given for the model test. Six model tests were designed by carrying out the plane strain condition of GRS mass with different gradations of backfill. According to the FHWA design guidance (Adams & Nicks 2018), the reinforcement spacing of the GRS composite is not more than 300 mm. As a result, the model test had a reinforcement spacing of 100 mm. A hydraulic jack was connected to a loading plate, applying load on the top of the GRS mass. During the loading test, a load increment of 85 kPa was applied at each stage until the GRS mass was failed.

Figure 1 also illustrates the layout of the instruments. Two linear variable differential transducers (LVDT) and a load cell were installed to record the vertical displacement of the loading plate and the applied load during the test. Two high-intensity lasers (650 nm, 150 mW) were placed on the same plane at both sides of the box as shown in Figure 1, producing speckles on the laser-lighted plane. A Canon 6D digital camera with a resolution of 26 megapixels was positioned right in front of the model box to properly focus on and visualize the analysis area. The Geo-PIV technique (Stanier et al. 2015) was adopted to determine incremental displacements and strains by comparing the successive pairs of photographs during the test.
Figure 1.   Setup of model test.

2.2 *Materials and preparation*

Transparent soil technology is one type of modern technology for simulating natural soil, which can be able to visually observe the deformation and seepage inside the soil. Therefore, this study adopted the transparent soil as the backfill. The transparent soil in this study was a mixture of high purity fused quartz particles and industrial white oil. The white oils of Nos. 3 and 15 were mixed at a volume ratio of 1.5:1, and the refractive index of the mixed oil was equal to 1.4584 at 25°C, which was the same as the refractive index of the quartz and sand. The maximum and minimum dry density of transparent soil were 1.41 g/cm^3 and 1.22 g/cm^3, respectively. Its internal friction angle was 43° by the direct shear test. The facing blocks were made of transparent plexiglass blocks of 100 mm (length) $\times$ 100 mm (width) $\times$ 50 mm (thickness). This study selected the grey polyamide mesh as geosynthetic reinforcement. The ultimate tensile strength (T_{ult}) was 10.1 kN/m at a strain of 2.93% based on the tension test. Each model test had 5 layers of reinforcement in the GRS mass.

The first layer of facing block was placed on the base of the model box. The prepared white oil mixture was poured into the model box, and then the weighted fused quartz particles were gently placed into the model box. The fused quartz particles were compacted manually by a steel hammer to a compaction degree of 95% with a lift thickness of 100 mm, which is equivalent to the height of the facing block. The compaction was controlled by the mass and volume in each lift. After the soil placement was complete, a reinforcement layer was directly placed on the top surface of the backfill, and a frictional connection between the reinforcement and the facing block was considered. These procedures were repeated until to the desired fill height.

The FHWA design guidelines recommend a particle size range of 0.39 mm to 25.4 mm, and the proportions of different particle size ranges are shown in Table 1 The modified analogy method proposed by Lowe (1964) was used to ensure the similarity of the gradation of the backfill as below:

$$\frac{D^b - D^b_{min}}{D^m - D^m_{min}} = \frac{D^b_{max} - D^b_{min}}{D^m_{max} - D^m_{min}} = A \tag{2}$$

in which, D^b is the prototype particle size, D^m is the corresponding similar model particle size, and the subscripts, min and max, represent maximum and minimum; A is the similarity ratio of the test. Accordingly, the calculated model particle size range is shown in Table 1. Table 2 shows the particle size distribution of backfill in the six model tests. The test No.1 followed the FHWA recommended particle size gradation, which is also referred to as the standard test, while the other five tests had backfills different from the FHWA recommended particle size gradation.

Table 1. Particle size and gradation of FHWA and model.

	Particle size (mm)			
FHWA	25.4 (94-100%)	9.5 (72-63%)	2 (32-41%)	0.39 (14-24%)
Model	8	3	0.7	0.2

Table 2. Gradation of backfills in the model test.

Test	8-3 mm (%)	3-0.7 mm (%)	0.7-0.2 mm (%)	<0.2 mm (%)	C_u	C_c
1	30	25	25	20	20.80	0.77
2	30	25	45	0	6.88	0.45
3	30	25	0	45	42.57	0.18
4	0	55	25	20	13.27	1.21
5	55	0	25	20	43.64	0.37
6	30	50	0	20	25.40	5.30

3 RESULT AND ANALYSIS

3.1 Standard test

Figure 2 shows the variation of the vertical displacement at the top surface with the increase of the applied load. The vertical displacement the GRS mass basically follows a linear trend, however as the load exceeded 850 kPa, the vertical displacement rapidly increased, followed by the failure of the GRS mass.
Figure 2.   Applied load versus vertical displacement.

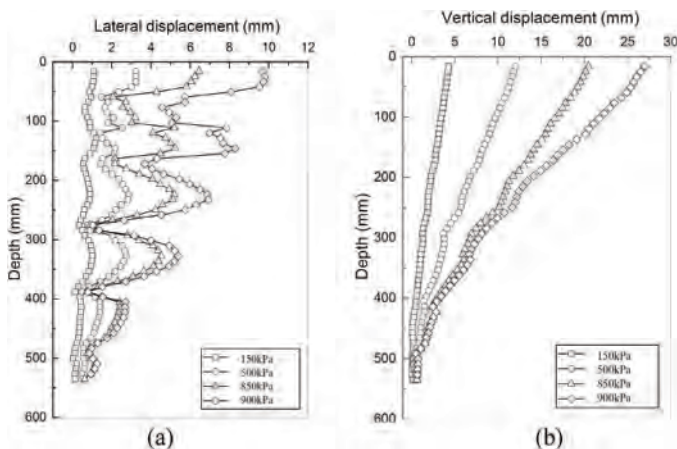
Figure 3(a) shows the lateral displacement of the backfills at different load stage measured by the PIV technique at a distance of 20 mm from the facing block. The lateral displacement of the backfills show an overall decrease with depth. The backfills near the reinforcement had small lateral displacement as they were restrained by the reinforcement. When the applied load reached 900 kPa, the lateral displacement of the reinforced soil had a surge increase. Figure 3(b) shows the vertical displacement along the depth at the center profile of the GRS mass. The vertical displacement in the GRS mass decreased gradually along the depth, and there was a sudden change in the vertical displacement of the GRS composite at the location of the reinforcement.


Figure 3.   Deformation of GRS standard test: (a) horizontal displacement; (b) vertical displacement.

3.2 *Failure pattern*

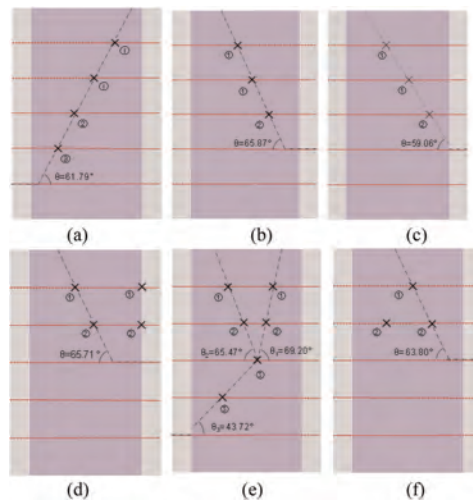
Figure 4 shows the broken locations of the reinforcement in each test, as well as the angle of the failure plane against the horizontal plane. The GRS composite failed mostly due to the shear rupture surface through the reinforcement, resulting in the broken of the reinforcement. The broken location of the reinforcement mostly appeared inside the composite or at the connection between the reinforcement and the facing block. The GRS mass failed by shear and finally slid out along the interface between the reinforcement and the facing block, but the shear damage varied in range and mode in each test. For the Test Nos. 1, 2, 4 and 6, the slip surface developed as a straight line and then sheared out from the interface between the block and the reinforcement. The test No. 5 had a bilinear slip plane, i.e., the upper part was steeper than the lower part. The angle of the measured slip plane to the horizontal plane basically confirms to the Rankine slip surface.


Figure 4.   Failure mode: (a) Test 1; (b) Test 2; (c) Test 3; (d) Test 4; (e) Test 5; (f) Test 6.

3.3 *Bearing capacity*

Figure 5 shows the variation of the bearing capacity of the GRS composite with the non-uniformity and curvature coefficient. There tends to be an increase in the bearing capacity as the non-uniformity coefficient increased. However, as the curvature coefficient increased, the bearing capacity gradually decreased. The non-uniformity coefficient increased from 6.88 to
Figure 5.   Influence of gradation on bearing capacity: (a) non-uniformity coefficient; (b) curvature coefficient.

43.64, and the bearing capacity increased by approximately 40%. The curvature coefficient increased from 0.18 to 5.30, and the bearing capacity decreased by about 22%. It can be seen that the particle size gradation of the backfill has a significant effect on the bearing capacity of the GRS composite, rather than being influenced by the maximum particle size only.

4 CONCLUSION

(1) The reinforcement plays a significant part in preventing the deformation of GRS composite, especially in the case of horizontal deformation. The broken location of the reinforcement mostly occurred inside the composite or at the connection between the reinforcement and the facing block. The angle of the slip surface to the horizontal plane was in basic agreement with the Rankine failure plane.
(2) The gradation of the backfill has a significant influence on the bearing capacity of the GRS composite. Moreover, the non-uniformity coefficient of backfill increased from 6.88 to 43.64, and the failure load increased by approximately 40%; on the other hand, the curvature coefficient increased from 0.18 to 5.30, while the failure load decreased by around 22%.

P.J. Naughton
Faculty of Engineering & Design, Atlantic Technological University Sligo, Ireland

ABSTRACT: Anchored earth is a derivative of reinforced soil. The pullout resistance and corresponding displacement of square mild steel anchor plates 100mm x 100mm, 200mm x 200mm and 300mm x 300mm, was investigated. Good repeatability of the pullout resistance – displacement was observed. However, both the peak pullout resistance and corresponding displacement indicated some scatter. Early stiffness of the tendon and anchors at displacements less than 10mm was observed. Once the peak resistance was achieved, tendon and anchor capacities reduced. The peak pullout resistance increased with the area of plate anchor. The smallest plates (100mm x 100mm) reached peak resistance at displacement less than 5mm, the large plates (200mm x 200mm and 300mm x 300mm) reached peak at similar values between 10 – 30mm. The peak pullout resistance for the 200mm x 200mm and 300mm x 300mm was found to reduce as the in-situ vertical stress in the wall increased.

1 INTRODUCTION

Anchored earth technology has been used to construct retaining walls for over 100 years (Jones 1996). The system consists of a facing element and a connecting rod or tendon that connects the facing system to an anchor located in the retained fill, Figure 1(a). Anchored earth systems differ from conventional steel and geosynthetic reinforced wall technologies in that the resistance to outward movement is mobilised, primarily, as passive resistance against the anchor plate, rather than friction along the reinforcement element (Jones 1996).

Jones (1996) reported on early anchored earth technologies, including an array of wooden timber reinforcement units developed in the USA (Munster 1925). A French engineer also developed a ladder wall in 1932, which consisted of precast concrete facing units, selected stone fill and ties with steel anchor plates (Coyne 1945). The ladder system allowed the facing units to move relative to each other to accommodate settlement.

The first anchored earth wall in the UK was constructed in 1984 (Snowdon et al. 1986). The wall, 6m high and 86m long, formed part of the A660 Otley bypass in West Yorkshire, UK. Different types of anchors, including plate anchors and anchor heads, were utilised on that project.

In this study, the pullout behaviour of plate anchors was investigated in a full-scale trial wall. Three plate anchor face dimensions of 100mm x 100mm, 200mm x 200m and 300mm x 300mm were investigated. The data was assessed in terms of peak pullout resistance, stiffness of the pullout response and the impact of both plate size and in-situ vertical effective stress on the behaviour of the plate anchors.

The test wall was constructed in Co. Offaly, Ireland, at the Lusmagh Quarry owned by Banagher Precast Concrete Ltd. The wall was 6.75m high, Figure 1(b), and faced with 0.14m

thick concrete panels. The panels were 1.5m x 1.5m in face area, with a full panel having four anchor connections.

2 METHODOLOGY

The wall was reinforced with 4.65m long high tensile steel tendons, 16mm in diameter, connected to steel anchor plates placed at 0.75m horizontal and vertical centres.

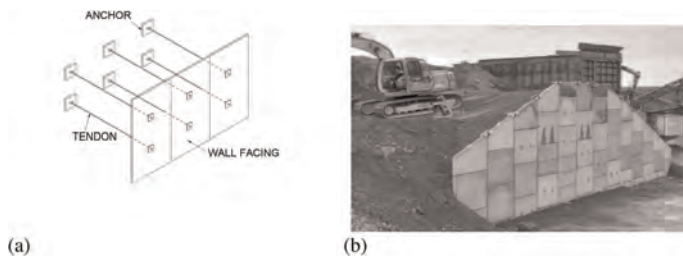
The anchor plates comprised of 10mm thick mild steel (S275) of different face dimensions: 100mm x 100m, 200mm x 200mm and 300mm x 300mm. The plates sizes used at each location are summarised in Table 1 The numbered locations on the front of the wall are shown in Figure 2(a), with a cross section of the wall shown in Figure 2(b). Kentledge, in the form of large concrete blocks, was placed on top of the wall to increase the vertical stress in the retained fill by 20kPa. The backfill consisted of Class 6I/6J fill (2013) compacted in accordance with the Specification for Road Works, Series 600 (2013). Class 6I/6J is a well graded backfill with a maximum particle size of 125mm and with less than 15% passing the 63μm sieve size.


Figure 1. (a) Schematic of an anchored earth structure and (b) Image of 6.75m high test wall constructed as part of this study.

Table 1. Plate sizes at different locations in the wall.

Plate size	Location number
100mm x 100mm	1, 2, 9, 10
200mm x 200mm	5–8, 11–18, 23–26
300mm x 300mm	19–22, 27–32
Figure 2. (a) Front elevation of test wall and (b) Cross section through the test wall.

2.1 Backfill properties & construction of the wall

Compaction testing on the Class 6I/6J backfill was in accordance with BS1377-1 (2016). The optimum moisture content was determined as 6.5%, with a maximum dry weight density of 22.3kN/m^3. Large shear box testing was conducted in accordance with BS 1377-7 (1990). The moisture content was 4.5%, with a dry weight density of 19.6kN/m^3, corresponding to 88% of maximum dry density. The peak angle of friction was 47.8° with an apparent cohesion of 8kPa.

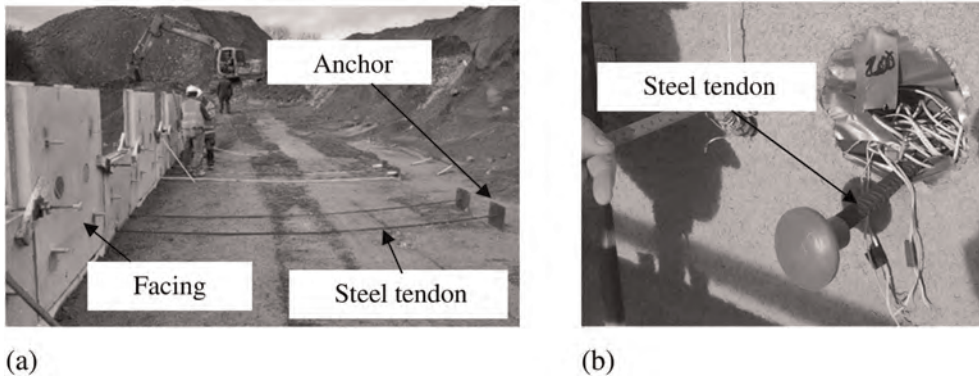
Figure 3(a) indicates the construction of the wall. The fill was placed and compacted in 150mm layers, using Method 2 of Series 600 (Anon 2013). During the construction process, the steel tendons connected to the anchors were left protruding through the wall face to facilitate testing, Figure 3(b).


Figure 3. (a) Construction of test wall, including installation of anchors and (b) Anchor tendon protruding at face of wall through preformed hole in facing panel.

2.2 Pullout testing

A 20-tonne jack was used in the pullout testing. The tendons and threaded bars were joined using bespoke steel slotted 'H' connectors which provided sufficient strength to prevent slippage between the components, Figure 4(a). The threaded bar was welded to the end of the 'H' connector, that passed through the hole in the centre of the jack and was locked off with a loading plate and wing nut. The displacement of the anchor/tendon was measured using a long-stroke linear voltage displacement transducer (LVDT). The experimental setup during a test is indicated in Figure 4(b).
Figure 4. (a) Connection between jack and anchor tendon during a test and (b) Experimental setup for conducting pullout testing.

A preload of 0.5kN, corresponding to 1% of the tensile strength of the test tendon, was applied. Pullout testing was conducted at 2mm/minute with pullout resistance and displacement recorded at 1-minute intervals. The horizontal displacements and loads were automatically logged by a Hydrotechnic Multi System 5060 data logger.

3   RESULTS & DISCUSSION

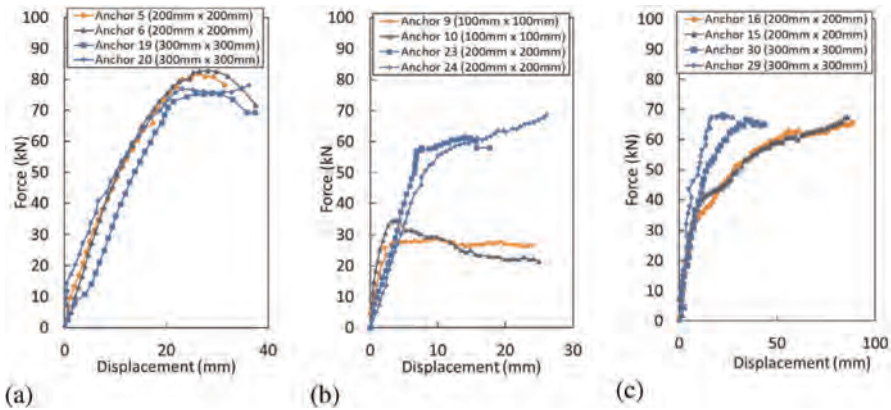
In total, 30 pullout tests were conducted. Figure 5(a) presents four pullout test results plotted against displacement for the anchors on Row 6: Anchors 5, 6, 19, and 20. Good repeatability with early stiffness, up to a displacement of 10mm, was observed. There was some scatter in the observed peak pullout resistance, with peak resistance varying between 65 – 85kN and corresponding displacement varying from 20 – 37mm.


Figure 5.   Pullout test data for (a) Row 6, (b) Anchors 9, 10, 23 and 24, (c) Row 3, Anchors 15 & 16.

3.1   *Impact of plate size on pullout resistance*

Figure 5(b) shows the displacement relationship for 100mm x 100mm (Anchors 9 & 10) and 200mm x 200mm (Anchors 23 & 24) anchors at Row 2 in the wall. Good repeatability in comparable data was observed. The 100mm x 100mm anchors appear to have a slightly stiffer response at small displacement than the larger 200mm x 200mm anchors. The smaller anchors also display a definite peak pullout, with the post peak behaviour displaying a plastic response or some softening. The 200mm x 200mm plates, in contrast, did not have a definite peak value and the force – displacement curve hardened at higher displacement.

Figure 5(c) presents the pullout resistance – displacement data for Row 3, Anchors 15 & 16 (200mm x 200mm plates) and Anchors 29 & 30 (300mm x 300mm plates). Good repeatability was found. The stiffness of the anchors on Row 3 was similar at low displacements. The 100mm x 100mm plates reached peak resistance at a lower displacement than the 200mm x 200mm at the same elevation in the wall. In Row 3, both plate sizes, 200mm x 200mm and 300mm x 300mm, had comparable displacements at peak pullout resistance.

The peak pullout resistance and corresponding displacement for each anchor is summarized in Table 2 In Row 2, the 200mm x 200mm plates had a higher peak pullout resistance at a slightly larger displacement compared with the 100mm x 100mm plates. However, the increase in peak pullout resistance was not proportional to the increase in the cross-sectional area of the plate. Similarly for Row 3, the larger 300mm x 300mm plates had a higher peak pullout resistance than the 200mm x 200mm plates, but again increased resistance was not proportional to the increase in plate area.

Table 2. Summary of peak pullout resistance and corresponding displacement for anchors on Rows 2 & 3.

Row	Anchor No	Plate size (mm x mm)	Peak pullout force (kN)	Displacement at peak pullout force (mm)
2	9	100 ×100	28	4
	10	100 ×100	45	4
	23	200 ×200	58	7
	24	200 ×200	54	9
3	15	200 ×200	48	15
	16	200 ×200	54	24
	29	300 ×300	68	18
	30	300 ×300	76	16

3.2 Impact of vertical stress on pullout resistance

The impact of vertical stress on pullout resistance was assessed by comparing the pullout resistance of similar sized plates located at different elevations in the wall.

Figures 6(a) & 6(b) show the respective pullout resistance – displacement relationship for the 200mm x 200mm plates located in Rows 1 – 7 inclusive and 300mm x 300mm plates located in Rows 3 – 6 inclusive. Both plate sizes displayed a linear and similar value of stiffness for a displacement less than 10mm.

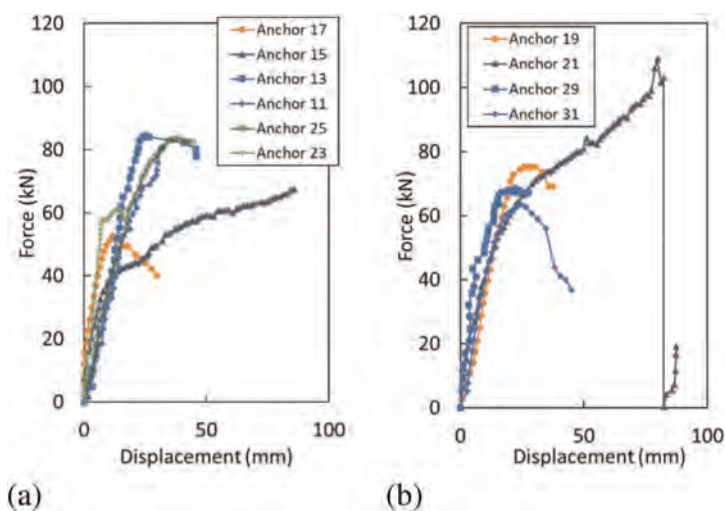
Figure 7 presents the relationship between peak pullout resistance and in-situ vertical effective stress. Overall, and irrespective of plate size, a reduction in peak pullout resistance with increased in-situ vertical effective stress was observed. The reduction in pullout resistance with increased vertical stress, while counterintuitive, was not unexpected. Pullout testing (Weldu et al. 2015) on inextensible steel reinforcement had found enhanced interaction between the reinforcement elements and the surrounding soil at low normal stress, which is attributed to dilation in the well compacted granular fill near the top of the wall (Weldu et al. 2015).


Figure 6. Pullout test data for (a) 200mm x 200mm plates and (b) 300mm x 300mm plates.
Figure 7. Relationship between pullout resistance and insitu vertical effective stress for (a) 200mm x 200mm plates and (b) 300mm x 300mm plates.
Figure 8. (a) Exhumed Anchor 28 and (b) Deformed Anchor 14 following exhumation.

Typically, the interaction between the soil and inextensible reinforcement reduces with vertical stress to a depth of 6m and then remains relatively constant (BS 8006-1:2010+A1, 2016).

