The immersion testing with site specific solids or liquids showed that different geosynthetic materials result in very different design lives, depending on the composition of the material. The key message is that HDPE materials varies widely and for many projects site specific immersion and associated durability testing is highly recommended to provide confidence that the material can meet the design life of the liner system. Geomembrane manufacturers are highly unlikely to have durability data for complex exposure conditions of facilities, noting that many facilities are required to store a mixture of materials that in combination can have unexpected impact on the durability of materials.

Resiliency of PVC coated polyester geogrid in high pH conditions

L.M. Spencer, Ph.D., P.E. & J. Lostumbo, P.E.
Solmax, Jefferson, Georgia, USA

ABSTRACT: The resilience of mechanically stabilized earth structures in elevated pH backfill conditions have typically been a concern due to the potential for elevated degradation due to hydrolysis. An investigation of the reduction in tensile strength of coated polyester (PET) geogrids exposed to pH of 10 was performed. Arrhenius modeling was used to extrapolate the degradation rate of the geogrid tensile strength to 20°C over a 75-year design life and determine the appropriate reduction factor for durability in higher pH environments. This study also identifies the importance of product specific testing by evaluating two types of PET geogrids and the limitations of only using CEG and molecular weight as guidelines for determining reduction factors. The two geogrid types exhibited distinctly different tensile strength degradation. The disparity in tensile strength degradation confirms the importance of the materials and the geogrid manufacturing processes in selecting appropriate durability reduction factors for field applications.

1   INTRODUCTION

The reuse of crushed concrete as reinforced backfill in MSE walls and reinforced slopes is a sustainable use of otherwise waste material. Utilizing recycled concrete reduces the need for high-quality imported materials, lowering the carbon footprint. However, using recycled concrete necessitates additional product testing to determine the long-term durability of the geogrid reinforcement.

According to the most recent EPA (2020) Advancing Sustainable Material Management 2018 Fact Sheet, 405 million tons of construction and demolition (C&D) concrete waste were generated, with 381 million tons of that being demolition debris. 71 million tons of concrete waste were disposed of in a landfill, while 301 million tons were reused as aggregate. This aggregate can be used as reinforced backfill for MSE walls.

Calcium silicate hydrates (CSH) and calcium hydroxide are produced during the chemical process of cement hydration. The presence of these compounds causes an elevated pH in the concrete structure. When concrete is exposed to air, carbonic acid is formed due to the presence of carbon dioxide (CO_2) in the air and free water within the concrete matrix. The calcium hydroxide then reacts with the carbonic acid to form calcium carbonate. The pH of the concrete decreases as the carbonation front moves through it due to the formation of calcium carbonate (Richardson 2002). Due to the increased surface area exposed to air in a crushed concrete structure versus an intact concrete structure, this carbonation process will accelerate. Even though crushed concrete is exposed to air and has the potential for pH reduction due to carbonation, using crushed concrete as reinforced backfill in MSE walls introduces the possibility of accelerated geogrid degradation due to elevated pH levels.

The mechanism by which polyester tensile strength is lost occurs during the reverse reaction known as hydrolysis. When terephthalic acid and ethylene glycol react, they produce polyethylene terephthalate (PET) and water. Because this is an equilibrium reaction, it is

DOI: 10.1201/9781003386889-81

reversible, so PET can react with water to reverse the reaction and return to ethylene and glycol. This reverse reaction is irreversible. The rate of this reaction is influenced by the carboxyl end group (CEG) concentration, molecular weight, temperature, humidity, and pH of the environment (FHWA 2009; Hsuan *et al.* 2008). The presence of more OH- ions speeds up the hydrolysis reaction when the pH of the environment is higher. The OH- ions will react with the polymer chain, causing the chain to split. This reaction reduces the molecular weight and reduces tensile strength (Elias *et al.* 1998).

The long-term strength loss due to degradation is accounted for by applying reduction factors to the ultimate tensile strength. The tensile strength used in the design of reinforced soil structures is known as the long-term design strength (LTDS). This value is derived from product-specific testing and is calculated by Equation 1 in accordance with AASHTO R69 (AASHTO 2015).

$$LTDS = \frac{T_{ult}}{RF_{CR} \times RF_{ID} \times RF_D} \tag{1}$$

where T_{ult} = ultimate tensile strength (MARV); RF_{CR} = reduction factor for creep; RF_{ID} = reduction factor for installation damage; and RF_D = reduction factor for durability.

The tests to determine the reduction factors are performed by third-party accredited laboratories. They involve measuring the strength loss due to creep, the strength loss over time caused by supporting a sustained load, and installation damage, the abrasion and strength loss due to backfill soil compacted over the geogrid. The reduction factor for durability, on the other hand, is a default reduction factor established by the Federal Highway Administration (FHWA) based on the material properties of the polyester yarn used to construct the PET geogrid and the pH of the soil backfill.

Polyesters with a higher molecular weight and lower CEG are less prone to hydrolysis (Elias *et al.* 1998). To minimize strength losses due to hydrolysis over the design life of the structure, the FHWA recommends PET geogrids have a minimum molecular weight of 25,000 and a maximum CEG of 30. FHWA also restricts the use of PET geogrids to soils with a pH less than 9, based in part on Elias' testing of a specific PVC coated PET geogrid (1998). FHWA 09-087 (FHWA 2009) does, however, allow for product-specific testing for the use of coated PET geogrids outside of the outlined yarn properties or in pH conditions other than 3 to 9.

The test program conducted by Elias (1998) used a PVC coated polyester geogrid with a CEG of 26.7 and a molecular weight of 30,200. The rate of strength degradation that occurred in the Elias testing for a pH of 10 and 12, was 0.17% per year and 1.61% per year, respectively.

2 MATERIALS AND METHODS

This paper outlines the testing performed on two PVC coated high tenacity polyester uni-axial geogrids (Geogrid A and Geogrid B). The PET geogrids are manufactured by different companies, therefore used different polyester yarn, different PVC coating, and different construction methods. The physical properties of the Elias PET geogrid and Geogrids A and B from this study are in Table 1. The geogrid was exposed to high pH aqueous solutions at elevated temperatures over time to determine the 75 to 100-year design life durability reduction factor to be used in the LTDS calculation per AASHTO R69 (AASHTO 2015).

Table 1. Physical properties of Elias (1998) and Geogrids A & B in this study.

Geogrid Tested	Geogrid Description	Carboxyl End Group (CEG) (meq/kg)	Average Molecular Weight	Mass/Unit (g/m^2)
Elias (P-6)	PVC-coated PET Fiber	26.7	30,200	334
Geogrid A	PVC-coated PET Fiber	15.2	34,855	271
Geogrid B	PVC-coated PET Fiber	14.2	33,320	280

Geogrid A & B were tested in accordance with ISO/TR 20432 and ISO/TS 13434. The PET geogrid samples were immersed in aqueous solutions held at a pH of 11.4. The aqueous pH solution was maintained at three temperatures: 40°C, 50°C, and 60°C. In each temperature environment, 35 samples were exposed. At predetermined time intervals, samples were removed from the aqueous solution and subjected to single rib tensile strength tests per ASTM D6637.

Geogrid coupons were hand cut from the geogrid roll with scissors; each coupon was 7 ribs wide and 42 inches long. The coupons were distributed among the chemical solutions and test temperatures. The samples were rolled loosely within the glass jars to allow for contact with the immersion chemical solution. The geogrid's cut ends were not covered and were exposed to the solution.

Preparation of the elevated pH solution began by calculating the amount of powdered calcium hydroxide necessary to produce the desired pH level of 11.4. Calcium hydroxide was weighed using an analytical balance and mixed with a placed in a small container. A drill mounted "paint" mixer was used to mix a specified volume of water and the measured calcium hydroxide powder. Once mixed, the pH of the solution was measured with a digital pH meter to confirm that the pH was correct. The calcium hydroxide solution was poured into the specimen jars, the jars were filled completely to limit headspace then sealed. Sealed jars were then placed in temperature chambers with fans and heaters located within the temperature chamber. The heaters were controlled with digital temperature controllers to maintain consistent temperatures during the full geogrid exposure time. Specimen jars were checked at least weekly and additional pH solution was added if needed and the jars were resealed. Solutions were replaced with new solution prepared as described above at each test interval.

Specimen coupons were removed at each test interval. The coupons were rinsed with water and then allowed to dry and condition at laboratory temperature for at least 48 hours. Single rib tensile properties were measured in accordance with ASTM D6637, Method A.

Multiple samples were taken at each elapsed time period for each temperature environment. Each sample underwent tensile strength testing to determine the strength loss in comparison to the baseline ultimate strength. The number of samples used in calculating the average tensile strength loss for a particular time/temperature environment varied from 3 to 5 samples.

A summary of the number of coupons obtained at each time interval is in Table 2. Three to five samples were pulled and tested at each time interval to determine the average strength loss. Where lower sample numbers were used to determine the average strength, it was to keep the limited number of samples remaining in the aqueous solution for later time interval pulls.

Table 2. Samples taken at each time interval to calculate the average tensile strength loss.

	Number of Samples to Determine to determine average tensile strength loss for 40°C/50°C/60°C						
Elapsed Time (months)	1	2	4	10	16	26	37
Geogrid A	5/5/5	5/5/5	5/5/5	5/5/5	5/5/5	5/5/5	3/3/3
Geogrid B	5/5/5	5/5/5	5/5/5	4/4/4	5/5/5	5/5/5	3/3/3

The data used in the Arrhenius modeling plots was the average tensile strength loss of the samples taken at that specific time and temperature. This research has been ongoing for over three years. By exposing the samples to the pH solution at higher temperatures, the time-temperature superposition principle can be used to extrapolate the tensile strength loss due to hydrolysis to 20°C over a longer time period, in this case 75 years (FHWA 2009).

3 RESULTS AND DISCUSSION

3.1 *Test results*

Arrhenius plots were created for each tested geogrid to determine the time required to achieve a specific strength loss extrapolated to 20°C (FHWA 2009). The average tensile strength retained obtained from single rib tensile tests of the exposed geogrid is plotted on a natural log scale versus time, as shown in Figure 1. The fit lines for each temperature obtained from this plot are used to determine the time to a certain percentage strength loss.
Figure 1.   Average tensile strength retained for Geogrid A in pH 11.4.

To extrapolate the time to reach a specific percent retained strength (of tensile ultimate strength) at 20°C, Arrhenius plots, a log plot of the time to reach a specific percent strength retained versus the inverse of absolute temperature (1/K), were developed for a range of percent strength retained values. An example plot of Geogrid A at 80% strength retained at a pH of 11.4 is shown in Figure 2.
Figure 2.   Arrhenius plot for Geogrid A at 80% strength retained at pH 11.4.

Arrhenius plots for Geogrid A were developed for retained strengths ranging from 95% retained to 20% retained, and Geogrid B plots were developed for retained strengths from 90% to 10% retained. These were used to determine the time to reach that specific retained strength at 20°C. The results were then compiled to obtain a degradation curve for a pH value of 11.4. The degradation curve plots the natural log of percent strength retained versus time at the reference temperature of 20°C. The degradation curve for Geogrid A is shown in Figure 3 and for Geogrid B in Figure 4. The reduction factor for durability in a pH environment of 11.4 is determined from these degradation curves and can be used in the calculation of LTDS. This
Figure 3. Degradation curve of Geogrid A in pH 11.4.
Figure 4. Degradation curve of Geogrid B in pH 11.4.

testing allows the reduction factor to be determined at different design life periods, up to 1,000,000 hours (114 years).

To calculate the reduction factor for durability, the design life should be known. An example reduction factor calculation is outlined using a design life of 75-years. The percent retained strength for Geogrid A at a pH of 11.4 at 75-years (657,000 hours) is 64.8%. The calculation for the 75-year design life of Geogrid A at a pH of 11.4 reduction factor for durability is shown in Equation 2.

$$RF_{DpH11.4} = \frac{100\%}{64.8\%} = 1.54$$ (2)

The percent retained of Geogrid B at a design life of 75-years at a pH of 11.4 was 25.3%, which equates to a reduction factor for durability for Geogrid B of 3.96.

3.2 Discussion

For reference, the Elias (1998) study showed a strength loss of 0.17%/year for the pH 10 solution, which is a strength loss of 12.75% over a 75-year period. The pH 12 solution loss was 1.61%/year, meaning there is no strength retained after approximately 62 years. However, it is difficult to compare to the Elias (1998) test results to the degradation in this testing program due to the different pH values.

Geogrid A had similar, albeit slightly higher, CEG and molecular weight with a lower mass/unit area than Geogrid B but had a marked greater resistance to elevated pH degradation. This indicates that more than just the physical properties of the polyester yarn used in the geogrid construction affects the degradation rate. This indicates the manufacturing

process, including the PVC coating, is important in determining the durability of coated polyester geogrid to elevated pH environments.

ISO 20432 (2007) notes that laboratory assessment of hydrolysis of polyesters should be performed on uncoated yarns; however, it also says, "Take care that the conditions during the accelerated tests are representative of those in service. There should be no change in the mechanism of degradation or in the physical structure of the material; and no barrier layers should form or be present that might retard the degradation process in a manner that does not occur in service." The method of testing uncoated polyester yarn is not representative of field conditions and as indicated in this study would discount the degradation resistance with the PVC coating. Further, Elias (1998) used PVC coated polyester in the accelerated durability testing that was used in the determination of the FHWA acceptable pH range.

The current test procedure is overly conservative and does not consider how carbonation will change the pH of the backfill overtime. To more accurately determine the tensile strength loss of in-service polyester geogrid, future testing should evaluate how to incorporate installation damage on coated polyester geogrid in accelerated durability testing.

4 CONCLUSIONS

The study evaluated the resistance of two different PVC coated polyester geogrids to strength loss due to elevated pH conditions. The reduction factor for durability for a pH of 11.4 and a 75-year design life for Geogrid A is 1.54 and for Geogrid B is 3.96. The CEG and molecular weight of the two geogrid samples were similar, thus indicating more than the physical properties of the polyester yarn determine the degradation rate. Therefore, degradation curves obtained from accelerated durability testing are only applicable for the specific geogrid and pH environment tested. The current degradation testing procedure does not adequately model the in-service condition and the method of testing uncoated polyester geogrid is overly conservative in comparison to field conditions.

Interaction between the PVC-P and HDPE geomembranes used in the waterproofing and re-waterproofing of a reservoir

B. Mateo, A. Leiro & R. Solera
CEDEX, Madrid, Spain

T. Vara & D. Cabrera
BALTEN, Tenerife, Spain

ABSTRACT: The Buen Paso reservoir, located in the island of Tenerife (Spain), was waterproofed with a PVC-P geomembrane with a polyester fabric. After 66 months, due to its poor condition, caused by a rapid loss of plasticizer, it was decided to re-waterproof the reservoir with a HDPE geomembrane, which was placed directly over the PVC-P geomembrane, without any kind of geosynthetic between them. The placement of the two geomembranes, in direct contact, makes the Buen Paso reservoir an opportunity to study the possible interaction between the two materials. To study the possible interaction between HDPE and PVC-P geomembranes, samples of the PVC-P geomembrane were extracted under the HDPE geomembrane and the content of plasticizer was determined. In addition, migration tests were performed on HDPE samples according to the UNE-EN ISO 177 standard. It has been proven that the PVC-P geomembrane has continued losing plasticizer and the migration of plasticizer to the HDPE geomembrane.

1 INTRODUCTION

The Buen Paso reservoir was built in 1989. It is located on the island of Tenerife (Spain) and has a capacity of 150,788 m^3. The reservoir was waterproofed with a PVC-P geomembrane reinforced with a 1.2 mm thick polyester thread fabric, which originally met of the requirements demanded at that time for this type of material. Once installed, periodic monitoring was carried out, the results of which led to the deduction, 66 months after its placement, that the reservoir had to be re-waterproofed due to its state of deterioration.

The re-waterproofing was carried out in 1995 with a HDPE geomembrane, which was placed directly over the PVC geomembrane, without any type of separating geosynthetic material.

Keeping the old geomembrane can be an extra element of protection against mechanical actions of the support, but it is necessary to guarantee that there are no chemical interactions between both materials (Aguiar 2015). In the case of the Buen Paso reservoir, considering the location of the reservoir, on an island, the removal of the vinyl material was difficult and made the work considerably more expensive, so it was decided to leave the old sheet, and place the new geomembrane above it.

The placement of another PVC-P geomembrane was discarded, due to the tendency of the plasticizers of the upper layer to migrate to the lower one, as has been experimentally verified in other reservoirs in Spain (Blanco *et al.* 2006) so it was decided to use an HDPE geomembrane.

The re-waterproofing was carried out with a 2-mm-thick HDPE geomembrane that was anchored at the crest under a perimeter ditch and at the berm and bottom using curb-type concrete ballasts. No type of geosynthetic material was placed between the two

DOI: 10.1201/9781003386889-82

geomembranes as a separator, since at that time it was considered that there would not be interaction between the two materials.

In Spain there are several references to reservoirs that were initially waterproofed with a PVC-P geomembrane and later re-waterproofed with an HDPE geomembrane (García 2004; Méndez *et al*. 2008), but these cases differ from the Buen Paso reservoir in that a geotextile was placed between the two geomembranes. The case of the Buen Paso reservoir, with the geomembranes in direct contact, is an opportunity to study the interaction between both materials.

2 PREVIOUS STUDIOS OF THE GEOMEMBRANES OF BUEN PASO RESERVOIR

The Central Laboratory for Structures and Materials of CEDEX has been studying the performance of the waterproofing system of Buen Paso reservoir since its construction, both initial PVC geomembrane and HDPE re-waterproofing one. This study includes carrying out a series of tests on samples taken from the reservoir over time.

2.1 *Performance of the PVC-P geomembrane*

In the case of the PVC geomembrane, one of the most important tests that have been carried out over time is the determination of the loss of plasticizer, since it is the main cause of deterioration. Although the PVC-P geomembrane initially met the requirements for its use in waterproofing reservoirs, a continuous and rapid loss of plasticizers was observed. After 66 months from its installation, the loss experienced was 56.3% at the crest and 55% in the intermittent zone of the northern slope of the reservoir (Figure 1).
Figure 1. Loss of plasticizer and decrease of tensile strength of the PVC-P geomembrane over time. NC: North Crest, NI: North Intermediate, L: longitudinal, T: transverse.

The loss of plasticizer led to a decrease in mechanical resistance (Figure 1) and elongation, as well as the detection of failures in the bending tests at low temperatures and dynamic impact. Simultaneously, the samples began to show deterioration symptoms, such as cracks, changes in color, and loss of resin, leaving the reinforcement of polyester threads exposed to the air.

The nature of the plasticizer was determined by IR spectroscopy and gas chromatography-mass spectrometry techniques. The plasticizer used in the geomembrane was bis(2-ethylhexyl) phthalate, which has a molecular weight of 390.56 g/mol, lower than the value of 400 g/mol, recommended to ensure the durability of geomembranes, and a branched structure, which makes it highly prone to migration, especially in the air. This was the cause of the great loss of plasticizer and the rapid degradation of the geomembrane.

2.2 *Performance of the HDPE geomembrane*

Once the re-waterproofing was carried out with the HDPE geomembrane, placed over the PVC-P one, follow-up controls continued in the new geomembrane. Characterization tests

were periodically carried out on samples extracted from the reservoir, which included tensile strength and elongation, static and dynamic impact, oxidation induction time (OIT), and resistance to stress cracking.

216 months after its installation, the geomembrane continued to meet the requirements for use in waterproofing with respect to the physical and mechanical characteristics, but cracks began to appear in the crest area of the reservoir, where the change in direction of the geomembrane occurs and it is subjected to the greatest stress. The cracks were found at the top of both slopes, although to a greater extent on the north slope (Figure 2).

Figure 2. Crest zone of the Buen Paso reservoir, where the geomembrane changes direction and cracks are detected, and examples of cracks.

The values of stress cracking resistance obtained were very low: 24 h in north crest and 26 h in south crest, not meeting the value required by the regulations (336 hours). The values of the OIT were also lower than 100 minutes, minimum value required, in all areas of the reservoir.

3 STUDY OF THE INTERACTION BETWEEN PVC-P AND HDPE GEOMEMBRANES

In the areas where the cracks appeared, a series of symptoms were detected that could indicated that some type of interaction may be occurring between the HDPE and PVC-P geomembranes. When the first cracks were detected, it was observed that the temperature between the geomembranes was very high. Subsequently, a system of breathing tubes was installed in the crest zone and even so, temperatures above 50ºC were recorded. Also, oily spots appeared around some cracks. For this reason, a series of tests were carried out aimed at studying the influence of the presence of the PVC-P geomembrane under the HDPE geomembrane, to determine the possible interaction between them and verify how this interaction could affect to the durability of the reservoir's waterproofing system.

216 months after the installation of the HDPE geomembrane, when cracks began to be detected in the northern crest, samples of the PVC-P geomembrane were taken from the crest and intermittent areas of the northern slope. They were also extracted at 258 months, in this case from the north and south crest zones, since there are currently cracks in the crest of both slopes, although mainly in the north. In addition to check the state of degradation of the PVC-P geomembrane, the plasticizer content and the HDPE geomembrane migration test were performed on the extracted samples according to the UNE-EN ISO 177 (AENOR 2001) standard.

3.1 *State of the PVC-P geomembrane*

Figure 3 provides the poor condition of the PVC-P geomembrane once the sample of the HDPE geomembrane was extracted, in the north crest.

Figure 3. Appearance of the PVC-P geomembrane under the HDPE geomembrane in the crest area of the north slope at 216 months.

The sample from the coronation was in worse condition than that from the intermittent zone. In both samples, the external face (in contact with the HDPE geomembrane) shows a greater state of degradation than the internal face and higher than that shown by the geomembrane before re-waterproofing.

258 months after the re-waterproofing, the PVC-P geomembrane was once again sampled. On this occasion, the extraction has been carried out in the crest area of the north and south slopes. Figure 4 corresponds to the sample from the crest of the north slope.

Figure 4. PVC-P geomembrane sample extracted from the north slope crest 258 months after re-waterproofing. A: external face, in contact with the HDPE geomembrane, B: internal face, in contact with the geotextile, C: detail of the state of the external face of the geomembrane.

The sample shows a higher state of degradation on the external face, in contact with the HDPE geomembrane. It presents a state of stiffness and deterioration superior to that shown by the sample extracted from the same area at 216 months and as can be seen in Figure 4 C, the polyester threads are almost completely separated of the resin and very deteriorated.

3.2 *Loss of plasticizer*

The extraction of the plasticizer was carried out using Soxtec equipment. Figure 5 provides the results of the loss of plasticizer experienced by each sample of PVC-P geomembrane, before and after re-waterproofing with the HDPE geomembrane. In the case of the sample from the crest of the southern slope, the evolution over time is unknown because no sample had previously been taken from this area of the reservoir.
Figure 5. Evolution of the loss of plasticizer experienced by the samples of the PVC-P geomembrane. NC: North crest, NI: North intermediate, SC: South crest.

3.3 *Plasticizer migration test to HDPE geomembrane*

The study of the plasticizer migration from the PVC-P geomembrane to the HDPE geo-membrane was carried out using the UNE-EN ISO 177 (AENOR 2001) standard test. In this test, the set of test pieces, on which a 5 kg weight is placed, is heated to 70 °C (Figure 6). PVC-P geomembrane samples extracted after re-waterproofing were used, at 216 and 258 months, with different plasticizer contents, and HDPE geomembrane samples extracted from the north slope at 216 months. Various combinations were made with them to determine the influence of the plasticizer content. Table 1 presents the combinations studied.

Figure 6. Plasticizer migration test. Arrangement of the test pieces in the combination that includes a separator geotextile, for carrying out the plasticizer migration test.

Table 1. Combinations of HDPE and PVC-P geomembranes samples used to perform the plasticizer migration test. NC: north crest, NI: intermittent north zone, NF: north bottom, SC: south crest.

	Samples of PVC-P geomembrane (extracted under HDPE geomembrane)	
Samples of HDPE geomembrane (extracted at 216 months)	Plasticizer content, %	Zone/Extraction time
North crest	3,8	North crest / 216 months
North crest	10,0	North intermittent/ 216 months
North bottom	10,0	North intermittent/ 216 months
North crest	14,9	South crest / 258 months
North crest+ Geotextile	14,9	South crest / 258 months

In the last combination, a polypropylene geotextile was placed as a separation between each HDPE geomembrane specimen and the PVC-P specimen, as shown in Figure 6. In the rest of the combinations, the PVC-P geomembrane specimen was in direct contact with the HDPE specimens.

The measurement of plasticizer migration is considered as the mass loss of the PVC-P specimen. If the migration to HDPE is complete, it will coincide with the increase in mass of the HDPE geomembrane specimens, although a difference is normally observed in the weights that coincides with the loss of volatile substances. To study the progress of migration as a function of time, the specimens were weighed at different intervals. The results are presented in Figure 7.

It can be seen in Figure 7 that the higher the plasticizer content of the PVC-P geomembrane sample, the greater the tendency to migrate to the HDPE geomembrane and
Figure 7. Weight gain experienced by the HDPE geomembrane depending on the plasticizer percentage of the PVC-P geomembrane sample.

consequently the increase in weight of the HDPE geomembrane. There is always a loss corresponding to volatile substances, which may be a part of the plasticizer that migrates into the air. This loss decreases as the plasticizer content of the PVC-P sample increases.

These results indicate that there is interaction between the two geomembranes, producing the migration of plasticizer from the PVC-P geomembrane to the HDPE one.

To verify the effectiveness of the interposition between the geomembranes of a protection barrier, in the last combination studied, two non-woven polypropylene geotextile test tubes have been placed between them, as shown in Figure 6. The HDPE specimens in this case practically do not experience weight variation, thus confirming the effectiveness of the geotextile as a barrier to prevent interaction between the geomembranes.

3.4 Discussion of the results

After re-waterproofing of the Buen Paso reservoir, although the PVC-P geomembrane has been covered by the HDPE geomembrane, it has continued to lose plasticizer, as indicated by the results of plasticizer loss obtained in samples taken from various areas of the reservoir. It has been observed that the higher the plasticizer content, the greater the tendency to migrate to the HDPE geomembrane, so probably the greatest migration occurred during the first months after re-waterproofing.

The interaction between both geomembranes, which has led to the migration of plasticizer, as well as the high temperatures recorded between the two sheets, has been able to influence the degradation of both geomembranes, mainly on the crest of the north slope. The PVC-P geomembrane has continued to deteriorate under the HDPE geomembrane, as has been verified by checking the condition of the extracted samples. Likewise, because of the interaction between the geomembranes and the migration of plasticizers, the degradation of the HDPE geomembrane has accelerated, favoring the appearance of cracking due to "stress cracking".

4 CONCLUSIONS

- After re-waterproofing the Buen Paso reservoir with a HDPE geomembrane, which was placed in direct contact with the initial geomembrane of PVC-P, the PVC-P geomembrane has continued to lose plasticizer and deteriorate under the HDPE geomembrane.
- The migration of plasticizer from the PVC-P geomembrane to the HDPE geomembrane has been confirmed, observing that the higher the plasticizer content, the greater the tendency to migrate.
- The use of a geotextile between the HDPE and PVC-P geomembranes would have delayed the interaction between them and therefore the migration of plasticizers from the PVC-P to the HDPE geomembranes.

ABSTRACT: The aim of this research was to compare the performance of cotton textiles when exposed to different environmental conditions namely categories "A" to "G", herein. The testing method complied with standard soil burial methods. The tensile strength of the cotton samples was examined after one week buried in different soil conditions, including gravel only (without compost), top soil only, top soil with 3, 6, 10 and 30% compost. Also, to investigate the effect of water drainage, the top soil with undrained condition was considered. Generally speaking the tensile strength of the samples was reduced due to biodegradation after one-week exposure. Moreover, the results highlighted the important role of water in degradation of the samples. Moreover, the reduction in tensile strength of the buried specimen were very low (few percent) for small percentage of compost and therefore, the presence of 30% compost in soil was resulted in 75% tensile strength reduction for the proposed cotton samples.

1 INTRODUCTION

The successful use of geosynthetics, as one of the most important constructing materials in geotechnical projects such as embankments over soft subgrades, road construction, slopes, retaining walls and railroads have been (Cardile *et al.* 2017; Moghaddas Tafreshi *et al.* 2011, 2015; Tavakoli Mehrjardi & Sardehaei 2017; Tavakoli Mehrjardi & Moghaddas Tafreshi 2020; Tavakoli Mehrjardi *et al.* 2012, 2013, 2015, 2016, 2018, 2019, 2020). Todays, geosynthetics are mostly made of Petro-based polypropylene (PP) or polyethylene terephthalate (PET). The dependence on petroleum as a raw material is controversial from social, political and ecological points of view. Therefore, bio-based biodegradable textiles can play a pivotal role in different types of temporary and even permanent earthwork structures such as traffic routes, shorelines and especially on slopes to be re-cultivated in opencast mines. For example, newly constructed, unvegetated slopes and embankments are protected against erosion due to wind and precipitation. The use of geotextiles increases the shear and flow resistance of the mostly uncompacted upper soil layer against surface erosion. This ensures the initial erosion protection until this function is taken over by natural vegetation after two to three vegetation periods.

Since the bio-degradable textiles should be designed for applications ending up in or on soil, therefore the durability and degradability of the textiles should be investigated towards passing the time. Several International Standards specify test methods to determine the

ultimate aerobic or anaerobic biodegradation of textiles in aqueous or compost conditions (DIN EN 12225, ISO 17556, ISO 11721-1, 2). DIN EN 12225 mentions that if the requirements for appropriate functioning of the geosynthetics demand proof of microbiological resistance or if they are manufactured from newly developed polymers whose resistance is in any doubt, the soil burial test should be performed. In order to examine the biodegradability of a bio-degradable textile by the soil burial test, the suitability of soil, in terms of the soil biological activity, should be firstly assessed by testing cotton fabrics. This study aims to discuss about the effect of compost percentage in degradability of a cotton-like textile buried in soil. Moreover, we will inspect the applicability of the current standard.

2 TEST MATERIALS

2.1 *Soils*

Two types of soils as filling materials with the medium grain size (D_{50}) of 60 and 8 mm were considered. A few technical parameters of the soils are tabulated in Table 1.

Table 1. Technical properties of soils used for burial test.

Characteristic	Unit	Testing Method	Gravel	Top Soil
Finer than 0.002 mm	%	DIN 18123	0.5	10
Specific Gravity	——		2.67	2.65
Loss on ignition	%	DIN 18128	0.73	2.76
Carbonate content	%	DIN 18129	1.58	0.53
Calcite content	%		0.58	0.43
Dolomite content	%		1	0.11
Lime content	——		Very low in lime	Lime-free
Soil Type	——	DIN 4022	S/G	U,s,t`,fg`

2.2 *Cottons*

Woven cotton fabric (bleached and de-sized) with the nominal mass per unit area 235 g/m^2 was utilized.