3.3 Anchor post-construction excavation and inspection

The backfill behind the top three anchors (Rows 5, 6 & 7) was excavated. The granular backfill was well compacted, cemented, and difficult to excavate with a spade. The plates were intact and well embedded into the granular backfill, Figure 8(a). Row 5 contained all plate sizes. The 100mm x100mm plates (Anchors 1 & 2) when exhumed had rotated by approximately 45 degrees from the vertical. The 200mm x 200mm (Anchor 13) & the 300mm x 300mm plates (Anchors 27 & 8) displayed evidence of slight deformation. However, Anchor 14 (200mm x 200mm) displayed noticeable bending and deflection - approximately 12mm at the centre of the plate, Figure 8(b).

4 CONCLUSION

This study presents pullout testing on a 6.75m high trial anchored earth wall. The wall was reinforced with three different size plate anchors which were connected to the concrete facing units by high tensile steel tendons. Kentledge of 20kPa was applied to the top of the wall.

Good repeatability of the pullout resistance – displacement curves, particularly at displacement less than 10mm, was observed in all tests conducted. The post peak behaviour was also found to vary, with softening, plastic displacement and hardening all observed. The smaller 100mm x 100mm plate failed at small displacements, less than 5mm, while the displacement at peak resistance for the 200mm x 200mm and 300mm x 300m plates was largely consistent and was in the range of 10 – 30mm. The peak pullout resistance was found to be not proportional to the anchor plate size as the area of the anchor plate increased. This anomaly may be the result of poor backfill compaction around the plate, the vertical alignment of larger plates or the slack of the tendon during the installation. The peak pullout resistance also varied with insitu vertical stress, reducing as the vertical stress increased. This response is in keeping with pullout testing on inextensible steel reinforcement reported in the literature (Weldu et al. 2015). The measured displacement of the anchor may be attributed to elastic deflection of the tendon & anchor plate. However, further analysis of the data is required. The passive resistance of the backfill was secondary to the mechanical properties of the tendons and anchor plates used in this study when high quality granular backfill was used.

When the horizontal deflection was limited to 10 – 20mm, the horizontal force that the anchor could resist was 30 – 60kN, depending on the anchor size. The working resistance of the anchor is considered the best approach to take in analysing pullout data.

Development of stability analysis of reinforced soil by rigid-plastic finite element method

Y. Yamakuri

E. Sakon & S. Kobayashi
Kanazawa University, Kanazawa, Japan

ABSTRACT: A rigid plastic finite element method for a stability analysis of a reinforced soil is discussed in this article. In the literature, deformation constraints such as no-length change or no-angle change between FEM nodes were introduced as internal constraints to model the interaction between reinforced members (RMs) and surrounding soils. It is noteworthy that this implementation requires no meshing of RMs. This idea can be extended to more general cases, such as one-directional-resistant (tensile only) RMs and slippage of RMs from soils, by using the duality of the limit theorems (upper bound and lower bound theorems). A mathematical framework of rigid-plastic finite element method with finite strengths of RMs and bonding between RMs and soils is presented. Some numerical examples are also demonstrated to show the ability of the proposed method.

1 INTRODUCTION

To increase the strength and stiffness of soil, reinforcement members such as anchors and geotextiles are placed in the ground. The stability of reinforced soil structures is assessed using traditional rigid-plastic analysis methods such as the limit equilibrium method and slope analysis. In these analysis methods, the resistance force of reinforcement is often assumed and a specific value is given before the analysis is conducted. However, the resistance force of reinforcement is essentially the value that should be obtained as the solution to the boundary value problem. If the predicted value differs from the actual resistance force exhibited significantly, the accuracy of the stability evaluation will be decreased.

The rigid-plastic finite element method (RPFEM) based on the limit theorem is one of the numerical analysis methods to evaluate the stability of soil structures. Several studies have applied RPFEM to reinforced soil problems. Otani et al. (1998) modeled the reinforcement and surrounding soil layers as a single composite material. Asaoka et al. (1994) and Kodaka et al. (1995) modeled the deformation constraint effect of the reinforcement by imposing linear constraints on the nodal displacement velocity of the ground mesh. Since only the ground mesh is used, the physical mesh of the reinforcement is not necessary. However, the reinforcement strength is assumed to be sufficiently large that the reinforcement does not yield.

The authors have developed a RPFEM based on a hybrid-type formulation (Kobayashi 2005; Yamakuri et al. 2020). The advantage of the developed analysis method is that it can handle inequality constraints. In other words, the anisotropy of the reinforcement strength and the adhesion strength between the reinforcement and the ground can be taken into account. In this paper, a stability analysis method for reinforced soil problems is developed

by extending the methods of Asaoka et al. (1994) and Kodaka et al. (1995) to consider the strength of the reinforcement and the adhesion strength between the reinforcement and the ground. Bearing capacity analyses of shallow foundations are conducted as numerical experiments to demonstrate the characteristics of the proposed method.

2   FORMULATION OF REINFORCED SOIL PROBLEMS BY RIGID PLASTIC FINITE ELEMENT METHOD

2.1   *Modeling of reinforcement member*

Asaoka et al. (1994) and Kodaka et al. (1995) proposed linear constraint conditions (invariant length between two nodes of the ground mesh in contact with the reinforcement members) to express the deformation constraint effect of reinforcement members such as anchors and geotextiles. It is called the "no-length change condition".

Figure 1 shows the concept of "no-length change condition". If we ignore the geometric nonlinearity and linearly approximate the ``no-length change condition" between node A and node B, we can derive the condition that the elongation velocity between AB is zero.

$$\boldsymbol{n} \cdot (\dot{\boldsymbol{u}}_B - \dot{\boldsymbol{u}}_A) = 0, \quad \boldsymbol{n} = (\boldsymbol{x}_B - \boldsymbol{x}_A)/|\boldsymbol{x}_B - \boldsymbol{x}_A| \tag{1}$$

where $\boldsymbol{n}$ is the unit vector in the AB direction. $\dot{\boldsymbol{u}}_A$ and $\dot{\boldsymbol{u}}_B$ are the nodal displacement velocities corresponding to node A and node B, respectively.

When the above constraint conditions are imposed on multiple two-node pairs in a three-dimensional ground mesh, Eq. (1) can be transformed and summarized in the following expression.

$$\boldsymbol{D}_r \dot{\boldsymbol{u}}_N = 0 \tag{2}$$

where $\boldsymbol{D}_r$ is a $n_r \times 3n_n$ matrix. n_r and n_n are the number of no-length change conditions and nodes, respectively. $\dot{\boldsymbol{u}}_N$ is a vector that summarizes all nodal displacement velocity fields.

According to the duality of the problem, the confining forces q act to maintain "no-length change condition". The positive direction of the confining force q is shown in Figure 1.

$$\boldsymbol{D}_r^T \boldsymbol{q} = \boldsymbol{f}_r \tag{3}$$

where $\boldsymbol{q}$ is a vector that summarizes all confining forces.

2.2 Modeling of reinforcement strength

To treat a finite reinforcement strength, the following inequality constraints on the confining force are introduced.

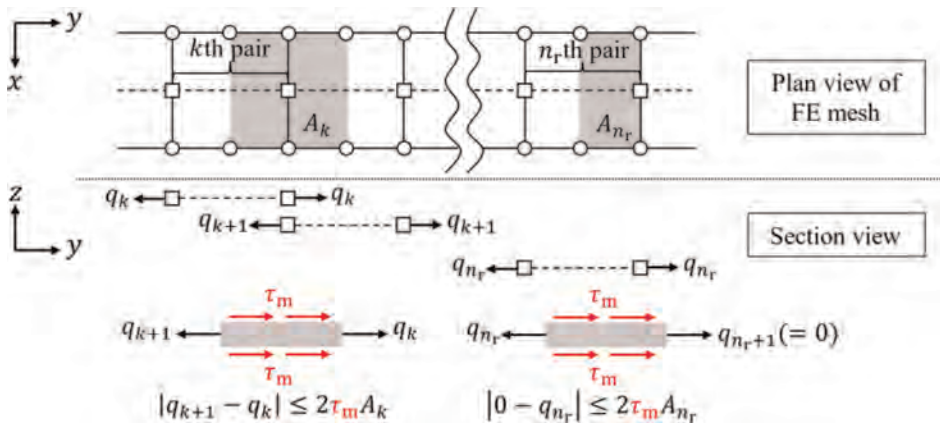
$$q_{min} \le q \le q_{max} \tag{4}$$


Figure 3. Concept of sticking/slipping interaction between reinforcement members and surrounding soils.

Note in Figure 1 that q_{max} corresponds to the absolute value of the reinforcement strength in the compression direction q_c, and q_{min} corresponds to the absolute value of the reinforcement strength in the tensile direction q_t multiplied by the negative sign.

For notational simplicity, Eq. (4) is expressed in the following form using the convex function $h(q)$ as shown in Figure 2.

$$h_k(q_k) \le 0, \quad k = 1, \cdots, \quad n_r \tag{5}$$

where the lower subscription denotes the kth two-node pair.

2.3 Modeling of sticking/slipping interaction between reinforcement members and surrounding soils

In this study, a novel modelling of a stick/slip interaction between reinforcement members and surrounding soils is proposed as shown in Figure 3. It should be noted that the proposed model can be embedded in a ground mesh, i.e., the deformation constraints by the reinforcement members can be expressed as confining forces acting on the nodes of the ground mesh.

It is assumed that the uniform plane strain behavior of reinforcement member in the x direction. 20-noded hexahedral elements per depth are used in this study as shown in the plan view.

A change in confining forces between adjacent two segments $(q_{k+1} - q_k)$ is related to share stress τ_{m}. $|q_{k+1} - q_k| = 2\tau_{\mathrm{m}}A_k$ is satisfied because the shear resistance force acts on both sides of the reinforcement member. Where A_k is a representative cross-section.

The maximum difference between the confining forces is defined as the adhesion strength, s. In the case of clayey soil, it can be assumed that the adhesion strength per side, i.e., $s/2$ is related to the cohesion c and the contact area A. The reduction parameter $w(0 \leq w \leq 1)$ reflects the bounding condition of the interface between the ground and the reinforcement member; $w = 0$ for a perfectly smooth case and $w = 1$ is for a perfectly rough one. Thus, the following equation can be derived.

$$s/2 = wcA, \quad 0 \leq w \leq 1 \tag{6}$$

Therefore, $|q_{k+1} - q_k|$ and adhesion strength s_k satisfies the following inequality constraints:

$$2\tau_{\mathrm{m}}A_k = |q_{k+1} - q_k| \leq s_k, \quad k = 1, \cdots, \quad n_{\mathrm{r}} - 1 \tag{7a}$$

$$2\tau_{\mathrm{m}}A_0 = |q_1 - q_0| \leq s_0 \tag{7b}$$

$$2\tau_{\mathrm{m}}A_{n_{\mathrm{r}}} = |q_{n_{\mathrm{r}}+1} - q_{n_{\mathrm{r}}}| \leq s_{n_{\mathrm{r}}} \tag{7c}$$

where $k = 0$ and n_{r} means the edge of the reinforcement member. When q_0 or $q_{n_{\mathrm{r}}}$ is zero, the constraint condition corresponds to the free-edge condition. When q_0 or $q_{n_{\mathrm{r}}}$ is unconstrained, the constraint condition corresponds to the fix-edge condition. If the equality holds in Eq. (7), the slippage between the reinforcement member and the ground occurs.

The deformation constraint conditions considering the interaction force model are summarized and expressed in the following form:

$$g_k(\boldsymbol{q}) \leq 0, \quad k = 0, \cdots, \quad n_{\mathrm{r}} \tag{8}$$

2.4 Lagrangian of reinforced soil problems based on the lower bound theorem

The lower bound theorem is to maximize a load factor α under satisfying the equilibrium equation and failure criterion. The Lagrangian for reinforced soil problems based on the lower bound theorem is expressed as follows:

$$L = \begin{cases} \alpha + \boldsymbol{\mu} \cdot (\boldsymbol{B}^T\boldsymbol{\sigma} - \alpha\Gamma_0 - \Gamma_{\mathrm{c}} - \boldsymbol{D}_{\mathrm{d}}^T\boldsymbol{p} - \boldsymbol{D}_{\mathrm{r}}^T\boldsymbol{q}) - \boldsymbol{\lambda} \cdot \boldsymbol{f}(\boldsymbol{\sigma}) \\ -\sum\limits_{k=1}^{n_{\mathrm{r}}} \omega_k h_k(q_k) - \sum\limits_{k=0}^{n_{\mathrm{r}}} \psi_k g_k(\boldsymbol{q}) \quad (\boldsymbol{\lambda} \geq \boldsymbol{0}, \quad \omega_k, \quad \psi_k \geq 0) \\ +\infty \quad \text{(otherwise)} \end{cases} \tag{9}$$

where variables $\boldsymbol{\mu}$, $\boldsymbol{\lambda}$, ω_k and ψ_k are Lagrangian multipliers. The physical meaning of the right-hand side of Eq. (9) is as follows. The first term shows a load factor α. The second term is an equilibrium equation where $\boldsymbol{\sigma}$ are stresses at the integration points, Γ_0 is a reference load, Γ_{c} is a constant load such as body force, $\boldsymbol{p}$ are nodal forces on the Dirichlet boundaries. The third term is a failure criterion where $\boldsymbol{f}$ are yield function at the integration points. The fourth term is an inequality constraint condition of reinforcement strength. The fifth term is an inequality constraint condition of the interaction of reinforcement members and surrounding soils.

2.5 *Karush-Kuhn-Tucker conditions (KKT conditions)*

The following Karush-Kuhn-Tucker conditions (KKT conditions) are obtained from the Lagrangian (Eq. (9)).

$$\text{Equilibrium}: \quad \boldsymbol{B}^T\boldsymbol{\sigma} = \alpha\Gamma_0 + \Gamma_c + \boldsymbol{D}_d^T\boldsymbol{p} + \boldsymbol{D}_r^T\boldsymbol{q} \tag{10a}$$

$$\text{External work rate}: \quad 1 - \boldsymbol{\mu}\cdot\Gamma_0 = 0 \tag{10b}$$

$$\text{Dirichlet boundary}: \quad \boldsymbol{D}_d\boldsymbol{\mu} = \boldsymbol{0} \tag{10c}$$

$$\text{Flow rule}: \quad \boldsymbol{B}\boldsymbol{\mu} = \left(\frac{\partial f}{\partial\sigma}\right)^T\lambda \tag{10d}$$

$$\text{Complementarity}: \quad \lambda\cdot f(\sigma) = 0, \quad \lambda \geq \boldsymbol{0}, \quad f(\sigma) \leq \boldsymbol{0} \tag{10e}$$

In addition, the following terms regarding the deformation constraint conditions hold for all constraints k.

$$\text{Nodal velocities of ground mesh}: \quad (\boldsymbol{D}_r\boldsymbol{\mu})_k = -\omega_k\frac{\partial h_k(q_k)}{\partial q} - \psi_k\frac{\partial g_k(q_k)}{\partial q} \tag{10f}$$

$$\text{Complementarity}: \quad \omega_k h_k(q_k) = 0, \quad \omega_k \geq 0, \quad h_k(q_k) \leq 0 \tag{10g}$$

$$\text{Complementarity}: \quad \psi_k g_k(\boldsymbol{q}) = 0, \quad \psi_k \geq 0, \quad g_k(\boldsymbol{q}) \leq 0 \tag{10h}$$

In this paper, we used the commercial optimization solver "Gurobi Optimizer" to solve Eq. (9) as a primal problem.

3 NUMERICAL EXAMPLES

3.1 *Bearing capacity of footing on reinforced soil*

A series of bearing capacity analyses on weightless c, $\phi = 0$ soils were conducted to demonstrate the proposed method. The von-Mises model was used as the failure criterion for the geomaterial, and the inequality constraint $I_1 \leq 0$ was imposed on the first invariant I_1 of the stress tensor to express the tension cut-off (Yamakuri et al. 2020).

Figure 4 shows a 3D FE mesh (number of nodes:18,687 and number of elements: 2,592) and boundary conditions. A rigid-rough footing was assumed under the plane strain condition.
Figure 4.　Finite element mesh and boundary conditions.

(a) Reduction parameter $w = 0.2$ (b) Reduction parameter $w = 0.5$ (c) Reduction parameter $w = 1.0$
Figure 5. Relation of reinforcement effect β and reinforcement length n (at burial depth $m = 0.5$, with no compressive strength $q_c = 0$ [kN/m]).

The reinforcement member was placed as shown in Figure 4. The reinforcement was assumed to be a geotextile, and the parameters were set as follows. The reinforcement depth m was set to 0.5 and the reinforcement compressive strength q_c was set to 0. The reinforcement length n, reinforcement tensile strength q_t and reduction parameter $w (0 \leq w \leq 1)$ which represents a shear strength of the interface; $w = 0$ is a perfectly smooth case and $w = 1$ is perfectly rough, for example. These parameters were all varied.

To summarize the numerical results, the reinforcement factor β was defined as,

$$\beta = q_u^* / q_u \qquad (11)$$

where q_u^* is an ultimate bearing capacity of reinforced soil and q_u is an ultimate bearing capacity of normal ground.

3.2 Numerical results

Figure 5 shows the numerical results. It can be seen from Figure 5(a) that the reinforcement factor depends on the reinforcement length only and the adhesion strength is dominant. When $w \geq 0.5$, it can be seen from Figure 5(b), (c) that not only the reinforcement length but also reinforcement tensile strength contributes to the reinforcement effect. In any of the reduction parameters, the reinforcement effect converges if the reinforcement length $n \geq 2$. The ultimate bearing capacity increased by up to approximately 14% over that before reinforcement.

Figure 6 shows the distributions of equivalent plastic strain rate. As shown in Figure 6(a), The obtained failure mechanism of normal ground was in good agreement with the Prandtl's solution. When $w = 0.2$, there is no significant difference between the failure mechanisms of reinforced soil and normal ground. On the other hand, when $w = 1.0$, the failure zone is expanded more than that of $w = 0.2$ and contributes to the bearing capacity.

The difference in ultimate bearing capacity due to the reinforcement condition is not so significant, and the reinforcement effect β is at most 1.14.

(a) Reduction parameter $w = 0.2$ (b) Reduction parameter $w = 0.5$ (c) Reduction parameter $w = 1.0$
Figure 6. Distribution of equivalent plastic strain rate (with length $n = 3$ at burial depth $m = 0.5$, with no compressive strength $q_c = 0$ [kN/m] and finite tensile strength $q_t = 100$ [kN/m]).

This is because the target ground is a c, $\phi = 0$ soil (i.e., clayey soil). However, it was found that the failure mechanism occurring in the ground varied greatly depending on adhesion strength.

4 CONCLUSIONS

A mathematical framework of rigid-plastic finite element method with finite strengths of reinforcement members and bonding between reinforcement members and surrounding soils is presented and discussed in this article. By using the duality of the limit theorems, no-length change constraint condition can be extended to more general cases of one-directional resistant (tensile only) reinforcement or finite / anisotropic strength of reinforcement members. To be specific, the authors have proposed a new Lagrangian function by introducing inequality constraints of Lagrangian multipliers corresponding to deformation constraints. A similar approach can be used for a sticking/slipping interaction between reinforcement members and surrounding soils. It should be noted that this modeling requires no specific meshing of reinforcement members and only FE mesh of a ground is necessary.

A series of numerical analysis for the bearing capacity of a shallow footing resting on reinforced ground was conducted to demonstrate the ability of the proposed method. Besides the influences of geometry, such as length and burial depth of reinforcement members, the influences of strengths of reinforcement members and interfaces between reinforcements and soils on the bearing capacity are observed in the numerical results. Failure mechanism is also greatly affected by the geometry and strengths. From the practical point of view, this modelling can express behaviors of sheet-like reinforcement members with no compressive strength and pull-out of reinforcement members.

ABSTRACT: The results of an experimental campaign of reinforcement of thin cohesive soil embankments in the case of cavity collapse are presented. In particular, the aim is to test the effectiveness of a new type of bi-stiffness geosynthetic. A coupled DEM-FEM numerical model is validated based on these results and allows a better understanding of the soil-geosynthetic interaction phenomena mobilized during the collapse. Comparison between the numerical and experimental results obtained with the two types of reinforcement (mono-stiffness and reversed bi-modulus) make it possible to underline the interest of the innovative product developed.

1 INTRODUCTION

The collapse of an underground cavity represents a major potential risk of ground movements, affecting the safety of the concerned infrastructures as well as people.

In order to limit the risks associated with a collapse of the embankment, a solution of reinforcement of embankments above a cavity by a geosynthetic sheet is generally adopted. During the collapse of the soil surface, the geosynthetic reinforcement is able, by deforming, to transfer the vertical load related to the weight of the collapsed soil and the overloads towards the edges of the cavity, by limiting the surface deflections to acceptable values. Numerous experimental works such as the RAFAEL project (Villard et al. 2022), the GeoInov project (Huckert 2015) and numerical studies (Le Hello 2007; Potts 2007; Pham et al. 2018; Villard et al. 2009) have led to an understanding of the load transfer mechanisms that develop within reinforced granular layers in particular when the tensile behavior of the geosynthetic reinforcement is assumed to be linear elastic and characterized by a single stiffness. On the other hand, knowledge on the load transfer mechanism for cohesive soils is still limited. Based on full-scale experiments, an analytical design formulation has

been proposed for such cohesive soils by Huckert (2015) and has been evaluated and partially validated by Hassoun (2019) through an experimental campaign on a small-scale laboratory setup.

To fill the existing gaps and to complete the current knowledge on the behavior of reinforced embankments made of cohesive soil, an experimental campaign has been conducted in the framework of the REGIC (Reinforcement by Intelligent Geosynthetics over Cavities) research project. The objective is to test innovative reinforcement solutions in the specific case of the reinforcement of a cohesive soil layer. This innovative reinforcement process, patented by the company Afitexinov under the name of "reversed bi-modulus" geosynthetics, ensures that the reinforcement layer has two tensile stiffnesses which are activated one after the other, the first being weaker than the second (unlike the "bi-modulus" for which the first is higher than the second). This new type of "reversed bi-modulus" reinforcement makes it possible to detect the beginning of a rupture of the soil layer (by means of an integrated optic fiber and thanks to the first low stiffness of the geosynthetics) while guaranteeing the same level of safety as a geosynthetic with only one stiffness (thanks to the second high stiffness mobilized after the threshold of deformation necessary to the detection of the movements related to the cavity).

The experiments carried out allowed the analysis of the behavior of the reinforced embankments during the opening of cavities 1 and 2 m in diameter, then during a progressive loading phase until the final collapse of the soil layer on the geosynthetic reinforcement.

In order to analyze the interaction behavior of the geosynthetic sheet (single- or bi-modulus) with the cohesive soil, during the opening of the cavity, the collapse of the soil on the sheet, and the loading phase, a numerical study, complementary to the experiments, using a coupled DEM-FEM numerical model has been conducted. This numerical model has been tested and validated in the case of a classical reinforcement (Delli Carpini et al. 2020).

The aim of this paper is to highlight, through the numerical study, the interest and specificities of the new "reversed bi-modulus" technology and to compare it to the classical solution of the single-stiffness geosynthetic.

2 THE EXPERIMENTAL CAMPAIGN

The experimental campaign, carried out in La Tour-du-Pin (France), consisted in the realization of 3 full scale tests for which backfills 0.5 or 0.75 m thick were implemented. For each test, three cavity openings were tested with a size of 1 m then 2 m in diameter and when the backfill did not reach failure under its own weight, an incremental loading was applied until collapse.

For this type of experimentation, different void generation mechanisms have been used for granular soils. One of the most commonly used techniques is the emptying of a cavity filled with materials. For example, Bridle and Jenner (1997) adopted emptying by sand suction, while in the RAFAEL project (Villard et al. 2002) clay balls were used. Another alternative is to implement inflatable pads or air chambers (Huckert 2015).

In this campaign, the cavity was filled with washed rolled gravel. A trap door device between two chambers allows to drain the aggregates from the upper chamber to the lower chamber and thus to create a cavity under the geosynthetic. In order to obtain a progressive opening, an inner cylinder was also placed in the upper chamber, in order to obtain a first cavity of 1 m in diameter when the central trap door is opened. The cylinder falls into the lower chamber when the four outer hatches are opened to create a cavity of 2 m in diameter.

After the installation of the opening device, the geosynthetic sheet was placed, equipped with backscattering fiber optic sensors that allows a distributed measurement of the deformation on the length of the optical fiber. After the placement of the cohesive soil and before the opening of the cavity, the compaction of the backfill (in 2 layers of 0.25 m) is controlled with a light dynamic penetrometer which allowed to conclude that the compaction is not

homogeneous on the backfill depth H = 0.50 m. Indeed, the surface layer of 0.10 m appeared denser than the rest of the backfill and this for both layers. After the opening of the cavities, the backfill was overloaded with steel plates of 80 kg each, placed on a steel cube 0.5 m in width and 38 kg in weight. The deformations obtained with the optical fiber will be presented when comparing with the numerical results.

2.1 *The materials*

Two coherent soils were used for the realization of the test plots: a sand treated with 1% of lime and a silty soil. Only the tests carried out on the 0.5 m thick treated sand will be presented here.

Preliminary Proctor compaction tests showed that the Proctor Normal optimum is obtained for the following conditions: an optimum water content equal to 16.7% and an optimum dry density γd_OPN of 16.3 kN/m3. In order to complete the characterization of this material which is in unsaturated condition and is loaded in a quick way, three triaxial Unconsolidated - Undrained tests (UU tests) as well as flexural tests were carried out on, following the same procedure as for the preliminary tests. The parameters are summarized in Table 1. These characteristics will be taken into account for the numerical back analysis of the full-scale tests.

Table 1. Treated sand main mechanical properties measured in laboratory tests.

	γ_d (kN/m^3)	w (%)	c_{uu} (kPa)	φ_{uu} (°)	σ_t (kPa)
Limed sand	15	16-18	18.93	34.9	$\sim$ 15

Two cavities were opened for each of the two full scale tests using the lime treated sand: cavity N°1 concerns a reinforcement sheet with reversed bi-modulus behavior, cavity N°2 was opened under a conventional reinforcement sheet (monostiffness). The monostiffness geosynthetic is composed of PVA cords with a breaking strength T = 165 kN/m and a stiffness Jsp = 2395 kN/m in the X direction (production), the non-woven support brings a low stiffness in the perpendicular Y direction (estimated at 30 kN/m). The reversed bi-modulus geosynthetic consists of PVA cords with a breaking strength of 45 kN/m in the weft direction and a breaking strength of 131 kN/m in the production direction. From standardized tensile tests performed on this product, it was determined that, in the reinforcement direction, the reversed bi-modulus geosynthetic has an initial stiffness Jsp_1=750 kN/m up to a threshold strain value of 1.5% (a strain value that allows the detection of cavity-related movements and remains well above the minimum strains that can be detected by fiber optics), and beyond that, a second stiffness Jsp_2= 2500 kN/m up to failure. An anchoring by simple covering of the sheet by the backfill allows the tensioning of the sheet above the cavity.

3 NUMERICAL MODEL

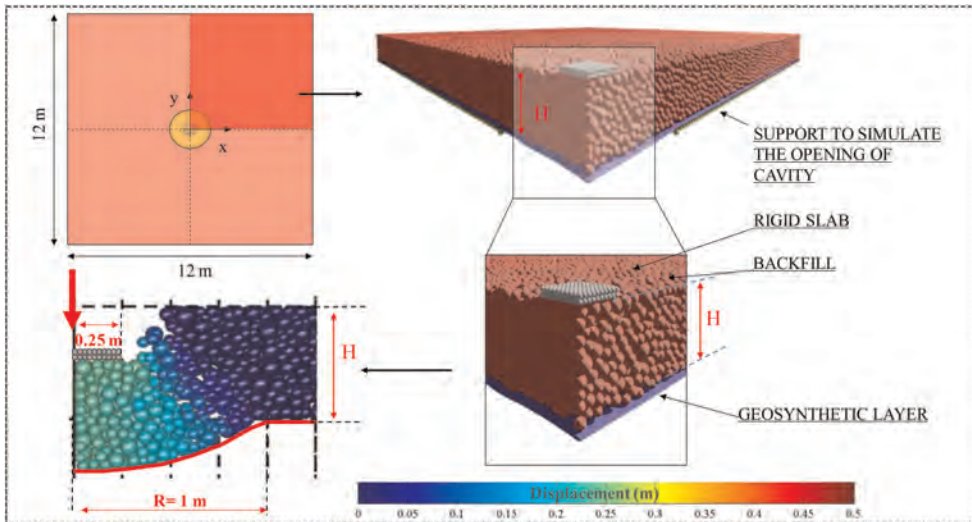
The numerical modelling (Figure 1) is based on the SDEC numerical code (Donzé 1997) that is coupling the Discrete Element Method (DEM) to model the soil and the Finite Element Method (FEM) to represent the reinforcement layer simultaneously. The DEM considers a set of particles interacting at the contact points, which makes it possible to describe the behaviour of soils under large deformations (shear, overturning or global rotation) and their failure by blocks, such as those observed for cohesive soils during the collapse of the soil


Figure 1. Geometry of the numerical model.

layer on the geosynthetics sheet. The embankment consists of several spheres of different diameters placed in a volume of 6 m x 6 m (boundary conditions with a minimum impact on the behaviour of the part of the backfill close to the cavity) x 0.5 m, corresponding to a quarter of the model for symmetry reasons. To represent the cohesive soil, the soil particles are linked together at their contact points by cohesive bonds (normal and tangential adhesion). The forces between particles are subjected to a Mohr-Coulomb type criterion (Delli Carpini 2021).

The contact micro-parameters that allow to reproduce the macroscopic behavior of the cohesive granular material (cohesion of 19 kPa, internal friction angle of 35° and tensile strength of 15 kPa, as identified by triaxial UU tests and bending tests) are: $c = Tn = 60$ kPa and $\phi = 40°$ (c is the microscopic contact shear resistance, Tn the microscopic contact resistance to traction and ϕ the microscopic contact friction angle). A thin geosynthetic layer, modelled by deformable 3-nodes triangular finite elements and which are assembled together to form a continuous sheet, is positioned below the embankment. The elements of the sheet interact with the soil particles by contact forces defined at the point of contact. The behaviour of the fibre's system is described in details by Delli Carpini (2021).

Some of the spheres in the support are moved downwards at a constant speed to create the void under the backfill and to simulate the opening of the cavity. After the cavity is fully opened, a loading procedure is applied by means of a rigid slab consisting of two layers of bounded spheres. Once the slab is in contact with the backfill surface, the actual loading test begins. A uniformly distributed load is progressively applied to the slab until the backfill breaks.

For the geosynthetic, the values of the numerical parameters retained are deduced from the average stiffnesses obtained during tensile tests. Figure 2 shows the good match between the experimental results and the numerical modelling of the tensile tests carried out in the production direction on the single-stiffness geosynthetic sheet (a) and the reversed bi-modulus geosynthetic sheet (b). A tensile stiffness in the perpendicular direction of 30 kN/m was considered for both products. In the absence of experimental friction test results, a friction angle of 30° was used to numerically characterize the soil/geosynthetic interface.

4 RESULTS OF COMPARISONS WITH EXPERIMENTAL MEASUREMENTS

A comparison with experimental results available for the 0.5 m backfill made of treated sand is used to test the validity of the numerical model (single-stiffness geosynthetic and reversed bi-modulus geosynthetics).

Several main phases can be highlighted during the test: opening of the cavity, rupture of the soil layer, collapse and stabilization of the cohesive block on the sheet, deformation of the sheet during loading. In this article, we would like to focus our attention on the failure of the cavity to better understand the different behaviour from a single stiffness and a reversed bi-modulus geosynthetics. The analysis of the shape of the collapsed block and the deformations of the geosynthetic layer are important elements that allow the evaluation of the relevance of the numerical model.

For the numerical model, the cohesive soil layer collapses for a loading force of 16 kN for the single-stiffness reinforcement and a loading force of 16.7 kN for the reversed bi-modulus reinforcement. The numerical values obtained for both types of reinforcement are higher than the failure force obtained during the full scale tests: F = 4.30 kN and 12.14 kN for the two tests done. The difference between the values can be attributed to the uncertainties on the real experimental mechanical characteristics of the backfill, related to the non-homogeneous compaction in depth of the soil layer for both tests. However, the shape of the collapsing rigid block of soil is similar between the experimental observation and numerical result, as Figure 3 shows. As it can be seen in Figure 4a, in both cases tested (mono-modulus or reversed bi-modulus geotextiles), the maximal vertical displacements of the reinforcement after collapse of the cohesive soil are rather similar (dn,v = 250 mm approximately).

Figures 4b and c show the deformations of the geosynthetic along the entire length of the model (12 m), during stabilization of the cohesive block on the sheet, after its collapse. The comparison shows in particular that the reversed bi-modulus geosynthetic undergoes a greater maximum deformation than the single-stiffness one, but that it is less stressed in the anchorage zones due to its low initial stiffness. On the other hand, the results obtained at the collapse of the soil layer are very comparable to the experimental measurements. For the single-stiffness reinforcement, the maximum numerical strain value $\varepsilon = 1.5\%$ is close to the experimental value $\varepsilon = 1.46\%$. Similarly, for the reversed bi-modulus reinforcement, the numerical value of deformation ($\varepsilon = 2.07\%$) is comparable to the experimental value ($\varepsilon = 1.96\%$).

Nevertheless, in the anchorage zone, the experimental measurements are bigger than the numerical results. This difference is due to the slippage of the measuring device from the geosynthetics.
Figure 3. Shape of the collapse soil. Comparison between experimental observation (a) and numerical model (b).
Figure 4. Displacement vs loading force (a), deformation of the geosynthetic at the collapse : (b) single-stiffness model (red curve) and (c) reversed bi-modulus model (green curve).

The numerical model clearly shows the different behaviour of the two types of reinforcement, especially in the anchorage zone, which leads to higher deformation values at the center of the cavity for the reversed bi-modulus geosynthetic, even though similar vertical displacements are obtained for the two products. After collapse of the soil on the sheet, the reversed bi-modulus geosynthetic leads to lower deformation of the sheet. This result confirms that the reversed bi-modulus reinforcement fulfils its function: the large initial deformations activate the warning signal transmitted by the optical fibres inserted in the product, while the high stiffness mobilised later ensures global deflections of the sheet.

5 CONCLUSIONS

The presence of a cavity in the subsoil represents a risk of collapse of the overlying soil that can be reduced by the installation of geosynthetic layer. In this context, different geosynthetic reinforcement products (single stiffness or reversed bi-modulus) associated with cohesive backfills were tested in the framework of the REGIC project. The instrumented reversed bi-modulus geosynthetic allows, in a first step, to activate the warning system based on deformation measurements by optical fibers installed on the sheet as soon as a threshold movement of the ground can be recorded. The second stiffness, much larger than the first

one, allows to contain the deformations and to limit the displacements of the sheet and the soil surface. In spite of the inherent limitations of the experiments and the numerical model used, it can be concluded that qualitatively the numerical model correctly represents the behavior of reinforced cohesive embankments (conventional geosynthetic, single stiffness and reversed bi-modulus geosynthetic). The difference between the two types of reinforcement highlighted during the experimental campaign is also confirmed by the numerical results, i.e. larger deformation values at the center of the cavity for the reversed bi-modulus sheet despite similar vertical displacements for the two products. As expected, the large initial deformations activate the warning signal while the high stiffness mobilized later limits the surface settlements during loading.

On the basis of the observations made, the numerical model, used also by Delli Carpini (2021) for parametric studies, will lead to an improvement of the existing design methods.

Laboratory testing of geosynthetics-reinforced soils under freeze-thaw cycles and mechanical plate loading

M. Huang & C. Lin
University of Victoria, Victoria, British Columbia, Canada

S. Pokharel
Stratum Logics, Acheson, Alberta, Canada

ABSTRACT: As part of an endeavor to develop a laboratory scale device for testing freeze-thaw behaviors of geosynthetics-reinforced soils, this study synthesizes outcomes from a survey of plate loading apparatuses developed in various labs in different countries. The survey specifically investigated the setup of each component, loading mechanism, instrumentation, and materials tested. The functions of the apparatuses and the implications of the test results are examined. The results from the survey were utilized to develop a new model test apparatus capable of performing freeze-thaw and plate loading tests. The apparatus was further upgraded to incorporate a water supply system. The preliminary tests based on the open system were conducted, and the results are discussed.

1 INTRODUCTION

Freeze and thaw action is the major cause of the dysfunction of roads due to expansion of water during freezing and formation of segregated ice lenes as well as the weakening during thawing. In freezing process, the formation of ice lenses is developed as pore water is forced to migrate to freezing fringe under the suction induced by the unidirectional freezing. In thawing process, after the upper frozen layer is thawed, the melted water is trapped in the thawed layer as the water is restrained in the lower frozen layer. The excess pore water pressure weakens the soil interparticle contact, resulting in a markable drop in the strength of base courses and subgrades. Pavements in the seasonal cold area, therefore, are prone to the distress by the traffic loads at the thawed seasons.

To ensure durability of road in cold regions, it is critical to implement varying measures to mitigate freeze-thaw damages. Among the available solutions, geosynthetics stabilization/ reinforcement can improve the freeze-thaw resistance of pavements. Limited field tests (Henry *et al.* 2005; Pokharel *et al.* 2017) indicated that the freeze-thaw performance could be improved when the base courses were stabilized / reinforced by geocells. In contrast to scarcity of field tests, the laboratory model tests on the freeze-thaw behavior of geosynthetics-reinforced bases are even less. This is probably attributed to the limited efforts for developing the model test apparatus. Extensive laboratory model tests, namely plate loading tests, have been widely conducted to investigate geosynthetics-reinforced bases, in which the apparatus consists of a box filled with compacted soils and a loading frame applying static or dynamic loads on soils. However, this apparatus is unable to run freeze-thaw tests.

This paper provides a synthesis of plate loading tests on geosynthetics-reinforced soils without considering freeze-thaw effects. On the basis of this review, a custom-made model test apparatus capable of performing both freeze-thaw and plate loading tests is introduced.

For the freeze-thaw tests, both closed and open systems can be accommodated. The test results based on the closed system have been reported by Huang *et al.* (2021, 2023). Here, the test results in an open system are discussed.

2 REVIEW OF PLATE LOADING TEST APPARATUS

Plate loading tests have been widely conducted to investigate the performance of geosynthetics-reinforced bases, from which static or dynamic responses such as load-movement curves and stress distribution in the soil can be measured. These results can be used to directly quantify the geosynthetics stabilization / reinforcement functions as well as calibrate the design parameters for geosynthetics reinforced bases (Han 2015). Table 1 summarizes the typical features of the plate loading test apparatus reported in literature. It shows that the apparatus in general includes a square box with the side length ranging from 600 to 3000 mm and a circular loading plate with the diameter ranging from 150 to 300 mm. For design purpose, the plate diameter is recommended to be 300 mm to properly simulate the tire contact with pavements (Han 2015). The choice of side length of the box should ensure the minimal boundary effect on the soil responses under plate loading.

Table 1. Summary of plate loading test devices for geosynthetics-reinforced soils.

References	Box dimension (length × width) mm × mm	Plate loading diameter mm	Loading type	Instrumentation
Al-Qadi *et al.* (1994)	3100 × 1800	300	Cyclic	LVDT
DeMerchant *et al.* (2002)	2200 × 3200	305	Static	LVDT
Pokharel *et al.* (2010)	605 × 605	150	Static	Dial gauge
Thakur *et al.* (2012)	2200 × 2000	300	Cyclic	LVDT, pressure cell, strain gauge
Tanyu *et al.* (2013)	3000 × 3000	250	Cyclic	LVDT, strain gauge
Mehrjardi *et al.* (2019)	1200 × 700	80/120/150	Static	Dial gauge

To investigate the mechanical properties of geosynthetics-reinforced bases, the apparatus may come with actuators that can apply static load, dynamic load or both. The static plate loading tests normally follow a quick test procedure. Plate loads are incrementally applied to the test soils and maintained for three to five minutes until the displacement reaches stable. The applied load (or pressure) and the displacement are monitored and the load-displacement curves allow for estimating the stiffness and ultimate bearing pressure of unreinforced and reinforced bases. The stiffness is defined as the slope of the initial portion of the curve (DeMerchant *et al.* 2002; Pokharel *et al.* 2010), and the ultimate bearing pressure is determined as the pressure corresponding to the inflection displacement point before failure (Mehrjardi *et al.* 2019; Pokharel *et al.* 2010).

For the dynamic loading tests, appropriate loading magnitude and frequency as well as waveforms need to be considered to simulate traffic loads. Table 2 shows the loads applied during the plate loading tests. As it is shown in the table, the magnitude ranges 550 to 710 kPa, frequency 0.5 to 1 Hz, and the maximum number of cycles 800 to 1000. During the tests, the cumulative deformation is monitored using displacement sensors such as linear variable displacement transducers (LVDTs). Pressure cells are also placed at the interface of base courses and subgrade to monitor the distributed stress on the subgrade during the cyclic loading, which allows for evaluating the geosynthetic stabilization effect. Sometimes, strain gauges are attached on geosynthetics materials to evaluate the geosynthetic reinforcement effect.

3 MODEL TESTS ON GEOCELL-REINFORCED SOILS IN AN OPEN SYSTEM

The existing model test apparatuses are designed to investigate the mechanical responses of geosynthetics-reinforced bases in room temperature. Limited model tests are concerned with the mechanical responses of the bases under freeze-thaw cycles. To advance the research in this area, the authors have dedicated to develop a new model test apparatus that can perform freeze-thaw tests and plate loading tests by adapting the existing plate loading model apparatus to incorporating the freeze-thaw function. Some essential features of this new apparatus will be described later in this section, while the details are contained in Huang *et al.* (2021). It is noted that the apparatus only includes the closed system (i.e. no water supply during the freeze-thaw process). This section introduces the apparatus that has been further upgraded to include the open system (i.e. the water supply is provided during the freeze-thaw cycles). Some preliminary results obtained in the open system are also presented.

3.1 *Model test apparatus*

This new model test apparatus consists of a freeze-thaw component, a plate loading component and a rail connecting component (Huang *et al.* 2021). The freeze-thaw component is made up of an aluminum square box with the side of 750 mm, a cooling plate with the dimensions of 745 × 745 mm, thermal insulation foams, and a chiller connecting to the cooling plate. During freeze-thaw process, the cooling plate, placed on the surface of the soils, can freeze or thaw soils by adjusting the coolant temperature in the chiller. To achieve unidirectional top-down freezing process, which is consistent with the natural phenomenon, a thermal sink is created by four aluminum angles which connect box walls and the cooling plate. Box walls serve as the temperature barrier to prevent soils from absorbing ambient heat, so the thickness of the insulation foams could be reduced to 51 mm under the normal environment. In thawing process, four aluminum angles are removed to prevent soils from absorbing excessive heat. Therefore, one-directional freeze and thaw is imposed to the soils. Plate loading tests are conducted right after freeze-thaw tests. The static loading system has a loading plate with the diameter of 150 mm, which is attached to a hydraulic cylinder with the maximum load of 109 kN.

The above features do not include the water supply. The apparatus is therefore upgraded to include a water supply component mounted to the box bottom. A valve is set to control the water ingress and egress during the freeze-thaw processes. The water supply component is the Marriott type tank as shown in Figure 1, which enables setting and fixing the water levels at the source (simulating groundwater level). Scientific Commodities® porous sheets with the thickness of 6.4 mm are placed at the box bottom to distribute water uniformly at the bottom.

3.2 *Test materials and experimental instrumentation*

3.2.1 *Materials*

Geocells used in this study were nano-polymeric alloy (NPA) Type-C geocells manufactured by PRS®. The tensile strength of ribs and seams was both 19 kN/m. The geocell ribs were
Figure 1. Setup of freeze-thaw system with water supply component and instrumentation plan.

150 mm in height and were perforated. The opening dimension of a single geocell was 245 mm × 210 mm when it was unfolded. The basic properties of this material are presented in Huang *et al.* (2021).

Base courses consisted of a mixture of 95% sand and 5% kaolin. The sands were classified as poorly graded sand (SP) according to the Unified Soil Classification System (USCS) with the specific gravity of 2.7, and the kaolin was commercial EPK kaolin manufactured by Edgar Minerals®. The mixture was thus a poorly graded sand with clay (SP-SC) having the mean particle size (D_{50}) of 0.674 mm with the coefficient of uniformity and curvature of 5.7 and 1.1, respectively. The maximum dry density and the optimum moisture content were determined to be 1970 kg/m^3 and 11.7%, respectively, according to the standard Proctor compaction test (ASTM D698).

3.2.2 *Soil preparation and instrument installation*

Four model tests were performed to investigate the freeze-thaw behavior of geocell-reinforced soils under an open system. In each test, soils were compacted to the maximum dry density and the optimum moisture content per standard Proctor compaction test as described previously. The compaction was carried out in four lifts, with 50 mm for the first three lifts and 20 mm for the last lift. The added mass of soils at each lift of the compaction was calculated by the soil density times the volume of each lift. The target level of compaction degree was achieved by controlling the added mass and the determined thickness of soils. After the complete of the compaction at each lift, the soil surface was scratched to improve the bonding between soil layers and minimize the layered effect in soils. T-type thermocouples were placed on the soil surface immediately after the compaction of each of the first three lifts to monitor the soil temperature during freeze-thaw cycles. T-type thermocouples were also embedded into the box wall, box bottom, top surface of the porous sheet and the cooling plate to monitor the temperature changes at these locations.

After the completion of soil compaction, the soil surface was covered with a plastic sheet to avoid water loss and the valve at the box bottom was switched on to supply water. This circumstance was kept for one night to achieve the hydraulic equilibrium in the soils. The freeze-thaw test was then performed. Figure 2a shows the setup of the freeze-thaw tests on soils. The cooling plate was placed on the soil surface. The box and the cooling plate were wrapped by the insulation foams. In the freezing process, the chiller temperature was set as −20°C. The soils were gradually frozen from the surface to the bottom. When the temperature of the box bottom reached −5°C, the freezing process was terminated. Immediately

Figure 2. Photographs: (a) freeze-thaw tests and (b) plate loading tests.

after that, the valve was switched off and the four aluminum angles were removed. The chiller temperature was then set to 20°C to initiate thawing process. The cooling plate heated soils from the surface to the bottom. When the temperature of the box bottom was 15°C, the thawing process was finished. This concluded one freeze-thaw cycle. The above procedure was repeated until the predefined freeze-thaw cycles were reached. During the freeze-thaw tests, National Instruments® datalogger was used to record the readings of T-type thermocouples and LVDTs every 30 minutes. The accuracy of T-type thermocouple and LVDT was 1°C and 0.01 mm, respectively. The four model tests included zero and five freeze-thaw cycles for unreinforced bases and zero and four freeze-thaw cycles for reinforced bases.

Static plate loading tests as shown in Figure 2b were conducted after the freeze-thaw cycles. The circular plate fixed to a load cell was placed at the center of the soil surface. The load exerted by the hydraulic cylinder was measured by the load cell and recorded by the datalogger PASCO® 550 Universal Interface. Load was applied in an increment of 62 kPa on the soils and maintained for five minutes. The incremental pressure was applied until the soil failed and then it was unloaded to zero. During the loading-unloading process, the plate movement was monitored using three dial gauges mounted on the plate perimeter at an angular spacing of spaced 120°. The accuracy of the load cell and dial gauge was 1 kPa and 0.025 mm, respectively.