2.3 *Compost*

A kind of humus compost (plant materials from gardening and landscaping) with grading size of 0-10 mm, was utilized. The compost includes different types of nutrients, notably nitrogen = 0.65 %, phosphate = 0.25, potassium oxide = 0.48 %, zinc = 0.012%, Iron = 0.60%, Manganese = 0.02 %. The C/N ratio of the compost was 20:1.

3 TEST SETUP, INSTRUMENTATION AND TEST PROCEDURES

In this study, two steps including burying stage and tensile tests were carried out. In order to exposing the cotton samples to the soil environment, According to DIN EN 12225, ten strip specimens of the cotton fabric were buried and kept in each of the testing soils for a period of seven days. Testing soils were included with gravel only (without compost), top soil only, top soil with 3, 6, and 10% compost. All the soils were drained from the bottom of the boxes. Also, to investigate the effect of drainage, the top soil with undrained condition was

considered. The top soil-compost composite was obtained by mixing the soil with relevant percentage (by weight) of compost at the natural moisture content. Moreover, five control strip specimens were stored at temperature (24) °C and relative humidity (40 ± 10) %. After seven days, the buried specimens were exhumed and submerged in an ethanol-water solution (70:30) for 300 s. Then, all the specimens were dried for 72 h in the room atmosphere. Figure 1 illustrates two selective photos for this stage.

Figure 1.   Photos for soil burial test (a) buried sample, and (b) dried samples.

After drying the samples, the tensile strength of the specimens should be assessed. As shown in Figure 2, the tests were performed on a tensile testing machine under standard climate conditions in accordance with DIN EN ISO 139. The clamping length at the start position is 50 mm. A pre-load of 5 N was applied. The specimens were loaded at a rate of 25 mm/min up to a force cut-off threshold of 75% of the maximum load.
Figure 2.   Photos for tensile tests.

4   RESULTS AND DISCUSSIONS

As it mentioned, 70 tensile tests divided in seven categories were carried out. Figure 3 illustrates the force-elongation plots for categories "A" and "D". As can be seen, the samples reached a peak strength at different strain levels and then, the tensile force dropped suddenly, ending up to the breakage state.

Table 2 presents the variation of different parameters, notably the weight of the samples after exhumation, PH of the soils, and tensile strength of the samples for the examined

categories. At it can be seen, the PH of all samples were in the range 6.80 to 6.95 which were quite similar for all the categories. Moreover, the weight of the samples for all categories, apart from category "D", were similar (7.9 g) and a bit more in comparison with the weight of virgin samples (7.6 g in category "A"). Based on the obtained values and visual inspection of the samples after exhumation and also, considering three scenarios for calculation of the mean value of peak tensile strength (refer to footnote of Table 2 and Figure 4), the following hints can be pointed out:

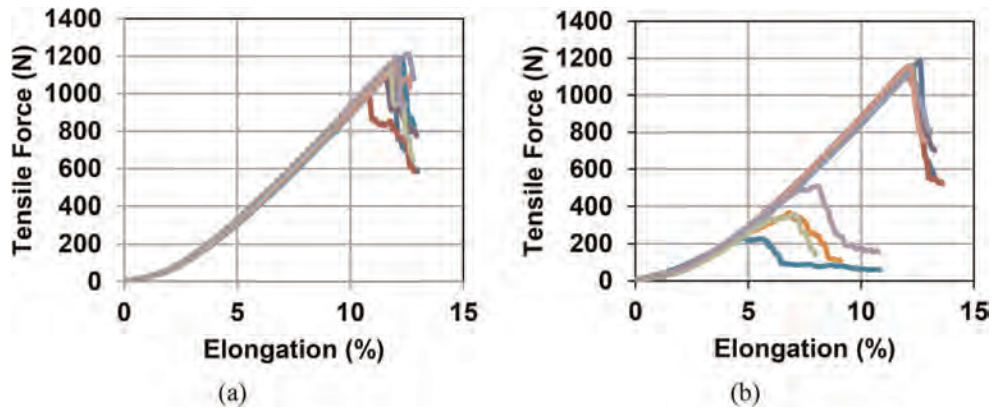
- Some samples in specified categories including "B", "D" and "G" witnessed clamp failure during tensile tests, giving rise to a kind of pre-mature failure. Therefore, from technical


Figure 3.   The force-elongation curves of the tensile tests for categories (a) "A" (b) "D"

Table 2.   A summary of testing results of the examined categories.

Category	Testing Conditions	Weight (g)	PH	Min-Max[1]	Tensile Strength (N) Mean value[1]	Mean value[2]	Mean value[3]	Reduced Strength[1] (%)	Reduced Strength[3] (%)
A	Virgin	7.6	——	1008–1213	1139 (0)[4]	1139	1139	0	0
B	Gravel	7.9	6.79	1080–1154	1107 (4)	1075	1107	2.8	2.8
C	Drained Top Soil	7.9	6.89	960–1183	1100 (0)	1100	1100	3.4	3.4
D	Top Soil + 3%C	7.5	6.82	232–1159	749 (4)	833	1132	34.2	0.6
E	Top Soil + 6%C	7.9	6.85	1128–1226	1155 (0)	1155	1155	-1.4	-1.4
F	Top Soil + 10%C	7.9	6.94	618–1170	1066 (0)	1066	1122	6.4	1.5
G	Undrained Top Soil	7.9	6.79	1046–1125	1085 (8)	1005	1085	4.7	4.7

Notes
[1]Clamp failures excluded.
[2]Clamp failures included.
[3]Clamp failures and out of range data excluded.
[4]Number of tests witnessed clamp failure (out of 10 tests for each category).
Figure 4.   Mean values of tensile strength for different categories and scenarios.

point of view, the results of the tests having clamp failure should be excluded so as to have an impair comparison.

- According to Table 2, the tensile strength of the samples, apart from category "E", was reduced due to degradation after one-week exposure. Be that as it may, the reduction ranges are not as high as it should be for a degrading soil. In effect, according to DIN EN 12225, the tensile strength of the cotton strips shall be ≤ 25 % of the original tensile strength after exposure for 7 days. However, this level of degradation cannot be expected even with mixing the natural soil with ten percent of compost. In the line with this claim, Margariti (2020) showed that there was no change in the thread diameters of the cotton textile samples before and after burial in soil.

- Category "G" in comparison with category "C" experienced the largest number of premature failure. This matter highlights the important role of water in degradation of the samples.

- Amongst all, category "D" (top soil mixed with three percent of compost) faced the highest reduction in tensile strength. Although the specimens adsorbed fine materials, the weight of the samples in this category was smaller than the others. Based on visual inspection, color difference (red color) was detected in few buried samples of this category which can be due to presence of few degrading grains in the soil or compost. Tomšič et al. (2007) stated that the smaller the color change, the more slowly the samples are degraded (Arshad et al. 2014).

- A significantly higher standard deviation can also be seen. The ratio of the standard deviation to the mean value of the maximum force is 2-6 %. In order to consider the data with enough precision, in one of the scenarios, the data being out of range in comparison with the other values in the same category was removed. In this scenario, the test results with clamp failure were also disregarded. Considering this scenario, which can be more reasonable, samples in category "D" had roughly the same reduction factor as others had.

As a whole, following the soil burial testing method prescribed by the standards, it was understood that the examined admixtures of soil and compost did not cause a considerable reduction on the tensile strength of the cotton samples. According to DIN EN 12225, since the tensile strength reduction was less than 75%, the biological activity of the soil was enhanced by increasing the percentage of the compost to 30% and the samples were exhumed and examined after one and two weeks. As Figure 5 shows, the tensile strength of the samples was decreased about 74% and 95% for the samples with one- and two-week exhumation.
Figure 5.   Mean values of tensile strength for different categories and scenarios.

5 CONCLUSIONS

The biodegradation of cotton samples under the attack of microorganisms present in different soils was studied by using standard burial method where textile materials were directly buried for a period of seven days. Visual observations and tensile tests on the samples after exhumation revealed that:

- The tensile strength of the samples was reduced due to degradation after one-week exposure.
- Samples subjected to undrained condition experienced the largest number of pre-mature failure. This highlights the important role of water in degradation of the samples.
- The reduction in tensile strength of the buried specimen were very low (few percent) for small percentage of compost and therefore, the presence of 30% compost in soil was resulted in 75% tensile strength reduction for the proposed cotton samples.

White polyethylene geomembrane: Forensic and laboratory evidence for superior durability

B. Ramsey
Boyd Ramsey Consulting LLC, Houston, TX, USA

A. Maskal
Solmax, Visalia, CA, USA

ABSTRACT: White Polyethylene Geomembranes have been available in the market for over two decades and have been used broadly, often exposed (uncovered) in demanding and sensitive applications. The performance of these materials has far exceeded the initial (circa 1990's) exceptions. There is increasing evidence that the durability and lifespan of a white geomembrane in an exposed application is longer, not only than projections, but perhaps longer than that of traditional black colored geomembranes of comparable composition. This paper presents data in support of that hypothesis and reaches the conclusion that in exposed applications, white surfaced geomembrane is the material of choice, based on durability as well as other pertinent considerations. Data and evidence from forensic evaluations as well as laboratory testing for durability is presented and new estimates on lifespan are presented.

1   INTRODUCTION

White Polyethylene Geomembranes have been available in the market for over two decades and have been used broadly, often exposed (uncovered) in demanding and sensitive applications. The performance of these materials has far exceeded the initial (circa 1990's) exceptions. There is increasing evidence that the durability and lifespan of a white geomembrane in an exposed application is perhaps longer, not only than projections, but perhaps longer than that of traditional black colored geomembranes of comparable composition. This paper presents data in support of that hypothesis and in fact, reaches the conclusion that in exposed application, white surfaced geomembrane is the material or choice, based on durability as well as other pertinent considerations. Data and evidence from forensic evaluations as well as laboratory testing for durability is presented and new estimates on lifespan are presented.

2   FORENSIC EVALUATIONS

The successful performance of white geomembranes in the field has been well established. Perhaps Cowlitz County, Washington (Thiel) is the most complete forensic examination, however, the Polk County, Florida site (Roberts and separately, Ramsey) (green surfaced, with very similar stabilization) has also been extensively documented. The Palo Verde Nuclear Generating Station has been one of the largest users of white geomembrane as reported by Eichelberger. Samples from each of these sites have been included in this study, as well as others. Further information on the performance of white geomembrane can be found in Rentz and other references. In general, white geomembrane materials present multiple benefits as

contrasted with traditional black geomembrane, these include improved damage detection, fewer and smaller wrinkles / less thermal expansion and contraction and expanded installation windows and improved safety and handling. Nearly all of these are on outcome of the lower temperature of the white geomembrane as a result of reflection of sunlight as contrasted with the exceptionally high absorption of solar energy of black materials.

3   SAMPLE IDENTIFICATION

The materials used in this examination came from various locations and climates around the world. The details of the samples reported are listed below:

Sample A – Polk County, Florida, USA 1.5 mm exposed green landfill cap. Sample exposed outdoors for 21 years at Latitude 27° North tropical environment

Sample B- Polk County, Florida, USA 1.5 mm exposed green landfill cap. Sample from original installation, but stored in a warehouse, aged 21 years but no UV/solar exposure

Sample C- Toowoomba, Queensland, Australia. 1.0 mm white geomembrane from an exposed outdoor evaporation pond in service since 2012 at Latitude 27° South, warm and temperate environment

Sample D – Cowlitz Country, Washington, USA 1.5 mm exposed white geomembrane from an exposed outdoor pond in service since 1993 at Latitude 46° North, Mild Mediterranean climate

Sample G- Palo Verde Nuclear Generating Station, Phoenix AZ, USA 2.0 mm sample from 1999 installation, but stored in a warehouse, aged but no UV/solar exposure.

Sample H – Commercial sample from 2013, 1.5 mm white geomembrane, but stored in a warehouse, aged but no UV/solar exposure

Sample J – Commercial sample from 2020, 1.5 mm white geomembrane, stored in a warehouse, no UV/solar exposure

Sample K – Commercial sample from 2020, 2.0 mm black geomembrane, stored in a warehouse, no UV/solar exposure

Sample M – Commercial sample from 2013, 2.0 mm white conductive geomembrane, but stored in a warehouse, aged but no UV/solar exposure.

In the presentation of data, the samples can be delineated into three groups: Those materials that have been exposed in-service (A, 21 years C, 8 years and D, 25 years). Those materials that have aged, but have not been exposed in-service (B, 21 years G, 21 years M and H, 7 years). Those materials that can be considered "new" – manufactured recently with no exposure in-service (J and K).

4   TEMPERATURES OF EXPOSED GEOMEMBRANE

There is existing literature and studies on the temperature differentials of black and white geomembranes exposed to the environment. Koerner (G.) in "Temperature Behavior of Field Deployed HDPE Geomembranes," addresses both the overall difference and the seasonality in the northern hemisphere (Latitude 40° North). Rentz reports a temperature delta (Black vs. White geomembrane) of 22°C at the Queen's University Queen's University Environmental Liner Test Site II (QUELTS II) in August at Latitude 44° North. Cadwallader reports a 25° temperature differential, presumably at Latitude 36° North. Further, Cadwallader includes the assumption proven in this paper:" Advantages of maintain a lower geomembrane temperature are also evident in long term aging tests." Pelte reports the largest differential of 35°C at latitude 45° North. Pelte also conducted laboratory scale testing demonstrating greater differentials in the temperature response of black and white geomembranes, both polyethylene and polyvinylchloride.

The author also has significant field experience in evaluating the temperature of geomembranes that comes in the form of both personal observation and the recording of weld/seaming activity temperatures.

Taking this all under consideration, for the purposes of this evaluation a temperature differential of 25°C is used to estimate the temperature difference / behavior of white vs. black polyethylene geomembranes when exposed to the environment.

5 SPECIFICATION OF DURABILITY CRITERIA

When the Geosynthetics Institute originally (June 1997) created the specification "GRI GM-13" consideration was given to durability. Similar to the other properties of the specification, multiple "successful" materials were tested, these values reported and a requirement was negotiated in relation to the performance of existing materials that were known to be functioning well. For durability considerations, this was agreed to be the retention of Oxidative Induction Time (OIT), proposed to represent the length of the "Stage A" of geosynthetic lifespan as reported by Hsuan and Koerner. The parties involved in the discussions were all participants in the geosynthetic and geomembrane industry, with manufacturers, design and quality engineers and major consumers all represented. This group agreed that the retention of OIT with the values enumerated within the specification should be acceptable. The long-term success and the broad global use of the specification proves this decision to be correct and this characteristic has become a reliable indication of durability performance.

For High Pressure OIT, this value is a minimum initial HP-OIT of 400 minutes with the retention of HP-OIT of 80% of the initial value after oven aging at 85°C for 90 days. The specifics of this testing are included in ASTM specifications: ASTM D 5885 and D 5721 respectively. To comply with GM-13, a geomembrane material needs to have a reduction rate for HP-OIT during Oven aging at 85°C of less than 0.89 minutes/day over a 90-day period. This performance level has served the geomembrane industry well in the following decades and is one of the basis for comparison in this paper's evaluation.

6 LABORATORY EVALUATION PROGRAM

The material sample listed above were subjected to Oven Aging in a modified fashion, generally as directed by GM-13 and ASTM 5721. The modification was a reduction in the oven temperature to reflect the difference in field temperatures as discussed above. The oven aging was conducted at 60°C. The oven aging was conducted at the Geosynthetic Institute, Folsom, PA in the summer of 2021. Samples of the materials as initially received, and after 30, 60 and 90 days of oven aging were tested for HP-OIT. This testing was conducted at the Solmax laboratory in Rechlin, Germany. This laboratory is certified within the GAI-LAP (Geosynthetic Accreditation Institute-Laboratory Accreditation Program) to conduct this test as well as multiple other certifications.

There have been recent significant changes to the HP-OIT testing document published by ASTM (5885). These relate primarily to sample preparation and are not completely addressed here. However, it is important to understand how the data reported herein was generated. The samples tested here were tested in the "as-is" condition. That is, a section was taken from the entire thickness of the sample, weighted and tested for HP-OIT properties as it existed at that point. No grinding, homogenization, plaque preparation or other alteration of the samples occurred prior to testing. In the opinion of the authors, this most directly reflects the "real-world" conditions in which these materials are used.

Further to sample preparation and testing, it should be noted how the values reported were calculated. In multi-layer geomembrane materials, it is common for the different layers to be stabilizer with different varieties of stabilizer, different levels of stabilizer, or both. In

HP-OIT testing, this can manifest itself in results that contain "shoulders" as indicated in Figure 1 below. This contrasts with other results that are more indicative of Figure 2.
Figure 1.   HP-OIT with shoulder.
Figure 2.   HP-OIT with no shoulder.

In this examination, small shoulders such as shown above in Figure 1 were ignored and the much larger exothermic reaction demonstrated by the large steeply sloped curve to the right was used to calculate the HP-OIT value for that sample. In some cases, retesting was done to validate results that appeared inconsistent or unexpected. In every case, no data points were discarded and the values reported below are the results of one, or the average of two test results.

The author is sympathetic to the attempts to improve the reliability and repeatability of the HP-OIT test by requiring sample homogenization. Striving to reduce testing variation is a good thing. However, in this case, and generally, the benefit of testing the material in the condition and state that it is actually used in greatly outweighs the need to reduce variation. One would not endeavor to try to explain to a design engineer, owner, or other stakeholder that rather than simply taking a section of material and testing it, it was justifiable to significantly modify the material prior to testing.

7 RESULTS

The results are reported below in three tables and three graphs: Figure 3 lists the numerical values for HP-OIT test results. Figure 4 lists these same results but in the format of a percentage of original OIT retained. Figure 5 presents the rate of reduction of HP-OIT as compared with the GM-13 requirements and discussed above.

Tested Values	T = zero days	T = 30 days	T = 60 days	T = 90 days
A (green)	110	108	107	97

Figure 5. Rate of sample OIT loss relative to GM-13 requirement.

The average rate of OIT loss for the seven colored samples was 0.48 minutes /day as compared with the GM-13 requirement of 0.89 minutes per day – an improvement of almost 50%

The result is that materials tested exceed the specification requirement for HP-OIT retention albeit at a lower temperature. However, as lower daily temperature is clearly a feature of the non-black/white materials, the author is confident that this is a clear, logical, and now demonstrated contributor to extended lifespan. This has been demonstrated across multiple locations, multiple materials and different applications. Exposed white surfaced polyethylene geomembrane materials should be expected to last longer than black surfaced materials in so far as the effects of temperature.

8   APPLICATION OF RESULTS TO CURRENT LIFESPAN PROJECTIONS

In the Koerner (R.M.) Keynote lecture at the 2016 GeoAmericas event, held in Miami, Florida a detailed analysis and calculation was presented for the estimated lifespan of exposed polyethylene geomembranes. One of the metrics used to estimate lifespan, in addition to OIT, was the retention of physical properties, specifically tensile strength and tensile elongation. These properties were used to prepare (Koerner) figure 19C (below) which lists the predicted lifespan of materials at a range of field temperatures. Using this data and the temperature ranges and impacts from the Koerner work and extending the results demonstrated in this paper, one can reason that the daily temperature reductions of white materials would add an additional 17 years of lifespan (correlating to 20 degrees Celsius of temperature reduction) for white polyethylene geomembrane materials as compared with black in an exposed application.

A second methodology for quantification of lifespan extension is the rate of OIT reduction as demonstrated in Figure 5. This decrease in the rate of stabilizer consumption would indicate an extension of the "Stage A" decomposition, as modeled in Koerner's text, Designing with Geosynthetics and multiple other publications. Again, drawing on data presented in the Koerner Miami 2016 Keynote address, Koerner presents an estimate of 207 years for Stage A for standard commercial materials, similar to materials evaluated in support of the GM-13 HP-OIT retention requirement(s), in Figure 6. The data developed and presented here indicates that the rate of HP-OIT retention for white materials at field temperatures is 53% of the specification requirement. This methodology would indicate a Stage

Site Temperature (°C)	Halflife (months)	Halflife (yrs)
80	177.3	14.77
70	280.3	23.36
60	383.4	31.95
50	486.5	40.54
40	589.6	49.13
30	692.7	57.72
20	795.7	66.31

c) Halflife field predictions in Phoenix, Arizona down to 20°C
Figure 6.   Copy of Figure (19 C) from Koerner Miami lecture.

A time of approximately 300 years, as compared with the 207-year estimate. The author does not suggest that this is an accurate absolute value, but clearly the materials examined here have performed significantly longer than was initially anticipated.

Clearly these estimations come with many caveats as there are multiple factors effecting lifespan. However, the results of testing of exposed forensic samples, field evaluations reported in literature, as well as the modeling and testing contained in this paper demonstrate consistently that white surface polyethylene geomembranes have lower temperatures in the field and this results in improved lifespan and durability.

9   CONCLUSIONS

What has been presented is a combination of forensic field evaluations, public literature information and in a new addition to the industry knowledge, the behavior of white surface polyethylene geomembranes in retention of HP-OIT at a temperature that reflects field exposure temperatures. This data and information all imply and support the hypothesis that these materials will have a longer lifespan than that of the equivalent black geomembrane materials. Literature suggests that this improvement is approximately 17 years and possibly more in terms of lifespan.

Durability of geogrid reinforcement from a sloped retaining wall after 25 years in-service

R.J. Fannin

Department of Civil Engineering and Energy Technology, Oslo Metropolitan University, Norway

ABSTRACT: This study presents a durability assessment of geogrid samples that were exhumed from a sloped retaining wall 25 years after completion of construction. The durability assessment is based on visual inspection and a series of index and strength tests, focusing on the identification of possible physical damage and/or degradation. The assessment lends confidence in the use of isochronous load-strain-time data for predicting the long-term strain of geogrid reinforced soil structures for design practice. This research belongs to the few well-documented long-term studies on geogrid durability.

1 INTRODUCTION

The determination of a long-term value of tensile strength for stability analysis of a geosynthetic reinforced soil structure involves use of a separate reduction factor to account for (i) the potential for damage of the reinforcement during installation and (ii) the durability of the reinforcement over the service life of the structure. The two factors account for any strength loss that may occur and appear in design guidelines and codes of practice (see for example, BS-8006). A limited number of field trials have sought to quantify durability from strength testing of specimens retrieved after long-term burial. They encounter a common difficulty in being able to distinguish between strength loss due to installation damage and change in strength arising from material durability, see for example Harney and Holtz (2006), Wayne *et al.* (1997), Onodera *et al.* (2004), and Jenner and Nimmesgern (2002).

Given a very limited body of data on geosynthetics after more than 20 years in-service, and recognizing that differentiation between a strength change due to installation damage and durability has not always been feasible, this contribution reports on the durability of geogrid exhumed from a sloped reinforced soil wall near Oslo, Norway, about 25 years after completion of construction. Little or no installation damage was anticipated in the geogrid reinforcement because of the practices used in construction of this instrumented research structure. Accordingly, the objectives of this study are to (i) assess exhumed samples for installation damage based on visual observations, (ii) quantify any changes in material properties in terms of geometry, composition, and tensile strength from isochronous load-strain testing, and (iii) based on the findings, comment upon the implications for consideration of durability in design practice.

2 THE NORWEGIAN SLOPED REINFORCED SOIL WALL

The structure is located 25 km northeast of Oslo, Norway. The steep (2V:1H) sloped wall is 20 m long and 4.8 m high (see Figure 1). It comprises two sections, termed Sections 'J' and

'N', each of which is 10 m long and with a different arrangement and spacing of Tensar SR 55 geogrid reinforcement (Fannin & Hermann 1990).
Figure 1. Section "N": (a) exhumed geogrid layers and (b) preparation for field sampling activities.

2.1 Construction details

The sloped wall seats into an existing slope in a borrow pit used by the local road authority. The backfill is a uniformly graded clean sand with trace of fine gravel, with median grain size d_{50} = 0.2 mm and coefficient of uniformity C_u = 2.6, obtained from the same borrow source. Construction took place in July 1987. Backfill sand was placed using a front-end loader, prior to spreading with a mini excavator to a minimum loose lift-thickness of approximately 350 mm. Thereafter it was moisture-conditioned to a water content $5 \leq w \leq 10\%$, and compacted using a vibrating plate to a thickness of approximately 300 mm and dry density greater than 92% of the maximum value from the Standard Proctor test (ASTM D698).

Eight layers of uniaxial geogrid were used in Section 'N' (termed layers N1 to N8, see Figure 1a). They were placed at a uniform vertical spacing of 0.6 m that equates to two finished compaction lifts. The length L = 2.2 m of the geogrid reinforcement does not satisfy modern design guidance: it was purposely chosen for Section 'N' as a parametric variable for investigation in the original field trial that predated regulatory design guidance by several years.

The front-end loader was not permitted to drive on the reinforced soil zone, and the mini-excavator was only permitted to move onto that zone after pushing a loose layer of backfill sand over it to a working-platform thickness of 350 mm. The commensurate supervision of all equipment operation afforded little or no opportunity for construction-related installation damage.

2.2 Service life

Following a month of self-weight loading commencing in July 1987, a single load-unload cycle of surcharge loading was applied to the crest of the structure over a period of nearly 2 months using water-tanks that were filled in August 1987 and subsequently emptied and removed in September 1987. Permanent surcharge loading was subsequently imposed on the sloped wall by means of a 3 m high berm that was constructed in October 1987 and then left in place. Upon completion, instrumentation established a maximum tensile load per unit width $T_{max} \approx 1.4$ kN/m the lowermost (N1) layer of geogrid, and values of $2.1 \leq T_{max} \leq 3.0$ kN/m in the other (N2 to N8) layers above it; the companion values of maximum tensile strain were in the general range $0.2 \leq \varepsilon_{max} \leq 0.8\%$. Although the force mobilized in the geogrid layers is relatively small, it was demonstrated entirely consistent with a geotechnical analysis informed by the frictional strength of the sand backfill (Fannin & Hermann 1990). The average temperature in the reinforced soil zone varied between 7 and 9°C, depending on location, with the near surface locations experiencing a seasonal range between 0 and 20°C. Long-term performance monitoring over a period of 10 years established that the tensile force per unit width in each layer remained essentially constant. The associated strain

exhibited a time-dependent increase: the invaluable time-series record of field data for independent measurements of load-strain-time to almost 90,000 h was found very consistent with laboratory creep test data for the geogrid to 100,000 h (Fannin 2001).

3 FIELD SAMPLING

A program of field sampling was conducted about 25 years after completion of construction in February 2013. Section 'N' was selected for sampling of the backfill sand and geogrid reinforcement because the site layout provides for easier access to that end-location of the structure.

3.1 Soil

Excavation proceeded in a 'top-down' direction from the crest of the structure near the lateral toe of the surcharge berm (see Figure 1b). Three grab samples of soil were taken at the mid-height between layers N8-N7, N7-N6, and N6-N5, respectively (see Figure 1a). At the time of construction, the backfill soil was classified as a uniformly graded sand with trace gravel and trace silt. Scanning Electron Micrograph (SEM) images of sand in the grab samples (see Figure 2a) suggests a generally angular to very angular grain shape. XRD analysis established the mineralogy as approximately 70% quartz, 20% feldspar, 5% mica, and 5% others. Index testing to ASTM 4972 established a pH of 8.3, believed consistent with the predominantly silicate content of the sand.
Figure 2. Sampled materials (a) sand grains and (b) geogrid reinforcement.

3.2 Geogrid

The backfill sand was carefully removed by machine-excavation, in a series of horizontal cuts. When the backfill cover thickness reduced to approximately 15 cm, the rest was then removed by hand-excavation using a shovel to move the bulk of the sand, and a combination of spade and soft-sweep push-broom to remove all of the remaining sand and expose the top surface of a geogrid layer for sampling. Four layers, N6 to N3 (see Figure 1a), were exhumed from the structure. The backfill was frozen to over a distance of approximately 0.75 m into the reinforced soil zone behind the slope-face, thus field exhumation yielded samples of geogrid reinforcement that were approximately 1.25 m long and 1.0 m wide. Hand-held visual assessment established no evidence, on any of the geogrid samples, of adverse damage that could be attributed to installation at the time of construction in 1987 or the process of field sampling.

SEM inspection of the N6 specimens (Quinteros 2014) identified a high frequency of low magnitude abrasions: they took the form of surficial scratches of variable length, typically less than 0.1 mm deep. A very low frequency of medium-size abrasions was detected: they took the form of pits and gouges that were typically 2 to 15 mm long and 0.2 to 0.5 mm deep (see Figure 2b). The absence of any damage is attributed to the supervision of all equipment

operation resulting in no opportunity for installation-related damage during construction of the instrumented field-trial.

4 CHARACTERIZATION OF THE GEOGRID AFTER 25 YEARS IN-SERVICE

The exhumed geogrid was characterized with reference to geometry, material composition, and analysis of its load-strain-time response in creep testing. Creep test data for the exhumed specimens are compared directly with typical data for the same product reported by the manufacturer. Given the absence of any observed installation damage, the methodology enables an assessment of material durability.

4.1 Tensile strength

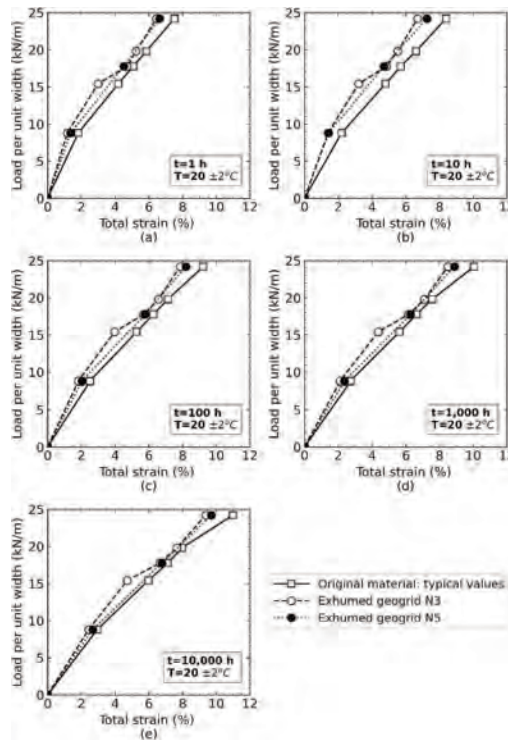
Rapid loading creep (RLC) tests were performed to ISO 13431:1999 at the Tensar International laboratory at Atlanta, USA, with oversight by an independent third-party inspector. Test specimens were taken from the exhumed samples of layer N3 and N5 geogrid material. A constant tensile load per unit width of 8.8, 15.4, 17.8, 19.8, or 24.2 kN/m was applied to five layer N3 specimens, and a loading magnitude of 8.8, 17.8 or 24.2 kN/m to three layer N5 specimens. The RLC tests were performed at a constant temperature of T = $20 \pm 2°C$, and all eight specimens were loaded to a total elapsed time of 10,000 h. The tests yield load-strain-time data, and are presented in the form of isochronous curves at t = 1, 10, 100, 1,000, and 10,000 h (see Figure 3).