3.3 Test results

Since the model apparatus was upgraded recently, only limited freeze-thaw tests were conducted. Here, the preliminary results are reported, including soil heave / settlement during freeze-thaw cycles and mechanical load-movement curves during plate loading tests.

3.3.1 Evolution of soil movement during freeze-thaw cycles

Figures 3a-b present the evolution of the soil movement in unreinforced and reinforced bases during freeze-thaw cycles. Included in the figures are the time histories of temperature in the cooling plate, soils, and the box bottom. The data of soil movement (e.g. heave) and soil temperature were the averaged readings of LVDTs and T-type thermocouples, respectively. The plateau of soil movement was achieved when the box bottom temperature reached $-5°C$ in the freezing process and 15°C in the thawing process. The maximum soil movement and the difference between two plateaus within the same freeze-thaw cycle were the peak heave and thaw settlement.

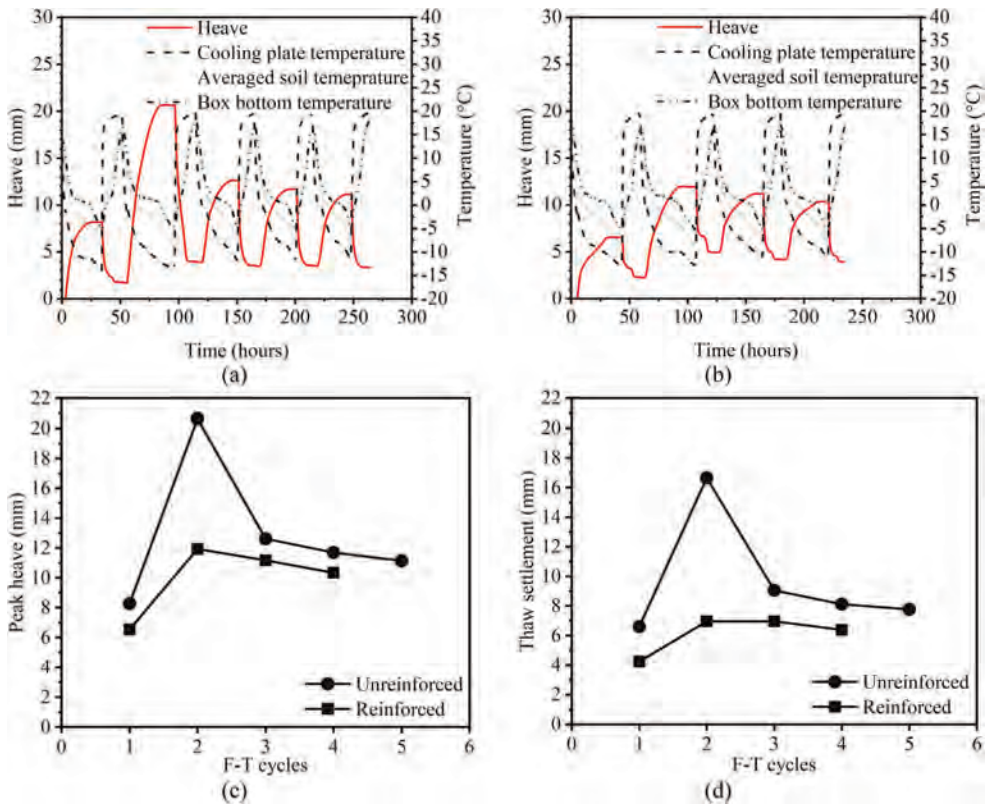
Figures 3c-d present variations of peak heave and thaw settlement with freeze-thaw cycles. They experienced the largest increase at the 2nd freeze-thaw cycle in both the


Figure 3. (a) Evolution of soil movement and temperature in unreinforced soils, (b) evolution of soil movement and temperature in reinforced soils, (c) peak heave and (d) thaw settlement.

unreinforced and reinforced soils, followed by a slight decrease for reinforced base but a drastic decrease for unreinforced bases in the further freeze-thaw cycles. The inclusion of geocell significantly reduced the soil heave by 42% and the thaw settlement 42% and 58%, respectively after one freeze-thaw cycle. After four freeze-thaw cycles, the peak heave and thaw settlement were reduced by 12% and 21%, respectively, due to the geocell reinforcement.

3.3.2 *Plate loading test results*

The plate loading tests were performed right after the freeze-thaw cycles. Figure 4 shows the pressure-displacement curves of the unreinforced and reinforced soils after the freeze-thaw cycles.

It is evident that the freeze-thaw effect significantly reduced the mechanical properties of both unreinforced and reinforced bases. After five freeze-thaw cycles, the stiffness and ultimate bearing pressure of the unreinforced bases were decreased by 82% and 88%, respectively. The corresponding values of reinforced soils were 88% and 90%. Figure 4 confirms that the effectiveness of geocell stabilization and reinforcement in improving the mechanical properties. The geocell increased the stiffness and ultimate bearing pressure by 148% and 117%, respectively without freeze-thaw cycles. The comparison of the results after freeze-thaw cycles is not possible as the reinforced bases experienced one cycle less than the unreinforced bases.

655
Figure 4. Load-movement curves for unreinforced and reinforced bases.

4 CONCLUSIONS

This paper presents a survey of existing plate loading test apparatuses on geosynthetics-reinforced soils. A customized model test apparatus capable of performing freeze-thaw and plate loading tests has been developed. This study further improves the apparatus to include the water supply system, and with this upgraded apparatus, some preliminary tests using the open system were conducted. The following conclusions are draw from this study:

(1) The largest peak heave and thaw settlement occurred at the second freeze-thaw cycle in both unreinforced and reinforced bases in the open system.
(2) The inclusion of geocells reduced the peak heave and thaw settlement by 42% and 58% after the second freeze-thaw cycle. After four freeze-thaw cycles, the reduction due to geocell reinforcement was lowered to 12% and 21%.
(3) The geocell reinforcement could improve the stiffness and ultimate bearing pressure by 148% and 117% respectively without freeze-thaw cycles.
(4) The unexpected early termination of freeze-thaw cycles for the reinforced bases rendered the comparison of plate loading test results between reinforced and unreinforced bases impossible at this stage. More open system tests for comparable freeze-thaw cycles will be performed in the future.

Numerical modeling and evaluation of passive grout-anchors in geotextile bags

D. Stathas, J. Glover, S. Braun-Badertscher & I. Lifa
Institute for Construction in Alpine Regions IBAR, University of Applied Sciences Graubünden, Chur, Switzerland

ABSTRACT: Passive grout-anchors are used in as the foundations of rockfall and avalanche barriers. In regions of high ground porosity, grout losses can increase construction costs and impact the environment negatively. Geotextile bags are applied to control grout losses. However, the complex interactions between geotextile bags, grout, and ground are little understood. This study investigates the behaviour of passive anchors in geotextile bags (PAGB) under tension loads in pull-out laboratory tests. The pull-out tests have been subsequently simulated numerically to provide modelling guidelines for design engineers. In summary, PAGB could provide a sustainable solution to anchoring problems in terrain with high porosity. Geotextile permeability has strong influence on the bonding strength and should be considered for optimal PAGB design. Multiple interfaces can be modelled, with a single interface element, using conventional Mohr-Coulomb models and properties acquired from laboratory pull-out tests.

1 INTRODUCTION

Passive anchors in geotextile bags (PAGB) are applied to foundations in porous terrain for rockfall and avalanche barriers in mountainous terrain. Their intended function is to contain grout around the anchor tendon ensuring full grout coverage and associated corrosion protection. The geotextile bags are installed into a borehole surrounding the steel tendon, spacer and a perforated (>50% shading) metal tube for wall support. The anchor is then filled with grout through an injection tube (Figure 1). On construction projects with high grout losses, anchor boreholes can be impossible to fill leading to high costs through construction delays, material waste and associated negative environmental impact. The use of PAGB is thus a common go-to solution for grout loss during construction projects in porous ground. PAGB solutions are available in a range of different geotextiles with varying properties thought to control grout loss. For example, impermeable elastic geotextile bags that allow the grouted column to mold to borehole topography, especially in voids. While other geotextiles offer more rigid meshed fabrics with sufficient opening to allow grout to bond with the surrounding aggregate. However, the application of PAGB remains unregulated and without a best practice guide.

In the framework of a research project commissioned by the Swiss expert commission for avalanche and rockfall (EKLS), the influence of geotextile bags on anchor pullout strength of anchors was investigated. The performance of common PAGB solutions were assessed through 1) analysis of a pull-out testing database of test anchors from construction projects, 2) a full-scale field experiment, 3) laboratory pull-out experiments and 4) numerical modelling. The research presented herein focuses on the laboratory and numerical investigations. An overview of the geotextile bags investigated are presented in Table 1.

2 ANCHOR PULL-OUT TESTING

The laboratory pull-out experiments were designed to determine the bond strength of PAGBs within a porous ∅ 8 – 32 mm gravel. The test cylinder arrangement consisted of a 0.5 m DN400 pipe section containing a 400 mm aggregate layer in which a 115 mm hole-space was formed and PAGB samples including anchor tendon grouted (Grout maximal grain size d$_{max}$ = 0.9mm) to a depth of 0.4 m. A covering 370 mm ring plate with inner diameter D$_i$ = 150 mm and 100 mm thickness was placed on the aggregate surface (Figures 2 & 3).

The test model was then placed in a universal testing machine and bespoke testing frame to exert the resultant compression load on the ring plate during PAGB anchor pull-out at a rate
Figure 2. A) samples with anchor tendon and geotextile bag prepared for grouting, B) preparation of the gravel layer and hole-space, C) application of the ring plate.
Figure 3. Schematic test configuration showing the PAGB sample grouted in the test cylinder gravel and set in the UTM test frame indicating pull-out kinematics.

of 0.1 kN/s. The ring plate forces the anchor to shear along the grouted anchor column and aggregate interface, testing bond strength (Figure 3). And thus excludes the surrounding aggregate as principal determinant of pull-out resistance. Force deformation curves of the PAGBs are used to develop a FE model of the experiments. A comparative plot of results from the pull-out experiments and numerical modelling are presented in the following section.

3 NUMERICAL MODELING

3.1 Introduction

Finite element (FE) models are applied in research and practice to design grouted anchor systems and estimate their pull-out resistance and displacements (O'Kelly B.C. *et al.* 2014; Zhou W.H. *et al.* 2011). A reliable simulation is based on verifiable modeling parameters. In practice simple models are required to reduce the problem complexity and computation effort. The modeling approach applied in this study to simulate the pull-out behavior of a PAGB uses common material models and the practice-oriented FE Software Optum G2

(Krabbenhøft K. *et al.* 2016). Optum G2 is a commercial FE software for geotechnical studies (Oberhollenzer S. *et al.* 2018; Stathas *et al.* 2021). The feature of axis-symmetry analysis was used to simplify the three-dimensional case of PAGB and solve it in a two-dimensional (2D) FE environment. The PAGB and aggregate contact surface was simulated with an interface feature using Mohr-Coulomb material model properties and associated flow rule which is commonly applied in practice. Data from the laboratory tests described in the previous chapter, were used to determine input material parameters of the FEM model, such as the bonding force τ_A [kN/m^2] and Elasticity modulus of the PAGB interface. Following chapters present the definition of material parameters, FEM analysis and comparison with the data acquired from the laboratory tests.

3.2 *Finite element model of pull-out test*

3.2.1 *Test cylinder and gravel*

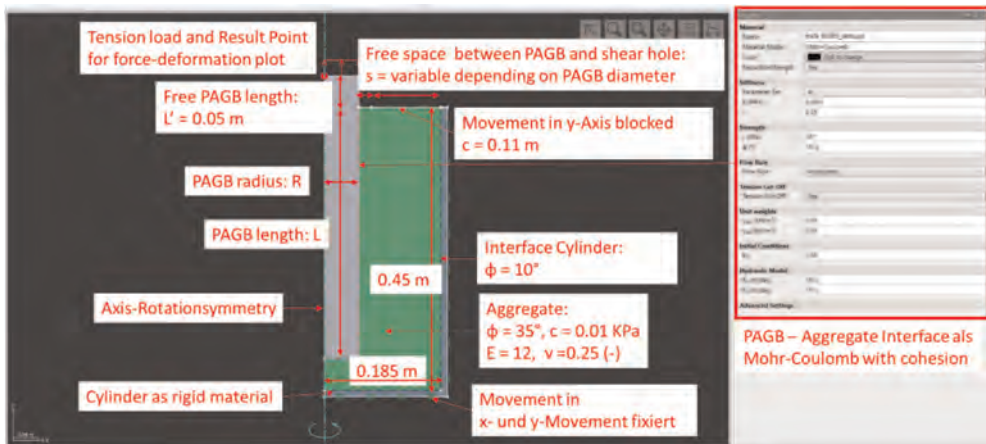
The geometry of the test cylinder was replicated based on scan data from the pull-out specimens and adjusted for axis-symmetry analysis to the FE model. Figure 4 shows the dimensions and fixations of the FE Model. The test cylinder was modelled as a rigid material by fixing its base in x- and y-direction (radius and height). The ring plate placed on the aggregate surface during the pull-out tests inducing shear along the PAGB-aggregate interface is fixed in y-direction (height) of the FE model constraining upward movement of the aggregate. The PAGB is pulled out through the 150 mm diameter shear hole of the ring plate. The free space (Figure 4) between PAGB and ring plate varies depending on the anchor diameter obtained from scans of the laboratory samples. The aggregate in the test cylinder was modelled as a Mohr-Coulomb material with a friction angle of $\varphi_{Aggr} = 35°$ and modulus of elasticity $E_{Aggr} = 12$ MPa (Loose). The surface between the test cylinder and the gravel was also modelled as a Mohr-Coulomb material with a friction angle of $\varphi_{Aggr/cylinder} = 10°$ (approx. φ_{Aggr} /3). The Unit-weight of the aggregate is 18 kN/m^3.


Figure 4.   FE model of pull-out test.

3.2.2 *Pull out anchors*

The PAGB specimens from the laboratory tests were scanned to acquire geometry data. The scan data were used to determine the PAGB dimensions in the FEM Model and in combination with the recorded force-travel data estimate the strength parameters of the Interface MC Model. The steel anchor-grout body of the PAGB was modelled as elastic material with a weight of 25 kN/m^3. The elastic modulus of the PAGB [E_A] can be estimated from the

elastic modulus of grout [E_G: 14,500 MPa] and steel [E_S: 205,000 MPa], and accounts for the deformation compatibility of the two elements, following equation (1):

$$E_A = \frac{E_s \cdot A_S + E_G \cdot A_G}{A_S + A_G} \qquad (1)$$

where E_A = modulus of elasticity anchor system [MPa]; E_S = modulus of elasticity of steel bars [MPa]; E_G = modulus of elasticity mortar [MPa]; A_S = Surface area of steel bar [m²]; A_G = mortar surface [m²].

During the pull-out tests, tensile force and vertical displacement data were recorded. The critical maximum force for PAGB from the Pull-out tests was set for a vertical displacement of 24 mm. This strength value [F_{24}] together with the topographic scan-data were used to calculate the bond strength of the PAGB according to equation (2):

$$\tau_A = \frac{F_{24}}{2 \cdot \pi R \cdot L} \qquad (2)$$

where: τ_A = bonding strength [kN/m²]; F_{24} = maximum pull-out force at 24 mm travel [kN]; R = anchor radius = ½ anchor diameter D [m]; L = anchor length [m].

The anchor-gravel interface was set as a Mohr-Coulomb material with a cohesion equal to the bonding force. The modulus of elasticity was calculated from equation (3) according to Stathas et al. 2021:

$$E_{int.} = \frac{\left[2(1 + v)\frac{t_{FEM}}{\delta} \tau_A \right]}{1000} \qquad (3)$$

where: $E_{int.}$ = E-modulus of the grout-aggregate interface [MPa]; v = Poissons number, here 0.25 [-]; t_{FEM} = interface thickness in FEM, here 1 mm; δ = displacement, here 24 mm; τ_A = bonding strength force anchor [kN/m²]; 1000 = Conversion of E-modulus units from kPa to MPa. Table 2 summarizes the critical input parameters resp. properties of the numerical PAGB for each geotextile bag.

Table 2. PAGB model parameters for the various geotextile bags.

Geotextile Bag	Radius R [mm]	Length L [m]	E-Modul E_A [MPa]	Max. Pull-out Force F_{24} [kN]	Bonding Strength τ_A [kN/m²]	E-Modul Interface $E_{int.}$ [MPa]
A	55	0.40	20,800	1.75	13	0.0013
B	50	0.40	22,100	10.22	81	0.0085
C	45	0.40	23,900	11.29	100	0.0104
D	55	0.40	20,800	12.95	94	0.0098
E	65	0.45	19,000	37.31	203	0.0211
F	73	0.45	18,400	71.61	347	0.0361

3.3 A multiplier elastoplastic analysis

Multiplier Elastoplastic Analysis is an integrated analysis feature in Optum G2 which allows the calculation of the ultimate load of a system by incremental load increase while computing system deformation at each load step. This type of analysis is suited to the laboratory pull-out tests. Using the "Result Point" feature of OptumG2, force-displacement diagrams were generated for the top of the PAGB and compared with the laboratory tests.

For each geotextile bag a FE Model was created and a multiplier elastoplastic analysis carried out. Figure 5a shows the force-displacement diagram for each geotextile bag with a dashed line. In the same figure, the corresponding laboratory data from the pull-out tests for 10, 20 and 24 mm deformation are shown with continuous lines.

The results from the FE numerical simulation show good agreement with the laboratory tests validating the input model parameters. The numerical simulation also allows an examination of the pull-out test failure mode. The primary shear plane is developed along the PAGB-aggregate interface, while a secondary slip surface is developed starting from the PAGB anchor bottom and reaches the test cylinder wall with some inclination (Figure 5b).

4   SUMMARY AND CONCLUSIONS

In this study different types of geotextile bags were used to prepare short passive anchors and investigate their pull-out performance in laboratory experiments. Subsequently the pull-out tests were simulated numerically using the recorded physical data. From the physical tests and numerical simulations, the following conclusions can be drawn:

- PAGB pull-out strength strongly depends on the bonding strength of the grout column to the surrounding aggregate which is governed by the passage of grout through the geo-textile membrane.
- For grout bags that prevent grout from seeping through the bag membrane and bonding with the aggregate, the pull-out strength is very low.
- The radial pressure and topographic molding of grout columns seen in impermeable grout bags offer insufficient bond strength to obtain reasonable pull-out strengths.
- Geotextile bags that permit sufficient grout to pass through the geotextile membrane and bond to the aggregate, pull-out strengths are higher and can be recommended for use in porous ground.
- PAGB can be modelled numerically using and an interface element following the MC parameters.
- The elasticity modulus and the bonding strength can be estimated from pull-out tests conducted in the laboratory for use with this numerical model.

Investigation of one-dimensional compression behavior of rubber chips mixed soil: Calculation of volumetric compression amount in the densest particle arrangement

T. Kimata
Osaka Metropolitan University, Sakai, Osaka, Japan

N. Kobayashi
Ehime University, Matsuyama, Ehime, Japan

ABSTRACT: This study aims to estimate the compressive properties resulting from the deformation of elastic particles as a foundation for constructing a model of soil mixed with elastic particles such as rubber chips. To determine these compressive components, a series of one-dimensional compression tests were conducted using rubber and aluminum chips. After that, the calculating method of these compression amounts was examined, considering the geometrical deformation of the component particles. The results indicated that if the specimen is in the densest particle arrangement state and the skeletal structure is not disrupted by compression, each compressive component of the mixture could be predicted with almost perfect accuracy.

1 INTRODUCTION

Efforts to promote a society that values recycling have made resource recycling a significant area of research. Geotechnical engineering research has focused on investigating the feasibility of using certain waste materials, such as scrap tire chips, expanded polystyrene waste, and scrap glass, as geomaterials (Kubo et al. 2004; Kohata et al. 2011; Hazarika et al. 2010; Yasufuku et al. 2000). The authors have also examined the potential for crushed expanded plastic waste to be utilized as a lightweight mixed soil, as its strength parameters, such as internal friction angle, were found to be nearly unaffected (Kimata et al. 2001), thereby demonstrating the material's viability for this purpose.

However, adding high-deformability materials, such as rubber or expanded plastic, to soil can lead to significant distortion. Similarly, layering of flexible geosynthetics in the ground can pose deformation issues. The authors examined the microscopic mechanisms of compressive deformation to understand the deformation properties of soil mixed with deformable particles. Specifically, the amount of mixed soil compression was assumed to consisted of ordinary soil compression (i.e., the amount of compression assuming no deformable particles in the soil skeleton) and an added compression amount due to the deformation of the deformable particles. The latter was further classified into the following three components: (a) a component resulting from the compression of the deformable particles themselves, (b) a component from the reduction in pore space volume caused by the deformation of the deformable particles, and (c) a component from the volume change in the pore space caused by the further rearrangement of the deformed particles. The authors conducted a one-dimensional rod-stack model compression test using aluminum rods and rubber or expanded polystyrene rods to predict each component introduced by the deformable particles. The test showed that a relatively simple model that considered the geometric deformation relationship during compression in

the two-dimensional cross-section of a rod-stack model could almost successfully predict the compressive components (a) and (b) (Kimata et al. 2010, 2013).

In this study, one-dimensional compression tests on a mixture of rubber and aluminum chips were conducted, to extend the previous research to three-dimensional conditions. The specimens were prepared in a state of 100% relative density (referred to as the densest state) to avoid disturbing the arrangement of particles. Accordingly, it is regarded that the generation of compressive component (c) due to particle movement within the skeleton is limited, and only the compressive components (a) and (b) can be considered. The basic three-dimensional compression behavior of the mixture was then determined, and the compressive component was modeled from a geometric standpoint.

2 SPECIMENS AND TESTING METHOD

2.1 Specimens

In this study, aluminum chips (equivalent to soil particles) and nitrile rubber chips with densities of 2.69g/cm^3 and 1.38g/cm^3, respectively, were used, and both chips have a diameter and length of 3 mm. The specimens were prepared by mixing these chips and packing them into an acrylic cylinder with an inner diameter of 50 mm and a height of 100 mm, in the densest state. The mixing ratio was defined as the volume ratio of rubber chips to all chips. The "Test Method for Minimum and Maximum Densities of Sands" (The Japanese Geotechnical Society 2015) was used as a reference to achieve the densest state. The chips were divided into 10 layers, and each layer was horizontally hit from all sides 100 times, resulting in a void ratio of approximately 0.52, considered the densest condition without altering the particle arrangement.

2.2 Testing method

A specimen was prepared, and a one-dimensional compression test was conducted using the apparatus shown in Figure 1, which includes an acrylic cylinder. One notable feature of this apparatus is that it saturates the specimen's pore space with water and measures the drainage from the pore space, which allows the volume change of the pore space to be quantified independently from the volume change caused by the compression of the entire specimen. The double negative pressure technique was used to saturate the samples with deaerated water. Compression tests were conducted at slow axial strain rates ranging from 0.1% to 0.4%/min based on the specimen stiffness until the axial stress reached approximately 500 kPa to avoid crushing the rubber chip.
Figure 1. One-dimensional compression test apparatus.