Figure 3. Isochronous load-strain curves: typical values for original material and results for exhumed layer N3 and N5 test specimens.

There is generally good agreement in the load-strain response with time for the exhumed N3 and N5 specimens. For example, at the largest magnitude of load per unit width (24.2 kN/m), the difference in total strain between the N3 and N5 test specimens is: 0.1% strain at t = 1 h; 0.5% strain at t = 10 h; 0.3% strain at 100 h; 0.3% strain at 1,000 h; and 0.2% strain at 10,000 h.

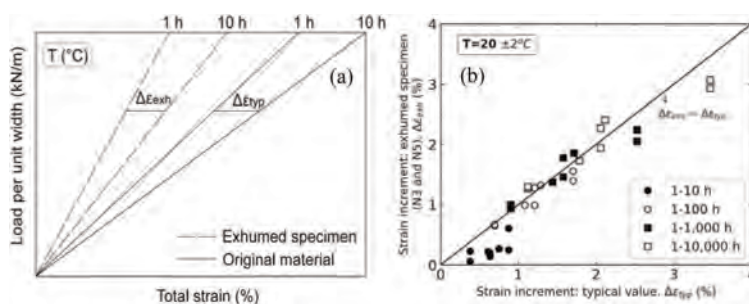
A comparison of the isochronous curves of the current study with curves reported by the manufacturer for the same Tensar SR55 geogrid product, termed herein typical values, indicates a plotting position for the exhumed N3 and N5 material that is consistently associated with relatively smaller values of total strain (see Figure 3). To investigate further the nature of the difference between the measured values for the exhumed field material and typical values for the same product, the magnitude of strain increment between isochronous load-strain curves was calculated for RLC test data on the exhumed material ($\Delta\varepsilon_{exh}$) and from the typical curves for original product type ($\Delta\varepsilon_{typ}$) as illustrated schematically in Figure 4a.


Figure 4. RLC test data: (a) schematic illustration of strain increment $\Delta\varepsilon$ (t = 1 to t = 10 h) and (b) comparison of data for field samples with typical values for the original product.

Results are reported for the four increments of 1 to 10, 1 to 100, 1 to 1,000, and 1 to 10,000 h (see Figure 4b). Strain increments for specimens of the exhumed geogrid at 1 to 10 h exhibit the least good agreement, while the data for increments of 1 to 100, 1 to 1,000, and 1 to 10,000 h are in good agreement with the typical values. The 32 data points establish $\Delta\varepsilon_{exh}$ = 1.03·$\Delta\varepsilon_{typ}$. Strain increments in rapid load creep testing of the exhumed specimens are thus believed very similar to those for the original product type. Taken collectively the evidence in Figure 3 and Figure 4 suggest the isochronous load-strain response of the exhumed geogrid compares very well with the typical behaviour reported by the manufacturer. The finding implies no degradation of strength or stiffness of the geogrid over the 25 year service life in the sloped reinforced soil wall at the Skedsmo location, near Oslo, Norway.

The British Standard (BS-8006) gives explicit consideration to a serviceability limit state, which is expressed as a limit value on the magnitude of permissible post-construction strain over the service life of a structure. Isochronous load-strain curves are used for purposes of estimating the post-construction strain in a reinforced soil retaining structure. The difference between 'the end of construction total strain' and 'the design life total strain' defines the strain increment of interest. The observed excellent agreement between strain increments in this study for exhumed and original uniaxial geogrid reinforcement lends strong support to the use of isochronous load strain curves for estimating long-term values of reinforcement strain in design to BS-8006.

5 CONCLUSIONS

Geogrid samples were exhumed from a sloped wall structure to investigate the material durability after 25 years in-service. Based on the results of this study, following conclusions are drawn:

(a) visual inspection and microscopic imaging revealed no installation damage of any significance, a finding that is attributed to the good quality of the backfill soil and the close inspection of all construction activities for this research structure. Accordingly, it is reasonable to compare properties of the exhumed material with typical values for the original product and attribute any changes to durability phenomena over the service life of the structure near Oslo, Norway;

(b) rapid loading creep test data to 10,000 h show excellent agreement between incremental strain in specimens of the exhumed geogrid and typical values for the original product type, with a finding of $\Delta\varepsilon_{exh} = 1.03 \cdot \Delta\varepsilon_{typ}$ that implies no degradation of strength or stiffness of the sampled geogrid;

(c) in the absence of any installation damage, the excellent agreement in rapid loading creep test data is believed indicative of no concern for durability manifesting itself as degradation in the strength or stiffness of the geogrid reinforcement after an elapsed time of 25 years; and,

(d) the finding lends confidence to the use of isochronous load-strain-time data for predicting the long-term tensile strain of geogrid in reinforced soil structures.

ABSTRACT: High-density (HDPE) and linear low-density polyethylene (LLDPE) geomembranes are used in barrier systems in various containment applications. The former is known for its better chemical resistance, while the latter is known for its higher stress-crack resistance (SCR). The SCR of high-density polyethylene is well defined in the literature, but the SCR of LLDPE as well as its failure mechanism are rarely addressed. This paper thus investigates the SCR of LLDPE versus HDPE geomembranes based on the fractured plane of unaged and aged specimens examined using the single-point notched constant load tensile test method. The GMBs were aged using a synthetic heap leaching solution with pH 13.5 at 85°C. Failed specimens are analyzed using scanning electron microscopy, after which the differences in fracture surface for both LLDPE and HDPE resins are discussed. The relationship between SCR, tensile break elongation, and melt flow index is also presented for the geomembranes examined.

1 INTRODUCTION

Stress-crack resistance (SCR) and its failure mechanism are some of the primary factors controlling the service-life of geomembranes (GMB). Environmental stress-cracking, in particular, arises when polyethylene geomembranes are exposed to sustained tensile stresses in the presence of fluids (e.g., municipal solid waste leachate or heap leaching liquors), and is a serious problem for base liners in geoenvironmental applications (Choi *et al.* 2009; Rowe *et al.* 2019).

High-density (HDPE) and linear low-density (LLDPE) polyethylene GMBs are typically chosen as the primary liners in these applications, but they do not have similar SCR. While the increased resin density of HDPE GMBs implies better chemical resistance and hardness, it increases the potential for stress cracking. For LLDPEs, the high side chain branching of the polymer molecule gives them more flexibility and a relatively higher off-roll SCR compared to HDPE (Brown *et al.* 1991; Lustiger & Markham 1983; Scheirs 2009). There are several methods for assessing the SCR for a broad range of polymeric materials (Robeson 2013), among which the notched constant tensile load test (NCTL; ASTM D5397) is well accepted and commonly used both in industry and research.

Examining crack growth and propagation can be very useful in identifying fracture mechanisms such as brittle, semi-brittle and ductile, and this becomes especially important in the case of GMBs with very different SCR values being exposed to high levels of stress in the field. Nevertheless, the morphology of slow crack propagation has not yet been clarified for LLDPE GMBs tested using the NCTL method and thus it is still not clear how the fracture mechanisms change as the polymer density varies for both unaged and aged conditions. To fill this gap, this paper investigates the fracture surface of HDPE and LLDPE GMBs based on a microscopical analysis of the cross-section of broken SCR specimens from unaged and aged samples.

2 EXPERIMENTAL INVESTIGATION

2.1 Geomembranes examined

Two commercially available 1.5 mm thick smooth black HDPE and LLDPE GMBs were investigated in this study and are denoted as MxC15 and LxD15, respectively (Table 1). The two GMBs were produced by the same manufacturer using the blown film method. The performance of these two GMBs in different geoenvironmental applications has been extensively investigated (Abdelaal et al. 2012; Abdelaal & Rowe 2014; Abdelaal et al. 2011; Morsy et al. 2021; Rowe et al. 2019).

Table 1. Initial properties of the GMBs examined.

Property	Unit		
Designator	–	MxC15	LxD15
Type	–	HDPE	LLDPE
Nominal thickness (ASTM D5199, 2012)	mm	1.5	1.5
Resin density[1] (ASTM D1505, 2018)	g/cm^3	0.936	0.924
SCR (ASTM D5397, 2019)	hours	800 $\pm$ 90[2]	18,700 (24,000-15,000)[3]
HLMI(ASTM D1238, 2020)	g/10min	15.2 + 0.8	13.4 $\pm$ 0.8
Type V Break Elongation[4] (ASTM D6693, 2020)	%	800 $\pm$ 16.5	980 $\pm$ 34

Notes
[1]Provided by GMB manufacturer based on their results.
[2]Standard deviation.
[3](Maximum-minimum) SCR readings.
[4]Measured in the cross-machine direction.

One could challenge the assessment of SCR from LLDPE since it may not display a clear yielding point, as is the case of HDPE (e.g., Krishnaswamy & Lamborn 2000). However, the resin density of LxD15 is at the upper bound of the LLDPE density range (0.919–0.925 g/cm^3; ASTM D883) and yields in a similar manner as medium density polyethylene.

2.2 Oven ageing and immersion solutions

Two-sided exposure tests (ASTM D5322, 2017) were used to investigate how the SCR value and morphology change with ageing. This immersion technique consists of placing 200 x 95 mm GMB coupons in 4 L vessels filled with synthetic chemical solutions that mimic the effluents found in field conditions. The vessels were incubated in a forced air

oven at an elevated temperature of 85°C to accelerate the ageing of the GMBs. Coupons were separated with glass rods to ensure that the chemical solution is in full contact with the GMBs. Samples were then periodically extracted at different incubation durations to assess changes in the SCR over time.

The incubation fluid was an extremely basic solution (pH = 13.5) simulating the extreme alkalinity found in pregnant liquors for gold and silver heap leaching (Abdelaal & Rowe 2017). This solution was prepared by mixing de-ionized water with a trace metal solution and inorganic salts and was titrated with a 15 mol sodium hydroxide solution to achieve the target pH.

2.3 *Single-Point Notched Constant Tensile Load Test (SP-NCTL)*

Both SCR and morphology of slow crack growth were assessed using the single-point notched constant tensile load test (SP-NCTL, ASTM D5397). In this test method, an engineered defect (notch) is made on one surface of a dumbbell-shaped specimen such that the ligament thickness (i.e., the portion of GMB uncut under the notch) is 80% of the nominal thickness of the specimen. The notched specimen is subjected to a load equal to 30% of the initial GMB yield strength in a stainless-steel tank filled with a 10% (v/v) solution of Igepal CO-630 in water at 50 $\pm$ 1°C. The SCR value is then taken as the elapsed time to failure. After failure, the specimens were examined using scanning electron (SEM) microscopy.

3 RESULTS AND DISCUSSION

3.1 *Slow crack growth in unaged GMBs*

In all the SEM micrographs presented below the direction of crack propagation is from bottom to top. The fractured plane of an unaged HDPE specimen with a SCR of 750 h had generally a three-phase morphology (Figure 1a). Zone A is a relatively small region in the vicinity of the notched area (i.e., ahead of the crack tip) where crazing effectively began at lower stress levels. There was a non-uniform fiber pullout across that area, suggesting that the fibers of the craze being formed did not rupture immediately after loading. Once this rupture occurred, crack growth transitioned into a zone of relatively less pullout (Zone B) characteristic of brittle failure (Chen 2014; Francey & Rowe 2021; Lu *et al*. 1991). This surface fracture appearance was more dominant than that observed at the other two zones, indicating that the failure mechanism of the examined HDPE GMB was predominantly brittle. As the crack extended and the cross-sectional area of the specimen was increasingly reduced, the applied load exceeded the yield strength of the GMB, which in turn led to large fibre deformations and failure in a ductile manner, i.e., Zone C (Francey & Rowe 2021). The lengths of Zones A, B and C measured from the SEM micrograph were approximately 130 μm, 410 μm and 290 μm, respectively.

The SCR morphology of an unaged LLDPE specimen that failed after 17,100 h in the NCTL test was quite different (Figure 1b). Near the razor blade cut and at the base of the craze (using the aforementioned designation, Zone A), there was a strong continuous film instead of the fibrous structure observed from the HDPE specimen. This suggests that the time required to engage a crack in the first craze was considerably greater (e.g., Lu *et al*. 1992). The region of brittle failure (Zone B) was characterized by several short, thin fibers uniformly distributed and of somewhat uniform length and orientation. Finally, Zone C still showed ductile, long-fibrous structures, but the fibres were less distinguishable than Zone B when compared with HDPE. Zones A, B and C in this case had approximate measured lengths of 230 μm, 275 μm and 400 μm, respectively.
Figure 1. SEM micrographs of the fracture surface from: (a) an unaged HDPE specimen (SCR_o = 750 h); and (b) an unaged LLDPE specimen (SCR_o = 17,100 h).

3.2 *Effect of ageing on the morphology of crack growth*

Ageing can significantly reduce the environmental SCR of polyethylene GMBs due to the relaxation of residual stresses and changes in the semi-crystalline structure (i.e., physical ageing), and/or due to oxidative degradation (Ewais & Rowe 2014; Koerner *et al.* 2017; Morsy & Rowe 2020). Thus, the surface fracture morphology for aged specimens is also expected to change (Figures 2a and 2b).
Figure 2. SEM micrographs of the fracture surface from: (a) a HDPE specimen aged for 6.8 years (SCR_{7years} = 5 h; $SCR_{7years}/SCR_0 < 0.01$); and (b) a LLDPE specimen aged for 4 years (SCR_{4years} = 617 h; SCR_{4years}/SCR_0 = 0.03).

For the HDPE specimen aged for almost 7 years in the synthetic heap leaching solution at 85°C (SCR$_{7years}$ = 5 h), fibre length was significantly reduced in Zones A and B (Figure 2a), although the number of residual fibres was greater. While these shorter, isolated fibres increased relative to the unaged specimen, their resistance to crack propagation became considerably lower. The least affected region appears to be Zone C. This implies that, even in a highly aged HDPE specimen there was a portion of the material experiencing ductile failure (Scheirs 2009). The lengths of Zones A, B and C after ageing were approximately 35 μ m, 590 μm and 235 μm, respectively.

In the LLDPE specimen aged for 4 years (SCR$_{4years}$ = 617 h; Figure 2b), initiation of crack growth was marked by a non-uniform long-fibrous detachment between Zones A and B very similar to that of the unaged HDPE specimen. Zone B displayed an increased number of long, thick fibres and flake structures that were not observed in the unaged specimen. The morphology of Zone C, once again, did not seem to be significantly affected. Zones A, B and C were 110 μm, 275 μm and 395 μm in length, respectively.

3.3 Ageing of other physical and mechanical properties

The SCR of the aged HDPE and LLDPE specimens are compared with the high-load melt index (HLMI) and tensile break elongation values at the same incubation duration (Table 2). The HDPE GMB retained 40% of its initial tensile break elongation after 7 years of ageing. The extremely low melt index value indicates the domination of cross-linking oxidative reactions. The generation of a more "tightly packed" structure due to excessive cross-linking makes the polymer more susceptible to brittle failure (Lustiger 1985), which might explain the short fibre structure depicted in Figure 2a.

Table 2. Physical/mechanical properties of HDPE and LLDPE GMBs after ageing.

Property	Percent retained (%)	
	MxC15 (aged for 7 years)	LxD15 (aged for 4 years)
SCR[1] (ASTM D5397, 2019)	0.6	3.3
HLMI[2] (ASTM D1238, 2020)	10.5	131.2
Type V Break Elongation[2] (ASTM D6693, 2020)	39.6	14.8

Notes
[1]Value from one single specimen
[2]Mean value

Even with less ageing time than the HDPE GMB, the LLDPE GMB lost 85% of its break elongation and 97% of its SCR. This was accompanied by a significant increase in HLMI, which implies chain scission reactions typically dominant in LLDPE GMBs (Morsy *et al.* 2021). Despite the extremely large reduction in SCR and break elongation, the GMB was still able to retain some flexibility, as depicted by the short to long-fibrous fracture surface (Figure 2b) and by the pullout of material in the macroscopic view of the specimen (Figure 2b, top left corner).

4 CONCLUSIONS

The environmental SCR performance of HDPE and LLDPE GMBs has been investigated. Unaged specimens as well as those aged in synthetic mining leachate at 85°C were tested

using the single-point notched constant tensile load (NCTL) testing method. Broken specimens were recovered from the SCR test and were further analyzed by scanning microscopy to investigate the differences in failure mechanisms. The SCR results from aged specimens were then compared to the melt index and tensile break elongation values at the same incubation duration. For the GMBs and test conditions (e.g., ageing temperature, incubation fluid) investigated in this paper, the following conclusions can be reached:

- LLDPE had an initial very high SCR but after 4-years ageing it had reduced to 3% of its initial value.
- The fractured plane of SCR specimens tested in the NCTL test generally displays a three-phase morphology, namely: (1) a small zone of relatively longer pullout in the vicinity of the notch, or Zone A, (2) an intermediate zone wherein brittle failure dominates (Zone B), and (3) a zone of ductile failure (Zone C). The main difference in brittle failure between unaged HDPE and LLDPE was the length, orientation, and distribution of fibres.
- The length of the aforementioned zones is markedly different between HDPE and LLDPE. In the unaged HDPE, Zone B was 40% longer than Zone C in the direction of crack propagation, while the unaged LLDPE had Zone B only about two-thirds the length of Zone C. For the aged HDPE specimen, Zone B was 150% longer than Zone C. In the aged LLDPE, the length of Zones B and C remained the same as the unaged condition. In other words, the large decrease in SCR of the LLDPE GMB mainly reflects the change in morphology of Zone A.
- The morphology of Zone A from a 4-year aged LLDPE specimen is relatively similar to its HDPE counterpart in an unaged condition.

Evaluation of durability of PVC-P geomembranes for tunnel waterproofing with laboratory tests

A. Luciani
TECNE – SYSTRA SWS Advanced Tunneling, Turin, Italy

ABSTRACT: Durability of waterproofing systems used in tunnels is of main importance because water highly influences durability, effectiveness and maintenance costs of underground structures. PVC-P geomembranes are one of the most applied technologies for tunnel waterproofing, nonetheless there is a lack of knowledge on their durability in underground applications. Even if long-term durability of PVC-P geomembranes has been analysed for outdoor applications (e.g. dams, roofs), few information are available for applications in underground conditions. In this paper the durability of two commercial PVC-P geomembranes for tunnelling applications is analysed based on the results on laboratory tests. Plasticizer absorption tests and mechanical tests are performed on the commercial geomembranes and on eight formulations of PVC-P specifically produced. The results of those tests permit to study the long-term degradation due to plasticizer loss and extrapolate the losses in time. Finally, an end-of-life time for the geomembranes has been defined merging mechanical requirements for the membrane and the long-term evolution of the degradation of the properties.

1 INTRODUCTION

Water is renown as one of the main causes of damages to underground structures and of their maintenance costs. Therefore, the use of effective and durable waterproofing systems is of overwhelming importance for tunnels. In conventional tunnelling, the waterproofing system is nowadays constituted by a geomembrane installed in between the primary and the final concrete lining (Luciani & Peila 2019).

The design life span for new tunnels is of about 100 years and, in some cases, it can rise to 150 years. This request, combined with the inner surface quality requirement of absence of leakages and moisture spots, point out the importance of durability of waterproofing system. Moreover, since waterproofing is installed behind the concrete lining of the tunnel, it is difficult or almost impossible to perform maintenance or substitute it. As a consequence, the durability requirement on waterproofing systems for tunnel applications has to be the same of the whole tunnel (i.e. 100 years). Nevertheless, there is a clear lack of knowledge on the durability of waterproofing membranes used in underground structures.

In this study the durability of plasticized PVC (PVC-P) geomembranes is analysed. PVC-P geomembranes are one of the most used material for underground applications.

Durability of PVC-P has been analysed in many applications (e.g. waterproofing of roofs, dams, channels) (Blanco *et al*. 2012; Cazzuffi 1995, 2016; Newman *et al*. 2004; Stark *et al*. 2005) but there are almost none studies on underground applications.

Moreover, there are also few reported cases in scientific literature of geomembranes naturally aged in underground applications for 30–40 years (Maehner *et al*. 2018; Usman & Galler 2014) while data for longer times do not yet exist. Therefore, the study of durability of geomembranes in these applications are still based on accelerated tests (Luciani *et al*. 2020).

2 PVC-P DEGRADATION IN TUNNELS

PVC degradation is mainly caused by dehydrochlorination, i.e. the loss of gaseous hydro-chloride from the PVC chain. The energy needed to initiate the degradation process comes from heat or ultraviolet (UV) rays. However, in underground applications, high temperatures or UV rays are absent, and so this phenomenon can be neglected.

Consequently, the main degradation phenomenon occurring to PVC-P in underground is the loss of plasticiser. Plasticizer is not chemically bonded to the polymer chain and so, during the life of the material, migrates from the geomembrane into the surface and then in the surrounding environment (Marcilla *et al.*, 2004; Storey *et al.*, 1989).

The plasticizer content is defined by the concentration expressed as percentage by weight. The loss of plasticizer is described with the plasticizer loss ratio P_L (Benneton 1994) defined as

$$P_L(t) = \frac{M_{P_0} - M_P(t)}{M_{P_0}} \tag{1}$$

with M_{P_0} the initial mass of plasticizer and $M_P(t)$ the mass of plasticizer at time t.

The study of durability of PVC-P waterproofing geomembranes consists in evaluating the evolution of this phenomenon with time and its impact on the mechanical properties of the material.

3 PLASTICIZER LOSS EVALUATION

The degradation of geomembranes is sometimes extrapolated on the long term with Arrhenius' equation. This equation permits to evaluate with accelerated tests at different temperatures a rate constant of the phenomenon. However, this simple correlation implies a constant rate of the phenomenon with time that is not realistic for the case of plasticizer loss, where the rate is dependent on the gradient of concentration between the geomembrane and the environment. Moreover, in PVC-P the rate is also influenced by the plasticizer content because as the plasticizer content reduces it becomes more difficult to the plasticizer to diffuse in the now stiffer matrix.

Since plasticizer loss can be analysed as a mono-dimensional diffusion problem, in order to have a better evaluation of the physical phenomenon, the evaluation of plasticizer loss can be performed using Fick's law of diffusion

$$\frac{\partial c(x,t)}{\partial t} = D \frac{\partial^2 c(x,t)}{\partial x^2} \tag{2}$$

with $c(x,t)$ the value of plasticizer concentration at time t and in the coordinate x inside the thickness of the membrane and D is the diffusion coefficient.

In tunnel applications, one side of the membrane is constantly cleaned by the flow of the water drained from the rock mass, and therefore it is possible to consider the plasticizer concentration on the external surface always equal to zero. On the other side of the geomembrane, in contact with concrete, diffusion is considered negligible. As an initial condition the concentration in all the points of the geomembrane is set constant as the initial value.

Solving Equation (2) in the given boundary and initial condition it is possible to obtain the concentration at any time inside the membrane as

$$c(x,t) = -\sum_{n=1}^{\infty} C_0 \frac{4}{(2n-1)\pi} e^{-D\left(\frac{2n-1}{2L}\pi\right)^2 t} \sin\left(\frac{2n-1}{2L}\pi x\right) \tag{3}$$

One of the factors governing the computation is the diffusion coefficient D, that must be dependent on the concentration and temperature in order to account for PVC-P behaviour.

To evaluate the dependence of D on these parameters, plasticizer absorption tests have been performed.

4 PLASTICIZER ABSORPTION TESTS

4.1 *Test procedure and materials*

Plasticizer absorption tests permit to evaluate diffusion coefficient of plasticizer in a geomembrane. Small specimens of geomembrane of regular and known surface are cut with a metallic hollow cutter, cleaned on the surface, dried in a desiccator and weighted. Specimens are then immersed in plasticizer at a specific temperature and the change of weight is measured overtime. The diffusion coefficient is obtained by fitting the data of weight-time curve with the diffusion law (Griffiths *et al*. 1984; Storey *et al*. 1989).

Tests have been performed at 4 different temperatures: 20°C, 45°C, 60°C and 75°C.

Since the study aims to evaluate the durability of waterproofing geomembranes used in underground applications, two commercial geomembranes have been considered: geomembrane A, that is a 2 mm PVC-P coloured geomembrane with filler, and geomembrane B, a 2 mm PVC-P translucent geomembrane without filler.

In addition to these commercial materials, 8 specifically produced geomembranes have been testes. These geomembranes have been formulated with different plasticizer contents, with and without filler. The production of both geomembranes with and without filler aims to evaluate the parameters for both commercial geomembranes. Table 1 summarises the composition of the 10 tested materials. For materials A and B, Table 1 reports the sum of the content of PVC and stabilizer because separated values are not available.

The plasticizer used for the tests is the same used to produce the geomembranes.

Table 1. Tested materials composition.

Material	PVC (%)	Stabilizers (%)	Plasticizer (%)	Filler (%)
A	56.0		24.0	20.0
B	73.3		26.7	0.0
1	67.4	2.6	30.0	0.0
2	72.4	2.6	25.0	0.0
3	77.4	2.6	20.0	0.0
4	82.4	2.6	15.0	0.0
5	47.4	2.6	30.0	20.0
6	52.4	2.6	25.0	20.0
7	57.4	2.6	20.0	20.0
8	62.4	2.6	15.0	20.0

4.2 *Results*

From the analysis of the results on the same material at different temperature, an exponential relation between diffusion coefficient D and temperature T has been observed, analogous to Arrhenius' equation. The correlation can be expressed as

$$D(T) = D_0 \cdot e^{-\frac{E_A}{RT}}$$ (4)

where D_0 is a constant, E_A is the activation energy, R the gas constant and T is the temperature.

Similarly, from the results of absorption tests performed at the same temperature on geo-membranes with different initial plasticizer content, the dependence of diffusion coefficient on plasticizer content has been evaluated. In this case a potential law has been obtained:

$$D(c) = D_1 \cdot c^b \qquad (5)$$

where D_1 and b are constants, and c is the content of plasticizer.

The values of diffusion coefficient obtained for material A is in good agreement with the ones of the geomembranes with filler, and the one of material B with the ones of geomem-branes without filler, thus confirming that the results of the tests can be applied to the two commercial geomembranes.

Diffusion coefficient for materials with filler are higher than the ones of materials without filler, confirming that the degradation of geomembranes without any filler is slower. Figure 1 and Figure 2 show examples of the results obtained in terms of temperature and con-centration correlation. Figure 2 also compares the results for the two commercial geomem-branes (A and B) and the 8 specifically produced geomembranes: Material A fits very well with the results of geomembrane with filler, while material B has a slightly worse fit.
Figure 1. Results of plasticizer absorption tests of the two commercial geomembranes (y axis in log scale).
Figure 2. Results of plasticizer absorption tests at 75°C.

4.3 *Long-term extrapolation of plasticizer loss*

Using Equations (3), (4) and (5), it is possible to evaluate the variation of concentration with time at different temperatures and the plasticizer loss ratio.

Table 2 reports the diffusion coefficients used in the extrapolation, as derived from the plasticizer absorption tests results.

Table 2.   Diffusion coefficients for 15°C extrapolation.

Material	D_1 (mm^2/s)	b $(-)$
A	$7.47 \ 10^{-7}$	4.94
B	$2.44 \ 10^{-8}$	4.94

Figure 3 reports the results of the extrapolation in terms of plasticizer loss ratio for the two commercial geomembranes at 15°C. This temperature has been chosen as representative of the site temperature for shallow and urban tunnels in ordinary conditions.

The rate of degradation is relatively high in the first years and reduces with time.
Figure 3.   Long-term extrapolation of plasticizer loss of the two commercial geomembranes at 15°C.

5   PLASTICIZER LOSS EFFECT ON GEOMEMBRANES

As plasticizer content changes within the geomembrane its mechanical properties change. The mechanical properties of the 10 materials used in the absorption tests have been tested.

With the reduction of plasticizer content, Shore A hardness, tensile strength and elastic modulus of the geomembrane increases. On the contrary, elongation at break reduces.

Figure 4 shows the results of tensile tests. It is evident that as the plasticizer content reaches values of about 15–20% the behaviour of the geomembrane passes from a soft-rubber like to a hardening elasto-plastic one with an evident yielding point. This means that for certain values of elongation of the geomembranes a plastic irreversible deformation occurs, causing the reduction of the section. For both geomembranes with and without filler,

this occurs for a plasticizer content of about 15% and the yielding point is reached for a deformation of about 6%.

Moreover, plasticizer loss causes the shrinkage of the geomembrane that creates tensile stresses in the geomembrane with time. Shrinkage progress with plasticizer loss can be evaluated with the correlation proposed by Giroud (1995).
Figure 4.   Tensile tests results on the 8 produced geomembranes.

6   DURABILITY ASSESSMENT

Benneton (1994) suggested that the end of effectiveness of a waterproofing PVC-P geo-membrane can be defined at the moment when the plasticizer loss ratio is equal to 0.5. However, the author does not give any explication about the origin of this assumption.

In order to define a performance-based end-of-life threshold, it is needed to establish a correlation between the action on the geomembrane and the mechanical properties during the life of the structure.

Once the tunnel is built, the waterproofing geomembrane is in perfect contact with the two concrete lining (with protection layers installed to avoid that some unevenness of the concrete can damage the geomembrane). On the long term, the geomembrane only transmits the geological load to the final concrete lining. This load is constant and uniform on the surface of the geomembrane, therefore there is not a specific request for mechanical properties. In case of any unpredicted unevenness (e.g. voids in the lining, protruding elements), the deformation of the geomembrane would be very small and compatible with the elastic behaviour of the geomembrane. Furthermore, as shown, with degradation tensile strength and surface hardness increase reducing the risk of penetration of external grains.

The only consequence of plasticizer loss that seems to affect the effectiveness of the water-proofing geomembrane is shrinkage, that, in association with the more rigid behaviour of the material with lower plasticizer content, can induce plastic deformations. Plasticization is not necessarily a limit condition for the effectiveness of the geomembrane but represents a change of behaviour and causes the reduction of thickness and possible opening of small holes.

Therefore, in order to be on the safe side, the end-of-life value for the geomembrane is defined as the limit value of plasticizer loss ratio resulting in a plastic deformation of the geomembrane. For the tested materials this means or the 15% of plasticizer content, or an elongation due to shrinkage higher than 6%. For both commercial geomembranes tested the

lower of these two values correspond to a plasticizer loss ratio of about 0.45, slightly lower than Benneton's limit.

From Figure 3, it is possible to state that both the commercial geomembranes tested are still within the defined end-of-life limit of plasticizer loss ratio after 100 years in an urban tunnel at 15°C.

7 CONCLUSIONS

The need of having effective underground structures calls for the request of durability of 100 years of the PVC-P geomembranes used for waterproofing.

Plasticizer loss from the geomembrane, that is the main degradation phenomenon in tunnel application, can be described has a diffusion problem. Through plasticizer absorption tests on 10 materials, the dependence of diffusion coefficient on temperature and concentration has been defined and an equation predicting the phenomenon has been proposed.

On the base of conservative evaluation on the possible consequences of shrinkage of the geomembrane, a threshold value of 0.45 has been defined for the plasticizer loss ratio as end-of-life value of the two commercial geomembranes analysed.

Both the commercial geomembranes tested fulfil this requirement for an application of 100 years in a shallow tunnel, thus confirming the capacity of the used materials to achieve the required goal during the life of the structure.

Effect of aged geomembrane extrusion welding on antioxidant depletion

M.M. Ali & R.K. Rowe
GeoEngineering Centre at Queen's-RMC, Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada

ABSTRACT: High-density polyethylene geomembranes (HDPE GMBs) are in-situ welded to create an "impermeable seal". Extrusion welds are primarily used for repairs, curves, and other welds not accessible to fusion welding machines. A welding rod which is fed into the extrusion machine is made from the same raw materials for adherence/compatibility requirements between the two materials. The examined geomembrane was welded using preheat and barrel temperatures of 230°C and 250°C, respectively. In a municipal solid waste (MSW) landfill, an extrusion weld facing upward will be in contact with leachate that can lead to chemical degradation. In this paper, the antioxidant depletion rate from welding bead and HDPE GMB sheet away from welding immersed in MSW landfill simulation is examined over an 11-month period at 85°C, 75°C, and 65°C. Preliminary results shows that antioxidant depletion rate of the welding bead was faster than that for the GMB sheet material at lower temperatures (i.e. 65°C)

1 INTRODUCTION

High-density polyethylene geomembranes (HDPE GMBs) are an essential component of the landfill barrier system (Abdelaal *et al.* 2019; Hsuan *et al.* 2008; Morsy *et al.* 2021;). The primary function of the GMBs is to prevent the leakage of fluids and gasses over the lifespan of the landfills, which may reach from decades to centuries (Rowe *et al.* 2004; Scheirs 2009). HDPE is usually selected due to its high resistance to chemical degradation compared to other polymeric geomembranes (Koerner *et al.* 2017; Scheirs 2009). HDPE GMBs consist of 96 to 97.5% of polyethlene resin, 2 to 3% carbon black, and 0.5 to 1% of other additives (i.e., stabilizers and antioxidants) (Hsuan & Koerner 1998). The additives delayed the polymer thermo-oxidative degradation which may occur during the manufacture process, installation, and ageing (Hsuan & Koerner 1998; Scheirs 2009). During installation, HDPE GMBs rolls are welded in-situ to create continuous impermeable seal using high welding temperatures. There has not been any previous study focused on examining the effect of extrusion welding on oxidative and chemical degradation.

There are two common methods of geomembrane welding: Fusion welding and extrusion welding (Müller 2007; Scheirs 2009). Fusion welding is used for the majority of the geomembrane welding length. Extrusion welding is used for welding patches, repairs, curves, and inaccessible areas by fusion weld machines (Scheirs 2009). Although numerous studies identified welds as a weak point of the HDPE GMBs liner system (Francey & Rowe 2022a,b, c; Halse *et al.* 1990; Peggs *et al.* 2014; Rowe & Shoaib 2017, 2018), there are no studies examining the long-term performance of extrusion welding compared GMBs sheet material.

HDPE GMBs ageing follows three stages until failure is reached (Hsuan & Koerner 1998): antioxidant depletion (Stage I), where the antioxidant is depleted without a reduction

in the mechanical properties; induction time (Stage II), where it occurs after full depletion of the antioxidants package, and there is no change in the mechanical properties; reduction in mechanical and physical properties (Stage III), where the oxidative reactions start leading to a reduction in the mechanical and physical properties. Some work has been performed on the effect of fusion welding on the long-term behaviour of the welds. However, no studies have been performed on the effect of extrusion welds on the longevity of the welds. This study presents the preliminary results of antioxidant depletion (Stage I) for extrusion welding based on the standard oxidation time test results (Std-OIT).

2 MATERIAL

One 1.5mm HDPE GMB, denoted by MwA15, with a Std-OIT of 165± 2 (min) was examined.

The extrusion welding of MwA15 was conducted on a landfill site by a licensed geosynthetic installer on a summer day using a Demtech. The geomembrane surface was prepared by grinding the surface to remove the oxidative layers and the additive blooms. The welding machine was fed by extrusion rods made from the same geomembrane materials. The GMB sheets were preheated with hot air to reduce the heat required and increase the size of the molten bead (extrudate).

The preheating was used to avoid the thermal shock that would weaken the polymeric structure along the edge of the weld. Afterwards, the welding rod was softened, mixed in the heated barrel, and pushed out on the GMB surface. The GMB sheet was melted and mixed with the molten bead and then cooled and solidified (Peggs *et al*. 2019). The welded zone has random and isotropic microstructure (Peggs *et al*. 2019). The examined extrusion welding preheats and barrel temperatures were 220°C and 230°C, respectively.

Extrusion welds contain weld beads and flashing (squeeze out) (Figures 1 and 2). Toward the terminal of the extrusion, welding is heat affected zone, which has a similar thickness to the sheet and is subjected to high welding temperatures. The flashing (squeeze out) zones are located toward the extrusion welding extremities, which is the result of the extrudate molten polymer exiting the weld zone during welding (Figures 1 and 2).
Figure 1.   Cross-section of typical HDPE extrusion weld.
Figure 2.   Photographic cross-section view of HDPE extrusion weld.

3 EXPERIMENTAL PROCEDURE

3.1 Jar immersion

Immersion tests were used to accelerate the ageing of the GMB extrusion welds in the laboratory. In the immersion test method, 90×170 mm welded coupons were immersed in 3.5L glass jars filled with simulated municipal solid waste leachate (MSW-Leachate 3; Abdelaal *et al.* 2014). The welded GMB coupons were separated using a glass rod to ensure that the coupons would be in contact with the leachate from both sides. The jars were placed at three different temperatures (85°C, 75°C, and 65°C). The GMB was sampled from the welding area and GMB sheet at different incubation times to monitor the change in Std-OIT with time.

3.2 Differential Scanning Calorimetry (DSC)

To assess the depletion of antioxidants, Std-OIT tests were conducted using a TA instruments Q-2000 series differential scanning calorimeter (ASTM D3895). First, test specimens were cut from the welding bead and sheet material. Then, the specimens were placed at the center of the aluminium pan and loaded into the DSC machine for testing. Hsuan and Koerner (1998) found that this depletion rate can be classified as a first-order decay model. The initial Std-OIT, depletion rate and residual Std-OIT are used to describe the change of Std-OIT with time for extrudate bead and SAW as follows:

$$OIT_t = OIT_o\, e^{-st} \tag{1}$$

Taking the natural logarithm of both sides of [1] gives:

$$\ln(OIT_t/OIT_o) - st \tag{2}$$

where OIT_t is the Std-OIT during ageing at time t (min); OIT_o is the initial Std-OIT (min); s is the antioxidant depletion rate (month^{-1}); t is the incubation time (month).

4 RESULTS

4.1 Unaged Std-OIT

Std-OIT was examined for aged and unaged GMB sheets and post-welding bead zone. The unaged Std-OIT of welding rod material was measured before feeding it into the welding machine to investigate the effect of welding temperature on the pre-welding bead. The measured unaged Std-OIT of welding rod material (348±16 min) was more than twice the Std-OIT of the unaged sheet material (165± 2 min). The high Std-OIT value of unaged pre-welded rods was due to using a high antioxidant package to decrease the effect of the high welding temperature on the possibility of reduction of Std-OIT of the unaged post-welded area. After welding, the Std-OIT of the extrudate bead was 181± 1 min, and this follows from it being twice initially and ~10% finally (after welding) above that of the sheet away from the weld (SAW). The post welding Std-OIT of the sheet and extrudate bead were higher than the minimum requirement (100 min) indicated by GRI-GM 13.

4.2 Depletion in oxidative induction time

The Std-OIT obtained from specimens taken from extrudate bead and sheet material immersed in MSW Leachate at three different temperatures (85°C, 75°C and 65°C) over 12 months of immersion were normalized based with respect to the initial Std-OIT value and plotted for the two locations examined in (Figure 3). The depletion was fastest in the GMB

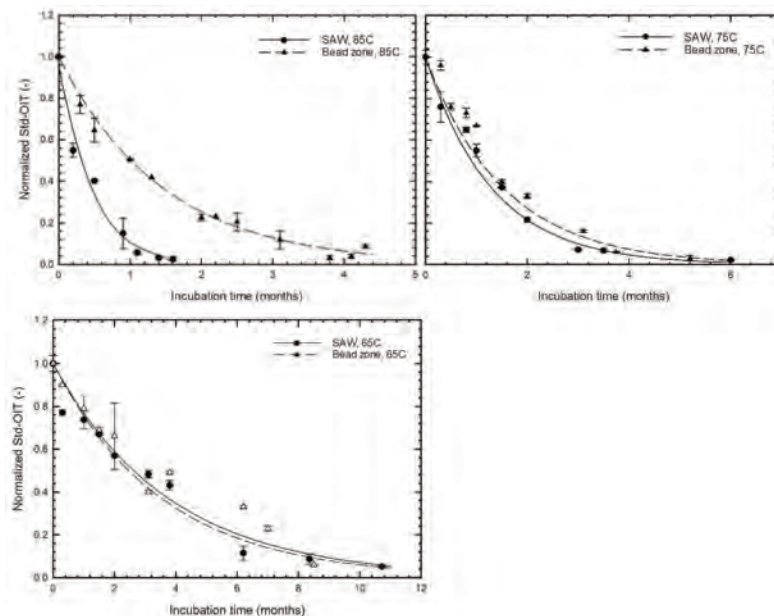
sheet material and slowest at the welding bead (where the geomembrane was thick) at 85°C (Figure 3). The depletion rates decreased with decreasing the temperature (Figure 3). At low temperatures (i.e., 65°C), the rate of depletion of the extrudate bead area (where the extrudate rod was molten and pushed into the geomembrane during the welding process) was faster than at the geomembrane sheet away from welding (SAW) (Figure 3).


Figure 3.   Normalized variation of Std-OIT of bead zone and sheet material with incubation time at two locations immersed in Leachate 3 at 85°C, 75°C, and 65°C.

The welding bead Std-OIT depleted to residual after four months at 85°C, five months at 75°C, and 10.5 months at 65°C. The sheet material Std-OIT depleted after 1.5 months at 85°C, five months at 75°C, and ten months at 65°C. Despite the higher initial Std-OIT of the extruding rod, the depletion rate was slow for the welding bead at 65°C, and the fastest rate was for the welding bead area at 85°C com to the pared sheet away from welding (SAW).

A trend of exponential decay was observed at all temperatures (Figure 3). Figure 4 is plotted as ln (normalized Std-OIT) to allow linear regression to be conducted.
Figure 4.   Linear regression of ln (Std-OIT (min)) depletion of sheet material and bead zone, aged at 85°C, 75°C, and 65°C.

Arrhenius model was used to predict the Std-OIT depletion rates at lower temperatures (i.e., typical landfill temperature). The predicted (based on Eqs. 1 and 2) Std-OIT depletion times are summarized in Table 1, which shows that the time to antioxidant depletion was lowest for the extrudate bead at lower temperatures.

Table 1. Predicted time to Std-OIT deletion in bead and sheet away from the weld (SAW).

| Temp. (°C) | Predicted Depletion time (years) | |
	Bead (220°C/230°C)	SAW
85	0.4	0.16
75	0.6	0.4
65	0.9	1.2
55	1.4	3.6
40	3	21
35	3.9	40
30	5.2	76

The predicted Std-OIT depletion time in MSW Leachate 3 at a typical landfill temperature of 30°C–40°C (Rowe 2005) was 5.2 to 3 years for the extrudate bead and 76 to 21 years for the geomembrane sheet material. The examined geomembrane showed a depletion rate in the extrudate bead (≥ 7 times) faster than in the sheet material. The depletion rates incubated in jars for sheet material have been shown to be substantially faster than in a composite liner system and may be 3.4-fold (or more; (Rowe *et al*. 2010, 2020) greater than in immersion tests (e.g., as given in Table 1) The same comparison has no been done for welds but that depletion can also be expected to be much slower than in Table 1in the filed, however the relative trend is suspected to be similar.

5 CONCLUSIONS

This paper has focused on the effect of extrusion welding on the antioxidant depletion from extrusion welds for a 1.5 mm HDPE GMB used in municipal soil waste applications. The extrusion welds performed on sheet at a temperature of 37°C for a combination of pre-heating and barrel temperatures of 220°C and 230°C. Accelerated ageing tests at 85°C, 75°C, and 65°C were conducted to increase the antioxidant depletion rate and the Arrhenius model was then used to predict the antioxidant depletion rate expected in the field. For the conditions considered, the following preliminary conclusions have been reached for the GMB sheet and extrudate bead:

(1) The unaged post-welding Std-OIT of the extrudate bead was higher than the same for SAW for the GMB examined.
(2) At a test temperature of 85°C, the Std-OIT depletion rate of the extrudate bead was slower than SAW immersed in MSW Leachate; this is attributed to the greater thickness of the extrudate bead compared to the SAW.
(3) The Std-OIT depletion rate of the extrudate bead was faster than SAW at a lower temperature (i.e. 65°C).
(4) The predicted antioxidant depletion times to the residual value for the GMB immersed in MSW leachate at a temperature of 35°C was 3.9 years for welding bead and 40 years for the geomembrane sheet (and probably 3-4 times longer in a full barrier system).

This paper only reported antioxidant depletion detected by Std-OIT test for one geo-membrane and one welding combination. An examination of the effect of different welding parameter combination on antioxidant depletion of welding bead and heat affected zone is important. Additionally, the effect of extrusion welding on physical and mechanical properties needs to be examined for unaged and aged extrusion welds specimens.

Determination of the reduction factors applied to polymeric coated steel woven wire mesh reinforcement in new Eurocodes

P. Rimoldi
Civil Engineering Consultant, Milan, Italy

M. Vicari & F. Trovato
Officine Maccaferri SpA, Bologna, Italy

ABSTRACT: The new norm prEN 1997-3 (at present under discussion in CEN TC 250), that is the new EuroCode for Geotechnical Design, is introducing specific rules for the design of reinforced fill structures. Polymeric coated woven steel wire mesh reinforcement is treated in specific clauses, with Reduction Factors suited to this peculiar type of reinforcement. In facts a product with a metallic core and polymeric coating exhibits different properties than Geosynthetics and fully metallic reinforcements. The present paper is aimed at presenting the durability criteria for woven steel wire mesh reinforcement and the way to derive the specific Reduction Factors proposed in new EuroCode. For design purposes it is required to address the concept of durability following mechanical and chemical damage. In practical terms this means that installation damage, as well as chemical degradation tests, are required for defining the Reduction Factors which need to be accounted for to reduce the tensile strength from the characteristic value to the design value. The paper presents the specific approach to durability for woven steel wire mesh reinforcement, for defining the Reduction Factors for design of reinforced fill structures.

1 INTRODUCTION

1.1 *Products presently used for soil reinforcement*

The products presently used for soil reinforcement can be classified in three homogeneous classes:

– Geosynthetics (GSY, purely polymeric products): the tensile resistant elements are polymeric;
– Polymeric coated steel woven wire meshes: the tensile resistant elements are metallic, made of steel wires, which shall be metallic coated (typically with zinc aluminium alloys) and polymeric coated (i.e. with PVC, PE, PA6 or other polymers);
– Purely metallic products: the tensile resistant elements are metallic, usually made of steel, which may be metallic coated (zinc, zinc – aluminium, etc.).

The durability of polymeric coated steel woven wire meshes should be addressed with specific criteria, which consider the mode of development of corrosion in the metallic core when the product is placed in soil; the set criteria shall be subject to laboratory testing for the definition of the durability and of the Reduction Factors for design of reinforced fill structures.

Polymeric coated steel meshes show a totally different behaviour than fully polymeric geosynthetics; as example, the installation damage will produce the following effects:

– On geogrid made up of polyester yarns with polymeric coating: the polyester yarns (tensile resistant elements) will be immediately damaged to a lesser or larger extent;
– On steel wire mesh with metallic and polymeric coating: the steel wires (tensile resistant elements) will suffer negligible immediate damage, while the polymeric coating may get damaged at multiple points; in points where only light scratches or bruises occurred on the polymeric coating, the metallic coated steel wire will not be exposed to outside environment (the compacted soil), hence the steel wire will not suffer damages even in the long term; only in points where the polymeric coating suffered nicks exposing the metallic coated steel wire to the surrounding compacted soil the tensile resistant elements may suffer long term damage, due to oxidation produced by contact with the chemicals contained in the soil.

By analysing existing norms, like EN 10223-3, EN 14475, and ISO/TS 20432, it appears that different approaches should be used for the two classes of products; the approach to the durability of polymeric coated steel meshes for soil reinforcement still needs to be defined.

2   POLYMERIC COATED STEEL WOVEN WIRE MESHES IN NEW EUROCODES

The new EuroCode EN 1997-3 (at present under discussion in CEN TC 250) will include provisions for polymeric coated steel woven wire meshes within Section 9 on Reinforced fill structures, and in particular:

– Reinforcement in the form of polymeric coated woven wire mesh should comply with EN 10223-3.
– Polymeric coated steel woven wire meshes should be treated with a zinc-aluminium alloy coating (Zn95Al5 or Zn90Al10) conforming to EN 10244-2.
– The minimum coating unit weight shall comply with Class A of Table 2 of EN 10244-2:2009 and be further protected (according to EN 10245-1) by a:
    – PVC coating conforming to EN 10245-2; or
    – PE coating conforming to EN 10245-3; or
    – PET coating conforming to EN 10245-4; or
    – PA coating conforming to EN 10245-5.

– The characteristic tensile strength of polymeric coated steel woven wire mesh reinforcement shall be determined in accordance with EN ISO 10319.

With reference to the topic of the present paper, the most important provision requires that the representative tensile resistance $R_{t,rep,el}$ of a polymeric coated woven wire mesh reinforcing element shall be determined from Formula (1):

$$R_{t,rep,el} = \eta_{pwm} \cdot T_k \qquad (1)$$

where:
    T_k is the characteristic tensile strength of the reinforcing element;
    η_{pwm} is a reduction factor accounting for anticipated loss of strength with time and other influences.
    The value of the reduction factor for tensile strength of steel woven wire meshes, η_{pwm} shall be determined from Formula (2):

$$\eta_{pwm} = \eta_{dmg} \cdot \eta_{cor} \qquad (2)$$

where:

η_{dmg} is a reduction factor accounting for the adverse effects of mechanical damage during transportation, installation, and execution;

η_{cor} is a reduction factor accounting for the adverse effects of degradation of the element by corrosion over the design service life of the structure.

It has to be noted that:

– The value η_{dmg} can be assessed by testing in accordance with EN 17738, as the ratio of the tensile strength of damaged specimens divided by the tensile strength of the undamaged specimens. Note that damage to the coating does not decrease the tensile strength in the short term and is accounted for in the determination of η_{cor}, as it will induce corrosion of the exposed wire.

– The determination of η_{cor} shall account for the long term effect of corrosion of the steel wires due to the local loss of protection caused by mechanical and chemical damage to the polymeric coatings, exposing the wires (with or without zinc-aluminium alloy) to the surrounding environment.

– The polymeric and the zinc-aluminium alloy coating have no structural function, since theirs only purpose is to protect the metallic wires.

– The value of η_{cor} is based on the residual strength of the product ignoring the wires that are exposed and assumed to be ineffective due to loss of polymeric coating. This assumes that the coating does not degrade chemically up to a level such that its protective function is lost over the design service life.

3 DURABILITY OF POLYMERIC COATED STEEL WOVEN WIRE MESHES

3.1 *Effect of mechanical damage on the tensile strength*

Mechanical damage, which affects the tensile strength of polymer coated steel wire meshes, can develop basically during installation, due to friction of the coarse aggregates during compaction of the soil layers; it is related to possible scratches, cuts, bruises, consequent to the mechanical friction of the sharp edges of stones during compaction of coarse soil.

The test for installation damage on double twisted steel wire meshes, according to the full scale procedure specified in EN 17738, is used to define η_{dmg}, but it can be also used as reference for determination of the mechanical resistance of the polymeric coating.

The application of this procedures allows determining the percentage of wires with polymeric coating damage (nicks exposing steel wire) caused by mechanical compaction, which can be used to define η_{cor}.

3.2 *Service life of polymeric coated steel mesh geosynthetics*

To provide the longest corrosion protection to the steel wire mesh, the steel wire is galvanized with a Zn+Al alloy (metallic coating), and additionally coated with a polymer of required characteristics.

The durability of polymeric coated steel wire meshes placed in soil relies primarily on the durability of the polymeric coating:

– the expected service life of the steel wire can be assumed to be at least equal to the expected service life of the polymeric coating if the coating remains intact or just slightly damaged, that is when in no point the metallic wire is exposed to the external environment;

– only at points where physical and/or chemical and/or thermal degradation of the polymeric coating occurs, then the metallic coating of the wires will start to rust and corrode.

Hence the lower limit of durability can be identified in the situation when local damages to the polymeric coating occur: where the metallic wire is exposed to the external environment then rust and corrosion start to develop.

When the polymeric coating is damaged and the metallic coated wire get exposed to the outside environment (usually the compacted soil), corrosion of the steel wire may be produced by the chemical composition of such environment, and corrosion may propagate along the wire.

In this situation two phenomena need to be considered:

(1) diffusion of corrosion along the wire starting from the point where the polymeric coating is damaged;
(2) accelerated corrosion due to differences of electric potential between adjacent points of damage along the same wire or between points of damage along different wires.

3.3 Corrosion of the steel wire

The constant exposure to outside environment always occurs (even without damage) at the ends of the steel wire mesh panels, where the full cross-section of the steel wire is in contact with the surrounding environment. Hence this is surely the worst case, since corrosion will affect the whole cross section of the wire since the beginning. Therefore the evaluation of corrosion propagation can be made by using end cut wires as reference specimens and referring to the corrosion spread test defined in ASTM A975-21. The procedure consists of immersing 250 mm long wire samples in a 5 % solution of HCl by weight. Samples are removed from the solution and analysed after 100, 500, 1000, 1500, 2500 hours of immersion. The polymer coating shall be removed, and the length of the corroded wire measured. The part of the wire with reduced diameter is considered as corroded. The average corrosion lengths measured versus time plot shall show the maximum length after which there is no more increase in length with time: this maximum length measured shall be always less than a mesh repetition.

The corrosion spread test allows to verify that the corrosion, when exposed to such an aggressive environment (pH = 0.137), does not progress further with time and that it remains confined within the size of a mesh only.

Tests using ASTM A975-21 procedure on Maccaferri Polimac coated steel wire mesh have shown that the maximum corrosion length (mm) is always less than a mesh repetition and has the tendency to reach a plateau after approx. 1500 h, as shown in Figure 1. As the length of corrosion penetration is less than half the twisted length, then corrosion occurring in one wire will not affect any other wire of the hexagonal mesh; in this case the effect of corrosion will be limited to the single wire where damage occurred.
Figure 1.   Length of the corrosion penetration along the polymer (POLIMAC) coated steel wire at pH = 0.137.

The corrosion spread test is focused on the evidence that very low pH (acid environment with pH lower than 0.2) produces the highest corrosion rates in steel, while very high pH (alkaline environment) has negligible effects on corrosion; this is consistent with the common experience that concrete, that is a highly alkaline material, does not produce corrosion of steel bars, rather it protects the steel from corrosion.

As for the possible corrosion due to differences of electric potential between two points (i.e., stray currents near railway tracks), being the polymeric coating of steel wires dielectric, it provides electrical insulation to the steel wire itself and avoids electrical connections between adjacent wires, hence corrosion cannot occur if the polymeric coating is not deeply damaged.

Since the general criteria for setting durability of a geosynthetic at X years is that the minimum retained strength shall be 50 % after X years, the evaluation of the durability of polymeric coated steel wire mesh geosynthetics will require the evaluation of the number of wires which can be considered as instantly corroded at the points where the polymeric coating is damaged and the steel wire is exposed. Hence in this case the effect of installation damage can be evaluated by the following procedure, which is consistent with ISO/TS 13434:2007 "Geosynthetics – Guidelines for the assessment of durability" (Figure 2):

– perform the installation damage procedure;
– retrieve the damaged specimens;
– carry out a visual and microscopic inspection for setting the points where the steel wire became exposed;
– cut the steel wires at the points where they were exposed (taking into account that multiple damages on the same steel wire will be counted as one wire exposed);
– perform tensile tests according to ISO 10319:2015 on the reference specimens and the damaged specimens;
– the ratio between the tensile strength of specimens with the damaged wire cut to that of specimens with no cuts provides the minimum retained strength.

Figure 2.   Procedure for installation damage of metallic geosynthetics: a) fill compaction on the sample; b) retrieving sample and identifying local damages; c) microscopic examination to assess exposure of the metallic core; d) indicating points where the metallic core is exposed.

For practical purposes the steel wire can be considered as totally corroded in very short time at the point of coating damage; that is, the steel wire can be considered as instantly corroded or, which is the same, it can be considered as totally cut and not contributing

anymore to the tensile strength of the steel mesh: this conservative assumption allows to include the effect of mechanical damages into the η_{cor} partial factor.

Tests according to the above procedure performed on the steel mesh of Maccaferri Terramesh units (8x10 mesh type and 2.7 mm diameter wire, coated with Polimac), provided the values of η_{cor} listed in Table 1.

Table 1. Results of installation damage tests on the steel mesh of Maccaferri Terramesh units (8x10 mesh type and 2.7 diameter wire, coated with Polimac).

Fill material	Maximum particle size (mm)	η_{cor}
Crushed stones	<200	0.820
Coarse gravel	<38	0.869
Sandy gravel	<9.5	0.952
Sands	<2	1.000
Silts and clays	<0.06	1.000

3.4 Chemicals resistance of the polymeric coating of steel wires

The chemical resistance of steel wires depends on the environment where they work during their service life. Considering the chemicals usually occurring in natural soils and their concentration, it is evident that the polymeric coating of steel wires mesh geosynthetics will suffer very little or even negligible degradation even over very long time. Moreover, the polymeric coating has no structural function, since it has only to provide protection to the steel wire. Hence the durability of the polymeric coating shall be evaluated taking into account its function: its service life shall be considered as the maximum time when it is still able to provide protection to the steel wire.

The resistance of the polymeric coating over time can be predicted by accelerating the ageing effect of the plastic specimens in a rigorously constant and replicable environment (oven), testing degradation by monitoring the variation of the property, the reduction of which will have an effect on the wire protection.

Tests to assess the long-term resistance of polymer coatings shall be performed according to EN 60216-8, where an extrapolation of service life is made by accelerating polymer degradation in oven at various temperatures and then using an Arrhenius plot extrapolation to predict degradation at the ambient temperature.

In the Arrhenius regression method the logarithms of the mean times to end point are plotted versus the reciprocal values of the exposure temperatures. The intersection of this curve with the inverse of the selected reference temperature (20°C) provides the service life T_{pc} (Figure 3).
Figure 3. Arrhenius plot for the Terramesh polymeric coating to determine its expected service life at 20°C.

4 CONCLUSIONS

The metallic core of polymeric coated woven steel meshes exhibits different properties than purely polymeric geosynthetics. Therefore, the durability of woven steel meshes needs to be addressed in a peculiar way.

In the present paper the Authors have proposed a rational procedure for assessing the durability of polymeric coated woven steel meshes, for the definition of the Reduction Factor η_{pwm} that will be required for design of reinforced fill structures according to the new EuroCode.

Risks and alternatives to the use of PET reinforcements in treated backfills

M. Aressy

ABSTRACT: The increasing demand to reuse excavation materials, to use soil in place or materials with high fine contents in the construction of Mechanically Stabilized Earth structures leads to the extensive application of soil stabilization technics such as lime, cement or fly ash treatment.

Soil treatment is an economical solution to exploit poor in-situ materials that cannot be implemented in their natural state. The treatment improves, in short terms, the physical parameters of the soils allowing its workability. However, such treatments also modify the chemical parameters of soil such as alkalinity in durable manner. The pH will remain well above 10 for very long period even at low dosage. Most of the MSE structure reinforced with geosynthetic uses PET based products. It is well established that PET is only suited for soil having pH ranging from 4 to 9. In highly alkaline environment, the degradation mechanism is strongly accelerated particularly when mechanical stresses are applied on the material. Then using PET in treated backfill is a clear risk for a structure integrity.In this paper, we will propose an extensive review of treatment technics detailing the gradual transformation of the soil alkalinity with time, then we will provide technical data showing the performances of PET reinforcement materials when exposed to alkalinity in the conditions of reinforcement applications, finally we will propose alternative solution such as the use of PVA reinforcement material and present their performances.

1 INTRODUCTION

Soil treatment is used to improve or stabilize soils addressing the handling and compacting problems resulting from high plasticity or high-water content found in backfills with elevated quantities of clay or Limestone.

Soil treatment principally involves mixing the soil with a binder to improve its geo-mechanical performance. Binders are mainly lime or cement, resulting in a strong and durable increase in soil alkalinity. The main compound impacting the mechanical and physicochemical properties is calcium hydroxide ($Ca(OH)_2$) (IDRRIM 2015). MSE structures are designed to perform 75 to 120 years depending on the codes, therefore the reinforcement used should be adequately selected.

Often, PET reinforcement is suggested for use in lime-treated backfills. While this option appears economically attractive, it goes against recommendations in international codes and is highly risky for the structure's integrity (L. Van Schoors 2013) (V. Elias 1998).

This paper will focus on lime treatment as it is the most common binder, introducing the treatment's requirements, mechanisms, and long-term properties in MSE structures context. We will also emphasize physico-chemical changes, particularly the alkalinity built up, which directly impacts the choice of reinforcements.

Then, we will provide a condensed literature review of the PET yarns hydrolysis degradation focusing on the influence of alkalinity, the impact of lime on the degradation, and its kinetic. We will provide technical evidence PET based reinforcement is not compatible with treated backfills.

Finally, we will introduce PVAl yarns, presenting some durability results obtained under various conditions and demonstrating why PVAl based reinforcements are the best high stiffness alternative product when construction is done with treated backfill.

2 PRINCIPLES OF LIME TREATMENT FOR MSE STRUCTURES

2.1 *Soil requirements*

Adding lime to soil induces several chemical reactions between the soil particles and the lime. Nevertheless, some geotechnical parameters shall be satisfied to ensure an optimal process:

- The presence of fine particles: Passing at $80 \mu m > 25\%$.
- The Plasticity Index (PI): PI > 10.

In addition, some chemical components that may have adverse consequences on lime treatment shall be limited (IDRRIM 2015):

- The organic matter which may consume the lime. Organic content shall not exceed 1% by weight.
- The chlorides can accelerate the lime treatment and induce swellings by forming chloroaluminates. Chlorides shall not exceed 2000 ppm.
- The sulfate and sulfides in soils (in the form of gypsum or pyrite) can induce ettringite formation, causing considerable swellings. The total soluble sulfate content shall not exceed 3000 ppm.
- The presence of phosphates and nitrates can slow down the curing process. They shall not exceed 1200 ppm.