3 TEST RESULTS

3.1 Concept of compressive component

After considering the findings of the earlier research, three deformable particle compressive components that need to be included were identified, as previously described. In the experiments, the volumetric strain resulting from the compression of the rubber chip was compared to the volumetric strain of the entire specimen and the pore space (corresponding to the amount of drainage) and became the component (a). Since the skeleton was kept in its densest state to avoid disturbing the arrangement of the particles, the component (c) related to the particle arrangement was not expected to occur. Therefore, only the component (b), the reduction in pore space resulting from particle deformation, was considered the cause of the drainage from the specimen. As a result, it is possible to focus on the components (a) and (b) among the components added due to deformable particles in this experiment.

3.2 Test results

The results of one-dimensional compression tests are presented in Figure 2, with filled marks indicating total volumetric strain and white marks indicating volumetric strain in the pore space, and the legend is the mixing ratio of the specimens. This figure shows that an increase in compressive stress increases the volumetric strains for all specimens. As the specimens were compacted to their densest state, there should be little volumetric compaction in ordinary soil. This result emphasizes the importance of anticipating soil compression levels when deformable particles are present. Furthermore, it is evident from this graph that volumetric compression of the rubber chips themselves accounts for a small portion of the volumetric strain, which is caused by component (b) (white plot), representing the volume change in the pore space.
Figure 2. Volumetric strains of overall and pore space of specimens.

Figure 3 illustrates the component (a) calculated from the test results, assuming zero volume change for the aluminum chip. It indicates that even at a mixing ratio of 1.0 (rubber chips only), the volumetric strain does not exceed 1%. This outcome is reasonable since rubber is generally regarded as nearly incompressible, with a Poisson's ratio close to 0.5.

Figure 3. Volumetric strain caused by rubber chips, component (a).

4 MODELING OF COMPRESSION AMOUNT

4.1 *Modeling method*

Based on earlier research, it was found that the geometrical consideration of the deformation and movement of rod elements in a two-dimensional cross-section can accurately represent the one-dimensional compression of the rod-stack model using rubber and aluminum rods (Kimata et al. 2010). The elastic modulus and Poisson's ratio of the rubber rod element are used to calculate the deformation and movement of the circular cross-section when compression, and developed a method to determine and assess the amount of compression of the rubber rod and the amount of volumetric change in pore space resulting from the change in cross-sectional area. This method can be extended to a three-dimensional approach for this current research.

Dealing with cylinder contact presents a challenge when using a cylinder-based model. The study examined various configurations, including the intersecting of two cylinders sideways. The findings revealed that the model shown in Figure 4 provided the results closest to the experimental data. Therefore, this section elaborates on the details of the study, which was conducted based on this particular model.
Figure 4. Geometric image of compression (rubber chips).

In this figure, two cylinders are present, each with a diameter and height of $2r$, and are enclosed within a rectangular prism with a dimension of $2r \times 2r \times 4r$ (length $\times$ width $\times$ height). The volume change, denoted as ΔV_1, resulting from the compression of one side of the horizontal cylinder by a, and the volume change, denoted as ΔV_2, resulting from the compression of the vertical cylinder by a, are represented by Equation (1) and (2), respectively.

$$\Delta V_1 = 2r \left\{ r^2 \cdot \sin^{-1} \left(\frac{\sqrt{2ar - a^2}}{r} \right) - (r - a)\sqrt{2ar - a^2} \right\} \tag{1}$$

$$\Delta V_2 = \pi \cdot a \cdot r^2 \tag{2}$$

In the case of rubber chips, compression occurs at all contact points, whereas with rubber and aluminum chips, it only occurs at the contact points on the rubber chip side. The compressive component (a) of volumetric stain due to rubber chips was calculated by considering the contact points on the rubber chip side based on the mixing ratio to calculate the volumetric strain resulting from the compression of rubber chips. The calculation also considered the lateral expansion of rubber due to Poisson's ratio. The compressive deformation of the rubber chip was determined by referring to experimental results for a mixing ratio of 1.0 (rubber only) and incorporating the converted axial strain value into the calculation. As the rubber chip was slightly compressed according to the experiment, Poisson's ratio was estimated to be 0.46 in the calculations.

4.2 Comparison with experimental results

Based on the theory presented in the previous section, Figure 5 illustrates the compressive component (a) caused by rubber chips. In this figure, the solid lines display the calculated values, while the experimental results are shown by marks (only mixing ratios of 1.0 and 0.5 are presented for clarity). Upon examining this figure, it can be observed that the calculated values are generally close to the experimental results. However, there are still some specific issues, such as an area where the volumetric strain increases in the initial stage. Consequently, modeling of the compressive components will continue in the future based on this line of reasoning.
Figure 5.   Prediction of compressive component (a).

4.3 *Overall volumetric strain*

Finally, the overall volumetric strain of the mixture was predicted using the cylindrical model. The volume of the mixture pushed in by compression was first calculated using the overall volumetric strain at a mixing ratio of 1.0, which was used to determine the volume of compressive deformation of the chips. The compressive stress at that time was then back-calculated using the elastic modulus of rubber, which was found to be 4.0 MPa for NBR70 based on the material of the rubber chip used. For mixtures with ratios other than 1.0 (including aluminum chips), the overall volumetric strain was calculated using the same method as for the compressive component (a) discussed earlier. The existence ratio of the contact state between the rubber and the aluminum chips was considered when calculating the overall volumetric strain since it is possible to obtain the compressive stress applied to the rubber chips and the amount of compressive deformation from the above calculation.

Figure 6 shows the results where the experimental data are represented by markers (filled markers indicate the whole space, while white markers indicate the pore space). The solid and dashed lines indicate the calculated values for the whole and pore spaces. Only the
Figure 6.   Prediction of overall and pore space volumetric strain.

mixing ratios of 1.0 and 0.5 are shown for clarity purposes. The figure shows that the experimental results can be roughly predicted, similar to the compressive component (a). Thus, even with a basic geometric model of the mixture's compression behavior, it is possible to predict the volumetric strain caused by compression.

5   CONCLUSIONS

In this study, the compressive mechanism of a mixture of rubber and aluminum chips packed in the densest state was evaluated using a one-dimensional compression test, and a geometric approach to calculate the amount of compression was examined. The results showed that, despite the relatively small volumetric compression of the rubber chip itself, the deformation of the rubber chip caused a significant volumetric change in the pore space of the mixture. A simple cylindrical model was proposed to calculate the amount of compression, and the calculated values were found to be consistent with experimental outcomes. Future research

should investigate the factors influencing particle mobility. Overall, a model for the compression characteristics of soil mixed with deformable particles, such as rubber chips, has been established.

Confinement effects of geocell under direct shear conditions

S. Miyamoto & Y. Miyata
National Defense Academy, Yokosuka, Japan

ABSTRACT: In this study, the confinement effects of geocells were investigated using medium-scale direct shear tests. The shear box had a transparent sidewall to view the soil deformation in the box, and the soil strain localization behavior was visualized using particle image velocimetry. In a series of tests, the interface shear strength between geocell-reinforced and unreinforced soil was investigated and compared with the soil shear strength. The test results showed evidence that the interface shear resistance is higher than the soil shear strength because the geocell confines soil shear and volumetric deformation. Moreover, a simple empirical formulation of the interface shear resistance was proposed based on the Taylor-Bishop energy correction formula.

1 INTRODUCTION

Rapid road construction techniques are important in the recovery and reconstruction stages of disaster areas. In such road construction under time constraints, it is important to use on-site soil as much as possible and avoid using heavy construction machines. In this study, the authors focused on reinforcement technology for base foundations using geocells to solve this engineering problem. Figure 1 shows an overview of geocell technology. A geocell is a reinforcing material consisting of polymeric sheets bonded thermally at regular intervals. A geocell is deployed on-site by constructing a honeycomb structure that is filled with on-site
Figure 1. Overview of a geocell.

soil to form a reinforced foundation. Figure 2 shows the effects of geocell reinforcement. Geocells can reduce the sinking of passing vehicles and prevent slip failure of the base foundation.

To design a geocell-reinforced foundation, various limit states should be considered. The internal stability of geocell-reinforced foundations has been investigated by several researchers (ex. Bathurst & Jarrett 1988). However, the external stability has not been investigated sufficiently, especially the slippage between the reinforced layer and unreinforced surface layer when the reinforced layer behaves as a quasi-rigid body.
Figure 2.   Effects of geocell reinforcement.
Figure 3.   Physical model overview of geocell-reinforced soil.

In this study, the interface shear resistance between geocell-reinforced and unreinforced soils was investigated using direct shear tests compared to unreinforced soil. The deformation of the reinforced/unreinforced soil was visualized using the particle image velocimetry (PIV) technique (Miyamoto & Miyata 2022), and the mechanism of the interface shear resistance was investigated (Miyamoto & Miyata 2021). Based on the results, an evaluation equation for the interface shear resistance between the geocell-reinforced layer and unreinforced surface layer is proposed.

2   EXPERIMENTAL METHODS AND CONDITIONS

A medium-sized direct shear test apparatus was used for a series of physical model tests (Miyamoto & Miyata 2021). Figure 3 shows a physical model of the geocell-reinforced soil

in this study. The shear box was rectangular with a length of 1600 mm and depth of 90 mm, and it was divided into an upper and lower box by height: 45 and 20 mm, respectively. The sides of the shear box were made of acrylic to visualize the deformation of the reinforced/unreinforced soil. Geocell-reinforced soil was set in the upper box, and the unreinforced soil layer was set in the lower box. Horizontal loading was applied to the upper box at a rate of 1 mm/min under constant vertical pressure. The vertical stress σ_v was set to $\sigma_v=10$ kN/m^2 by considering the actual height of the geocell-reinforced layer and the weight of the light vehicle. Silica sand with an average grain size of 0.32 mm was used as the soil sample. The specimens were prepared by mixing commercially available colored silica sand, which was colored black with a special dye at a ratio of 50%. The prototype of the geocell was prepared by a PET polymer sheet with a stiffness of 71.8 kN/m at 5% strain. The specimen was prepared by compacting air-dried colored sand mixtures with a relative density of $D_r = 80$ % using 8-mm-diameter round bars. For the reinforced soil layer, a geocell was placed 2 mm above the top of the lower box to allow for smooth shearing.

3 EXPERIMENTAL RESULTS AND DISCUSSION

The shear stress τ and vertical displacement v–d relationships with shear displacement d obtained from the direct shear tests are shown in Figure 4. In the unreinforced case, τ reached its peak value at $d = 5$ mm and did not reach the residual state in which v remained constant at a large shear displacement. In the reinforced case, greater shear resistance and a steeper initial slope of the τ–d relationship were observed than in the unreinforced case. The shear stress peaked at a small shear displacement, and the vertical displacement was smaller than that of the unreinforced case. After the peak shear stress was reached, the vertical displacement was almost constant when the shear resistance reached a residual state.
Figure 4.   Shear stress, shear displacement, and vertical displacement relationships.

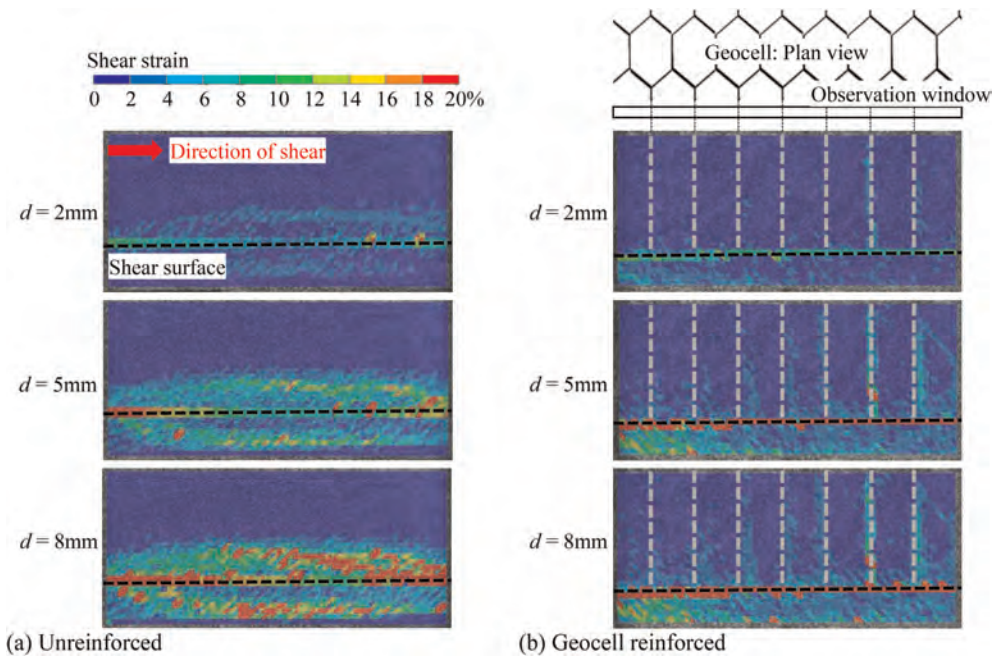
Figures 5(a) and (b) show the results of the PIV analysis used to visualize the deformation of the specimens for the unreinforced and reinforced cases, respectively. In the unreinforced case, the shear strain was concentrated near the boundaries of the upper and lower shear


Figure 5. Development of shear displacement in soil.
Figure 6. Mobilizations of tan ϕ and tan ψ.

boxes with an increase in the shear displacement, as previously reported. In the reinforced case, shear strain occurred near the boundaries of the upper and lower shear boxes and at the boundaries between the geocell and filled soil. No local deformation of the soil in the geocells was observed. It can be considered that the geocells constrained the soil dilatancy, which increased the shear resistance in the geocell region.
Figure 7.   Back calculated confinement effect parameter, λ.

Based on the above results, the shear resistance between the geocell-reinforced layer and the supporting foundation was investigated. The shear resistance τ_r of the two layers can be expressed using the following equation:

$$\tau_r = \sigma_v \tan \phi_r \tag{1}$$

where ϕ_r is the shear-resistance angle of the two layers. In the above equation, $\tan\phi_r$ can be expressed as follows, based on the Taylor-Bishop energy equation for soil dilatancy (Taylor, 1948).

$$\tan \phi_r = \tan \phi_s + \lambda \tan \psi_s, \tag{2}$$

where ϕ_s is the shear-resistance angle of the soil, ψ_s is the dilatancy angle of the soil, and λ is the confinement effect parameter that shows the increase in the shear resistance owing to the geocell constraining the soil dilatancy.

When evaluating the shear resistance between the geocell-reinforced and surface layers, it is difficult to evaluate the coefficient λ using a simple theory. Here, the authors performed a back calculation of λ using the test results. The estimated $\tan\phi_s$ and $\tan\psi_s$ for the unreinforced and reinforced cases are shown in Figure 6. The coefficient λ is almost constant regardless of the shear displacement and can be evaluated as $\lambda = 3.4$ in this analysis, as illustrated in Figure 7.

4   CONCLUSION

The confinement effects of the geocell were investigated by conducting medium-scale direct-shear tests. The results of this study are as follows:

(1) The interface shear resistance between the geocell-reinforced and unreinforced soil was higher than the soil shear strength.
(2) The geocell confined the soil shear deformation, that is, dilatancy.
(3) Interface shear resistance can be determined using a simple empirical formulation. The proposed equation is based on the Taylor-Bishop energy correction formula. It is

expressed by the shear resistance and dilatancy angles of the soil, the ratio of the cell confinement area to the total shear area, and an empirical coefficient on the dilatancy confinement.

The present evaluation was limited in that the test results were based on a single vertical stress condition. To validate the proposed method, future research should be done to perform laboratory tests under wide vertical stress conditions and investigate under full-scale test conditions.

ABSTRACT: Geogrids are widely used as a soil reinforcement technique in many engineering applications, however a detailed study of the mutual interaction between these structures and the granular soil is complex and generally faced only with specific laboratory tests. In the last decades, the recourse to numerical methodologies has experienced large growth, and among the different methods, the discrete element method (DEM) has proven its reliability in understanding both the micro and macro aspects of the soil-geogrid interaction. In this study, 3D discrete element simulations of pull-out tests are performed. The shape of the numerical geogrid and the contact properties of its elements are calibrated using the results of laboratory tests referring to a real PET woven geogrid. The geogrid mechanical properties investigated control its strength and stiffness. Their role and influence on pullout behaviour are investigated in different soil conditions regarding the confinement stress, the soil particle size and shape. The granular soil is modelled using both spheres and clumps to simulate different fine-graded gravels.

1 INTRODUCTION

Geogrids are specifically designed polymer materials used in many geotechnical applications: from earth-reinforced retaining walls to ground and foundation improvement in embankments (Koerner 2012; Moraci *et al.* 2014). Their mechanical behaviour is related to a combination of the mechanical properties of the geogrids themselves and to the mutual interaction with the soil in which these structures are embedded. For this reason, different geogrids may be proposed for different soil types in order to enhance the mechanical coupling between the reinforcing materials and the soil around them. Focusing on their use with coarse granular soils like rock fragments, gravel and coarse sand, the standard experimental and numerical approaches to study their behaviour appear more complex since the size of the grains is of the same order of magnitude as the mesh opening size and width of the elementary members. This reflects on several aspects that must be accounted for: the grains apply puncture loads on the product with possible indentation problems; the interlocking effect is enhanced by the sharpness and angularity of grains; local damage and failures of single strands are possible; soil compaction effort becomes a relevant variable; pretension and bending stiffness of the geogrid starts to play a relevant role.

These effects, even at a local scale, may have a great impact on the performance of these structures and cannot be studied efficiently with a continuum-based approach. In order to face this problem, in this work a discrete element modelling approach was adopted to describe a

real PET woven geogrid. The strands of the mesh are represented as chains of bonded spherical particles while the grains are modelled both as spherical and angular particles to study the effect of the grain shape on the macro-scale mechanical response of the mesh.

The mechanical properties of these bonds have been calibrated on the base of simple laboratory tests. Finally, pull-out tests on different configurations have been considered.

2 NUMERICAL MODEL

2.1 *Geogrid*

Mesh grids can be numerically modelled with DEM using different approaches: node-wire-based, cylinder-wire-based, and bonded-particles-based (Gabrieli *et al.* 2017). The first approach is the simplest: mesh grids are represented as a collection of nodes joined by user-defined long-range interactions taking into account the tensile forces in the elastic and plastic domain. This approach has been proven to provide very good results to model steel wire meshes, especially for mainly tensile problems, like puncture and plate bearing capacity (Gabrieli *et al.* 2018; Pol & Gabrieli 2022) but it fails in reproducing problems where the real shape of the grid element and its bending stiffness plays a relevant role. The cylinder-wire-based approach may be more realistic in terms of shape description and contact detection but cylinders must be split into many parts to describe the flexural properties of the strands and problems may arise to correctly describe a variable-section mesh fiber or strands with cross-sections different than circular, with an increase of the computational cost (Pol *et al.* 2018). The bonded-particles approach is the most accurate and can be viewed as an extension of the cylinder-wire-based approach with a cylinder length equal to zero. It can take into account the fiber tensile strength and bending stiffness. Moreover, different geometrical shapes of the fibers can be reconstructed and also frictional properties at the interface are more realistic (Miao *et al.* 2014).

In this work, a PET woven geogrid has been modelled with the bonded-particles approach as a collection of spherical particles having different particles size and joined together by means of normal, tangential and rotational bonds. This permits (a) to control the tensile and bending properties of the strands (b) to simulate the variable cross-section of transversal fibers and (c) the real spiral geometry of the longitudinal strands. The DEM open-source code Yade has been used for the simulations (Šmilauer *et al.* 2015).

The geogrid considered in this work is the coated woven PET geogrid Fortrac® by Huesker (Figure 1). Longitudinal members are twisted while transverse ribs are constituted by fibers knitted together to form an irregular flexible sheet and maximize the frictional and bonding effect. The mesh opening size is 2 cm in both directions. The thickness of the grid is about 3 mm.
Figure 1. Woven PET geogrid Fortrac® by Huesker and its numerical model (modified from Dijak 2012).

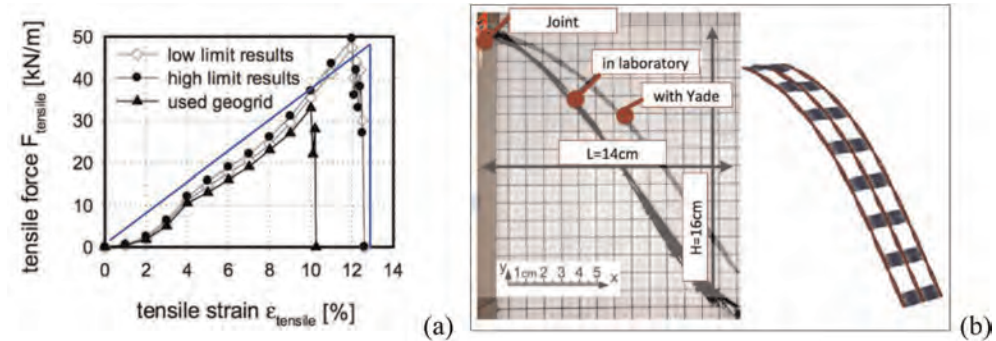
In order to calibrate the contact mechanical properties of the spheres constituting the geogrid, laboratory tensile and bending tests in longitudinal and transversal directions have been considered. The tensile response of the geogrid in the longitudinal direction and the result of one bending test are reported in Figure 2. The geogrid reacts mainly elastically up to a brittle failure representing the maximum tensile strength. From sensitivity analyses, the Young modulus, and the bond cohesion at the contact mainly control its tensile stiffness and strength while the Young modulus and the rotational stiffness at the contact rule the bending response. The final calibrated mechanical properties of the particles composing the mesh grid are reported in Table 1.


Figure 2. (a) Result of real (black curves) and simulated (blue curves) tensile tests with the geogrid (modified from Lackner 2012) (b) lateral view of a cantilever bending test (modified from Dijak 2012).

Table 1. Particle's characteristics and mechanical properties at the contact for the geogrid model.

Particle size mm	Young modulus Pa	Normal and tangential strength Pa	Rotational stiffness
0.5–0.78	3.5e9	8.7e8	0.02

2.2 Granular soil

Two types of soils have been considered in this work: a coarse granular soil constituted by spherical particles (soil A) and a more realistic granular soil with angular particles (soil B). The first soil type facilitates the study of the interaction mechanism keeping low the complexity and computational cost of the simulations.

The shape of the angular particles has been obtained through photogrammetric 3d reconstruction of a sample of some real grains. Then, the external surface of the grains have been used as containers to fill the volume with a set of spheres clumped together that mimic the irregular shape (see Figure 2). The algorithm used for this purpose is the power crust (Amenta et al. 2001) which allows controlling the number of spheres to be used in the sphere-filling procedure to create the clump and the ratio between the coarsest and the finest sphere.
Figure 3. (a) Example of the 3d surface reconstruction of one sample grain and (b) corresponding clump generation by applying the sphere-filling procedure.

The micromechanical properties of the grains have been calibrated from previous laboratory tests (Zarattini *et al.* 2019) and are reported in Table 2.

Table 2. Particle's characteristics and mechanical properties at the contact.