2.2 *Soil-lime reaction*

Lime includes all products manufactured from the decarbonization of calcitic or dolomitic limestone:

- Quicklime is the product of the calcination of limestone.
- Hydrated lime is obtained from the hydration of quicklime.
- Precipitated calcium carbonate.

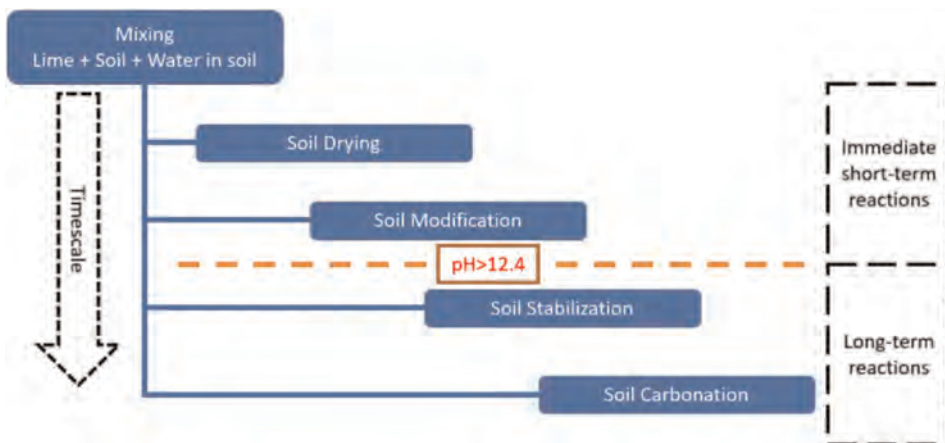
When mixed with soil, different reactions occur following chronological order (Figure 1).


Figure 1.   Chronology of lime/soil reactions.

Short-term actions consist of soil drying, soil modification, and improving the workability and compaction characteristics. In contrast, long-term actions consist of soil stabilization and carbonation, improving the soil's mechanical behavior.

2.3 Soil drying

When the soil is mixed with lime, immediate action is to induce the reduction of the water content. The lime is a dry product, and its addition to soil increases the total mixture weight, whereas the water weight does not change, reducing water content. When using quicklime, the water in the soil activates the hydration of the calcium oxide, thus consuming water. The exothermic reaction induces further water consumption through evaporation (Equation 1).

$$CaO + H_2O \rightarrow Ca(OH)_2 + Heat\ Release \tag{1}$$

2.4 Soil modification

Soil modification is a step in the stabilization process or can be achieved alone using a limited amount of lime. The so-called "lime modification optimum" (LMO) can be determined using the soil-lime pH test described in ASTM D6276. Generally, the LMO lies between 1 wt% to 3 wt% and draws the line between short-term and long-term actions of the treatment or soil modification and stabilization (DigueELITE 2015).

The soil modification mechanism is based on the flocculation process. In the presence of water, hydrated lime or calcium hydroxide will ionize, leading to Calcium (Ca2+) ions and Hydroxyl (OH-) ions (Equation 2)

$$Ca(OH)_2 \rightarrow Ca^{2+} + 2OH \tag{2}$$

The presence of Ca^{2+} in great quantity induces a cation exchange with the soil particles leading to the saturation of the surfaces of the particles with calcium. This mechanism reduces the repulsions forces between the particles and disturbs the water adsorption mechanism. Consequently, the soil particles agglomerate, forming larger and stronger particles.

This modification of the soil induces an instantaneous improvement of the treated fill's physical properties. The following consequences are generally observed:

- Textural change: the fill grading curve changes there are fewer fine particles.
- Plasticity: changes of the Atterberg limits, decrease of the PI.
- Swell potential: significant reduction in swell potential
- Shrinkage: decrease of shrinkage potential
- Compaction characteristics: Modification of the Proctor curve

All these short-term improvements occur in a matter of hours after treatment and facilitate construction. The use of soil modification as the primary process solely concerns granular or intermediate backfills that are too wet or high plasticity, preventing workability and optimal compaction in their natural state. The minimal lime content for soil modification results from the targeted treated soil's immediate bearing index value to be reached. Table 1 gives a range of values for the type of soil. (SETRA 2000).

Table 1. Immediate bearing index values.

Type of soil	Immediate bearing index value after treatment
Granular	15 to 30
Intermediate	7 to 15

2.5 Soil stabilization

In soil stabilization, the treatment influences the long-term performances of the material. The geomechanical characteristics are modified to get a sustainable strength gain and a permanent stability. Here, the quantity of lime added is sufficiently high (superior to the LMO) to generate long-term pozzolanic reactions between the calcium of the lime and the silica and alumina from the soil particles (Equation 3 and 4).

$$Ca(OH)_2 + SiO_2 + H_2O \underset{pH>12.4}{\rightarrow} Calcium\ Silicate\ Hydrate\ (CSH) \tag{3}$$

$$Ca(OH)_2 + Al_2O_3 + H_2O \underset{pH>12.4}{\rightarrow} Calcium\ Aluninate\ Hydrate\ (CAH) \tag{4}$$
The pozzolanic reactions form cementitious products enhancing the shear strength and the stiffness of materials. The lime treatment progressively increases the soil cohesion but has little impact on the friction angle (G. Herrier April 2013). This stabilization process is possible when the silica and the alumina become soluble. The solubilization only happens at elevated pH (pH > 12.4). As lime is a strong alkaline, the treatment increases the pH of the soil. However, to achieve a pH of 12.4, enough lime, superior to the LMO, shall be added. Because of the heterogeneity of the soil mass, lime is always added in excess compared to the LMO value determined to ensure the treatment's durability.

2.6 Carbonation reaction

Finally, a carbonation reaction occurs during the life of structure, the remaining calcium hydroxide reacts with the carbon dioxide present in the soil forming cementitious products, furthering improving the cohesion of the fill.

2.7 Treatment's durability

Chemical stabilization significantly changes the geotechnical characteristics of the treated backfill to achieve long-term permanent strength and stability. External factors can alter the design performance along the service life. Therefore, the durability of soil stabilization shall be considered at the formulation; this often results in adding an excess of lime to cover the uncertainties.

Indeed, the long-term strength gain can be considered durable only when the chemical stabilization mechanism remains active; this means keeping the pozzolanic reactions active. If there is enough calcium hydroxide in the soil, the pH will remain sufficiently high to ensure the solubility of silica and alumina. Thus, the pozzolanic reaction will continue.

One of the primary impacting environmental factors is hydraulic solicitations. These can be found in retaining structures with hydraulic exposure or structures exposed continuously penetration of rain. The presence of water and its circulation inside a stabilized backfill alter the long-term performance by leaching out the calcium hydroxide, which ultimately will reduce the pH and alter the cementitious compounds, inhibiting pozzolanic reactions, and deleteriously changing soil properties.

Whilst, proper drainage management is always highly recommended, to obtain a durable treatment in MSE structures as it necessary to prevent water circulation inside the treated backfill (fully integrated drainage system, a properly designed barrier at the top of the structure, etc.). It should be noted that drainage management is also essential to avoid contamination of adjacent areas, soil treatment use chemical additives that are deleterious to vegetation growth.

2.8 Long-term properties: pH gradual transformation

Treatment of long-term properties has been the subject of numerous studies. It was shown that long-term changes are observed in the soil's physicochemical and mechanical properties,

whether the treatment is done for modification/workability or stabilization. In the scope of MSE structures and the choice of reinforcement, a stable pH in the soil should lead to different reinforcement choices dues to materials compatibility.

Daniele *et al.* (Deneele D. 2016) presented an accelerated leaching study comparing lime-treated silty soil with 1wt% and 3wt%. The pH of these soils after a percolation protocol equivalent to about 11.5 years of heavy water circulation presented values of 9 and 12, respectively. The non-treated soil sample kept a constant pH of 8. De Bel and al. (De Bel R. 2013) who followed the pH evolution of a silty soil over two years showing a stable pH value between 11.5 and 12. Also C. Jung and al. (Jung C. 2008), studied six structures aged from 5 to 11 years old, measuring pH values at different depths. An average pH value of around 10.5 was obtained for all structures, with none of the structures showing a pH lower than 9 at any depth.

All those studies demonstrate that lime-treatment impact the long-term physico-chemical characteristic of the soil and particularly its alkalinity, which can be expected to present a pH>9 whether the treatment is done for modification (short-term) or stabilization (long-term).

3 PET REINFORCEMENT DURABILITY: ALKALINE ENVIRONMENT CONSIDERATIONS

It is well established that PET degradation is hydrolysis. Polyester hydrolysis occurs following two different mechanisms depending on the exposition environment (Van Schoors 2007).

The two environmental conditions considered in MSE structures applications are:

- Acid or neutral environment $1 \leq pH \leq 9$.
- Alkaline environment pH>9.

In acidic or neutral environments, hydrolysis occurs under a mechanism called internal hydrolysis well described in the literature. The water molecules diffuse into the polymer matrix leading to a homogeneous degradation of the polyester chains through a random chain scission process. This induces a reduction of the mechanical properties at a moderate rate after a considerable induction period.

In alkaline environment, the hydrolysis mechanism strongly differs. The reaction is catalyzed by hydroxyl anions (OH-) which transforms the esters functions into alcohol and carboxylate ions. Carboxylate ions can then recombine with cations (such as Na^+, Ca^{2+}, ...) to form carboxylate salts.
Figure 2.   PET alkaline hydrolysis.

Elias and al. theorized this degradation mechanism (V. Elias 1998). They stated that the molecular split described in Figure 2 modifies the polyester's dielectric properties, creating a barrier that hydroxyl ions cannot penetrate. As a result, the hydrolysis intensity at the fiber surface is increased, creating shorter polymer chains that can later be dissolved in the solution, ultimately leading to a drop in the fibers' diameters. This phenomenon can be assimilated to surface erosion of the fibers occurring at a very fast rate. The rate of alkaline hydrolysis also highly depends on the type of environment and the type of cations present.

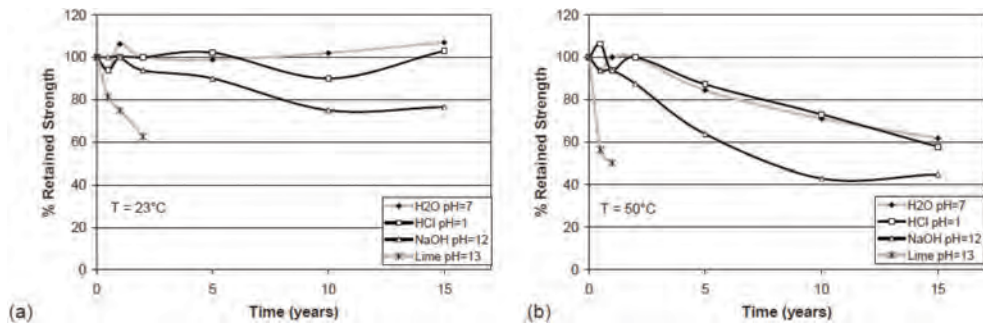
Figure 3 shows the results of hydrolysis exposure test carried out at 23°C and 50°C over 15 years in various solutions (K.L. Nait Ali 2009). Two alkaline compounds were used in this


Figure 3. Hydrolytic degradation of PET yarns in various media (1<pH<13) at (a) 23°C and (b) 50°C over 15 years.

study sodium hydroxide and calcium hydroxide (or lime). Despite the difference of one point in pH value, it is easily noticeable that the ageing in calcium hydroxide is much faster than in sodium hydroxide. The results show that at 23°C PET yarns lose about 40% of strength when exposed to saturated lime solution in only 2 years. The fast degradation rate observed in lime is not only the result of calcium hydroxide being a very strong di-base (carrying two hydroxyl) but also to the presence of Ca^{2+} cations which accelerate the surface hydrolysis rate (H.F Schroeder 2000).

The results show that lime or calcium hydroxide is highly damaging to PET yarns, even at low temperatures. Indeed, at 23°C after two years, the yarn lost almost 40% of its original strength.

Other papers reported that tensile loading of PET yarns further accelerates the hydrolysis rate, particularly when subjected to alkaline hydrolysis. Finally, given the recommended level of compaction in MSE structures, the use of PET based reinforcement products, even if protected with a coating, will lead to yarns being exposed to the surrounding environment and thus to strong alkalinity. This is reminded in many standards but often ignored. The combination of all these remarks highlight that PET reinforcement products are not well suited to lime-treated backfill, and the risk involved in doing so is incredibly high for the reinforcement and, ultimately, for the structure. Other polymers such as polyolefin-based reinforcements provide good chemical compatibility but lack good stiffness and long-term creep performance. It is possible to consider aramid-based reinforcement but, their cost effectiveness and chemical compatibility is limited.

4 PVAL: A HIGH STIFFNESS ALTERNATIVE

PVAl yarns are known to degrade following an oxidation mechanism (Sakurada 1985). While oxidation mechanism can be accelerated in acidic environments, exposition of PVAl fibers to alkaline environments has never shown a considerable impact on the mechanical strength even after a long time of exposure at elevated temperatures (L.K. Nait Ali 2014) (Y. Bian 2018) (M. Nishiyama 2006).

Its chemical behavior associated with its high stiffness (twice as compared to PET yarns) combined with a reasonable cost makes PVAl reinforcement products the best alternative material for MSE structures where treated backfills will be used.

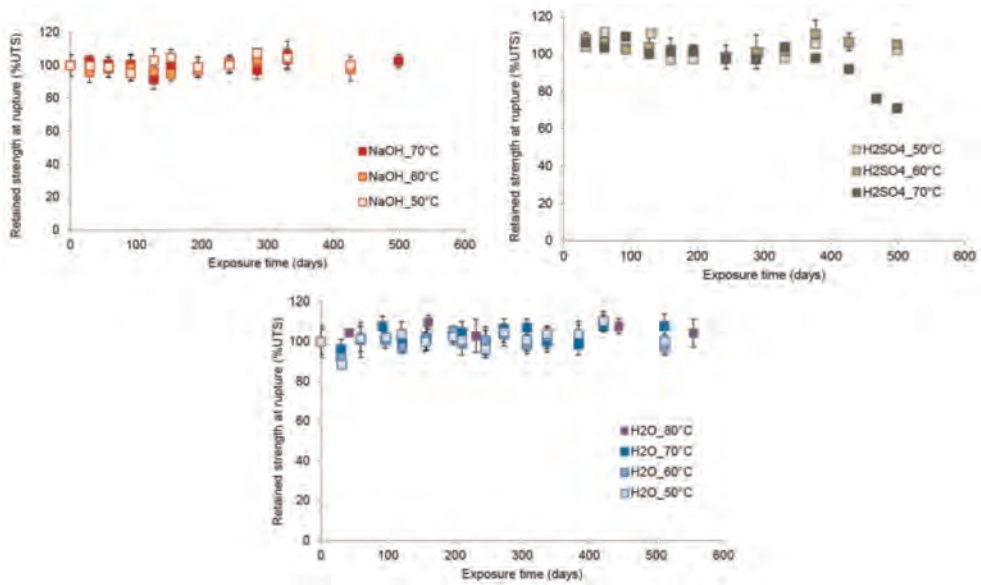
To fully understand the degradation mechanism of PVAl yarns, a durability study exposing yarns to three different solutions (H_2SO_4 pH = 2.4, distilled water pH = 7, and sodium hydroxide pH = 12). Aging conditions were conformed to EN 14030. In this study, the tensile properties were followed as a function of time, and the results are presented in


Figure 4. Progression of the retained strength at break of PVAl aged yarns as a function of exposure time in NaOH, H2SO4 and H2O.

Figure 4. Part of this data was presented in a previous paper (Y. Bian 2018). The results are in Figure 4.

The results clearly show that an alkaline environment does not impact the tensile properties of PVAl yarns even after an extended exposition period (more than 500 days) at elevated temperatures. As expected, PVAl oxidation will only be accelerated when exposed to a strong acidic medium.

As a matter of comparison, we exposed PVAl yarn and PET yarn to a solution of saturated lime at a temperature of 80°C for about ten days (Figure 5). The picture clearly shows the difference in behavior between PVAl and PET yarn. While the PET yarn is degraded, PVAl yarn shows a slight color change due to heat exposure (Y. Bian 2018), but no loss in strength.

Figure 5. Comparison between PVAl and PET yarn exposed to a saturated lime solution at 80°C.

These results clearly show that PVAl yarns are well suited to provide long-term performances when exposed to strong alkaline and thus compatible with treated soils such as lime-treated fills.

5 CONCLUSIONS

Where high and long-term stiffness is required, PET yarns-based geotextile reinforcements are preferred to other materials in MSE structure design. PET yarns benefit from excellent mechanical properties and good chemical resistance (as long as pH<9) at a particularly attractive cost.

In this paper, we have shown that when designing a MSE structure with treated backfill PET based reinforcement is not well adapted, and the risk involved in using this type of material is extremely high for the structure's durability, even if these products are coated for installation damage protection.

Alternatively, we propose that PVAl yarns-based reinforcement is an ideal candidate for MSE structure construction, combining chemical compatibility, high stiffness, and long-term mechanical performances.

Feedback from the bituminous geomembrane (BGM) implemented 20 years ago at the Galaube dam

N. Pepin & L. Deroo

B. Breul
Axter, France

B. Gasc
Institution des Eaux de la Montagne Noire, France

ABSTRACT: The Galaube dam is a 40 m high French rockfill dam commissioned in 2001. The upstream facing is ensured by a 4.6 mm thick bituminous geomembrane (BGM) directly laid on a cold mix layer and an impregnated layer gavel.

During construction, control measurements were first carried out in the factory. The BGM was then installed by vertical strips, in one piece, from top to bottom. Welds were subject to a strict quality control plan and all defect immediately rectified.

After 20 years of operation, the hydraulic behavior of the dam shows that piezometry is low and leakage through the membrane is deemed to be negligible. The dam has settled very few in practice and has already undergone its first filling and a complete emptying in 2007. No defects have been identified and almost no maintenance operations carried out. The design and construction of the upstream facing has been very successful.

1 INTRODUCTION

The Galaube dam on the Alzeau river, located in the communes of Lacombe (Aude department, France) and Arfons (Tarn department, France), was built in 1999-2000. It is operated by the Institution des Eaux de la Montagne Noire and was designed to store and regulate water resources for drinking water, irrigation and navigation on the Canal du Midi.

The dam is a rockfill dam with a tight upstream facing. The maximum height of the structure on the natural ground is 33 m. It creates a reservoir with a volume of 7.7 hm^3 below the normal reservoir level of 720.5 m NGF. The structure is class A according to French legislation on the safety of hydraulic structures.

The purpose of this article is to analyze the behavior of the dam after more than 20 years of operation, and more particularly of the bituminous geomembrane (BGM) which ensures the upstream sealing of the structure. We summarize the reasons for the choice of a rockfill dam, then describe the characteristics of the structure and its waterproofing membrane. Finally, we analyze the hydraulic and mechanical behavior of the dam. Our study indicates that the BGM waterproofing system is very effective.

2 CHARACTERSITICS OF THE DAM AND DESIGN OF THE UPSTREAM FACING

2.1 *Initial design options at the Galaube dam*

Two possibilities were studied and compared at the Basic Preliminary Design stage for the Galaube dam: a roller-compacted concrete dam (RCC) or a rockfill dam with an upstream face. The rockfill dam was finally selected by the project designers because it made the most of the poor foundation and could be easily adapted to the lack of watertight materials by adding a specific watertight component.

Two solutions were possible, depending on the position of the watertight component: an upstream facing or a central core dam, either with an asphalt core or a plastic concrete core. The rockfill dam solution with an upstream facing was considered the most suitable for the Galaube dam because of the following advantages: it was less expensive (in this case), there were lower risks of internal erosion of the sandy gouges of the foundation thanks to a better connection with the granite foundation, there was better handling of the interface with hydraulic galleries and, construction schedule was more flexible.

2.2 *Design of the upstream facing*

2.2.1 *Cross-section of the dam*
The typical cross-section of the dam is shown in Figure 1. The rockfill consists of two main zones:

– an upstream zone with a horizontal width of 3 m (Zone 2), consisting of a material with a grain size of 0/150 mm, ensuring a triple function: *i)* a transition zone between the rockfill and the support layers of the geomembrane, *ii)* a semi-permeable zone limiting leaks in the event of a localized defect on the upstream facing, and *iii)* the creation of a contrast in permeability with the downstream rockfill. The latter contributes to the lowering of the water line in the event of accidental loading by damage to the upstream facing or accidental impounding during construction.
– the compacted rock fill 0/500 mm (zone 3).
– the reinforced concrete plinth is founded and anchored on fresh or slightly weathered granite. A grout curtain ensures that percolations in the foundation are cut off.

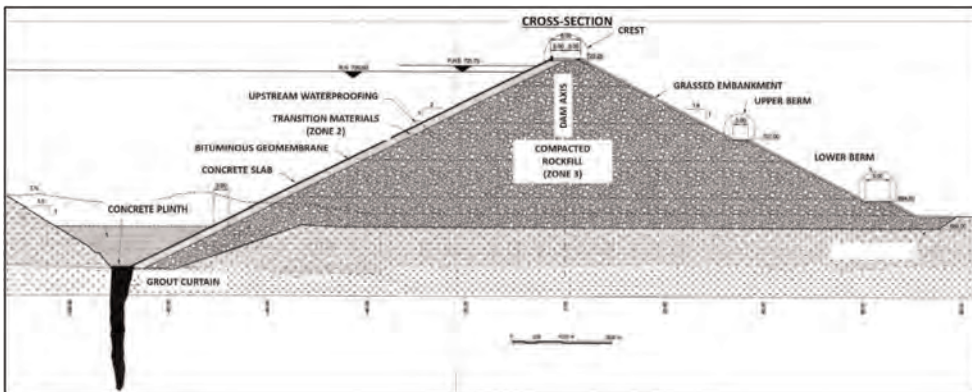
Prior to the placement of any material of the upstream facing, the upstream slope of the dam embankment was compacted with two static rollers of 4 tons each, specially designed and manufactured, and pulled from the dam crest. This compaction complemented the previous compaction of the backfill.


Figure 1. Typical cross-section of La Galaube dam (ISL).

2.2.2 Technical specifications of the upstream facing

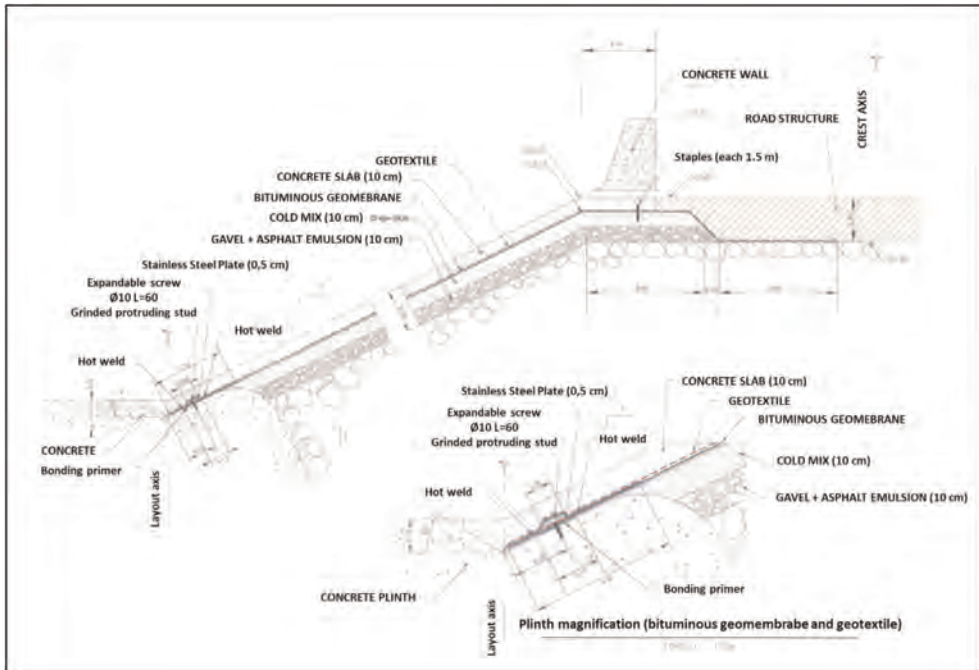
The typical cross-section of the upstream facing of the Galaube dam is shown in Figure 2.


Figure 2. Typical cross-section of the upstream facing.

2.2.2.1 Membrane supporting layers

The membrane supporting layer consists of two sub-layers:

– a layer of gravel, with a grain size of 0/20 mm, with a minimum thickness of 10 cm impregnated with bitumen. It is designed to absorb most of the irregularities in the flatness of the dam body and those that may occur because of prior compaction of the slope.
– a cold semi-permeable asphalt mix layer with a nominal thickness of 10 cm and permeability between $0,75 \times 10^{-6}$ et $1,25 \ 10^{-6}$ m/s. The controlled breaking behaviour of the emulsion was selected so that the cold asphalt mix manoeuvrability was ensured throughout the implementation and compaction phases.

2.2.2.2 Bituminous geomembrane

The upstream facing of the dam is ensured by a 4.6 mm thick "Coletanche NTP3" bituminous geomembrane with the following data:

– Mass per unit area of 5.5 kg/m2
– High tensile strength in both directions: 28 kN/m in longitudinal direction, 20 in transverse direction, together with more than 70 % elongation at break, according to French standard NF P 84-50
– High resistance to puncture: 500 N according to French standard NF P 84-507
– tensile/shear joint strength greater than 75% of the tensile strength in the current part, according to French standard NF P 84-502.1.

A series of measurements on each of the components was carried out in the factory for each laid strip. The membrane was laid directly on the cold mix layer without the

interposition of a geotextile and by following a detailed installation drawing. The membrane was unrolled from top to bottom and each strip was laid in one piece from the crest attachment to the weld on the concrete plinth. Horizontal joints were not permitted.

Welds were performed according to the procedure recommended by the geomembrane manufacturer. The minimum overlap to be achieved by welding was 20 cm. Welds should only be carried out on perfectly clean surfaces, free of dust, moisture, and grease. A continuous control of all the welds between the strips was carried out. For the Galaube dam, the weld quality was checked by a continuous non-destructive device called CAC 94. This machine had a measure wheel, which included 24 ultrasonic sensors that could detect flaws of a minimum surface of 0.8×0.5 cm at the interface between the two geomembranes, on a 21 cm wide strip. If a section of welds showed defects, repairs had to be carried out immediately. A wider patch with at least 30 cm around the flaw was then applied, hot welded and checked again.

The concrete plinth was anchored into the rock foundation. The geomembrane was fastened to the plinth at the foot of the slope and along the whole periphery of the impervious face. It was hot-welded on the 2H/1V sloping part of the concrete surface, which has been previously covered with a tack-primer, then anchored with stainless steel plates bolted into the plinth, each 15 cm.

At the crest, the geomembrane was clamped using metal staples spaced 1.5 m apart, driven into the cold mix asphalt layer and into the concrete slabs overlying the membrane. The membrane was flipped under the road structure over a length of 0.80 m.

For the cconnection to concrete structures, the materials used were the same as those used for fixing to the concrete plinth.

2.2.2.3   Geotextile

A geotextile was placed above the BGM: it provided a puncture protection function when the protective slabs were laid and now ensures a drainage function for the underside of these slabs. The geotextile presented a mass per unit area of 500 g/m^2 (NF G 38-013), a tensile strength of 20 kN/m (NF G 38-014), and a transmissivity higher than 10^{-6} m^2/s (NF G 38-018).

2.2.2.4   Concrete slabs

The dimensions of the protective slabs for the geomembrane were 5 m width (horizontal) and 10 m length (along the slope). The concrete (35 MPa standard compressive strength) was cast in place. The anti-cracking device was made of polypropylene fibres (0.4% by volume) which tensile strength had to be greater than or equal to 500 MPa.

Horizontal joints were continuous and consisted of simple concrete interfaces. Vertical joints were staggered and designed as dilatation joints and filled with a strip of expanded polystyrene type material of about 20 mm. After concreting and hardening of the second panel, they were cleared of the joint material and left open.

The horizontal and vertical joints between minimum and maximum water level were filled with a flexible mastic to prevent the joints from being filled with silt and vegetation.

3   FEEDBACK ON THE MONITORING OF THE UPSTREAM FACING

3.1   Analysis of the hydraulic behavior of the dam

The filling of the reservoir took place in two seasons. In June 2001, the reservoir reached a maximum level of 710.94; the level then progressively decreased until it reached 704.50 in December 2001. In February 2002, the reservoir exceeded the maximum level reached in 2001. The normal reservoir level of 720.50 was finally reached in June 2002. The reservoir had an average annual tidal range of 15 m until the 2007 drawdown. Afterwards, the range has been about 5 to 10 m until today.

The piezometry at the downstream foot of the plinth (Figures 3 and 6) appears to be well draw down with a low (less than 30%) to very low (less than 10%) dependence on the reservoir level. Only PF03 piezometer shows particularly sensitive to the level of the reservoir
Figure 3.   Time evolution of the piezometric levels in the foundation, downstream of the plinth.

and reacts by faithfully reproducing the reservoir curve. This singular behavior, detected immediately after the first filling, is not reproduced by its neighbors (PF07 and PF08). As PF03 is drilled in a zone where the rock is of good quality and low permeability, it is likely that PF03 measures a singularity of piezometry, for example by capturing a fine fissure, where pressures can become high due to the low permeability of the medium. Watertightness of the geomembrane is therefore not in question.

Overall, the analysis of piezometric levels downstream of the plinth over the period 2001–2021, shows that they are constantly decreasing since impound, on average by about −10 cm/year. It is most certainly a consequence of the progressive sealing of the upstream foot of the dam in connection with the progressive silting of the reservoir.

In the axis of the dam (Figure 4), PF06 and PR03 were apparently above the piezometric level at the first filling but they have shown a continuous decrease since then confirming the very good behaviour of the upstream facing. The piezometry at the bottom of the valley (Figure 4, PR01, PR02, PF04), is quite homogeneous under 690 m NGF, which corresponds to the foundation level of the dam in this area. The rockfill, which is very draining, does not allow piezometry to develop.

Regarding the piezometry downstream of the dam (Figure 5), only the piezometers at the top of the bank (PD01, PG01 and PG02) reacted to first filling and show now a strong dependence on the reservoir level. These piezometers are the closest to the reservoir and they are located in an area (the upper bank) where the foundation is permeable (upper left bank made up of deeply altered granite, and upper right bank where there is an interface between the granite foundation of the dam and the shale that overhangs it). All these piezometers are traditionally influenced by weather conditions, especially the heaviest rainfall events which lead to reversible peaks.