	Particle type	Particle size mm	Solid density kg/m^3	Young modulus Pa	Poisson ratio	Friction angle °
Soil A	spheres	6, 10, 16, 22	2700	1e8	0.2	40
Soil B	clumps	16	2700	1e8	0.2	40

3   PULL-OUT TEST SIMULATION

A numerical pullout box has been built with dimensions 0.3 x 0.1 x 0.35 m considering the criteria suggested in the literature (ASTM 2001; Konietzky *et al.* 2004; Moraci & Recalcati 2006; Palmeira 2009). The smaller transverse dimension of 0.1 m is compensated by periodic boundary conditions that allow simulating an infinite-width geogrid and infinite box. The height of 0.35 m (about 0.3 m after the compression) is the minimum recommended in literature to allow the development of the bearing effect (Konietzky *et al.* 2004). The upper rigid plate applies the desired vertical stress. Its friction angle is set equal to 25° to simulate the steel-soil contact friction angle. The other facets (front, back and bottom) have a friction angle decreased to 6° to reduce their influence as suggested in the literature and carried out in the laboratory with lubrication (Palmeira & Milligan 1989; Palmeira 2009). The length of the geogrid specimen is 295 mm. Figure 4a shows the dimensions of the pullout apparatus and the position of the geogrid.
Figure 4.   (a) Sketch of the pullout box and grid; (b) initial soil packing with cut and geogrid positioning; (c) application of the vertical load and beginning of the pullout test.

The compacted granular soil is created by a gravity-pluviation procedure starting from a cloud of particles inside a tall prismatic box without the geogrid. After the deposition, the granular soil reaches a porosity of about 0.4 – 0.45. The geogrid is imported and left to adapt to the irregular soil surface in a thin cut inside the soil (Figure 4b). A variable vertical velocity through a PI controller function is applied to the plate in order to exert constant vertical pressure. When the vertical stress reaches a stable value under a threshold of 2%, a constant horizontal displacement rate of 0.05 m/s is applied to the clamp, thus starting the pullout test (Figure 4c).

4 RESULTS

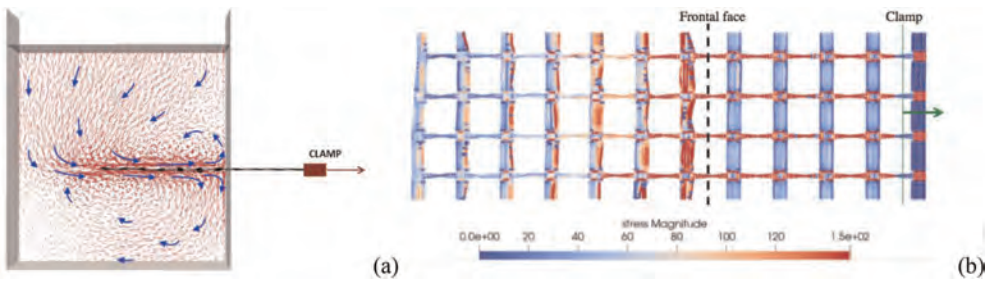
Before the beginning of the test, due to the medium-low flexural stiffness of this geogrid, the soil particles slightly bent the transversal and longitudinal members with benefits in terms of initial interlocking. After pulling the geogrid, the mobilized frictional resistance starts to increase almost linearly with deformation and a quite large volume of soil is involved in a convective motion especially considering Soil A (Figure 5a). Moreover, the large flexibility of transversal members helps the geogrid to trap particles in the mesh openings and to facilitate the development of the bearing resistance mechanisms. The latter can be seen in the bent and stressed transversal elements close to the front wall of the box (Figure 5b). At the end of the test, the geogrid slides (sliding failure mechanism) or breaks close to the front wall (yielding failure mechanism) where the longitudinal fibers experience the highest tensile stresses.


Figure 5. (a) Lateral view of the typical soil displacement field during the pullout test carried out with soil type A; (b) Top view of the tensile stress distribution in the geogrid before the failure.

4.1 *Effect of the confinement stress*

The first set of simulations was carried out by modifying the vertical stress (i.e. the soil thickness z above the geogrid) using the soil A (spheres). The results in terms of tensile force vs longitudinal strain are reported in Figure 6. A transition from a sliding failure to a yielding failure is visible increasing the thickness of the soil: at low vertical stresses (z < 2 m;
Figure 6. Numerical results of pull-out tests varying the vertical stress.

$\sigma_v > 30$ kPa) the typical geogrid failure mode is characterized by sliding while increasing the vertical stress ($z > 3$ m; $\sigma_v > 45$ kPa) the geogrid failure is of the yielding type. The maximum yielding strength at failure is 10% lower than the tensile strength of the geogrid evaluated without the soil (compare Figures 2a and 6) due to the inhomogeneous tensile stress distribution in the geogrid fibers. Moreover, it is more or less constant (for $z > 3$ m) but with very different maximum elongation values.

4.2 *Effect of the grain size and shape*

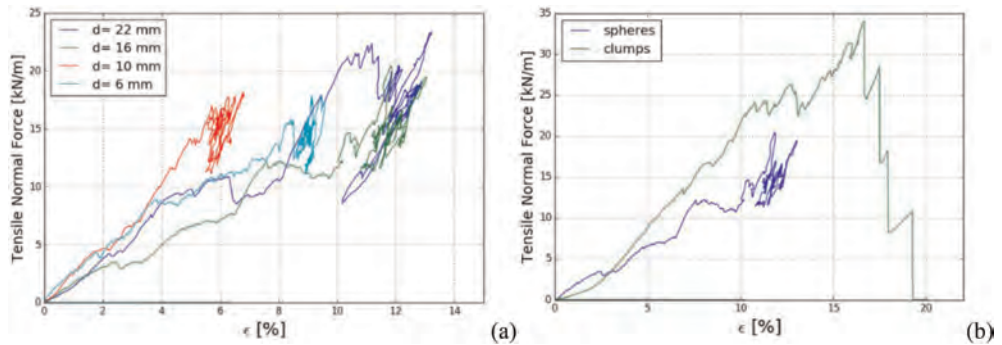
The second group of tests have been performed using soil A (i.e., spheres with different grain sizes) and soil B (clumps characterized by one diameter), keeping a constant vertical stress σ_v = 30 kPa, corresponding to a soil thickness z=2 m. In all cases, the reinforcement does not reach the yielding point but starts to slide. The maximum shear strength seems to be independent of the grain size but smaller particles provide better results in terms of maximum elongation (Figure 7a).


Figure 7.   (a) Numerical results of pull-out tests varying the grain size (Soil A) (b) Comparison of numerical results using the different grain shape (Soil A and B) (d=16mm).

Comparing the results of the simulations carried out using soil A and B (i.e. spheres and clumps with the same mean diameter d = 16 mm) at the same vertical stress, the pullout response moves from a sliding failure to a yielding failure mechanism with a maximum tensile strength that is 25% lower than the tensile force obtained without the soil. However, the overall tensile stiffness is higher than in the case of spheres. The use of angular particles (i.e. clumps) in place of spheres has the same effect of increasing the particle size: The contact force network is less homogeneous and local effects prevail.

5   CONCLUSIONS

The interaction mechanism of a flexible geogrid with coarse soil is investigated using the discrete element method and considering a pullout test configuration. The frictional and bearing behaviour can be noticed in the stress distribution on the geogrid members. The use of a micromechanical approach allows for considering a real interlocking between the geogrid and the grains. Moreover, local effects like puncturing, local failures and bending are taken into account. The numerical results show the important effect of stress confinement in the transition from a sliding-prone failure to a yielding-type failure condition. The coupling with coarse soil having a grain size larger than the geogrid opening size increases the chance of premature failure. The use of angular particles allows for considering more realistic

conditions with an increased rotational frustration of the particles and overall stiffer behaviour of the soil-reinforcement interaction.

Experimental evaluation of the pullout resistance of geostrips within sands and recycled Construction and Demolition Waste (CDW)

A.G. Corrales
University of Brasília, Brazil
University of Costa Rica, Costa Rica

G.L.S. Araújo
University of Brasília, Brazil

ABSTRACT: The massive generation of construction waste is one of the priority urban environmental problems in recent years, causing losses in urban populations' quality of life, where 54% of the world population currently lives (84.3% of the Brazilian population) (IBGE, 2019). In this context, this paper presents the results of an experimental investigation on the interaction between synthetic strips with sand and low-cost alternative material (recycled Construction and Demolition Waste). The objective is to determine their possible suitability as landfill material in Mechanically Stabilized Earth retaining structures. Large-scale reinforcement pullout tests were carried out. Based on the results, it was possible to carry out a comparative analysis of the mobilized resistance, allowing to determine design parameters. The experiments also showed favorable results, and the CDW can be considered a viable option for partial and/or total replacement of commonly used natural materials.

1 INTRODUCTION

In Brazil, CDW from construction works, renovations, demolitions, and excavations represent up to 70% (by mass) of total solid waste (Angulo *et al.* 2022). Only in Brasília (Brazilian capital), more than 6,200 t/day of CDW are generated and most of which are deposited in more than a thousand irregular deposition points (Brazilian Federal District Government 2016), causing the loss of ecosystems, contamination of natural resources such as air, water and soil, and deterioration of the landscape. The growing production of CDW and an increasing demand for materials for civil construction works makes necessary to reuse the CDW material.

Overall, reinforced soil standards suggest the use of good-quality granular soils as backfill material. However, there is often no availability of this type of material, therefore, several researches have been developed using unconventional materials, such as fine-grained soils (Araujo *et al.* 2021; Pierozan *et al* 2022), tire derived aggregates (Arulrajah *et al.* 2019; Ghaaowd1 & McCartney 2020; Zhang *et al.* 2020), industrial wastes (Mashifana & Sithole 2021; Mymrin *et al.* 2021; Pant *et al.* 2019) and recycled construction waste (Mandloi *et al.* 2022; Ok *et al.* 2023; Vieira 2020).

In this context, the present study comparatively analyzes the mechanical behavior of soils reinforced with synthetic strips in Mechanically Stabilized Earth Retaining Walls, using natural sands and CDW as backfill materials, through large-scale pullout tests, to determine its suitability as a backfill material.

2 INTRODUCTION MATERIALS AND METHODS

2.1 *Backfill and reinforcing materials*

In this research, natural sand, CDW sand, and CDW gravel were used as filling materials. The natural sand it was used, as a reference backfill material, usually used in earth structures. Figure 1 presents the particle size distribution curves and Table 1 presents the main geotechnical properties of the tested materials, as well as some compaction properties adopted for the pullout tests. As reinforcing elements, 50mm wide and 3 mm thick smooth synthetic strips were used, with maximum strength of 45kN, composed by polyester fibers (PET) with a low-density polyethylene coating (LDPE).
Figure 1.   Particle size distribution curves.

Table 1.   Physical and engineering properties of the materials.

Geotechnical Properties	Sand	CDW sand	CDW gravel
Grain specific gravity, G_s	2.71	2.68	2.66
Effective particle size, D_{10} (mm)	0.17	0.10	3.29
Fine content (%)	0.9	3.9	0.0
Coefficient of curvature, C_c	0.98	1.17	1.23
Uniformity coefficient, C_u	2.19	2.87	1.73
Unified soil classification system	SP	SP	GP
Relative density, DR (%)	96.3	96.1	95.2
Void ratio, test, $e_{95\%}$	0.67	0.61	0.82
Maximum dry unit weight, $\rho_{d\ 95\%}$ (g/cm^3)	1.63	1.66	1.56
Friction Angle, ϕ (°)	35	33	45
Cohesion, c (kPa)	0	3.7	0

2.2 *Test equipment*

The laboratory pullout test instrumented apparatus consists of three components (Figure 2): (1) the pullout box (Figure 3a), (2) a vertical load application system, and (3) a horizontal load application system (Figure 3b). The pullout box was designed and built for Palmeira

(1996) as recommended by D6706-01 (ASTM 2013). It is made of steel plates and consists of a rectangular cross-section box, with internal dimensions equal to 570 mm high, 900 mm wide, 1450 mm long, and a reaction structure for the application of horizontal loads. The horizontal load application system (pull-out system) is composed by a reinforcement-load transfer system connection element, a mobile load transfer system, a hydraulic cylinder, and a manual hydraulic jack. On the other hand, the vertical stress system consists of a lid with a rubber bag, an air-water interface system and a vertical reaction frame.
Figure 2.   Overview of pullout test apparatus and data acquisition systems. 1) pullout box; 2) vertical load application system; 3) horizontal load application system; 4) Spider acquisition system and 5) LYNX acquisition system.
Figure 3.   Overview of pullout test; (a) pullout box and (b) horizontal load application system. *1) reinforcement-load transfer; 2) load transfer system; 3) hydraulic cylinder; 4) manual hydraulic jack; 5) Load cell and 6) displacement transducers.

The instrumentation of the tests was consisted by (1) two displacement transducers, to control the rate of displacement of the reinforcements during pullout, to control the rate of displacement of the reinforcements during pullout, (2) one load cell, (3) four pressure cells and (4) three displacement transducers, to measure the axial deformation of the reinforcement elements. For recording and converting the sensors' analog readings into digital readings, the Spider-8.0 and LYNX data acquisition systems was used.

In order to avoid friction between the granular material and the box walls, lubricant was spread over the surface. The lower half of the pullout box is filled in 3 layers of 9cm thick compacted (CR>95%, as recommended by NBR 19286 (ABNT 2021). Then, the reinforcement is installed in the middle of the soil box in pairs, one parallel to the other and separated by 50 mm. The anchored length of the strips was equal to 1225 mm. The upper half of the box was filled using the same procedure as in the lower part. The upper lid with a rubber bag was installed and then the vertical frame was assembled. After the assembly, the normal stress (equal to 12.5 kPa, 25 kPa and 50 kPa) was applied and the pull-out force was applied with a strain rate equal to 1mm/min (ASTM D6706-01 2013).

3 RESULTS AND DISCUSSION

3.1 *Pullout test*

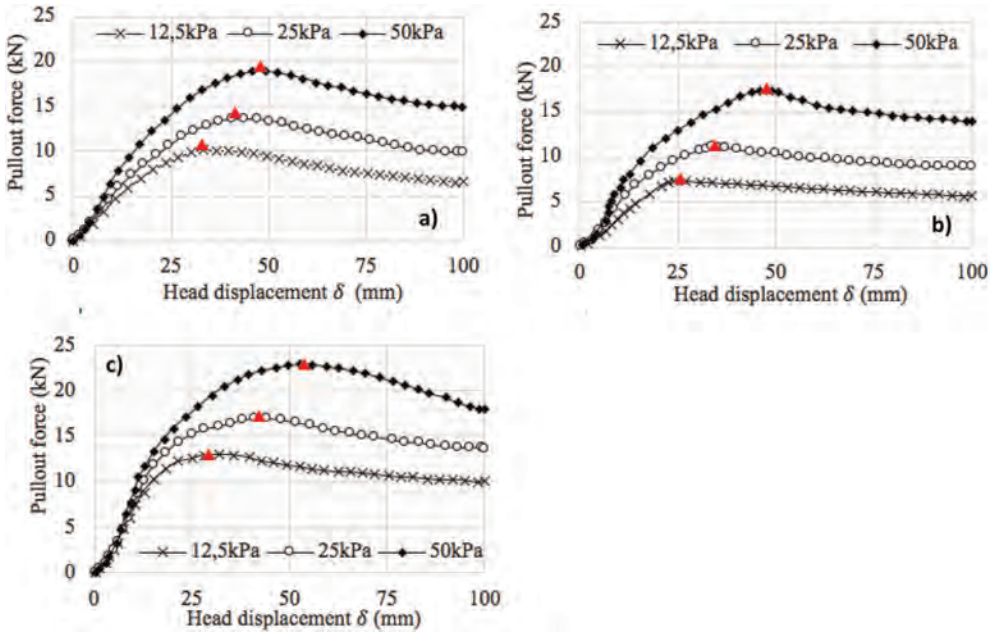
The results from pullout tests of geostrips with the normal stresses of 12.5 kPa, 25 kPa e 50 kPa are presented below. The variation of pullout force with the reinforcement displacement can be observed in Figure 4. The maximum pullout force ($F_{max.}$) or peak resistance (red triangles) is also shown.


Figure 4.   Pullout tests with a) Sand, b) CDW sand, and c) CDW grave.

From the maximum pullout force, the value of the pullout friction factors (f'^*) can be obtained according to the AASHTO (2012) standard, based on the hypothesis that the pullout strength is uniformly developed on both sides of the reinforcement along its length (Equation 1):

$$f'^* = \frac{F_{max.}}{w_g \times \phi \times C \times L_e \times \sigma_v} \tag{1}$$

where w_g = width of the geosynthetic; L_e= reinforcement length in the resisting zone; Φ = resistance factor for reinforcement pullout (0.90 for Service Limit State (SLS) and 1.00 for Ultimate Limit State (ULS)); α = scale effect correction factor (1 for geostrips); and σ_n= vertical overburden stress at the reinforcement level and C is the overall reinforcement surface area geometry factor (2 for strips).

The variation of the maximum pullout resistance as a function of vertical overburden stress and the pullout friction factors (f'^*) with the overburden thickness are shown in Figure 5.

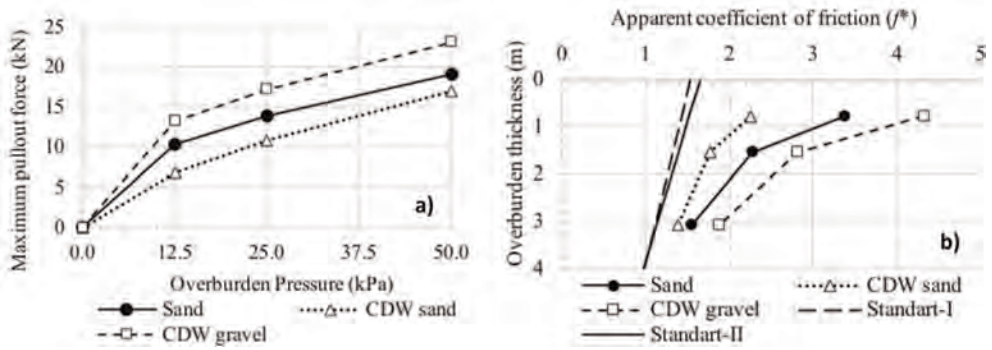
As expected, the value of the pullout resistance for the three materials increases with increasing confining levels, and the value of the pullout friction factor for the three materials decreases with increasing overburden thickness, according to ABNT (2021), due to the influence of the material dilation in the vicinity of the frame.


Figure 5. a) Maximum pullout force and b) Pullout friction factors (f^*) from laboratory tests.

3.2 Design standard

For comparison purposes, the values of the pullout friction factor (f^*) proposed by the French Standard (Norme Française 2009) were estimated. According to this standard, for class A (draining) materials the value of f^* varies linearly with the depth (z) and is given by Equation 2:

$$f^* = f_0^* \times \left(1 - \frac{z}{z_0}\right) + f_1^*\left(\frac{z}{z_0}\right), \; for \;\; z < 6m \qquad (2)$$

where, z_0 = depth at which there is no longer any dilation effect (6.0m); f_0^* = coefficient as a function of the uniformity coefficient (1.1 for $C_u < 2$ and 1.3 for $C_u > 2$); and f_1^* = coefficient as a function of the internal friction angle of the embankment, and is given by Equation 3:

$$f_1^* = 0,9 \times \tan\varphi' \qquad (3)$$

Table 3 presents the values of the apparent pullout friction factors calculated from the pullout tests (f^*) and estimated according to the French standard f^* (Norme Française 2009).

Table 3. Apparent friction coefficients calculated and estimated according to Norme Française (2009).

Geotechnic Material	Pullout Test			Coefficients	
	Normal stress (kPa)	Overburden thickness (m)	Max. pullout force (kN)	f^*	f^*
Sand	12.5	0.77	10.35	3.28	1.23
	25	1.54	13.92	2.27	1.17
	50	3.07	19.04	1.55	1.04
CDW sand	12.5	0.77	6.90	2.25	1.26
	25	1.54	10.80	1.76	1.21
	50	3.07	17.00	1.39	1.13
CDW gravel	12.5	0.77	13.24	4.32	1.10
	25	1.54	17.23	2.81	1.09
	50	3.07	23.08	1.88	1.08

It can be observed that the values obtained of the friction coefficients from laboratory tests are greater than the calculated according to the procedures established by the reinforced soil standard and design manuals. This was expected, once standards are conservative because they consider different types of soils.

4 CONCLUSIONS

In this study, large-scale pullout tests were carried out, using natural sand and two types of recycled construction and demolition waste as backfill materials and smooth synthetic strips as reinforcement elements, aiming at investigating the possibility of using CDW as backfill alternative material in mechanically stabilized walls. The findings of this study are summarized below:

(1) The maximum pullout resistance increased with the normal applied stress, while the pullout resistance factor, f^*, decreased. These tendencies were more pronounced under low overburden-pressure conditions.
(2) The CDW gravel friction coefficient was significantly greater than those obtained in sandy materials, once this material presented better geotechnical properties.
(3) The lowest pullout resistance values were obtained for the CDW sand, showing that the internal friction angle had a greater effect on the pullout resistance.
(4) The pullout resistance factors calculated for all materials used in this study were higher than the default f^* values recommended by the French standard (Norme Française, 2009) and design manuals (The Reinforced Earth Company 1995).
(5) The tested materials have excellent granulometric properties and excellent mechanical behavior in terms of pullout resistance and therefore are suitable to be used as backfill material in mechanically stabilized walls.

Laboratory study and meso-mechanical analysis of geogrid-reinforced sand under variable angle shear

MengXi Zhang, Hao Zhu & Cen Li
Shanghai University, Shanghai, China

ABSTRACT: In this paper, a series of laboratory tests were carried out through large direct shear apparatus, and the variation law of shear strength with different geogrid reinforcement angles was analysed. Using discrete element simulation, the influence of different placement angles on the meso-characteristics of geogrid reinforced soil is analysed from the perspectives of force chain evolution, geogrid deformation, shear band and particle displacement. The results show that when geogrid is placed at 60°, the shear strength is the highest and the tensile performance is fully exerted, which effectively prevents the displacement of soil. The force chain is concentrated and passes through the middle of the geogrid. The movement of soil particles in the lower box leads to the compression of the longitudinal ribs of geogrid placed at 120°, which fails to prevent the movement of soil particles, and the force chains are scattered due to the compression of soil.

Keywords: Geogrid, Direct shear tests, Discrete element simulation, Force chain

1 INTRODUCTION

Since geosynthetic-reinforced soil was first applied to engineering practice in 1970 (Leflaive 1988), this kind of reinforcement technology has received attention and been widely adopted with obvious advantages of low cost, high efficiency and good servicea-bility (Jia *et al*. 2021). A large number of research have been done on the performance of geosynthetic-reinforced structure under different conditions through field and laboratory tests and achieved remarkable results (Korini *et al*. 2021; Xue *et al*. 2014). Furthermore, the interface characteristics and the meso-reinforcement mechanism analysis through nu-merical simulation are also becoming new research focuses (Chen *et al*. 2021; Esmaeili *et al*. 2018; Grabowski *et al*. 2021).

At present, most of the interface characteristics analysis is based on the experimental study of geosynthetics placed in parallel to simulate the actual construction environment such as subgrade or slope. But the potential failure surface of reinforced soil often forms an angle with geosynthetics, which affects the performance of materials. For example, geogrid can effectively limit the displacement of soil due to its excellent tensile performance, but too large shear angle will also make it in compression, which will affect the reinforcement effect (Baadiga *et al*. 2021). Therefore, it is necessary to study the interface characteristics of geogrid reinforced soil under the condition of variable angle. In addition, for soil, a granular material, discrete element simulation has unique advantages in the analysis of interface characteristics between geosynthetics and soil, and provides a key data source for evaluating meso-performance and improving design methods (Liu *et al*. 2022). Feng *et al*. (2017) used discrete element simulation to analyse the direct shear behavior of the interface between geomembrane and sand, and proved that surface roughness and normal stress are important factors affecting the interface shear behavior. Wang *et al*. (2018) conducted a discrete

element model for rubber and sand mixtures, and analysed the parameters such as particle displacement, void ratio, stress state and force chain in the shearing process.