With respects to the leakage flows, the absolute value of the measured flows at the end of impoundment was of the same order of magnitude as what had been observed on other dams of the same type in France. Given the greater height of the Galaube dam, and especially the greater dammed surface area than that of these previous dams, the level of measured runoff was considered satisfactory (0.7 liters per hour and per square meter of facing). Leakage
Figure 4. Time evolution of the piezometric levels at the interface of the dam body and the foundation.
Figure 5. Time evolution of piezometric levels downstream of the dam and on the riverbank.

rates have remained generally moderate – on average about 20 l/min for the flow drained by the drainage gallery – which is well correlated to the reservoir level and increases significantly above 720 m NGF. The flow drained by the temporary diversion tunnel on the left bank – on average about 60 l/min – is also dependent on the reservoir level, but it has a higher dispersion, mainly due to rainfall.
Figure 6. Maximum piezometry in the foundation - downstream of the plinth (period 2018-2019).

The monitoring of leakage flows over the period 2001–2021 shows a continued favourable downward trend of almost −2 l/min/year. This confirms the good watertightness of the upstream facing and the absence of leaks.

3.2 *Analysis of the mechanical behaviour of the concrete plinth and upstream facing*

3.2.1 *Deformations of the upstream facing*

Calculations of the deformation of the dam's upstream facing under the effect of the structure's own weight and the water pressure exerted by the reservoir were carried out in 1996 when the dam was designed.

The calculated deformations of the facing during the operation of the reservoir show that the most stressed area of the membrane is located near the plinth where the differential settlements created by the variation in the height of the embankment cause the geomembrane to be put under tension.

Careful excavation and plinth geometry aimed to limit discontinuities in the upstream facing foundation to limit localized differential settlement. The same applies to the connection of the facing to the upstream structure and to the spillway, where 0.5H/1V facing slopes have been provided to limit membrane extension deformations. These slopes also made it possible to ensure satisfactory compaction in the entering angles near the concrete facings.

The expected membrane deformations – of the order of a few millimetres per metre at most – are negligible compared to the specified elongations at failure of the membrane, which are greater than 40%. The weight of sediment in the lower part of the upstream facing does not seem to be able to alter these conclusions. The deformations generated by the incremental vertical stress (of the same order of magnitude as those calculated under the effect of hydrostatic pressure alone) are in fact considered negligible compared to those generated by possible differential settlement of the fill, which are themselves considered very unlikely in view of the deformations:

– The proven behavior of the structure: it has settled very few in practice (cumulative settlement less than 4 cm at the crest, i.e. less than 0.1% of the total height of the dam) and less than most upstream facing rockfill structures of the same type (see comparison in the graphs on Figure 7 and Figure 8 with 11 well compacted dams, i.e. with materials of medium to high quality $20 < RC < 70$ MPa) ;
– The precautions taken during the construction phase to compact the rockfill, in particular: a maximum layer thickness of 80 cm, a minimum of 8 passes (one way) of a heavy smooth

795
Figure 7.   Comparison of maximum crest settlements in relation to 5 dams of the same type, some of which were sensitive to first filling.
Figure 8.   Comparison of maximum crest settlements in relation to 6 other dams of the same type.

vibratory roll, a travel speed of less than 3 km/h, specific compaction in the vicinity of concrete structures (using mechanical tampers), specific compaction in the vicinity of the plinth with a backfill built directly above the structure to ensure optimal compaction, the excess volume being removed before the membrane support layers are placed, and a strict control plan, particularly in the transition zones under the upstream facing (geometry, granulometry, density weight and permeability).

3.2.2   *Effect of welding*
The welding of geomembrane panels is an essential aspect for the success of their implementation as an impermeable barrier. For the Galaube dam, the geomembrane was installed

by vertical strips in a single piece, so there are no horizontal joints. The vertical joints were subjected to a strict quality control plan. All welding defects were immediately rectified by welding a piece of geomembrane that was larger than the identified defect. One should thus expect criteria at break close to those of the geomembrane itself (elongation at break $\geq 60\%$).

3.3.3 Risk of puncturing

Geomembranes, especially polymeric geomembranes, placed on any type of aggressive rough substrate or soil containing stones, pieces of wood or other debris are vulnerable to puncturing stresses, which may cause leakage. ICOLD Bulletin No. 135 states that "*the lining with a needle-punched non-woven geotextile, whether above or below, improves puncture resistance quite impressively.*" The risk of puncture can occur at three different points in the life of the liner:

– During the installation of the geomembrane (tool falls, snags and wear caused by site workers and equipment, etc.),
– During the installation of the covering layer (the most crucial step, regardless of the sealing system),
– After impounding, due to the hydrostatic pressure pushing the geomembrane against protrusions of the support.

From this point of view, the Galaube dam has many favourable factors:

– A geotextile is placed above the membrane: it provides a function of protection against puncturing during the installation of the protection slabs and a function of drainage of the underside of these slabs.
– The bituminous membrane is laid directly on the cold mix layer without the interposition of a geotextile because the layer is smooth (gravel with a regular grading curve of between 0 and 10 mm) and is itself laid on a transition layer consisting of a 20 mm minus well-graded gravel.
– The dam has already undergone its first filling, a complete emptying in 2007, as well as 20 years of service without any observed defects.

3.2.4 Ageing of the geomembrane

Geomembranes are sensitive to UV radiation, thermal, biological or chemical aggression. However, ICOLD Bulletin No. 135 states that: "*It goes without saying that the lifetime of protected geomembranes will be much longer than that of exposed geomembranes. It seems reasonable to expect a geomembrane protected by a permanent concrete layer to have a life expectancy of more than 200 years.*"

At the present time, there is no reason to suspect any issue with the BGM of the Galaube dam; leakage through the geomembrane is deemed to be negligible.

3.3 Lessons from 2007 drawdown

3.3.1 Behaviour of the dam during the drawdown

The reservoir of the Galaube dam was emptied for the first time in the fall of 2007 as part of the first "five-year" inspection of the dam, which generally takes place 5 to 6 years after the dam is impounded according to French regulations.

The inspection reports n°3 (February 2008) and n°4 (February 2009) prepared by ISL Ingénierie) did not reveal any anomalies in the hydraulic and mechanical behaviour of the structure, which proved to be completely reversible.

It should be noted that a slight elevation of the dam crest was recorded (of the order of 1 to 2 mm and visible on all the height benchmarks on the crest of the dam), during the emptying (cf. Figure 9). This is a mechanical consequence of the decrease in hydrostatic
Figure 9. Time evolution of crest elevation measurements.

pressures of the reservoir on the upstream face of the structure (decompression of the rockfill).

It was also checked that the under-pressure behind the facing remained below the hydrostatic pressure exerted by the reservoir on the facing, which did not create a risk of lifting the geomembrane or the concrete protection slabs (cf. Figure 10).
Figure 10. Maximum piezometry downstream of the plinth at the time of the 2007 reservoir emptying.

3.3.2 *Maintenance work carried out on the upstream facing*

The mechanical protection of the facing membrane of the Galaube dam consists of juxtaposed 5 m wide × 10 m long slabs cast in place with a fibre-reinforced concrete. The horizontal joints are parallel and the vertical joints are offset by half a slab. An expansion joint made with expanded polystyrene was present on the periphery of each slab, after the drying and shrinking of the concrete. It was observed that this joint was no longer held and it was torn off by wave action. Silt had begun to settle in this void and vegetation to grow.

A first area in the upper part of the upstream face had been treated during the construction site (a row and a half of slabs vertically and from bank to bank horizontally), but despite this, as the water level was lowered, plant growth began to take root in the unfilled spaces.

The owner and operator of the Galaube dam (IEMN) decided to extend the filling of the joints to the lower slabs with identical product, so that the usual tidal height is now completely treated. The work was carried out as part of the 2007 drawdown.

The horizontal joints have been filled in. For the vertical joints, a gap of approximately 20 cm was left at the bottom of each joint to allow water that had passed behind the plate to drain away as the level of the reservoir was lowered. The product used was cold bituminous mastic applicable even under water: Shell Tixophalte Wet.

This is the only work carried out on the upstream face of the Galaube dam during the first 20 years of the structure's life. Underwater inspections conducted in October 2020 as part of the exhaustive review of the dam thus showed no adverse changes to the upstream facing.

4 CONCLUSION

All the elements presented in this article allow us to affirm that the BGM upstream facing has been very successful at the Galaube dam: great care in the construction of the structure, low piezometry, absence of leaks and no notable disorders for 20 years of operation. It also has a very good record on other French dams, some of them a bit older than the Galaube dam (though not as high).

Of course, every project still requires adaptations and, despite its great success, the Galaube dam design shall probably not be directly applied to other project. The need from adaptations might come from three reasons:

– The design of an upstream facing depends a lot on the nature of the backfill materials and of the foundation.
– At Galaube dam, the rockfill and the foundation were of poor quality, which led to a gentle 2:1 upstream slope; steeper slopes might be considered – but stability of the upstream facing must be checked carefully.
– The Galaube dam design may be considered as "very safe" and could probably be optimized.

Assessment of creep behavior in aged geotextiles

J.L.E. Dias Filho
Department of Geotechnical Engineering, São Carlos School of Engineering (EESC), University of São Paulo (USP), São Carlos, São Paulo, Brazil

ABSTRACT: Considering the exogenous environment of the geotextile application, the characterization is more representative when tests and analysis are performed with sample exposed by sunlight or artificial UV light. Then, this paper aims quantitative evaluation of creep in specimens from field and laboratory degraded conditions. All analysis was done in two different types of geotextiles differing by their weights and composition. Results obtained with the aged specimens were larger than virgin samples and varied according to the base polymer and weight. The behavior of the aged materials did not show rupture results and the deformations were up to 40% greater. Thus, it can be concluded that simulating different conditions of exposure make the results more accurate as the application of geosynthetics in design and this makes the data from the studies more reliable for dimensioning engineering design.

1 INTRODUCTION

Creep is the deformation that occurs in a material subjected to constant stress over time. This test is important for characterizing the durability of geosynthetics, as the results serve as an estimate of the material's useful life. The design involving the use of geosynthetics require long-term performance, it makes sense to characterize materials by this property. Therefore, geosynthetics are often characterized using a standardized creep test (ASTM D5262) under controlled temperature and relative humidity conditions. However, this technique requires the use of expensive long-term testing to obtain a significant creep deformation response, which can take up to 10,080 hours.

There are three stages of creep behavior that can be seen in the measured strain curve as a function of time for the geosynthetic material under constant load for over time. The first stage, also known as the transition phase, is characterized by a decrease in strain rate with time. In the case of secondary stage, the linearity of the curve dominates. Tertiary stage, on the other hand, is characterized by an increase in the creep strain rate, which causes the material to rupture within a short period of time. It is important to highlight that this behavioral pattern will vary depending on the type of polymer (Dias Filho *et al.* 2021; Guimarães *et al.* 2016), the stress level of the specimen (Balakrishnan & Viswanadham 2017; Dias Filho *et al.* 2022), and the rate at which the stress is applied (Bathurst *et al.* 2012; Naftchali & Bathurst 2021). From these variables, the creep curve can acquire a dominant stage. Mathematical models can be characterizing the curve format (Dias Filho *et al.* 2019a; Dias Filho *et al.* 2021; Kongkitkul *et al.* 2014) that allow extrapolation of laboratory-derived data to identify interests such as creep deformation rate relative to temperature or load change and rupture.

The creep test method is designed to determine the unconfined tension creep and creep rupture behavior of geosynthetics under permanent tensile load and constant temperature.

According to ASTM D5262, there are two variants of the creep test: the determination of the creep deformation behavior and the determination of the creep rupture. In this paper, four tests were performed at different load levels from 5% to 60% and test times up to 1008 hours to determine the creep deformation behavior.

Evaluation of alternatives for rapid, precise and representative collection of creep results has been the focus of many papers. These papers investigate the factors that influence the deformation behavior of geosynthetics under constant load. Key methods include: stepped isotherm (SIM) and time-temperature superposition (TTS), which accelerate creep with increasing temperature (Achereiner *et al.* 2013; França & Bueno 2011; Zhao *et al.* 2021); methods to study exposure degradation (Dias Filho *et al.* 2019b; Pinho-Lopes *et al.* 2018); and analysis of the effect of soil confinement on the behavior of geosynthetics (Plácido *et al.* 2018; Nuntapanich *et al.* 2018).

Researcher papers (Liu *et al.* 2017; Zhao *et al.* 2019) reported strain limit data under 10% in structures dimensioned with geosynthetics, which in engineering practice indicates low deformation. It is also important to highlight that several of these geosynthetic design are exposed to the weather, mainly to ultraviolet (UV) radiation. Then, this paper seeks to contribute to the understanding of creep deformation behavior in woven geotextiles by evaluating different conditions testing (field and laboratory) using short-term unconfined creep test.

2 MATERIALS AND METHODS

2.1 *Study material*

Two different mass per unit area of woven geotextiles were selected for testing. As shown in Table 1, tests were performed on monofilament polypropylene (PP) and multifilament polyester (PET) according to American Standard Test Method - ASTM. The geotextile nomenclature is formed by the union of the base polymer and its weigh.

Table 1. Reference values for the nominal characteristics of the woven geotextiles.

Property	Test standard	PET340	PP500
Tensile strength (kN/m)	ASTM D5035-11	52.5 ± 1.6	106.2 ± 2.0
Elongation at rupture (%)	ASTM D5035-11	16.5 ± 1.8	20.1 ± 1.3
Mass per unit area (g/m^2)	ASTM D5261	340 ± 8	500 ± 9
Thickness (mm)	ASTM D5199	0.51 ± 0.02	1.53 ± 0.04

2.2 *Methodology*

The test procedure included characterizing the creep deformation of two selected woven geotextiles. Taking into account the exogenous environment of the application, testing and analysis are performed on representative samples exposed to sunlight or artificial UV light, and traditional tests can then be used to evaluate the effectiveness of virgin samples and other samples exposed to UV damage characterization.

2.2.1 *Outdoor exposure*
Samples were exposed to natural climatic conditions in Campos dos Goytacazes/RJ from August 2013 to August 2015. The test specimens were installed in appropriate exposure racks using suitable holders, which were affixed to the racks. The samples are mounted on support that are inclined 21°48' relative to the horizontal, corresponding to the local latitude, i.e. 21° 48' 14" S and 41° 19' 26" W. The method ensures a higher incidence rate and

therefore a stronger absorption of solar radiation. It was used the ISO TS 13434 and ASTM D5970. The field degradation times for performing the tests specified in the experimental procedure were 360 and 720 days.

The climate characteristics of this site during the natural exposure test were: the highest average temperature was 33°C, the lowest average temperature was 20°C, 14 meters altitude, precipitation in 292 days with the cumulative value of 1487.8 mm, the relative humidity was 81%, the largest irradiation of solar energy accumulated by month was 847.7 MJ/m^2 and 13.44 GJ/m^2 for the total irradiation of solar energy for two years of analysis. Briefly, the ultraviolet radiation was 1.01 GJ/m^2, i.e. a value corresponding to 7.5% of the total cumulative incidence of solar radiation according to ISO TS 13434. Such information was obtained directly from the National Institute of Meteorology - INMET.

2.2.2 *Accelerated UV test*

Samples were degraded by condensation and ultraviolet radiation, simulating natural changes during temperature variation over day, precipitation rain and ultraviolet radiation from the sun. These conditions closely replicate the natural degradation process because they simulate, with greater intensity, the main degradation mechanisms of geosynthetics used in geotechnical design.

The degradation times accelerated in the laboratory to be subjected to the tests set out in the experimental program were 400 and 800 hours. UVB lamps and ASTM D4355 guidelines were used. The UVB lamps disponible at laboratory give a short wavelength output in comparison to field exposure, but promote the degradation of materials quickly.

2.2.3 *Creep test*

Tests are carried out in a laboratory with a controlled room temperature of 20 ± 2 °C and a relative humidity of $65 \pm 5\%$ for a duration of up to 1,080 hours. The creep deformation behavior of two woven geotextile samples was determined at loads of 10%, 20%, 30%, and 40% of the ultimate tensile strength (T) according to ASTM D5262. The creep deformation behavior of the degraded samples was determined over a period of 3 days (Dias Filho *et al.* 2019) at 10% and 20% loads. According with Dias Filho *et al.* (2019), short-term loading tests may be used to extrapolate long-term creep deformation in woven geotextiles.

At scheduled times of 1, 2, 4, 8, 15, 30, and 60 minutes, then at 2, 4, 8, and 24 hours, and finally at 3 days (data collection limited degradation samples), 7, 14, 21, and 42 days, measurements of the displacements in the test samples were taken.

The test specimens were 50 ± 5 mm wide, gripped in the clamps with a gauge length of 25 mm, according to tensile strength strip tests (ASTM D5035-11), which obtained a lateral contraction of less than 10% (NBR 15226). It is important to note that the device basically consists of a grip to hold the sample without slipping and damage, a system to determine the length of the measurement over time and a load to apply the load within a minute system, according to Brazilian standards NBR 15226.

3 RESULTS

Based on the methodology, in order to demonstrate the behavior of the creep deformation of degraded samples, Table 2 shows the evaluation of the variations of the mechanical behavior due to degradation exposure of the material, naturally in the field or accelerated in the laboratory by condensation and ultraviolet radiation.

As can be seen from Table 2, the loss of tensile strength was greater in the polyester. Then, the tests degraded less PP and more PET, as expected for UVB lamp. In the laboratory, results show 66% reduction in tensile strength of PET340 and 16% of PP500. The reductions were 90% for PET340 and 55% for PP500 to exposure time in the field.

Table 2. Retained values of tensile strength and elongation at different UV total irradiation.

| | | | Retained tensile strength/elongation (%/%) | |
| | | UV total irradiation | PET340 | PP500 |
Condition	Time	(GJ/m^2)		
Intact	0	0	100/100	100/100
Laboratory	400 hours	0.14	39/44	90/95
	800 hours	0.28	34/28	84/91
Field	12 months	0.49	21/24	57/59
	24 months	1.01	10/16	45/55

The results test showed that there are no significant changes their stiffness along the stress-strain curve. Observing the deformations in the tests, the PET340 and PP500 samples increased their deformations up to 84% and 45% respectively.

Based on the mechanical characterization of the materials and their behavior according to the degradation conditions presented (Table 2), Table 3 presents an important comparison of the relationship between the tensile loads used in the creep tests (10%T and 20%T), from virgin samples, by tensile strength according to with the conditions found in the tests.

Table 3. Relation tensile load and tensile strength.

| | | 10%T/20%T (%/%) | |
Condition	Time	PET340	PP500
Intact	0	10/20	10/20
Laboratory	400 hours	26/52	11/22
	800 hours	29/59	12/24
Field	12 months	49/97	18/35
	24 months	103/207	22/44

The proportionality between the tensile loads/tensile strength shows that the values of the loads for the creep tests reach the rupture stage. Particularly in polyester, several ratios between load and tension exceed 50%. This explains the nonappearance of some of the creep results in the degraded samples that are shown in Figure 1.

Only one PET340 degraded sample was obtained to the fluence curve (Figure 1a). The sample degraded in the laboratory (400 hour and 10%T) obtained a curve between the results of 20%T and 30%T of the virgin creep test and very close to the value of the tensile loads/tensile strength ratio in Table 3 (26%). The last data collection point may be indicating the beginning of stage 3 of the creep test, where the strain rate over time is no longer linear and increases significantly until failure. In fact, the degradations in the laboratory and in the field greatly altered the other samples, as shown in Table 2. It is also noteworthy that the load in the others degraded specimens exceeds 29% (Table 3), which indicates more than 4% of deformation in virgin samples. This justifies the absence of the other 7 tests in the PET340 samples, since even before counting the deformations, the specimens were lost at the beginning of the test execution.

Figure 1b shows all tests on PP500 samples. The strain rates were all linear and the results were very close to the relation between tensile load and tensile strength according to the condition of Table 3. Among 10%T and 20%T of the creep results in virgin sample, data from samples degraded in the laboratory (400 and 800 hours) and field (12 months) under
Figure 1. Mean curve of tensile strength (T) and deformation (for geotextile by different conditions. (a) PET 340 (b) PP 500.

10%T are observed. Another set of data were between 20%T and 30%T of the creep results, including samples degraded in the field (24 months) under 10%T, as well as samples degraded in the laboratory (400 and 800 hours) under 20%T. Finally, the data obtained by samples degraded in the field at 12 and 24 months under 20%T was of 30%T-40%T and above 40%T, respectively.

It is important to highlight that these results are a safe and fast way to obtain geotextile de-formations under creep and radiation exposure. In this way, it is possible to estimate the deformations in the field by determining the ultraviolet radiation absorbed over time (Dias Filho *et al.* 2019b) preparing sample by accelerated degradation in the laboratory. Then, the test is carried out as presented in this paper for example (following the 3-day test proposal by Dias Filho *et al.* 2019a). However, it is believed that the deformations will be smaller than those obtained in this paper, since the exposure of the geotextile in the project does not cause accumulated ultraviolet radiation immediately, and consequently, the loading of the geo-textiles as well as the development of creep stage 1 and 2 will be gradual. Therefore, the deformations tend to increase and as the ultraviolet radiation accumulates over time, the response will be a fluence curve that varies between the response of virgin and degraded samples.

4 CONCLUSIONS

The study paper presented fluence results of intact samples and under different conditions of ultraviolet degradation in the field and laboratory.

Evaluation of the data from only 3 days of testing yielded reliable results and according with Dias Filho *et al.* (2019a) can for achieving fast, efficient and findings show that short-term data measurements can be safely extrapolated to obtain long-term durability estimates for the material, in accordance with deformation limits defined by a project.

A susceptibility of polyester to degradation by ultraviolet radiation was also observed in relation to polypropylene. This may be related to the possibility of stabilizers in the PP samples. The retained tensile strength of 10% from PET 340 and 45% from PP500 demonstrate this.

In the creep of samples produced by PET, despite showing generally good creep resistance, the only result indicated an increase in deformations and a possible indication of stage 3, confirming how much radiation degradation actually contributed to this behavior. Meanwhile, PP samples increased their strains according the relation tensile load and tensile strength. The results show that the creep response followed according to the stiffness of the degraded samples.

Finally, this study is relevant because contributes to a discussion of the effect of degradation and creep act in conjunction in routine applications of geosynthetic materials. Therefore, this paper contributes to the study of durability of geotextiles, based on the comparison between the variation of mechanical properties of degraded and virgin material, and which have different applications in civil, geotechnical and environmental projects.

Design requirements and long-term performance of multi-component coated GCLs

K.P. von Maubeuge
NAUE GmbH & Co. KG, Espelkamp, Germany

A. Shahkolahi
Global Synthetics, Brisbane, Australia

ABSTRACT: This paper will touch mainly geosynthetic clay liners (GCLs) and the recent development of multi-component GCLs in landfill applications and show their benefits. GCLs are mostly needle-punched, fibre-reinforced composites that combine two durable outer layers and an intermediate uniform core of high-swelling powder sodium bentonite clay, which acts as the barrier component. These uniform needle-punched GCLs form a direction-independent shear strength transferring sealing barrier. When the bentonite core hydrates with fresh water, the bentonite swells and forms a low permeability gel layer, which outperforms traditional, thick compacted clay liners, due to the bentonite's ability to self-seal and re-heal. GCL improvements, since the invention of needle-punched GCLs in 1987 and contribution to the understanding and adoption of GCLs in engineering and construction, have been numerous. This paper will discuss the new GCL technology, the advantages of the polymer coating added to the GCL, the current test results, the applications where such GCL products are ideally used and the necessary design considerations.

1 INSTRUCTIONS

Needle-punched GCLs can be either single component or multi component. In multi-component GCLs, either a thin plastic barrier is attached to one geotextile component of the GCL (Laminated GCL) or a durable polyolefin polymer is firmly coated to the slit-film woven geotextile component of the GCL (Coated GCL). This development enables GCLs to challenge particular site conditions where the use of GCLs has previously been limited. The following definitions are currently being used in GRI-GCL5 specification and ASTM D35 terminology: (a) Multi-component GCL, a GCL with an attached film, coating, or membrane decreasing the hydraulic conductivity or protecting the clay core or both. (b) Laminated GCL, a GCL product with at least one geofilm or geomembrane layer superimposed and bonded to the GCL by an adhesive usually under heat and pressure. (c) Coated GCL, a GCL product with at least one layer of a synthetic substance applied to the GCL as a fluid and allowed to solidify. In general, multicomponent GCLs can be used in all applications where long-term sealing barriers are requested. These applications can include landfill caps and cover systems, landfill base sealing systems near coastal areas, tailing dams or in oil and gas tank farms where hydrocarbons may be present for example.

2 DESIGNING WITH MULTI-COMPONENT GCLS

Although using single component GCLs has solved many challenges and made using clay liners possible in many applications, there are still some potential risks and design challenges

807

related to GCLs including gas permeation, ion exchange, root penetration, bentonite desiccation in low confinement areas or applications with high temperature gradient (e.g. brine ponds, etc.), downslope bentonite erosion, internal erosion and/or bentonite piping, and effect of critical liquids. Multi-component GCLs have been developed to overcome these risks by either reducing or eliminating the risk completely. The multi-component GCL is most effective when at least one of these issues is an important project criterion. With its multiple variables, multi-component GCLs offer economical, long-term barrier solutions that are ideal for a wide range of sealing applications.

When designing with multi-component GCLs to replace a traditional composite lining system, there is a need to focus on specific design issues to ensure the functionality of the final design. These can include but are not limited to the following topics.

2.1 Gas barrier

In applications in which the GCL has to perform immediately as a gas barrier (e.g., landfill cap), the porous bentonite core might not have time to fully hydrate with water and fulfil its sealing performance due to immediate gas migration. Applications of this nature include the waterproofing of underground structures, landfill caps, and other applications in which the GCL is installed over an active source of gas production. The coating/film component of the needle-punched multi-component GCL would act as the gas-impermeable barrier, thus allowing the installation and welding of a geomembrane. In applications where no additional barrier is installed in combination with the GCL, such as where a multi-component GCL is replacing the composite lining system, the coating/film will take over the immediate sealing performance against possible penetrating gas. In both cases the sealing of the coated over-laps of the GCL can easily be carried out with a special bituminous tape.

2.2 Barriers against ion exchange

If there is a supply of free available calcium or magnesium or other polyvalent cations from the surrounding soil, fluids and soils containing leachable cations to the sodium bentonite of a GCL, an ionic exchange within the bentonite can occur over a time in a very short period of time (Egloffstein 2000; Egloffstein et al. 2002). If it does, the clay structure of the GCL core can be affected, which might impact its swelling capacity and the hydraulic conductivity performance. Investigations by Rowe and Abdelatty (2012) has shown considerable increase in the hydraulic conductivity of the GCL within less than a year when in direct contact with the subgrade with high calcium content.

Using calcium bentonite instead as the sealing core in a GCL, even with a higher mass per unit area (e.g., 8 to 10kg), is not a suitable option. Published results (Henken-Mellies 2010; Mueller-Kirchenbauer et al. 2010) have shown that the hydraulic conductivity results of field exposed calcium bentonite are far higher than ion-exchanged sodium bentonite GCLs.

In applications with soils that have a high concentration of free available leachable cations, a coated GCL is an ideal solution. The thin coating, facing the source of exchangeable cations, acts as a barrier and protects the sodium bentonite sealing core of the GCL. A Full-scale field trial was conducted by Hosney and Rowe (2014) on different GCL materials used to line the capping of a tailings dam, to investigate the effect of cation exchange between the tailings and GCL on the long-term performance and hydraulic conductivity of the GCL. Test results on the exhumed GCL products showed no change in the permeability and hydraulic conductivity (K) of the multicomponent GCL with a coating/film facing the tailings, while there was a high increase in the hydraulic conductivity of the normal GCL (without coating/film) due to the Ion exchange with the tailing, which increased the K value of that GCL (GCL A) to higher than acceptable limit in few months.

2.3 *Increasing resistance against bentonite desiccation in low confinement areas*

As the GCL is installed in a dry condition, the performance of the bentonite in the GCL will depend on the hydration of the bentonite. Eberle and von Maubeuge (1998) have reported a moisture content of 100% in less than 24 hours and 140% after 60 days, when placed over sand with a moisture content of approx. 9%.

Low confinement areas include locations with zero confinement such as exposed batters, below geomembrane wrinkles and areas with not enough cover soil to protect the GCL against desiccation. As an example, field and laboratory tests suggest a thickness of 0.75m to 1m for the cover soil in landfill caps and similar application such as tailings dam closures (Hosney & Kerry 2014; Müller-Kirchenbauer *et al.* 2010; von Maubeuge & Lenze 2007). Especially when the GCL is used as a single liner, the thickness of the cover material is suggested to be at least 1m (Müller-Kirchenbauer *et al.* 2010). Hoor and Rowe (2013) research results showed that in a composite liner application, if the liner temperatures is less than 40 degrees, overburden stress is more than 150kpa and there is no wrinkles in the geomembrane, the risk of desiccation will be low. Those results also showed that for lower stresses ($< 100kPa$), desiccation can occur for liner temperature of less than 40 degrees even without wrinkles (due to thermal gradient).

If this is not acceptable for the designed application, a multi-component GCL should be used with the coating facing the direction of expected desiccation. In most cases, this will be the upper side of the GCL. The upside-facing coating of the GCL would prevent moisture escape and allow the bentonite to stay hydrated and act as a barrier, even in arid areas or under very low confining stresses. Boley and Höppner (2014) investigated the desiccation effectiveness of a coated GCL. The initial bentonite water content (prior to saturation) was about 9.3%. After 19 days of saturation, the water content amounted to 133%. After this period, the surrounding conditions were set to constant 40°C and a relative humidity of 40% to allow the investigation of desiccation over a fine sand layer. In the first two weeks after achieving full hydration, a water content loss of approximately 2% was recorded. For the subsequent 213 days the water loss remained nearly constant with an average loss of about 0.11% per week. After 230 days of constant desiccation, the water content was 126.5%. Therefore, during this period a total water loss of 6.5% was noticed. Other than in field where a moisture uptake from the subgrade or from water condensate could occur (due to changing temperature conditions), in these tests there was absolutely no possibility for the bentonite to absorb any additional water, so that these results represent an unrealistic worst-case event.

Due to the mechanism of desiccation protection in multi-component GCLs, these products can be used with less confinement (less total cover soil, e.g. 500mm in a landfill cap) compare to single component GCLs where about 1.0m of cover soil is required. This will not only reduce the cost of supply and placement of cover materials, but also will lead to increase in the landfill volume and capacity in applications such as landfill caps (Figure 10).

2.4 *Root penetration protection*

Roots can penetrate into the GCL seeking water. They can extract water from bentonite. Field investigations by Benson *et al.* (2007) have shown root penetration into the GCL under 760mm of cover soil. Using a multicomponent GCL with the coating against the direction of potential root growth can protect the hydrated bentonite core from root penetration - thus, maintaining a high bentonite moisture content and a high level of safety and performance. Test results in accordance with DIN CEN/TS 14416: Geosynthetic barriers - Test method for determining the resistance to roots which have verified that coated GCLs are resistance against root penetration, even though their overlaps.