In this study, a large shear test of sand reinforced with geogrid at different angles is carried out. The influence of geogrid reinforcement angles on shear characteristics is ana-lysed from shear strength, cohesion and internal friction angle. In the mesoscopic analysis, the deformation, force chain evolution and particle displacement of sand reinforced with geogrid at different angles are studied through discrete element simulation. The conclusions drawn from this study provide a new idea for the research of geosynthetics.

2   EXPERIMENTAL SETUP

2.1   *Materials*

A sand was used in this study, with uniformity coefficient (Cu) of 2.78 and curvature co-efficient (Cc) of 1.14. Figure 1 shows the particle size distribution curve of the sand. which is then classified as poorly graded sand (SP) in accordance with ASTM D2487. A geogrid was used as the reinforcement material, and the tensile-strength test as per ASTM D6637 was carried out to obtain the technical indices, as shown in Table 1.
Figure 1.   Particle size distribution of test sand.

Table 1.   Technical indices of the geogrid.

Parameter	Value
Aperture size (mm)	40 × 40
Thickness (mm)	1.6
Tensile strength at 2% strain (kN/m)	10
Tensile strength at 6% strain (kN/m)	14
Ultimate tensile strength (kN/m)	17

2.2   *Test system*

The test system consists of direct shear instrument and data collection device, as shown in Figure 2. The dimensions of upper shear box are 300 mm × 300 mm × 100 mm, and 400 mm × 300 mm × 100 mm for the bottom shear box. The vertical stress was controlled by an air pump, which kept stable in the shearing process. The displacement is detected by a displacement meter, and the maximum range is 10 mm.
Figure 2. Schematic diagram of direct shear test system.

2.3 *Test procedures*

In order to analyse the relationship between shear stress and displacement of geogrid reinforced at different angles, the interface characteristics of specimens were tested under vertical stress of 50 kPa, 100 kPa, 150 kPa and 200 kPa, respectively. Samples were prepared by layered filling method. Sand was filled every 20 mm and compacted to the relative density (Dr=0.8). By changing the relative angle between geogrid and shear box, five different test conditions were designed, as shown in Figure 3. During the test, the upper shear box was fixed, and the shear plane was formed by moving the bottom shear box.
Figure 3. Schematic diagram of different arrangement angles of geogrid.

3 EXPERIMENTAL RESULTS

3.1 *Shear strength*

The shear stress-displacement curves for sand reinforced by geogrid, with five arrangement angles, under different normal stress, as shown in Figure 4. It can be seen that with the increase of shear displacement, the shear stress of all samples increases rapidly at the initial stage and then remains relatively stable after reaching the peak stress. In addition, the arrangement angle of geogrid has great influence on shear strength. The shear strength of the soil strengthened by geogrid arranged at 60° is the highest, and the geogrid gives full play to its tensile strength. However, when the arrangement angle is larger than 90°, the geogrid is mainly in a compressed state and leads to the decrease of reinforcement effect. Figure 5 shows the fitting lines for peak shear strength and vertical stress. The sample with best reinforcement effect when the arrangement angle is 60° has the maximum cohesion and internal friction angle, which are 25.2 kPa and 38.7° respectively.
Figure 4. Shear stress-displacement curves for sand reinforced by geogrid at different angles under different vertical stress (a) 50 kPa, (b) 100 kPa, (c) 150 kPa, and (d) 200 kPa.
Figure 5. Fitting lines for peak strength and vertical stress under different geogrid arrangement angles.

4 NUMERICAL SIMULATIONS

4.1 *Model development*

The meso-characteristics during shear process are helpful to analyse the mechanism of reinforced soil. In this study, PFC^{3D} is used for discrete element simulation, which provides a powerful supplement for indoor shear test. The wall was generated to simulate the shear box, and its size was consistent with the experiment. In order to effectively simulate the friction and embedment between sand and reinforcement, the structured triangular cluster particles (clump) were used. The particle density of sand is 2600 kg/m^3. Both normal contact stiffness

and tangential contact stiffness are 3×10^5 N/m. The particle range of sand is 0.5-2 mm. The porosity is 0.4 and the friction factor is 0.2.

Geogrid was built by circular particles and big balls were used at nodes. The parallel bonding model was used for geogrid, and the tensile properties of geogrid were fitted by macroscopic tensile-strain relationship. The arrangement scheme of geogrid is the same as the experimental design. The numerical sample model is shown in Figure 6(a). The particle density of geogrid is 1800 kg/m^3. Both normal contact stiffness and tangential contact stiffness are 1×10^5 N/m. Both parallel bonding normal stiffness and parallel bonding tangential stiffness are 6×10^8 N/m. The particle range is 0.75-1.5 mm. The friction factor is 0.3. By numerical simulation, the macroscopic shear characteristics of the experiment were matched. Figure 6(b) shows the comparison of shear test and simulation results for different angles of geogrid under vertical stress of 200 kPa. Solid marks represent test results, and hollow marks represent simulation results. The curves show that the experimental and simulation results are very close, showing a good match.
Figure 6. Discrete element simulation (a) Numerical model (b) The comparison curve of shear test and simulation results for different angles of geogrid under vertical stress of 200 kPa.

4.2 Force chain

The characteristics of load transfer between reinforcement and soil particles can be reflected from the distribution of force chain network. Figure 7 shows the evolution of force chain network of samples with different geogrid reinforcement angles under the vertical stress of 200 kPa. In order to save space, 60°, 90° and 120° are selected for analysis. Black indicates the compression state, and red indicates the tension state. It can be seen that under the action of shear stress, a strong chain penetrating the geogrid is formed in the soil. The geogrid with reinforcement angles of 60° and 90° are obviously stretched and deformed in different degrees. and the force chain remains stable. However, the geogrid with reinforcement angle of 120° is mainly subjected to compressive stress, and the force chain is broken and dispersed, which shows the shear zone characteristics on the shear plane.
Figure 7. Force chain network of samples with different geogrid reinforcement angles under the vertical stress of 200 kPa (a) 60°, (b) 90°, and (c) 120°.

4.3 Geogrid deformation

Figure 8 shows a schematic diagram of geogrid deformation with different angles under vertical stress of 200 kPa. Red represents tension, black represents compression, and the thickness of force chain represents force value. It can be seen that when geogrid is reinforced at 60°, the tensile force near the shear zone is larger, and the force chain is thicker. The direction of geogrid arranged at 90° is quite different from the shear direction, but with the movement of particles, the angle of geogrid gradually deflects, and the longitudinal ribs tend to deflect downward. The geogrid arranged at 120° is obviously more deformed at both sides due to compression. It is worth noting that under all conditions, the transverse ribs of geogrid are generally in tension. This shows that whether the whole stress state of geogrid is tension or compression, the displacement of soil particles will be limited by the transverse ribs of geogrid.
Figure 8.　Schematic diagram of geogrid deformation with different angles under vertical stress of 200 kPa (a) 60°, (b) 90°, and (c) 120°.

4.4 Displacement field

Generally speaking, it is difficult to observe the internal displacement of the sample in the actual direct shear test. In this paper, the displacement field of soil particles and geogrid is clearly reflected by discrete element simulation, as shown in Figure 9. Different geogrid angles have great influence on the results. The lower part of the sample with geogrid placed at 60° has a small particle displacement around the geogrid and hinder the movement of the lower soil. Therefore, the tensile performance of the geogrid can be fully utilized. The upper box soil prevents the geogrid from being pulled out, which leads to the increase of vertical stress. However, when the geogrid is placed at 90° and 120°, the movement of soil particles in the lower box causes the longitudinal rib of geogrid to be compressed, which fails to effectively prevent the movement of soil particles.
Figure 9.　Displacement field of samples with geogrid placed at different angles under vertical stress of 200 kPa (a) 60°, (b) 90°, and (c) 120°.

5 CONCLUSIONS

In this study, the influence of geogrid angle on the shear characteristics of reinforced soil was studied by using large-scale direct shear apparatus, and a discrete element simulation was carried out to analyse meso-characteristics. The conclusions can be summarized as follows:

1. In the laboratory test, the geogrid with less than 90° is helpful to exert its tensile performance. The shear strength of soil strengthened by geogrid at 60° is the highest. When the arrangement angle is larger than 90°, the geogrid is mainly in a compressed state and leads to the decrease of reinforcement effect.
2. The force chain of samples reinforced by geogrid with reinforcement angles of 60° is thicker passes through the geogrid. However, the geogrid with reinforcement angle of 120° is deformed greatly, mainly bears compressive stress, and the force chain breaks and disperses, showing the characteristics of shear band on the shear plane.
3. The tensile property of geogrid with an angle of 60° can be fully utilized, and the movement of soil particles can be effectively prevented. However, when the geogrid is placed at 90° and 120°, the movement of soil particles in the lower box causes the longitudinal ribs of geogrid to be compressed, which fails to effectively prevent the movement of soil particles.

Modelling temperature dependent behavior of soil-polyethylene contact surfaces

Ö. Bilgin
University of Dayton, Dayton, Ohio, USA

B. Shah
Clayton Concrete, Edison, New Jersey, USA

ABSTRACT: Polyethylene has temperature dependent properties. As a thermoplastic material, it softens on heating and hardens on cooling. This behavior affects the contact surface areas of materials made out of polyethylene, such as geomembranes, adjacent to other materials. Interface strength properties depend on the contact area and stress at the interface. Since the soil-geomembrane interfaces are relatively weak and potentially form the critical failure planes, modeling temperature dependent soil-polyethylene contact surfaces is important. A theoretical model to determine soil-polyethylene contact areas was developed during this study and presented in this paper.

Keywords: Polyethylene, geomembrane, contact surfaces, interfaces, temperature effects, thermal properties

1 INTRODUCTION

Polyethylene is one of the most widely used materials in geosynthetics and in their civil engineering applications. For example, polyethylene material is used in 70% of the geomembranes, which are relatively thin and impervious sheets of polymeric materials used primarily in hydraulic structures, e.g. reservoirs and canals, and landfills as impervious boundary for liquid and/or gas containment (Koerner 2005). Some of the example applications of geomembranes are: as liners for potable water, radioactive and hazardous waste liquid, solar ponds, agriculture industry, aquiculture industry, waste conveyance canals, solid-waste landfills; as covers for solid-waste landfills; as cutoffs within zoned earth dams for seepage control; as linings for emergency spillways; as waterproofing liners within tunnels and pipelines; as waterproof facing of dams; as a barrier to odors from landfills, to vapors (such as radon) beneath buildings; to control expansive soils and frost-susceptible soils; and to shield sinkhole-susceptible areas from flowing water (Koerner 2005).

The interfaces between soil and polyethylene material these materials are relatively weak and constitute critical potential failure planes. Therefore, the soil-geomembrane contact surfaces and interface shear behavior is critical to an overall performance of the structure in majority of the applications listed above. With the increased use of geosynthetic materials in civil and geotechnical engineering applications, interface shear behavior between sand and geosynthetic materials have been investigated by several researchers. Studies showed that the interface shear depends on soil properties (such as composition, grain size, water content, and density) and geosynthetic properties (such as tensile strength, modulus, surface roughness, surface hardness) as well as the loading conditions (Bilgin & Stewart 2006; Bilgin & Stewart 2009; Dove & Frost 1999; Dove & Jarrett 2002; DeJong & Westgate 2005; Dove *et al.* 2006; Martin *et al.* 1984; O'Rourke *et al.* 1990; Saxena & Wong 1984; Williams & Houlihan 1987).

The polyethylene has also temperature dependent properties. Temperature-induced changes in the modulus of polyethylene material are significant. For example, between 0 and 50°C, the modulus of the polyethylene increases by nearly a factor of two, with higher modulus at lower temperatures. Therefore, the soil-geomembrane interface shear strength will be affected by the temperature, since the interface shear depends on the geosnythetic material's modulus as mentioned earlier.

The objective of this study was to develop a model for the temperature dependent contact surface areas of soil-polyethylene interfaces. The model developed and the effect of temperature and its variations on the soil-polyethylene contact surface areas is presented in this paper.

2 EFFECT OF TEMPERATURE ON POLYETHYLENE

Polyethylene has temperature dependent properties. The operating temperatures of geosynthetics made out of polyethylene used in civil engineering applications are well below the melting temperature and well above the glass transition temperatures. However, the geosynthetics are exposed to different temperatures in the applications that they are used and during their design life. Within the operating temperatures, temperature dependent properties of polymers affect the behavior of geosynthetics. The modulus of polyethylene changes nearly by a factor of two between 0 and 50°C, with higher modulus at lower temperatures as shown in Figure 1 (Bilgin 2007). The modulus of medium density polyethylene (MDPE) is approximately 80% of the high density polyethylene (HDPE).
Figure 1. Temperature dependent modulus of high density (HDPE) and medium density (MDPE) polyethylene (after Bilgin *et al.* 2007).

Geomembranes are used as a part of liner systems in modern landfills. The studies showed that significant amount of heat is generated in landfills, resulting in long–term elevated waste temperatures (Lefebvre *et al.* 2000; Yesiller *et al.* 2005). As much as 87°C temperatures were measured inside a landfill (Klein 2001). These high temperatures will affect the modulus of elasticity of the polyethylene materials significantly which will affect the soil-geomembrane contact surface areas and the interface shear strength characteristics.

3 CONTACT AND FRICTION BETWEEN SURFACES

A friction behavior of smooth geomembrane-particle interfaces has been studied in details and the shear mechanisms involved has been discussed by Dove & Frost (1999). A frictional

force between two solid surfaces is proportional to the normal force at the surface. The constant of proportionality is defined as coefficient of friction, μ, and given by:

$$\mu = \tan \delta = \frac{F}{W} \quad \text{or} \quad \mu = \tan \delta = \frac{\tau}{\sigma} \tag{1}$$

where δ = interface friction angle; F = friction force; W = normal force; τ = shear stress; and σ = normal stress. These equations are used commonly in geotechnical engineering and holds reasonably well for the materials involved. However, it is not valid for many materials since their friction coefficients can vary with normal load.

The friction force, F, is governed by two fundamental shear strength components (Adamson 1982; Briscoe 1992; Bowden & Tabor 1956; Shooter & Tabor 1952), adhesion and plowing, or plastic deformation components, and it is given as:

$$F = F_{adhesion} + F_{plowing} \tag{2}$$

The adhesion component is identified as microscale process formed because of the pressing of two materials at the contacts and becoming like one continuous material. It is given as:

$$F_{adhesion} = \tau_a \ A_c \tag{3}$$

where τ_a = material shear strength at points of contact; and A_c = real contact area between two materials. It has been reported that τ_a is the bulk shear strength of the softer material and can be stress level dependent (Stachowiak & Batchelor 1993).

The plowing component is given as:

$$F_{plowing} = \tau_p \ A_p \tag{4}$$

where τ_p = bulk strength of the softer material; and A_p = cross-sectional area of plowed track.

The contact area, A_c, for the elastic contact conditions is given by Hertz as (Adams 1992):

$$A_c = \pi \left(\frac{3WR}{4E'} \right)^{2/3} \tag{5}$$

where W = applied load; R = mean radius of curvature = $(1/r_1 + 1/r_2)^{-1}$; where r_1 and r_2 are the particle radii; and E' = composite elastic modulus given by:

$$E' = \left(\frac{1-v_1^2}{E_1} + \frac{1-v_2^2}{E_2} \right)^{-1} \tag{6}$$

where E_1 and E_2 = modulus of elasticity of each material; and v_1 and v_2 = Poisson's ratio of each material.

4 MODELLING TEMPERATURE DEPENDENT CONTACT SURFACE AREA

As previously discussed, the modulus of polyethylene is temperature dependent and this will affect the soil-geomembrane contact surface area as schematically shown in Figure 2. Figure 2(a) shows the soil particles and the geomembranes before the contact, i.e. just before the loading. For better visualization uniform grain size and orderly packed configuration is shown, although in reality the grain sizes and particle configurations vary. While Figure 2(b) shows the penetration of soil particles into the geomembrane due the soil weight (plus surcharges, if any) right after the placement of the soil at relatively lower temperatures, Figure 2 (c) shows the increased penetration and the contact area at relatively higher temperatures. For this study, a smooth under-support to the geomembrane is assumed. Another soil layer below the geomembrane (depending on geomembrane thickness, size of soil particles, and orientation of soil particles), could cause waviness along the geomembrane and could affect the mean radius of curvature, R, given in Equation 5.
Figure 2.   Effect of temperature on soil-geomembrane contact area: (a) Soil grains and geomembranes before construction, (b) Penetration of soil particles and contact area of the soil grains on the geomembrane surface at relatively low temperatures, and (c) At relatively high temperatures.

To account for the temperature dependent behavior of polyethylene, the contact area given by the Hertz equation (Equation 5) can be modified as:

$$A_c(T) = \pi \left(\frac{3WR}{4E'(T)} \right)^{2/3} \tag{7}$$

where $A_c(T)$ = temperature-dependent contact area; and $E'(T)$ = temperature-dependent composite elastic modulus that can be given as:

$$E'(T) = \left(\frac{1 - v_1^2}{E_1} + \frac{1 - v_2^2}{E_2(T)} \right)^{-1} \tag{8}$$

where $E_2(T)$ = temperature-dependent modulus of polyethylene (Figure 1) in contact with soil particles. The modulus of soil particles, E_1, can be assumed to be constant during the service life of the structure.

The effect of temperature on the soil-polyethylene interface contact surface area using the proposed modified Hertz equation (Equation 7) is given in Figure 3. The temperature-dependent composite section modulus, $E'(T)$, for the soil-geomembrane interface calculated using Equation 8 is shown in Figure 3(a). The modulus and Poisson's ratio of 72,000 MPa
(a) Composite section modulus of soil-geomembrane interface
(b) Change in soil-geomembrane contact area at the interface

Figure 3.   Effect of temperature on the soil-geomembrane contact area: (a) Temperature-dependent composite modulus of the interface, and (b) Contact area ratio (contact area at any temperature over the contact area at 21°C).

and 0.17, respectively, (for quartz) were used for the soil particles. The change in the contact area is shown as the ratio of temperature-dependent contact area, $A_c(T)$, (Equation 7) to the reference contact area, $A_c(T = 21°C)$ as:

$$\text{Contact Area Ratio} = \frac{A_c(T)}{A_c(T = 21°C)} \tag{9}$$

Figure 3 shows that temperature increase of approximately 40°C, with respect to reference temperature of 21°C, will results in 60% increase in the soil-geomembrane contact area. On the other hand, a decrease of approximately 40°C will result in 38% drop in the contact surface area.

5   CONCLUSIONS

Many of the geomembrane materials have temperature-dependent properties. In this paper, the effect of temperature on the soil-polyethylene material contact area was studied using a theoretical approach. An existing model used for the contact area between surfaces has been modified to include the temperature-dependent material property of geomembranes. The results show that the contact area at the interface can change significantly (as much as 60%

with respect to baseline temperature of 21°C or as much as 150% within the range of temperatures (−20 to 60°C) investigated during this study.

Machine learning for soil-geosynthetic interface shear strength analysis

T.T. Abenezer*, G.L.S. Araújo*, F. Evangelista Jr.* & R.M.S. Gomes*
University of Brasilia, Brazil

ABSTRACT: This paper presents geosynthetic interface friction angle prediction by using the Random Forest algorithm. A number of 495 interfaces consisting geomembrane and cohesionless soil and fourteen influencing parameters for each interface are used. In the analysis the Pearson's correlation coefficient is used to measure the linear interdependence between each pair made by input-input and input-output parameters. After the linear analysis, an optimized Random Forest has been initialized to make a prediction of the interface friction angle. Random Forest splits the implemented data into training and testing sets and it is observed only for 3% of the training set and 6% of the testing set the estimation has exceeded $\pm 5°$ from the actual records. R^2 measures shows strong coherence between predicted and laboratory study friction angles by resulting $R^2 = 0.93$ for training and $R^2 = 0.92$ for testing set. Thus, the Random Forest has forecasted interface friction angle adequately.

1 INTRODUCTION

Several soil structures and waste disposal areas can be constructed by single or multilayer of geosynthetics for filtration, drainage containment or reinforcement. The interaction between geosynthetic layers and the reinforced soil is an important section for determining the overall structure stability. Laboratory experiments are the main practice to study geosynthetic interface strength and direct shear test, medium size direct shear test, and inclined plane (ramp) test are the most practiced ones. Several authors states that interface shear strength can be affected by some critical factors like type of test equipment, applied normal stress, the strain rate, contact area between interface components, type of geosynthetics, thickness of geomembrane, asperity height of geomembrane, relative density of reinforced soil, specific gravity of soil, coefficient of curvature, coefficient of uniformity, D_{50} and friction angle of soil (Araujo *et al.* 2022; Bacas *et al.* 2015; Carbone *et al.* 2015; Choudhary *et al.* 2016; Cen *et al.* 2018; Lashkari & Jamali 2021; Pavanello 2021, 2022; Sánchez 2018; Vangla *et al.* 2017).

Based on the finding of these practical laboratory results it is possible to build a prediction model by using Machine Learning algorithms. Machine Learning algorithms are set to learn from an available data and trained to make a projection of a certain parameter. In this study Random Forest regression will be initialized to predict geomembrane-sand interface shear strength. Some researchers applied Random Forest to geotechnical engineering parameters analysis (Dutta *et al.* 2019; Ly *et al.* 2020; Pham *et al.* 2020; Zhang *et al.* 2019, 2021, 2022; Zhou *et al.* 2019).

Although there are investigations over the years on the topic, there is a need to improve the interface shear strength determination between geomembranes and other materials, and

Machine Learning has great potential for this application. A number of 495 interfaces from three test types (conventional direct shear, medium size direct shear and inclined plane tests) and 14 influencing factors for each interface are recorded. The impact type and level of each parameter can be determined by the other factors in the test. To measure the inter-dependence between the variables their corresponding values corelated by Pearson's correlation. The Pearson's correlation coefficient results are indicating that, the influence level between most parameters is not considerably strong. These values indicate the nonlinearity of the database and the need of a multivariate algorithm for studying this type of interface. This investigation aims at evaluating Random Forest algorithm of Machine Learning, projecting interface shear strength. To improve the performance of Random Forest, a powerful minimizer tool called Differential Evolution is applied.

2 DATA ANALYSIS

The laboratory results from the three different test types compiled together to build single prediction model. In this work, 495 interface friction angles from different works of literature are accumulated and employed in the regression analysis. The types of studies and the number of samples they provided are listed in Table 1.

Table 1. Types of data providing studies.

No.	Type of studies	No. of samples
1	Dissertations/Theses	103
2	Research papers from journals	357
3	Manufacturing companies' results	35

3 APPLIED METHODS

3.1 *Pearson's correlation measures*

The influence of each considered interface component on the interface friction angle, may vary depending on the other involved strands. For example; the level of the effect of the applied normal stress on the interface shear strength outcome depends by other parameters such as the sliding velocity of the upper box in the inclined plane test (Carbone *et al.* 2015; Lashkari 2021; Pavanello *et al.* 2021; Sánchez 2018). This is due to when the ramp proceeds on tilting, the upper box tends to slide quickly and the applied stress level tends to decrease. These inter-correlations between the affecting elements and the friction angle and among the input variables are analyzed by Pearson's coefficient.

The Pearson coefficient (ρ) is a type of correlation coefficient that represents the linear relationship between two variables that are measured on the same interval or ratio scale. It is a measure of the strength of the association between two continuous variables. Its value ranges between -1 to 1 and a value close to |1| indicates higher influence level and when it is closer to 0 it shows lower interdependence between the observed parameters. In this study the value $\bar{\rho} \geq |0.2|$ is considered as indication of the presence of a certain influence level (Pant & Ramana 2021).