2.5 *Increasing resistance against downslope bentonite erosion*

According to full scale field study by Rowe *et al.* (2014), GCLs are at risk of downslope bentonite erosion when used in a composite liner being exposed for few months. This is the process where

the moisture content of the GCL evaporates and concentrates underneath the geomembrane wrinkles during the day (hot hours) and condenses again at night (cold hours) into the GCL surface and washes down the bentonite. Same field investigations and field study by Rowe *et al.* (2014) the only GCL with no evidence of bentonite erosion even after 28 months was the multi-component GCL, with the coating facing upwards (Figure 14). The presence of the coating will prevent moisture evaporation which is the source of downslope bentonite erosion issue.

2.6 *Controlling internal bentonite erosion and piping resistance under high water gradients*

When placed over coarse grain soils or other open structures (such as geonets), a question remains as to whether bentonite extrusion or piping can occur under high hydraulic water conditions. Though needle-punched GCLs with scrim-reinforced nonwovens will provide under laboratory conditions the best performance against bentonite erosion (Rowe & Orsini 2003), the highest safety against this on-site condition involves the attachment of a polymer coating against the slit-film woven side of the GCL. According to *GRI GCL5: Design Considerations for Geosynthetic Clay Liners (GCLs) in Various Applications*, the bentonite erosion issue is somewhat mitigated when using a GM/GCL composite or multicomponent GCL instead of a GCL by itself. Bentonite erosion with the coated side facing against the porous subgrade is now virtually impossible, even under high and extreme hydraulic conditions. The long-term sealing performance of the polymer coated GCL is ensured.

2.7 *Resistance to differential settlements*

Geosynthetic clay liners (GCLs) are hydraulic barriers used as single liners or as apart of a composite lining in various applications, such as landfill caps, base seals, canal liners or in environmental protection applications and in some applications might be subject to settlement. In order to investigate the behavior of GCLs settlement conditions and hydraulic pressure, experiments were performed (Boley & Höppner 2014) using two different GCLs as test materials under different test conditions (saturated or air-dried GCLs, coating facing the water pressure or on the outstream side, GCLs with or without mechanical damages (manual holes), GCLs with or without overlap). The experimental results have showed that GCLs have three different forms of failure: 1) holes forming and expanding; 2) tearing of coating; 3) separation of overlap. In summary, the maximum stretching e_{max} [%] of the GCL in these simulated settlement tests under hydraulic pressure was 13–21% for Coated GCL with 200 g/m2 of coating, 17–22% for Coated GCL with 500 g/m2 of coating, 11–18% for dry GCL, and 16–22% for hydrated GCL.

2.8 *Interface shear stability*

For slope designs, the critical friction plane needs to be investigated with the site materials and is typically confirmed with multiple shear box tests. This is true of nearly all materials considered in slope applications, such as soil, GCLs, other geosynthetics used on slopes, etc.

Where needed, coated GCLs with dimpled/structured surface should be used to provide a high interface friction with the cover layer (Figure 17). Various tests results have confirmed a high interface shear and friction angle between the structured coating and the cover soil, in the range of 30–40 degrees depending on the soil type and testing conditions. Of course, interface friction test needs to be conducted with specific soil for any project individually to determine the exact value. For steeper slopes, the use of geogrid reinforcement can significantly improve the slope friction angle.

2.9 *Durability of the coating*

In most cases it is recommended that the additional barrier component of the GCL can fulfil a long service life. For this reason, the polymer barrier should be manufactured with

a chemically resistant polyethylene resin. According to GRI-GCL3, the geofilm/ geomembrane in its as-received condition should be evaluated for durability via the appropriate GRI specification. The polymer coating ($\geq$ 200g/m^2) should be evaluated by incubation in a forced air oven per ASTM D5721 set at 60°C for 50 days. The minimum percent tensile strength retained at break for either MD or XMD, as measured by ASTM D882, should be reported accordingly and must meet or exceed the specification value (85%).

When in service, the coating of the GCL might be subjected to chemical attacks. This is more likely to happen in a landfill base seal. Therefore, it is important to know the general chemical resistance of this additional polymer barrier to well defined chemicals. Manufacturers need to provide the chemical resistance of the polymeric barrier in at least an independent test report.

3 CONCLUSION

The decisions that designers make about the GCL selection must heavily be influenced by the performance and durability of the system. These decisions start with the overall cross-section (e.g. single lining, composite lining or double lining system).

Geosynthetic clay liners (GCLs) are often used as a stand-alone liner or in combination with a geomembrane, where the GCL replaces thick compacted clay liners due to many advantages. By using a multi-component GCL, the single barrier can be improved by combining the advantages of a polymer and a clay barrier.

A multi-component GCL has add-on values: e.g. root protection, desiccation resistance, gas and water impermeability, downslope erosion protection, internal erosion protection, and Ion exchange protection. While a multi-component GCL improves the overall GCL performance as a single lining system, it opens the possibility to use this type of GCL as a composite lining system. The main advantages are lower installation costs, intimate contact between the clay and the polymer barrier with little till zero transmissivity and likely reducing a shear interface issue between these two barriers (not for glued multi-component GCLs). However, the additional thinner barrier component cannot replace a geomembrane.

ABSTRACT: This paper is part of a series focusing on the use of geosynthetics in Nordic climates. It focuses on sealing applications, while others in this series are addressing general considerations, and other functions of geosynthetics. In this paper, a review of the main concerns and performance requirements associated to the installation of geosynthetics for sealing applications is first proposed. These are essentially based on a review of the current practice, the interview of several installers specializing in the installation of geosynthetics in cold climates and a literature review. A strategy to assess the suitability of Geosynthetic Barriers in sealing applications under Nordic conditions is then proposed. The proposed requirements were drafted by the authors and approved after revisions by a committee constituted of contributors to the ROUGH project. Guideline on the "Use of GeosyntHetics in Nordic conditions" are being prepared and will be published within the next months by the Nordic country's authorities.

1 INTRODUCTION

Geosynthetic Barriers may be damaged during installation or in service, with numbers of leaks per hectare reported in the literature ranging between 0.25 (Gilson-Becks 2019) and 7 (Nosko 2015) for projects where Electrical Leak Location Surveys were specified and conducted. This number may be even higher where no or insufficient quality control is conducted, as reported by Forget (2005). On the other hand, Phaneuf (2001) suggests that 73% of damages in geosynthetic barriers occurs when the soil layers are placed on top of the geomembranes, 24% occurs during geomembrane installation, and 2% occurs during the post construction phase – i.e., that most damages in geosynthetics barriers take place during installation or soil covering.

These studies do not differentiate the environmental conditions that were prevailing during the installation of the Geosynthetic Barriers. However, it is reasonable to consider that the harsher the environmental conditions, the more likely can the liners be damaged, considering the effects of low temperature on soil and geosynthetic material properties, as well as human factors.

In 2018, several Canadian installers were consulted to obtain their opinion on what are the most critical parameters influencing the risk of damages to geosynthetic liners installed in harsh Nordic conditions. From these observations, a series of recommendations were

developed, focusing on design strategies and preferred geosynthetic material properties. These recommendations were approved by a committee constituted of members of the ROUGH project and will eventually be submitted to authorities of European Nordic Countries for consideration.

2 FACTORS AFFECTING CONSTRUCTION UNDER COLD CLIMATE

This section summarizes the key information obtained while interviewing installers used to work in Northern regions of Canada, interviewed in the first quarter of 2018. The interviews were based on a few generic questions, and a general discussion on how to do things better. The information gathered within each interview was then compiled and structured afterward as presented below. More details are available in the RoUGH project report (2022), accessible through Sintef.

2.1 *Design*

Current practice for the selection of geosynthetic barriers and the design of lining systems typically does not include anything addressing winter installation conditions. Usual design considerations such as soil / geosynthetic interaction, durability and chemical compatibility are approached similarly to what is done for installation under mild environmental conditions. However, soil / geosynthetic interaction may be different when products are frozen, which could affect the design of the structure (slopes, cushions, management of differential settlement, etc.).

2.2 *Contracts and costs*

A clause allowing the installer to stop working with no penalty should be included in geomembrane installation contracts, because of the high risks of delays and unexpected problems. A preferred structure of contracts for winter work is based on time + materials, instead of a lump-sum contract, which is typically preferred in the summertime.

Design-built' contracts are also preferred because they favor the development of teams who become used to work together (general contractor, earth work, geosynthetic installers). Contracts given to the lowest bidder are very likely to generate problems for winter work as this approach favors the use of unexperienced workers, while harsh conditions are anticipated. Although this is applicable to any project, it is more critical when installation is done during the winter.

2.3 *Planning*

Coordination between parties is critical for the success of the project. From a contractual standpoint, the geosynthetic installer is a subcontractor to the general contractor, who typically assigns time slots and defines a master schedule. This schedule must be updated regularly, with a good understanding of the concerns associated with the installation of geosynthetics.

The schedule must consider the risk of weather events and ensure they will not affect installation. For example, if snow falling between preparation of a subgrade and laying of the geomembrane must be removed, it may be necessary to re-do all the earth work after snow removal.

External causes of delay must be avoided. This includes contractual delays, material delivery, QA / QC approval by a third party, or other. Planning must account for more equipment failure.

2.4 *Productivity*

Workable hours may be significantly smaller in winter because of the reduced number of daylight hours and harsh work conditions. Hours worked per week may be as low as

10–15 hours (instead of 40+ hours). An overall productivity of 50% is considered a maximum realistic target, hence a project will typically take twice as much time to complete in winter, as opposed to summer. Most important factors affecting productivity include days cut-off because of bad weather, time needed for the crew to warm up periodically, and a slower welding speed.

2.5 *Packaging, storage and handling*

Existing and well-known good practices such as ASTM D4873 offer adequate guidance: sur-elevation of the storage platform, avoiding direct contact with soil, etc. In addition, geosynthetics must be adequately protected from water to avoid requiring storage in a warm enclosure. An excessive amount of water within a roll of geotextile, geocomposite, or Clay Geosynthetic Barrier (GBR-C) must be avoided. A water-filled, frozen geosynthetic can hardly be unrolled, and may require several weeks to thaw.

Good handling and storage practices must be maintained until the rolls are delivered to their final location, immediately before installation. When feasible, last-minute delivery of the products is preferred to minimize risks of damage caused by sensitive packaging and storage issues.

2.6 *Subgrade condition*

The same criteria apply to both frozen and unfrozen soils, which are typically defined by the size of maximum protrusion or discontinuity of the surface. However, it is not always possible to flatten a subgrade already frozen. Hence, many installers prefer avoiding installation of a Polymeric Geosynthetic Barrier (GBR-P) directly on frozen soil, without a thick cushion layer.

The need to remove snow, especially on already-approved subgrades, is determined on a project-by-project basis. Thin layers of snow, up to about 5 centimeters, are typically left in place to avoid damaging the surface. What often dictates the decision to lay a GBR-P on snow and proceed with welding is the risk of having humidity in the welding area at the time of welding, more than the risk of settlement, which can be handled by providing more slack.

2.7 *Material-related issues*

2.7.1 *Slipperiness*
Smooth polyethylene GBR-P becomes extremely slippery under freezing temperatures. As soon as dampness or snowflakes are observed, it is virtually impossible to walk on a smooth GBR-P. Koerner et al. (2019) conducted preliminary laboratory investigations on smooth HDPE GBR-P tested against geotextiles, which confirmed this higher slipperiness at low temperature.

2.7.2 *Weldability at low temperature*
Welding GBR on a frozen substrate is perceived by installers to be overall easier, as long as water remains frozen. However, it requires more preparation, in particular scraping-off traces of ice from the surface of the GBR, which may affect productivity and accidentally damage the GBR. Pre-heating is sometime recommended, but not always: the release of water vapor must be avoided, as vapor could condensate in the welding area and affect the quality of the weld.

The geosynthetic Institute guide GRI GM9 on the welding of polyethylene geomembranes is often cited in bids and construction guidance. It is typically followed by installers, but the proposed minimum welding temperature is sometimes questioned: several factors other than temperature affect the weldability of geomembranes beyond the temperature itself: wind, humidity, snowflakes, water running down from thawing areas, frost condensate, etc.

Overall, there is a consensus that LLDPE is easier to manipulate and to weld than HDPE.

2.7.3 Stiffness

Stiffness may increase significantly at low temperature for some materials, which can create different problems. This affects the ability of the material to lay flat, adding complexity during installation. HDPE can be installed in winter, but the use of more flexible materials such as LLDPE is typically preferred by installers.

Under cold temperature, HDPE geonets are often stiffer than HDPE geomembranes, which heavily affects their ability to lay flat. They exhibit a 'shape memory': they could either unroll or re-roll in unexpected ways, surprising workers and creating a safety concern. They do now warm-up in the sun as quickly as geomembranes. Possible explanations include a higher resin density, a lower surface exposure to solar radiation, and a larger air supply through the ribs which maintain the temperature close to the air temperature.

Unfolding prefabricated panels made using standard grades of PVC may be extremely difficult at low temperatures, if ever possible. Lay-flat of PVC is very poor at low temperature, and corner folds tend to tear easily. There may still be formulations of PVC material offering better behaviors than others, with types of plasticizers better suited to cold temperature installations. Common grades of PVC – i.e., complying with ASTM D7176 – are not suitable for installation in winter.

2.7.4 Brittleness and cold-cracking resistance

Installers have observed that some HDPE GBR-P tend to have a higher sensitivity to cracking under low temperatures than LLDPE GBR-P, which was confirmed by Cornellier (2014).

Many installers favor the use of bituminous GBR (GBR-B) for winter installation. However, surface cracking may still be observed, depending on the temperature and type of material used.

2.7.5 Thermal contraction

Thermal contraction is a well-documented concern for polymeric GBR-P, with thermal expansion coefficients in the range of 10^{-4} mm/mm/°C. Thermal contraction must be considered for projects extended into winter, whether the GBR-P is to remain exposed, or eventually covered by soil. This usually involves adding enough slack in strategic locations.

GBR-B are considered easier in that regard, given their lower coefficient of thermal expansion.

2.8 Backfilling

Backfilling is not under the scope of the installer. However, it is a critical task with respect to the integrity of the structure. Only aggregates exempt of fines must be used to prevent ice from creating an apparent cohesion in the soil: frozen agglomerates can behave like boulders and damage the geosynthetic during backfilling.

Before backfilling, the geomembrane must be secured against wind uplift, which is typically achieved using 'sandbags', using pea gravels instead of sand to avoid creation of hard blocks of icy sand under freezing temperature – these sandbags also behaving like boulders.

2.9 Health and safety

Worker safety must be proactively managed considering the very harsh work environment. Not only accidents are more likely to happen, but an accident happening under very low temperatures must be treated very quickly as the condition of the injured person can deteriorate quickly. A safety-trained employee must be present on-site at all times.

3 GENERAL RECOMMENDATIONS ON THE DESIGN AND THE SELECTION OF GEOSYNTHETIC PRODUCTS

Following the survey of installers and a literature review, a series of recommendations were developed, focusing on design strategies, considering typical service conditions and performance

requirements needed for a lining system to perform adequately. Preferred geosynthetic material properties applicable to GBR-P, GBR-B and GBR-C are presented in the report of the project. They were approved by a committee constituted of members of the RoUGH project and will eventually be submitted to authorities of European Nordic Countries for consideration.

3.1 *Impact of the environmental conditions on the design of the structure*

ISO/TR 18228-9:2022 provides general concepts which can be used to design a lining system and select an adequate GBR. This Technical Report identifies the installation conditions as one of the factors influencing the design. Indeed, installation in winter implies a low temperature, presence of ice and snow, and freeze / thaw cycles which may influence the selection of the type of sealing product (polymer / type, thickness, finish). Installation conditions will also affect the use of complementary products (especially cushions); the thickness of the soil cover; some details of the design itself, such as the characteristics of the slopes (angle and length, presence of berms), due to lower interface friction properties; the installation process (e.g., scheduling, welding strategy); and the quality assurance program (type of control, approval process, use of leak location).

Geosynthetic Barriers may be damaged during installation or in service, and it is a fair assumption to consider that holes may be present on a structure installed in the wintertime.

To reduce leakage rate into the environment while acknowledging that the GBR is more likely to be damaged if installed during winter, engineered, multi-layered lining systems should be preferred to single liners. These engineered lining systems typically include:

- A geotextile protection layer, or cushion, installed above the geosynthetic lining system to protect it from static or dynamic aggregate puncture during backfilling or in service.
- A compacted clay liner (CCL) or a clay geosynthetic barrier (GBR-C) that will create a composite liner when in contact with the geosynthetic barrier.
- Two geosynthetic barriers separated by a geocomposite drain between the primary (upper) and the secondary (lower) barrier, to create a double lining system. This design reduces the head of liquid prevailing on the secondary liner, hence the flow of liquid released into the environment.

Typical structures of composite, double, and double-composite lining systems are depicted in Figure 1. A more detailed discussion on the benefits and limitations of multi-layered geosynthetic barrier systems can be found in Rowe (2005).
Figure 1. Typical structures of composite and double lining systems.

3.2 *Aspects related to the raw material/structure of the products*

The ease of installation and long-term performance of geosynthetics are partially defined by how much the products will be exposed to cold weather, and at what period of their life:

transportation, storage, installation, and/or during their service life. E.g., if the product is temperature-sensitive but intended to be covered by a thick layer of soil protecting it from cold temperatures immediately after installation, it is theoretically possible to store it at a warm temperature and wait until weather permits its installation and soil cover. The possibility to use a product should therefore be assessed on a case-by-case basis, considering the flexibility of construction schedule and likelihood of encountering extreme environmental events during the projected construction period. Figure 2 summarizes the various issues that must be considered for any given project.

The following classes of service were defined. They reflect the different exposures that could be experienced by the product, once it has been installed under harsh environmental conditions. Each of them reflects a type of stress that may affect the selection of the geosynthetic barrier, and/or that may be mitigated with adequate measures during storage, installation and backfilling.

- Class 1 – Exposed applications: The geosynthetic barrier system is intended to be left exposed in a Nordic environment. It will experience extreme temperatures, temperature cycles, ice and snow, and it will NOT be covered by a material providing a confining stress while in service. Examples of such application include liquid containment or secondary containment structures where the geosynthetic barrier is left exposed.
- Class 2 – Shallow cover: The geosynthetic barrier will be permanently covered by a material providing some confinement stress, but no thermal protection – such as a shallow layer of gravel. The geosynthetic barrier system will be exposed to the same temperature conditions as for Class 1, but the confining stress will prevent temperature-induced contraction/expansion, offer a protection against impact, prevent wind uplift, etc. Examples of such applications include road ditches, as well as ponds where the geosynthetic barrier could be covered by 300 to 500 mm of gravel.
- Class 3 – Fully covered applications: The geosynthetic barrier is intended to be covered by a thick layer of soil and will never be exposed to extreme environmental conditions once installation is completed. In these applications, exposure of the geosynthetic barrier to freezing temperatures is limited to the construction, and its behavior will be essentially independent from the environmental conditions thereafter. Examples of applications include landfills and other waste containment structures where a sufficient thickness of material is installed rapidly, some heap leach pads. Depending on the service and operating conditions of the structure, class 3 may first have to be considered as class 2 for a certain duration.

1. The GBR must preserve its integrity during transportation and storage
2. It must be possible to unroll the GBR in place under freezing temperatures, on a frozen soil subgrade, without damaging it
3. Worker safety must not be affected by a behaviour of the GBR
4. Welding of GBR-P or GBR-B to assemble panels or to repair a tear must be possible under the anticipated environmental conditions.
5. The GBR must not be affected by the installation of the next layer, such as the soil cover (when applicable)
6. The long-term performance of the GBR must not be affected by the installation process
7. The (installed) GBR must exhibit adequate long-term properties when exposed to cold temperatures during service

Figure 2. Issues to consider when selecting geosynthetic barriers installed under freezing temperatures.

4 DISCUSSION AND CONCLUSIONS

Installation of geosynthetic lining systems under harsh Nordic conditions may not always be prevented. In this study, the current practices and concerns associated with such conditions

of installation have been assessed, interviewing those doing the work, and typically holding liability for these projects: the installers. A literature review was also conducted. Based on the information gathered, general recommendations were proposed to maximize the success of these structures.

- Designers should acknowledge there is a higher risk of damage to GBRs when they are installed under harsh conditions. The use of composite and double lining systems should therefore be favored to mitigate these risks, and limit seepage into the environment.
- The integrity of the product must be preserved throughout the installation process. Seven steps were identified as requiring attention, from transportation and storage to the effects of low temperature on the product in the long run.
- The suitability of a product to serve as a barrier when installed in Nordic conditions should be evaluated considering its actual exposure. Three classes of application are proposed: exposed, covered by a shallow layer of soil, or fully covered.

Recommendations were developed and are available in the detailed report of the RoUGH project. They will be used to prepare Guideline on the "Use of GeosyntHetics in Nordic conditions", that will eventually be published by the Nordic country's authorities.

The authors like to have a special thanks the Traffic authority in Finland (FTIA), the Norwegian Public Roads Administration, the Swedish Transport Administration, GRK Infra Oy and the 12 manufacturers for their active participation.

Reinforced walls and slopes

Impact of geogrid arrangement on the deformational response of geosynthetic reinforced soil – integral bridge systems

D. Naughton
RPS Consulting Engineers, Galway, and formerly Atlantic Technological University, Sligo, Ireland

P.J. Naughton
Atlantic Technological University Sligo, Ireland

ABSTRACT: Plaxis 2D was used to investigate the deformational response of a geosynthetic reinforced soil – integral bridge system with three different geogrid arrangements. The deformational response was found to be independent of the length of geogrid, independent of having secondary geogrid layers directly beneath the bank seat and also independent of vertical geogrid spacing near the base of the wall. The response was found to be only marginally dependent on the direction that the horizontal load was first applied. Applying the horizontal load towards the abutment resulted in inward movement of the wall face and the greatest rotation of the bank seat. Applying the horizontal load away from the abutment resulted in outward movement of the wall face and a slight reduction in the rotation of the bank seat in all models.

1 INTRODUCTION

An integral bridge is a continuous geo-structural system initially developed to overcome some of the problems associated with conventional bridges, i.e., those with expansion joints and bearings (Dicleli 2000). Conventional bridges require periodic maintenance resulting in increased cost and the possibility of extended road closures (Springman *et al.* 1996). However, although integral bridges are relatively cheaper; faster to construct; and require less maintenance, they come with their own problems (Flener 2004). As the structure moves as one unit, temperature fluctuations result in increased earth pressures on the face of the abutment and, over time, settlement of the soil at the abutment-embankment interface. In winter, when temperatures decrease, the superstructure contracts and moves away from the structure, while in summer, when temperatures increase, the superstructure expands and moves towards the soil. This phenomenon of cyclic temperature induced creep, otherwise known as strain ratchetting, can result in much greater earth pressures than the structure was designed for (Horvath 2005).

An alternative to the traditional integral bridge is the geosynthetic reinforced soil – integral bridge system (GRS-IBS). This system is constructed using alternating layers of compacted granular fill and geosynthetic reinforcement, typically in the form of a geogrid. Many GRS-IBS abutments consist of a segmental modular block wall with the bridge beams resting directly on top of the structure, with no bearing or bank seat provided (Adams & Nicks 2018).

The Federal Highways Administration (FHWA) (Adams *et al.* 2011) developed a dedicated design method for GRS-IBS. However, Adams *et al.* (2011) showed that this method was heavily empirically based and only provided a 'recipe' for design.

In this study, the plane-strain modelling software Plaxis 2D, Version 20, (2021) was used to determine the influence that different geogrid arrangements had on the deformational response of a GRS-IBS abutment.

2 METHODOLOGY

2.1 *GRS-IBS abutment validation model and results*

The Plaxis 2D model was initially validated against data from a full-scale instrumented GRS-IBS abutment reported by Ardah *et al.* (2017, 2021) to ensure that the Plaxis 2D model adequately captured the deformational response of a GRS-IBS system. The validation model was discussed in detail by Naughton (2022) and Naughton & Naughton (2022). Overall, reasonable agreement was found between the measured values and those predicted by Plaxis 2D. During validation it was found that fixing the lowest masonry block in both the horizontal and vertical directions, greatly improved the overall correlation with the validation model, but did result in an underestimation of the horizontal deformation at the bottom of the wall. This is discussed in detail by Naughton & Naughton (2022).

2.2 *Parametric study*

A parametric study was conducted to assess the impact the geogrid arrangement in the reinforced block had on the deformational response of a GRS-IBS abutment subject to both vertical and horizontal loading.

The numerical model developed in this study was based on the Maree Michel Bridge reported on by Ardah *et al.* (2017, 2021) and which was used in the validation model. The model consisted of 19 segmental blocks, 400mm wide x 200mm high, forming the abutment wall, Figure 1. Primary geogrid layers, 2.66m long, were placed between each of the segmental blocks, with secondary geogrid layers, 1.6m long, introduced at mid-height vertically at the top six blocks, Figure 1. The segmental blocks were set vertically above a reinforced soil foundation (RSF), which had a width of 2.83m and was 0.46m deep. Foundation soil was present beneath the RSF, with backfill soil extending 9.20m from the back face of the segmental block wall. The water table was not considered during the modelling process in this study. The bank seat was 1.2m wide and located 205mm from the back of the facing blocks.
Figure 1.   Schematic of validation model used in this study.

The soil elements of the Plaxis 2D model were developed using a plain-strain model with 15-node triangular elements. The model was horizontally fixed along both the vertical extremities and the base of the model. Additionally, a line displacement was introduced along the lower boundary of the lowest block. This allowed this block to be fixed in place or free to move as required in the modelling process. A medium mesh was used for the model in this study with a tolerated error of 1%. In contrast to Ardah *et al.* (2017, 2021) the wall was wished-in-place.

The Hardening Soil model was used for the backfill soil, the Mohr-Coulomb model for the foundation soil and the Linear Elastic model for the masonry blocks and rip rap at the front of the wall. The geogrid was modelled using geogrid elements in Plaxis 2D, with an elastic normal stiffness, EA, of 600kN/m and an axial tension, NP, of 80kN/m. Interfaces were applied

between the geogrid and backfill soil, the geogrid and facing blocks and at the horizontal interface between facing blocks. The model properties are listed in Table 1. In all models the geogrid layer extended to the front face of the blocks. In this case, the interface between blocks was determined by the geogrid – facing block interaction properties, Table 1. At locations with no geogrid between facing blocks, an interface strength reduction ratio of 0.8 was applied.

The bridge load consisted of a vertical component of 100kN/m and a horizontal component of 85kN/m, determined in accordance with IS EN 1991-2 using Load Model 1 (LM1) (Anon., 2006).

This study investigated three geogrid arrangements, Figure 2. Model 1, Figure 2(a), examined the influence of primary geogrid length on performance. Three lengths of primary geogrid were investigated; notably 1.66m, 2.16m and 2.66m. The secondary geogrid length remained constant at 1.6m. Model 2, Figure 2(b) had the secondary geogrid layers removed. The primary geogrid had a length of 2.66m and was spaced every 0.2m vertically. Model 3, Figure 2 (c) had the secondary geogrid removed and also six alternative layers of primary geogrid at the base of the wall removed. In this model the length of the geogrid was 2.66m, with the layers spaced 0.2m vertically at the top of the wall and 0.4m vertically at the base of the wall.

Table 1. Model parameters for GRS-IBS model.

Material	γ (kN/m^3)	E (MPa)	E_{50}^{ref} (MPa)	E_{oed}^{ref} (MPa)	E_{ur}^{ref} (MPa)	ν	$e_{initial}$	c (kPa)	φ_p (°)	ψ (°)

Figure 2. Geogrid Arrangements (a) Model 1, primary and secondary geogrid layers in place, (b) Model 2, secondary geogrid layers removed (c) Model 3, secondary geogrid and six alternative layers of primary geogrid at the base of the wall removed.

During the modelling process a horizontal load was first applied at the location of the bank seat in one direction and then in the other. This was to replicate the cyclic nature of the horizontal loads. The vertical load from the bank seat remained constant throughout the modelling process.

Two cases were examined, Case A and Case B. For Case A, the load was firstly applied towards the abutment and then away from the abutment. For Case B, the reverse occurred with the load firstly applied away from the abutment and then towards the abutment. The model was divided into three phases with Phase 1 (P1) representing pre-loading, with just the vertical load in place and no horizontal load. For Case A, Phase 2 (P2) represented the horizontal load being applied towards the abutment, while Phase 3 (P3) represented the horizontal load being applied away from the abutment. For Case B, P2 and P3 were reversed, with the horizontal load first applied away from the abutment (P3) and then towards the abutment (P2) respectively.

3 RESULTS AND DISCUSSION

The predicted results from the Plaxis models are presented in terms of the horizontal displacement of the wall face and the vertical displacement of the bank seat. For each load phase the displacements refer to the predicted values after application of the loadings for that phase.

3.1 *Impact of primary geogrid length, model 1*

The impact of the primary geogrid length on the deformational response of the structure was investigated for three geogrid lengths, 1.66m, 2.16m and 2.66m. The horizontal displacement of the wall face and vertical displacement of the bank seat are presented in Figure 3(a) and (b) respectively for Case A, where the horizontal load was first applied towards the abutment (P2) and then away from the abutment (P3).

When the horizontal load was applied towards the abutment, the wall face displaced inwards and the bank seat rotated away from the load application direction, Figure 3(a). Overall, very little difference in horizontal and vertical displacements were observed between the shortest and longest primary geogrid lengths (1.66m & 2.66m respectively). Rotation of the bank seat was also largely independent of the geogrid length, Figure 3(b).

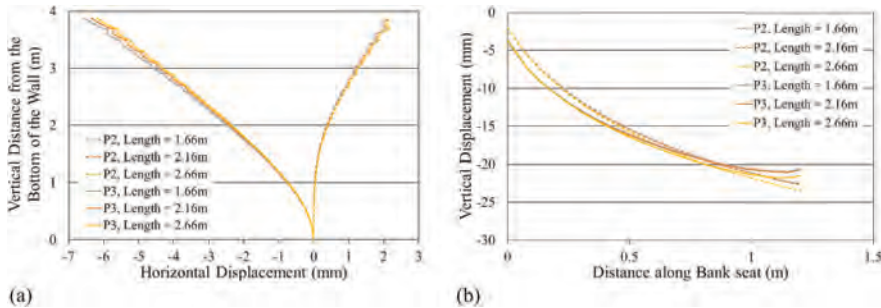
When the horizontal load direction was reversed, and it acted away from the abutment (P3), larger horizontal displacements, with outward movement of the wall face, were observed. Shorter geogrid lengths resulted in slightly larger outward horizontal displacements, Figure 3(a). Slightly larger rotations of the bank seat were observed when the load was applied towards the abutment (P2) and smaller rotations when the load was applied away from the abutment (P3), Figure 3(b). However, the rotation of the bank seat only changed marginally when the load direction was reversed.