3.2 *Performance measures*

Two performance assessment criteria namely Coefficient of Determination (R^2) and Root Mean Square Error (RMSE) are used to evaluate the prediction capability of the Random

Forest algorithm. R^2 measures how much variability in dependent variable can be explained by the model and presents the linear correlation between the actual and predicted outputs. Values of R^2 range from 0 to 1, and higher value close to 1 indicates a better accuracy and lower values closer to 0 indicates poor prediction.

$$R^2 = 1 - \frac{SS_{Residuals}}{SS_{Total}} \tag{1}$$

Where $SS_{Residuals}$ = the sum of square of residuals; SS_{Total} = the sum of the square of the observed variable.

While, the root mean square error (RMSE) is defined as the square root of differences between predicted and observed values. The RMSE estimates the magnitude of the errors which are known as "residuals". RMSE is a standard way to measure the error of a model in predicting quantitative data and its lower value indicates a better performance of the model.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - \widehat{y_i}\right)^2} \tag{2}$$

where y_i = the observed variable $\widehat{y_i}$ = dependent or prediction variable.

3.3 Random Forest (RF)

RF is developed by Breiman, (2001) and it is a supervised machine learning algorithm which is constructed from decision trees and used to solve regression problems. RF is implemented based on bagging decision trees by employing random split selection and it extracts multiple sub-sample sets from the original sample set, each of them independently forms a decision tree. A five-fold cross-validation method is applied during random sampling, where 4/5 of the selected features will be utilized for training the model and 1/5 of the randomly selected features applied for testing the performance. Thus, the database is split in to 80% for training and 20% for testing purpose and decision trees randomly select features to split nodes internally to form a random forest. For the regression algorithm, the prediction result is the average of all decision tree output results (Zhang *et al*. 2021). Number of trees, maximum depth of trees and minimum number of samples to split a node are called hyperparameters of a RF. A proper optimization of hyperparameters leads to a more accurate prediction of the algorithm (Zhou *et al*. 2019). To optimize the RF hyperparameters, Differential Evolution, which is a powerful minimizer adopted in this study (Pierre *et al*. 2021).

3.4 Differential Evolution (DE)

Differential Evolution (DE) is a heuristic approach for the global optimization of nonlinear and non-differentiable continuous space functions (Storn & Price 1997). It starts with an initial population of candidate solutions. These candidate solutions are iteratively improved by introducing mutations into the population, and retaining the fittest candidate solutions that yield a lower objective function value. DE can handle nonlinear and non-differentiable multi-dimensional objective functions, while requiring very few control parameters to steer the minimization. These characteristics make the algorithm easier and more practical to use. The algorithm works in two phases, i.e., (i) Initialization: population is generated randomly and, (ii) Evolution: the generated population goes through mutation, crossover and selection processes which are repeated until a termination criterion is met. The RF hyperparameters which are the number of trees, maximum depth and minimum number of samples to split a node are the populations for the DE application. These hyperparameters are optimized by the mutation, crossover and selection steps of DE. The number of trees optimized to 103, the maximum depth in each tree is 30 and the minimum number of samples to split a node are determined as 4.

4 RESULTS

4.1 *Linear correlation results*

The influence extent of each considered interface parameter on its adjacent pair is analyzed by Pearson's correlation coefficient results. There are 44 pairs of variables which are showing the presence of influence among the total 105 pairs of variables analyzed herein. Of the 44 pairs, 37 pairs show moderate, 6 of them are showing strong and one of them is showing very strong linear correlations. This designates that 58% of the total pairs have negligible linear relationships. If the ruling observation focuses only on the Pearson's coefficient results it can mislead to a stipulation of a lack of influence between studied variables. However, the analysis can be interpreted as an implication of non-linearity between the pairs (Spanos 2003).

4.2 *Optimized RF results*

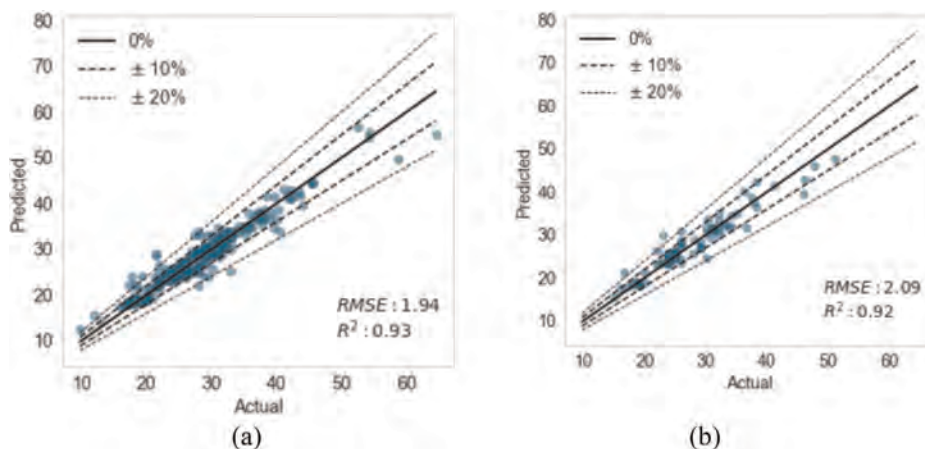
The prediction performance of RF is assessed by calculating R^2 and RMSE. As shown in Figure 1, the interface friction angle estimation for the training data resulted in $R^2 = 0.93$ and RMSE = 1.94. And for prediction of the testing set, it is measured $R^2 = 0.92$ and RMSE = 2.09. This indicates a good agreement and less residual error between interface friction angle from RF estimation and laboratory test results. In civil and geotechnical engineering parameters prediction utilizing ML algorithms, $R^2 > 0.90$ is considered as an indication of a very good fit (Dutta *et al*. 2019; Farooq *et al*. 2020; Liu *et al*. 2020; Zhang *et al*. 2021). Figure 1 shows most of the predicted friction angles varied less than ±10%, and few of them are exceeded ±10% and prediction exhibited ±20% error is very rare, either on training or testing set.


Figure 1. Optimized RF prediction performance measures (a) training set, (b) testing set.

Furthermore, the performance of the RF algorithm was performed by determining residual errors. Figure 2 shows that the actual laboratory results (O marks) and the predicted interface friction angles (X marks) obtained by the RF model are in strong agreement. From the total interfaces, 80% of the samples are utilized in the training set. As shown in Figure 2a from 396 predicted interface shear strength, only for 12 of them the friction angle has a ±5° variation from laboratory test results. For the remaining 384 interfaces the difference between interface friction angles of RF estimation and actual laboratory test is lower than 5°. As aforementioned, 20% of the data is utilized in the testing set and Figure 2b shows that from 99 predicted interfaces, only for 8 of them the friction angle has outlined a ±5°

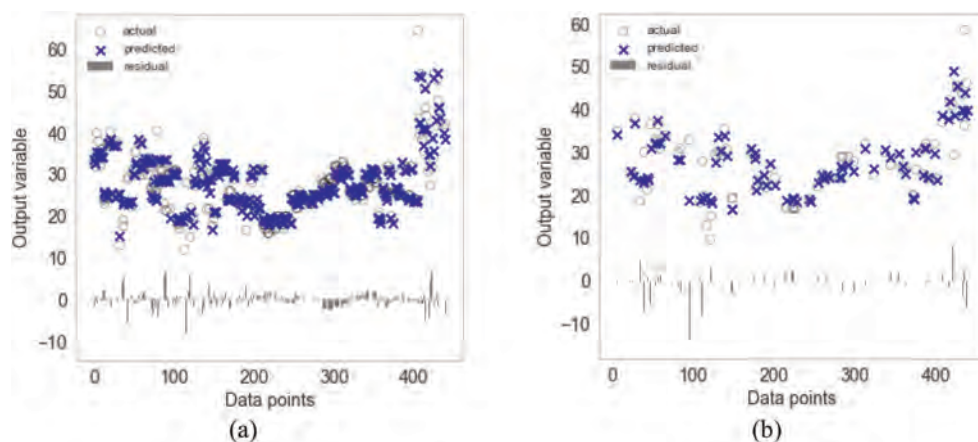
difference from the literatures. For the remaining 91 interfaces, the difference between predicted and actual laboratory test friction angles remained lower than 5°.


Figure 2. Predicted, actual and residual values for interface friction angle by RF model: (a) training set, (b) testing set.

5 CONCLUSIONS

This paper initiates a discussion about the application of Random Forest for geomembrane interface shear strength analysis. A total number of 495 interface friction angles and 14 influencing factors for each interface are used to create the data set. Based on the analysis and results the following conclusions are driven;

- Pearson's correlation coefficient measurements showed limitations for the utilized database by resulting for 58% of the total 105 pairs, $\overline{\rho} < |0.2|$.
- The optimized Random Forest regression algorithm predicted geomembrane-sand interface friction angle adequately by resulting $R^2 = 0.93$ for training and $R^2 = 0.92$ for testing set.
- The Random Forest regression model functioned better with the nonlinearity of the data and delivered a prediction in strong coherence with laboratory test results.

Durability and long term performance

Durability of HDPE geomembranes under different challenging exposure conditions

ABSTRACT: Understanding the life expectancy and performance characteristics of geo-synthetic products is critical in the design of containment and storage systems. Standard testing methods do not enable assessment of the expected long-term performance of products exposed to challenging exposure conditions such as those related to storage of unique solid and liquid waste by-products generated by industrial and mining sectors. Therefore, the adoption of alternate approaches for assessment of material durability under anticipated exposure conditions is necessary. Accelerated exposure testing programmes were undertaken on several different HDPE geomembrane product samples to assess the material performance under different expected service conditions. The laboratory testing programmes included the simulation of a very high pH environment, very low pH environment and extreme UV exposure conditions. The results were used to assess the expected performance of the candidate products proposed by manufacturers for use in different applications. The outcomes of the testing indicated significant variability in expected long term durability under the different assessed conditions for the different HDPE geomembrane products. These results indicate the need for this type of testing to provide evidence to support the choice of geomembrane materials for applications involving exposure to challenging conditions.

1 INTRODUCTION

The industrial and mining sectors require liquids, solids and semi-solid by-products to be stored and contained long term in order to mitigate the environment impact of the industrial and mining processes. The design of these containment facilities typically requires a composite lining system and include a geomembrane liner underlain by a mineral liner. Initial commercial selection for the geomembrane liner resulted in a preference to use HDPE for the geomembrane liner, if technically viable. The HDPE geomembrane is a key component of the lining system and must be designed to perform long term when subjected to the by-products.

WSP Golder has designed containment systems for a range of industrial and mining applications subjected to a variety of by-products and a range of climatic conditions. The HDPE geomembrane selection process requires careful consideration as the operating

---

conditions (including chemical characteristics and environmental conditions) for each application vary.

This paper intends to demonstrate importance of adopting a thorough geomembrane selection process as experience shows that different products perform differently when subjected to challenging environmental conditions and chemical characteristics.

2   TYPICAL GEOMEMBRANE SELECTION METHODOLOGY

Geomembranes used in containment systems are often selected based on data sheets supplied by the geomembrane manufactures related to indicative durability to some mono-chemicals, and material properties relative to Geosynthetics Research Institute (GRI) nominated properties outlined in GRI 2019. The GRI nominated properties have been developed to reflect the material properties of materials available from a range of geomembrane manufacturers and experiences. The nominated properties are intended to be a starting point for consideration and should be refined to suit the intended application based on the specific project conditions and performance requirements.

Industrial and mining by-products can be unique and the combination of various chemical and operating conditions of the by-product containment facilities are unlikely to have been considered during the development of the GRI documents. The GRI documents do not provide an indication of service life. Manufacturers may have chemical resistance information for some conditions however, these are unlikely to represent the complete by-product chemistry and the information can become outdated as resin properties are re-engineered over time.

3   SERVICE CONIDITIONS

3.1   *Acidic liquid storage pond*

The acidic storage pond is located in an arid area with ambient temperatures recorded between 6°C and 48.5°C. The Average monthly Solar UV Index at the location is greater than 6 between September and April and peaks at over 12 during summer (Australian Government Bureau of Meteorology 2019).

The acidic liquid is a by-product of the processing of ore and contains high concentrations of dissolved solids (mainly heavy metals with some organics) and has a low pH.

To assess which HDPE geomembrane products could perform when subjected to the acidic storage pond's service conditions for the required design service life of at least 20 years, a laboratory testing programme was developed to simulate the service conditions.

3.2   *Caustic solid containment facility*

The caustic containment facility is required to contain by-product of alumina refining which is delivered to the storage facility and has potential to generate leachate to which the geomembrane liner would be exposed. The containment facility liner system is intended to be buried and covered with a sand layer with limited UV exposure during the construction period and expected minor temperature variation during service conditions.

A 2mm thickness HDPE geomembrane was nominated for inclusion in the liner system for the facility. To assess which HDPE geomembrane products could perform when subjected to long term exposure to the leachate a laboratory immersion and testing programme was developed.

4   CANDIATE PRODUCT SHORTLISTING

To help establish a 'shortlist' of candidate products for inclusion in the testing program key geomembrane manufacturers were approached to nominate proposed products. The

manufacturers approached were provided with a description of expected service conditions to assist them in nominating a product that they considered to be most suitable for the application. The products proposed typically comprised specialist 'high performance' geomembrane products or 'special runs' with a formulation developed specific to the application. A total of 4 products were selected for laboratory testing for each application.

5 LABORATOR TESTING REGIME

A laboratory testing regime was designed to simulate accelerated aging of the various products in the acidic and caustic service conditions. The programme was informed by the research published by Rowe *et al*. for selecting geomembranes (Rowe *et al*. 2019) and included:

5.1 *Ageing of candidate samples*

The candidate samples were immersed in representative liquids or leachates from the by-products recovered from the sites to replicate the expected service conditions. The candidate samples were immersed for up to 90 days at three temperatures (55°C, 70°C and 85°C for the acidic exposed samples and 50°C, 75°C and 90°C for the caustic exposed samples) in general accordance with ASTM D5322 and ASTM D5747. Samples were recovered from the immersion liquid and subjected to laboratory testing to assess changes in the materials.

In order to estimate the service life of the candidate materials, extrapolation of the OIT depletion time at various temperature was undertaken using the Arrhenius equation. The Arrhenius extrapolation of the various temperature data enabled the prediction of the degradation rates of the geomembrane products, which were applied to the estimated service temperature and informed a service life assessment.

5.2 *Representative field conditions*

For the acidic liquid storage pond the geomembrane liner will be subjected to varying temperatures and UV exposure depending on its location within the lining system and its environmental exposure. The climatic data was therefore assessed to estimate representative operating temperatures for the geomembrane and estimate of UV exposure where appropriate. Where the geomembrane was expected to remain submerged a representative service temperature of 25°C was adopted based on temperature measurements recorded on existing ponds at site.

Published field measurements by Take 2015, *et al* has shown that the temperature of exposed polyethylene geomembrane is linked to exposure to UV radiation/sun. So, for the exposed geomembrane on the upper portion of the slopes and embankments crests of the pond the service temperature was estimated by utilising the UV Index data published by the Bureau of Meteorology for the site. Based on research by Rowe & Ewais 2014, the daily, monthly and annual UV index trends were correlated to the temperature of black HDPE geomembrane to develop a degradation ratio of the geomembrane. This approach indicated a representative service temperature of 40°C for the site conditions which resulted in an equivalent degradation rate of the geomembrane considering diurnal and seasonal variations.

For the caustic exposure project the liner will be covered and not subject to solar radiation or elevated temperature effects so a constant representation temperature of 25 °C was adopted.

6 ASSESSMENT OF AGEING EFFECTS

The aged geomembrane samples underwent a range of laboratory tests which included the following:

- Both standard (S) and high pressure (HP) oxidative induction time (OIT) testing in accordance with ASTM D3895 and ASTM D5885 respectively. Samples were tested

pre-immersion and after immersion to estimate the retention rates of antioxidants and stabilisers. Samples were recovered and tested periodically throughout the 90 days testing.

- Geomembrane stress crack resistance (SCR) was considered critical to the performance of the geomembrane as experience indicates HDPE geomembrane becomes crack sensitive as it degrades over time. Therefore, the SCR of the candidate geomembrane samples was also assessed periodically throughout the testing process. Notched Constant Tensile Load (NTCL) SCR testing was undertaken in accordance with ASTM 5397 on parent geomembrane samples prior to immersion and after immersion for 90 days at 55°C. For the acid exposed samples Strain Hardening modulus (SHM) testing was also undertaken in accordance with DIN EN 17096 on parent geomembrane samples prior to immersion and periodically throughout the 90 days of immersion at each temperature. The values of the Strain Hardening test results were correlated to the NTCL SCR method for the various samples to estimate a stress crack resistance value in hours.
- Tensile testing of the candidate products was undertaken in accordance with ASTM D6693 prior to immersion and periodically throughout the 90 days. Tensile testing of the candidate geomembrane products was intended to provide an early indication of any performance issues. Testing on samples of welded seams subjected to the immersion tests were also carried out to assess any early changes in mechanical behaviour of the samples.
- Carbonyl Index testing of the caustic exposed candidate products was undertaken in accordance with a modified ASTM F2102 method prior to immersion and periodically throughout the 90 days to detect oxidised groups in the samples

6.1 *Outcomes of laboratory testing of samples immersed in acidic conditions*

6.1.1 *SOIT*
Based on the results of the SOIT testing the following observations were made:

- The initial SOIT values varied between 250 minutes and 150 minutes.
- The retained SOIT values after 90 days immersion at 55°C varied between 70% and 90%
- The retained SOIT values after 90 days immersion at 70°C varied between 40% and 90%
- The retained SOIT values after 90 days immersion at 85°C varied between 2% and 52%

The depletion rates of retained OIT over time at different immersion temperatures varied significantly between the different geomembrane samples.

6.1.2 *HPOIT*
Based on the HPOIT testing results the following observations were made:

- The initial HPOIT values varied between 500 minutes to 1800 minutes.
- The retained HPOIT values after 90 days immersion at 55°C varied between 80% and 100%
- The retained HPOIT values after 90 days immersion at 70°C varied between 50% and 100%
- The retained HPOIT values after 90 days immersion at 85°C varied between 20% and 85%

The depletion rates of retained HPOIT over time at different immersion temperatures varied less than the SOIT results significantly between the different geomembrane samples. The HPOIT values of some products returned erratic results, so those results were considered to be secondary indicators only.

6.1.3 *Stress crack resistance*
The following observations were made related to SCR testing:

- The rate of change of SCR of the different samples varied significantly. The SCR of some samples reduced by more than 50 % over the immersion period, while others only reducing by approximately 20 %.

- Some samples resulted in apparent increased SCR with time. Research undertaken by Rowe *et al.*, indicates such changes in the SCR trend of some samples is explained by the initial stages of material relaxation after manufacture before stabilising for an extended period of time, which is referred to as the equilibrium SCR (Rowe *et al.* 2019).

6.1.4 *Oven aging and UV exposure testing*
Samples were also exposed to oven aging and UV testing in accordance with ASTM D 7238 and ASTM D 5721. The UV energy applied in the ASTM test method was correlated to the measured UV energy of the site, to interpolate the test results relative to site conditions. The results of these tests were adopted as an initial screening method for potential samples.

6.2 *Outcomes of laboratory testing of samples immersed in caustic conditions*

6.2.1 *SOIT*
Based on the results of the SOIT testing the following observations were made:

- The initial SOIT values varied between 165 minutes and 291 minutes.
- The retained SOIT values after 84 days immersion at 50°C varied between 85% and 95%
- The retained SOIT values after 84 days immersion at 70°C varied between 39% and 82%
- The retained SOIT values after 84 days immersion at 90°C varied between 8% and 52%

The depletion rates of retained OIT over time at different immersion temperatures varied significantly between the different geomembrane samples.

6.2.2 *HPOIT*
Based on the HPOIT testing results the following observations were made:

- The initial HP-OIT values varied between 165 minutes and 291 minutes.
- The retained HP-OIT values after 84 days immersion at 50°C varied between 69% and 102%
- The retained HP-OIT values after 84 days immersion at 70°C varied between 25% and 99%
- The retained HP-OIT values after 84 days immersion at 90°C varied between 14% and 104%

The depletion rates of retained HPOIT over time at different immersion temperatures varied more significantly than the SOIT results between the different geomembrane samples. Some samples showed no reduction in HPOIT during the testing period.

6.2.3 *NTCL*
The following observations were made related to SCR testing:

- The rate of change of SCR of the different samples varied significantly. The SCR of some samples reduced by more than 95 % over the immersion period, while others showed no reduction to the limits of testing (1000 hours).
- Result of testing for some samples returned higher results for 90°C immersed samples than 50°C and 70°C immersed samples

7 FINDINGS

7.1 *SOIT and HPOIT depletion*

The testing results were used to estimate the rate at which the SOIT properties and HPOIT properties reduced in each geomembrane product (i.e. the depletion rate). The SOIT and HPOIT degradation rates varied for each candidate product.

Using the Arrhenius method, the degradation rates of each product were extrapolated to assess the times to when the stabilisers and antioxidants were considered to no longer providing benefits. Based on the degradation rates developed for each product, the time for each geomembrane product to achieve residual values was estimated for the representative service temperatures, referred to as Stage 1 in the HDPE geomembrane degradation model developed by (Hsuan & Koerner 1998).

7.2 The assessment indicated the following

7.2.1 Acid exposure samples

- A number of the geomembrane candidate products when subjected to pond floor service conditions would retain their stabilisers and antioxidants for at least 20 years, meeting the design life requirements.
- The estimated time for effective depletion of the SOIT and HPOIT stabilisers varied between 1 year and 20 years at a representative service temperature of 40°C for the exposed slopes and crest areas. Only a couple of geomembrane candidate products were considered to meet the required design life.

7.2.2 Mechanical and physical properties

The results of the stress crack resistance, seam strength and tensile properties testing were considered to assess whether changes in the physical and mechanical properties of the geomembrane samples had occurred due to the immersion testing.

The SCR test indicated that some of the samples stress crack resistance had reduced substantially during the immersion testing. This was considered to be a reason to exclude the materials for further consideration in the project. None of the samples showed any meaningful changes in the seam or tensile strengths of the samples subject to the effects of the immersion tests.

7.2.3 Caustic exposed samples

- The estimated time for effective depletion of the SOIT and HPOIT stabilisers (to residual values of 1min and 50min respectively) varied between 7 year and 102 years at a representative service temperature of 25°C. Only a couple of geomembrane candidate products were considered to meet the required design life.
- Similar to the acid exposed samples stress crack resistance, seam strength, Carbonyl Index and tensile properties testing were considered to assess whether changes in the physical and mechanical properties of the geomembrane samples had occurred due to the immersion testing. The SCR test indicated that for some products the samples stress crack resistance had reduced substantially during the immersion testing. This was considered to be a reason to exclude the materials for further consideration in the project. None of the samples showed any meaningful changes in Carbonyl Index or the seam or tensile strengths.

8 CONSTRUCTION QUALITY ASSURANCE MEASURE – 'FINGERPRINT' TESTING

Material composition ('fingerprint') testing was undertaken on a sample of the geomembrane product selected for use in construction of the caustic facility to assess the stabiliser and antioxidant package concentrations for this material. This was then compared to the results of material composition testing undertaken on materials supplied for the works to provide increased confidence that the supplied materials have characteristics consistent with the sample subjected to the accelerated exposure immersion testing program.

9 CONCLUDING SUMMARY