Figure 3. (a) Horizontal displacement for model 1 for Case A and (b) Vertical displacement of bank seat in Model 1 for Case A.

3.2 *Impact of removing secondary geogrid layers, model 2*

The impact of secondary geogrid layers on the deformational response of the structure was investigated in Model 2, Figure 2(b). The six layers of secondary geogrid at the top of the wall were removed and the response compared to that observed in Model 1 which contained the secondary geogrid layers. The horizontal displacement of the wall and the vertical displacement of the bank seat for Case A and B are presented in Figure 4.

Applying the horizontal load towards the abutment in both Case A and B resulted in inward movement of the wall face, Figure 4(a) and rotation of the bank seat, Figure 4(b). When the horizontal load was reversed and acted away from the abutment, outward movement of the wall face was observed accompanied by a slight reduction in the rotation of the bank seat. Removal of the secondary geogrid layers resulted in both a slight reduction in the inward movement of the wall when the horizontal load was applied towards the abutment and a slight reduction in the rotation of the bank seat for all directions of the horizontal

load. Applying the horizontal load away from the abutment resulted in the same outward displacement of the wall for all cases examined. The deformational response of the structure was largely independent of the first direction that the horizontal load was applied.

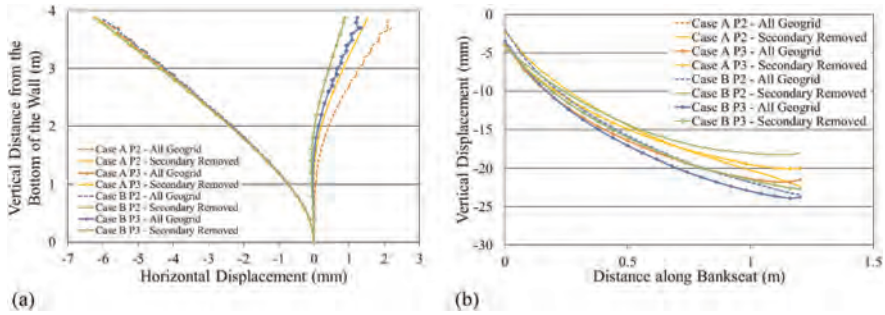
Overall, the data indicated that there was little advantage in including secondary geogrid layers in the top of the wall directly beneath the bank seat to control horizontal displacement of the wall face and vertical displacement of the bank seat.


Figure 4. (a) Horizontal displacement for model 2 for Case A and B and (b) Vertical displacement of bank seat in Model 2 for Case A and B.

3.3 *Impact of removing secondary and six alternative layers of primary geogrid at the base of the wall, model 3*

In Model 3 both the secondary geogrid layers and alternative layers of primary geogrid layers near the base of the wall were removed, Figure 2(c). The deformational response of Model 3 was compared with that of Model 1 to assess the impact of removing the geogrid layers. The horizontal displacement of the wall and the vertical displacement of the bank seat for Case A and B are presented in Figure 5.

When the horizontal load was applied away from the abutment almost identical horizontal displacement of the wall face was observed for both Case A and B, Figure 5(a), indicating that the first direction that the horizontal load was applied is not significant in terms of wall displacement. Applying the horizontal load first towards the abutment, Case A, resulted in slightly larger inward displacements of the wall face than Case B. The horizontal displacement of the wall face was largely independent of the number of geogrid layers in the wall.

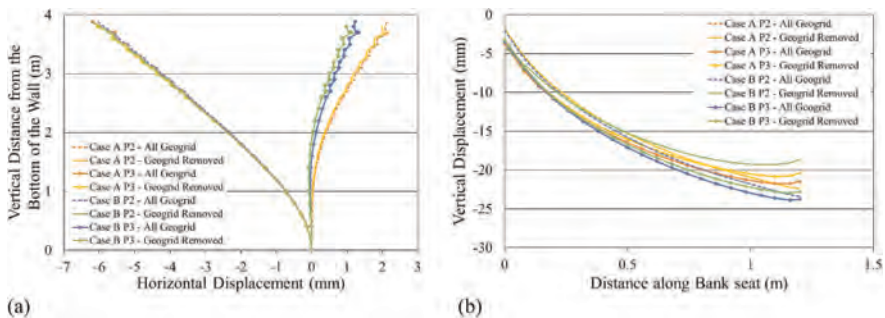
Like in Model 2, applying the horizontal load towards the abutment resulted in slightly greater rotation of the bank seat, while reversing the direction of the horizontal load resulted in a reduction in the bank seat rotation, Figure 5(b). No significant difference in the rotation


Figure 5. (a) Horizontal displacement for model 3 for Case A and B and (b) Vertical displacement of bank seat in Model 3 for Case A and B.

of the bank seat was observed between Model 1, containing all the geogrid layers, and Model 3, with both the secondary geogrid and alternative layers of primary geogrid removed.

4 CONCLUSIONS

This study investigated the deformational response of a GRS-IBS with different geogrid configurations. The deformational response was assessed in terms of the horizontal displacement of the wall facing and the vertical displacement under the bank seat. Three models were investigated; Model 1 examined the influence of geogrid length, Model 2 the influence of secondary geogrid layers near the top of the wall and Model 3 the impact of removing the secondary geogrid and alternative layers of geogrid near the base of the wall.

Overall, a similar trend was observed in the three models investigated. The deformational response was found to be independent of the length of geogrid, the presence of secondary geogrid layers directly beneath the bank seat and also independent of removing alternative layers of primary geogrid layers near the base of the wall.

The response was also found to be only marginally dependent on the direction that the horizontal load was first applied. Applying the horizontal load towards the abutment resulted in inward movement of the wall face and the greatest rotation of the bank seat. Reversing the direction of the horizontal load, with it acting away from the abutment, resulted in outward movement of the wall face and a slight reduction in the rotation of the bank seat in all models.

Reinforced soil walls/slopes and piling platforms for a causeway route over very soft soils using geogrids–HS2 Thame Valley Viaduct, Aylesbury, United Kingdom

Pablo Vazquez Bernardini & Patricia Guerra-Escobar
Geosynthetics Ltd, Leicestershire, UK

ABSTRACT: The High Speed Two (HS2) is the new high-speed railway for Britain. Thame Valley Viaduct is part of HS2 Phase One from London to West Midlands. In order to cross the Thame River and adjacent flood plain area, The Thame Valley Viaduct made up of 36 spans an overall length of 880m it is proposed. The foundation for the viaduct involves large diameter bored piles. The temporary works to construct the causeway over very soft soils consist of 18no. piling platforms with approximate 15,000m2 and an adjacent haul road connecting the platforms with an overall length of 1,000 m. The ground conditions generally consists of very soft to soft alluvium with undrained shear strengths of 0kPa-36kPa. It is proposed to support the perimeter of the piling platforms with a 45°/70° reinforced soil wall using layers of geogrids wrapped. A design is also required for the 18no. piling platforms.

1 INTRODUCTION

1.1 *Description & location*

The High Speed Two (HS2) is the new high-speed railway for Britain. It will connect eight of Britain's ten largest cities and their regions. Faster, easier and more reliable travel will put more opportunities within reach for millions of people for work, business and leisure.

Thame Valley Viaduct is part of HS2 Phase One from London to West Midlands. The Thame Valley Viaduct is located in the Northern Vale to the north-west of Aylesbury. It travels across the River Thame within a broad, shallow floodplain.

In order to cross the Thame River and adjacent flood plain area, the Thame Valley Viaduct made up of 36 spans an overall length of 880 metres it is proposed. The foundation for the viaduct involves large diameter bored piles. The viaduct will carry HS2 trains at speeds of up to 360km/h between London, Birmingham and the North.

1.2 *Problem geometry*

The design of temporary works to construct the causeway over very soft soils consist of 18no. piling platforms with approximate 15,000m2 and an adjacent haul road connecting the platforms with an overall length of 1,000 metres.

It is proposed to support the perimeter of the piling platforms and the western side of the haul road with a 45° reinforced soil slopes using layers of Biaxial geogrids wrapped around the face with permanent erosion control blanket pinned to the slope face.

The eastern side of the haul road is former via a 70° reinforced soil wall using topsoil filled geotextile bags with horizontal layers of Uniaxial geogrids wraparound in the face. The maximum slope height is 2.5m.

2 DESIGN CONSIDERATIONS

2.1 *Existing ground conditions*

The ground conditions along the causeway route, as revealed by the Ground Investigation Report and borehole logs, generally consists of superficial deposits described as very soft to soft Alluvium/Head Deposits which are encountered to between 1.2m and 4.9m below existing ground level. The Alluvium is generally underlain by firm to stiff Clay of the Ampthill Formation.

SPT "N" values of alluvium were typically 1-8, however close to the northern side of the River Thame, SPT "N" values of 0 were recorded right through the alluvium down to the Ampthill Clay at approximately 4mbgl.

The undrained shear strength for the Alluvium was derived from the results of SPTs with undrained shear strengths between 4.5kPa–36kPa.

It should be noted that SPT "N" values in soft Alluvium are not the most appropriate test requiring correlations to determine the undrained shear strength due to the low blow counts determined in the material and the material sensitivity. Direct methods such as insitu shear vanes or testing on thin wall tube samples will provide more indicative results.

There was no laboratory testing provided to confirm the undrained shear strength of the alluvium and Ampthill Clay at shallow depths. Hand shear vane testing was carried out within the upper 1m of ground at 28no. locations along the causeway. The tests were repeated 3 times at each location and recorded average undrained shear strengths of 19kPa–176kPa.

2.2 *Ground model*

In order to perform the calculations, we have assumed the following geotechnical properties:

Table 1. Ground model used for design.

Description	Location	Unit weight (kN/m^3)	Total Stress Analysis Undrained shear strength–Cu (kPa)	Effective Stress Analysis Effective Angle of Shearing Resistance – Ø'	Effective Cohesion – C' (kPa)
Blended 10/100mm angular Fill	Reinforced/ Retained Fill/ Basal layer	20	–	34°	0
Soft Clay (Alluvium/ Head deposits)	From existing ground level to a maximum depth of 4m bgl.	16	Case 1) 40 (0.75m deep basal starter layer analysis) Case 2) 20 (1.5m deep basal starter layer analysis)	23°	0
Firm Ampthill Clay	4m bgl.	18	50	27°	0

2.3 Existing groundwater conditions

Groundwater was recorded at shallow depths (i.e., <1.0m below existing ground level) according to the borehole logs provided. It should be noted that groundwater levels can be subject to seasonal, tidal and other fluctuations and should not be taken as constant.

The causeway is to be located close to the River Thame and we have been advised that the causeway should be designed for a 1 in 20 year flood event, which is at a level of 70.8m AOD (i.e. 400m below finished haul road/piling platform level).

Analysis has therefore been carried out considering water level at the 1:20 year flood level and also at existing ground level. To allow the floodwater to move freely a series of culverts were proposed crossing the Haul Road in between each piling working platform.

2.4 Surcharges on the piling platform with 45° slopes

To design the 18no. piling platforms with 45° slopes with a maximum height of 2.50m, we have considered a superimpose dead load of 8kPa applied at a distance of 20m from the crest. To take into account the thickness of the granular material for the working platform on top of the wall.

In addition, the 182 tons piling rig Bauer BG45 was considered with an equivalent uniform bearing pressure of 227 kPa at 4.0m spacing with 2no tracks 4.51x1m. The maximum loading considered was approximate 1500 kN.

Construction traffic was considered as a variable load in accordance with Table 2:

Table 2. Summary of variable loads on piling platform with 45° slopes.

Type Traffic	Loading Details (Worst Case)
General Traffic <60 Tons	20kPa over full platform area
Volvo A60 (Laden)	70T load of rear axles over area of 2.14 x 3.884m (85 kPa or 327kN/m over 3.884m) 2no. Wheel point loads of 17.5T over 800x800 bearing area (275kPa) at 3m centres

A minimum 3.0m exclusion zone is to be provided around the edge of the piling platform where no surcharge loading greater than 20kPa is permitted at any time. When the piling rig is operating no plant loading of greater than 15kPa us permitted in this 3m exclusion zone.

2.5 Surcharges on the Haul Road with 70° slopes

To design the Haul Road with 70 slopes with a maximum height of 2.50m and overall length of 1,000 metres, we have considered a superimpose dead load for the road pavement and the safety barriers in accordance with Table 3.

Table 3. Summary of dead loads on Haul Road with 70° slopes.

Item	Width (m)	Slope Crest Setback (m)	Load (kPa)
VCB Foundation Cradle	0.95	0	7.8
VCB	0.45	0.25	15
Road Pavement	11.5	0.70	4.2
Road Pavement Found	11.5	0.70	4.5

Construction traffic was considered as a variable load in accordance with Table 4:

Table 4. Summary of variable loads on Haul Road with 70° slopes.

Type Traffic	Loading Details (Worst Case)
General Traffic <60 Tons	20kPa over full platform area
Cranes up to 750T	99T (6 axles) over 8.6x3m (38kPa or 115kN/m over 3m)
Low Loaders	75T (5 axles) over 6x2.55m (50kPa or 125kN/m over 2.55m)
Bauer BG45 Piling Rig	2no tracks 4.51x1m w/ uniform pressure of 227 kPa at 4m spacing
Volvo A60 (Laden)	70T load of rear axles over area of 2.14 x 3.884m (85 kPa or 327kN/m over 3.884m)
	2no. Wheel point loads of 17.5T over 800x800 bearing area (275kPa) at 3m centres

A minimum 2.5m exclusion zone is to be provided around the edge of the haul road where no surcharge loading greater than 20kPa is permitted at any time.

In addition to the surcharge loads on the surface of the piling platform/ haul road as advised above, a stability check was performed on the proposed Komatsu PC360LC-11 excavator lifting the proposed culverts into place on the starter layer with 2no tracks 3.1×0.7m with uniform pressure of 135 kPa with a maximum 7,100kg lift.

3 DESIGN SOLUTION

3.1 Design method and standards

The design of the Reinforced Soil Wall/Slopes considered the surcharges applied on top and behind the wall, the pressure of the soil at the back and all the properties of the soils (reinforced soil, retained soil, foundation soil). The internal and global stability were considered for the design.

The internal stability design process determined the amount of soil reinforcement required to maintain integrity of the reinforced soil mass and considers tensile and bond failure of the reinforcement. Internal stability checks have been carried out in accordance with the methods allowed in Section 7: Reinforced Slopes, of BS 8006-1:2010+A1:2016 Code of Practice for Strengthened / reinforced soils and other fills. Checks were made for the ultimate limit Combinations A and B and serviceability limit states Combination C.

The global stability analyses were carried out in accordance with BSEN1997-1:2004 – Eurocode7 (EC7) and the UK National Annex. In particular, the analyses are in accordance to BS EN 1997-1 (Eurocode 7) using Design Approach 1, Combination 1 with partial factors on loading and Design Approach 1, Combination 2 with partial factors on soil parameters and variable unfavourable loads. The global stability was performed on the overall structure including the retained soil and the foundation soil using slope stability methods such as Bishop's modified method of slices.

The internal stability analyses were carried out using ReSlope, Geosynthetic Reinforced Steep Slopes from ADAMA Engineering, Inc software version 4.0. Additionally, the internal and global stability analyses were verified using GEO5- MSE Wall, Analysis of mechanically stabilized slopes software version 2021.49.

The depth required for the piling platform has been determined based on the Tenax reinforced soil raft method which uses layers of Tenax biaxial geogrid to improve the load spread through the platform to the subgrade and hence reduce the bearing stress on the subgrade. This method has been verified by experimental testing and experience as advised in TWf guidance 2019 "Design of granular working platforms for construction plant".

3.2 *Final design*

The analysis of the piling working platform and the Haul Road indicated that due the presence of soft superficial deposits in form of Alluvium with Undrained shear strength (Cu) of ≥ 20kPa to <40kPa a minimum 1500mm deep basal starter layer is required, reinforced with layers of Biaxial geogrid Tenax LBO HM4. Additionally, due to the presence of soft soils and to satisfy the global stability analysis in accordance with Eurocode 7, the perimeter of the piling platform requires sheet piling to cut off rotation slips within the Alluvium.

The internal & global stability analysis of the 45° reinforced soil slope supporting the piling platforms requires layers of Biaxial geogrid Tenax LBO HM4 reinforcement at maximum 420mm vertical spacings with a horizontal length of minimum 11.5m.

The analysis of the piling working platform and the Haul Road indicated that due the presence of soft superficial deposits in form of Alluvium with Undrained shear strength (Cu) of ≥ 40kPa a minimum 750mm deep basal starter layer is required, reinforced with layers of Biaxial Tenax LBO HM4. The internal & global stability analysis of the 70° reinforced soil slope supporting the Haul Road requires layers of Uniaxial geogrid Stratagrid SGU60 reinforcement at maximum 420mm vertical spacings with a horizontal length of minimum 8.0m.

4   CONCLUSIONS

The use of geogrids reinforcement was the most cost-effective and environmental solution to construct the temporary causeway to enable the installation of the piles for the Thame Valley Viaduct.

With the Internal Stability analysis, it was possible to determine the required strength of the geogrids, the spacing and the minimum length the layers of reinforcement to meet the equilibrium for each possible failure mechanism. Once the strength, length and spacing of reinforcement were determined, it was required to check the external stability of the reinforced block against overturning, sliding and bearing capacity failure. The use of biaxial geogrid Tenax LBO HM4 improves the load distribution through geogrid-aggregate interlocking mechanism and the use of uniaxial geogrid Stratagrid SGU60 helped to stabilise the 70° & 45° reinforced soil slope.

The geogrid reinforcement solution for a 70° reinforced soil slope supporting the Haul Road and the 45° reinforced soil slope supporting the piling platforms with maximum height of 2.50m, vastly helped in the reduction of CO_2 footprint during construction by reducing the imported reinforced concrete wall, the on-site excavation and reducing the time taken within the construction process.

The use of polyester geotextiles in civil engineering

M. Peroński*, P. Radziemski* & K. Gęsicki*
ViaCon, Poland

ABSTRACT: In the article, the author presents the implementation of construction with the application of polyester woven geotextiles. By using of woven geotextiles, it's possible to reduce significantly the time and the cost of construction. The author presents selected projects to inspire other engineers to use polyester woven geotextiles in their everyday design work or work on the construction side. The application of PES woven geotextiles solves many technical problems while being trivial and easy to build.

1 INTRODUCTION

The technological development of the production of polyester woven geotextiles has made them extremely competitive compared to other geosynthetics. The weaving technology and the production of yarns allow to produce products with very high tensile strengths at a low cost of production. Commonly used are PES woven geotextiles with tensile strength: 100, 200, 300, 600 or 1000 kN/m. A few years ago materials with such parameters were very expensive and produced only on special order. Currently, polyester geotextiles have practically replaced polypropylene or polyethylene geosynthetics on the Polish market due to better mechanical properties and lower production cost.

It should be also noted that polyester woven geotextiles are characterized by a lower elongation at break than polypropylene products. The average elongation at break of polyester woven geotextiles is 10% and polypropylene products 18%. For this reason, designers started more likely to use polyester woven geotextiles. Another reason, why polyester products are designed, is the development of knowledge about them. Today, polyester geotextiles are the so-called qualified geosynthetics. A full range of tests are available, what enable to determine long term design strength, as well as durability and resistance in acid or alkaline environment.

Moreover, these materials are resistant to damage during backfilling (e.g. high static puncture resistance). Therefore, it is very common to use geotextiles together with a crushed backfill aggregate. As a result, geotextiles are widely used in Poland not only in applications with natural aggregate, but also using crushed aggregate backfill. Of course, due to the geological structure of Poland, the backfill is more often made of natural aggregates, which is more available compared to crushed aggregate transported from the mountains – the south of Poland. The above-described features of polyester woven geotextiles caused the use of them in the solutions presented below. Examples of realized projects confirm that technology with use of polyester woven textiles was the best choose from technical and economical point of view.

2 TEMPORARY CONSTRUCTION ON RAILWAY 286

2.1 *Description of the technical problem*

The extension of the Ścinawka Średnia station along the 286 Railway Line assumed the overhaul of the railway viaduct at km 13.665. Due to the lack of consent for the closure of train traffic, the overhaul of the viaduct assumed staging of works – the works were to be completed in half.

First stage (Figure 1) assumed the construction of steel sheet piles GU 16N, 15.0 m and 16.0 m long, with 10m long anchors 116 kN/pcs load capacity each. Then, rebar works were performed in the excavation as a part of the overhaul of the railway viaduct together with the construction of a retaining structure reinforced with polyester woven geotextiles. Retaining structure made of geosynthetics in these case was to provides the stability of the trackway during second stage of works.

Second stage (Figure 2) included the dismantling of the track and transferring the traffic over the retaining structure made of geosynthetics. Then, the excavation works were performed in front of the reinforced soil together with the disassembly of the anchors and further work on the railway viaduct. The sheet piling was not removed.
Figure 1.   Stage I.
Figure 2.   Stage II.

2.2 *Design assumptions*

It was assumed that the reinforced soil structure will be temporary and that is why the long-term tensile strength has been reduced to only 5 years (through appropriate reduction factors due to creep). Polyester woven geotextile with high tensile strength in MD direction was used. Live load – model LM71 (Figure 3). The height of analysed structure is 6.40m and geometry is according to Figure 2. The backfill was made of non-cohesive soils with a minimum internal friction angle of $\varphi = 35°$. The soil laying below are silty clay soil with internal friction angle $\varphi = 14.2°$ and cohesion 15 kPa.

Figure 3.   Live load example – LM71.

Reinforced soil structure design assumed that the geotextile cannot press the sheet piling. It was based on the assumption that the allowed elongation of the reinforcement could not exceed 2%. After determining the strength in individual reinforcement layers, it was possible to choose the appropriate strength of the geotextiles and finally determine the technological empty space between the sheet piling and the face of the reinforced soil structure. Empty space size was designed to cumulate allowed elongation of geotextile (SLS).

The design was carried out in static condition according to Eurocode 7 (EN 1997-1) using partial safety factor concept. Using this concept, it is assumed that the structure is stable when overdesign factor is ≥ 1. For the stability check it was required to verify the structure using design approach A2 + M2 + R3. The characteristics of PES woven: long term design tensile strength based for 5 years rheological coefficient (temporary structure). Of the attention to difficult structure long term strength has been calculated with safety factor value 1.3. Serviceability Limit State (SLS) was calculated to tensile strength by 2% elongation and reduced to 5 years long term strength.

During calculations, local and global stability of a reinforced soil structure was checked. The following factors were taken into account: overturning, sliding, reinforcement pull-off, ultimate load-bearing capacity of the reinforcement. At the end global stability calculations was checked separately – where critical slip failure was beyond the structure.
Figure 4.   Critical slip failure.

The calculations were made using the GEO5 – Reinforced Embankments computer program based on the assumptions of the standard: Eurocode 7 and calculation sheets
Figure 5.   Temporary retaining.

integrating forces depending on the zone in which the reinforcement is located (zones: active and passive).

A major design problem was the location of the live load next to the face of the retaining structure- the load is shown in Figure 2. To prevent displacements of the rail truck decided to design precast retaining wall a 1.6m height.

The design solution is presented in Figure 5.

2.3 *Summary*

Live load test after end of construction works confirmed the correctness of the assumptions and design calculations. During the test geodetic measurements of the wall and tracks were done. Displacement and track deformation observed were in the limit. The use of soil reinforced with polyester geotextiles made it possible to replace the classic anchoring of the sheet piling in the second stage of works. In this case, it accelerated significantly the construction works and allowed for significant financial savings.

Figure 6.   Construction works.

3   TECHNOLOGICAL ROAD – BYPASS

3.1   *Description of the technical problem*

As part of the construction of a new road viaduct over the Railway Line no. 009 Warszawa Wschodnia – Gdańsk Główny along the road in Tczew, it was necessary to build a bypass road for the construction period. Embankment was designed as a soil reinforced with polyester geotextiles. It was alternative solution to MSEW structure (concrete panels as facing).

3.2   *Design assumptions. Methods of calculation*

It has been assumed that the reinforced embankment will be a temporary structure as bypass around the road for the time of the of the railway viaduct construction. The construction time was planned for 2 years (determining the long term design strength of geotextiles).

In order to optimize the solution, the retaining walls were replaced with a reinforced embankment with a slope angle of $80°$. This solution was cheaper and faster to implement. The normal section through the embankment is shown in Figure 7.

Determining the stability of the embankment, the load with the A-class load was assumed (according to PN-85/ S-10030) The geological condition is good. Subsoil is build of loose sands. For backfill used the same soil but with proper density. Before project calculations existing soil was tested and internal friction angle was determined. The soil properties has shown in Table 1.

Table 1.   Geotechnical characteristics of the soils.

Soil type	Properties		
	Internal friction angle, φ (°)	Cohesion, c (kPa)	Unit weight, γ (kN/m^3)
Subsoil	29	0	18
Backfill	34	0	19.5

3.3   Stability calculations

MSE stability checks were performed using the proprietary software GEO5 – Reinforced Embankments. The most unfavorable cross section was chosen to evaluate the system. During calculation, local and global stability of a reinforced soil structure was checked. The following factors were taken into account: overturning, sliding, reinforcement pull-off, ultimate load-bearing capacity of the reinforcement and displacement. For reinforcement has been used PES geotextile with strength 150/ 50kN/m. MSE wall sliding safety factor is 2.6, overturning safety factor is 3.0 and bearing capacity safety factor 2.1. This calculations does not cover the global stability calculations as the global stability – it was checked separately in GGU Stability program. Stability analysis with circular surfaces according to Bishop's Method showed Factor of Safety of 1.2.

Geometry of structure with vertical specimen of reinforcement has shown in Figure 7.
Figure 7.   Geometry of reinforced soil.

After determining the global and local stability, it was analyzed, how to secure the 80°slope. A well-known disadvantage of geosynthetics is the lack of resistance to UV. Polyester woven geotextiles need to be covered in two weeks after installation due to the UV resistance. UV resistance is tested according to EN 12224 standard and declared by the producer. Leaving the half-mattresses rolled up to direct sunlight would damage the reinforcement and damage the structure's stability, either locally or globally.

Several solutions were considered to protect the geotextile against UV, e.g. anti-erosion geomats, precast concrete. Finally, due to the temporary construction, it was decided to protect against UV rays by covering the face with polypropylene geotextile – Figure 8. The solution was not aesthetic, but was extremely cheap and easy to instal.

3.4   Summary

The presented example shows how to speed up works and reduce the costs of implementation. The construction of reinforced soil was done faster and without the need of additional elements: for example the foundation which is required for the construction of retaining

Figure 8. Bypass temporary construction – facing.

walls. Also, the disadvantage of geotextiles, which is the lack of resistance to UV, has been solved. The author hopes that this simple example will point out that these are materials sensitive to UV, which is often forgotten by designers and contractors – without securing geotextiles.

4 SOIL REINFORCEMENT

4.1 Description of the technical problem

As a result of optimization – reducing the costs of the bridge's construction, direct foundation was decided to support the bridge structure. It was possible only after reducing lateral earth pressure to the abutment. Soil reinforced with polyester geotextiles was designed, to take over the earth pressure and not transfer it to the abutment. The project was part of the S-3 Express Road Nowa Sól – Legnica Project.

4.2 Design assumptions. Methods of calculation

In the construction of reinforced soil the following design assumptions were made: high-strength polyester woven geotextiles as reinforcement. Calculations were conducted for each heights of abutment. A class A load was assumed in accordance with PN 85/ S-10030. Cross section with loads has presented in Figure 9. In calculation has been provided loads from: cars, pedestrians and soil weight, concrete plate weight and earth pressure from dead and live loads. Also has been considered horizontal force from brake load.

In calculation has been assumed backfill made of non-cohesive soils with an internal friction angle of minimum $\varphi = 34\,°$, cohesion c = 0kPa and maximum weight $\gamma = 19.0kN/m^3$. An empty space is made between the reinforced soil and the abutment. The calculations were made using the GEO5 – Reinforced embankments computer program based on the assumptions of the standard Eurocode 7 and original calculation sheets integrating forces depending on the zone in which the reinforcement is located (zones: active and passive). After determining the forces in each reinforcement layer, the appropriate strength of the geotextiles was chosen, and then the stress of each reinforcement layer in the active zone was determined. On this basis, the width of the technological space was determined, that will prevent the transmission of the strength to the abutment. During the performed calculations local and global stability of a reinforced soil structure, sliding, reinforcement pull-off, ultimate load-bearing capacity of the reinforcement and displacements was checked. As

840
Figure 9. Calculation cross section.

reinforcement has been used PES geotextile with strength from 200 – 400kN/m. MSE wall for that assumptions has factors: sliding safety factor is 1.8, overturning safety factor is 2.0 and bearing capacity safety factor 1.6.
Figure 10. Section of reinforced soil – solution.

According to the requirements for the reinforced soil, the space behind the abutment and the reinforced soil should be made in such a way that during the service live of the structure, after all displacements (construction period, load, rheological effect), the reinforced soil does not come into contact with the abutment and transfer any load. The width of empty space should take into account the following stages: construction stage, service live of structure. Calculation of space between abutment an face of MSE has been considered difference elongation at construction stage and end of predicted service time of structure (100 years). Has been used force by 2% elongation and considered long term material behaviours. Each layer has been calculated and checked displacements. At end has been determinated width of dilatation gap. Elongation length has been considered in active zone L_a.
Figure 11. Active zone graph.

5 CONCLUSIONS

The presented projects have shown that the use of polyester woven geotextiles can significantly accelerate and reduce construction costs. The number of designed and implemented soil structures reinforced with polyester woven geotextiles shows that both Designers and as well Contractors have gained confidence in this type of solution.

Finally, it should be underlined that the complicated implementation of reinforced soil is in fact trivial compared with the performance of works that could be avoided thanks to its use. Reinforced soil does not require the use of specialized machines or the work of specialists. Reinforced soil can be made by unskilled workers using basic machines used in earthworks.

Nowadays, when construction sites struggle with the lack of workers, may be very important by choosing the technology of works.

The author, as a popularizer of technical solutions with the use of polyester geotextiles, hopes that the popularity of solutions based on these geosynthetics will increase, and that the constructions themselves will be the best advertisement for them among Designers and new Contractors.

Dynamic response of an innovative reinforced soil embankment subjected to high energy impacts

O. Korini & Y. Bennani
Terre Armée, Rueil-Malmaison, France

ABSTRACT: Rockfall hazard in mountainous areas is often mitigated by placing reinforced soil embankments at the bottom of the slopes. The Terre Armée Company invested in an important research project for designing an innovative reinforced soil embankment, which had vertical facings and a relatively slender shape. High strength geosynthetic reinforcements assured its stability when subjected to impacts. During this project, real scale tests were performed on a 15 m long embankment with rectangular cross section and a foundation width that was almost half of its height. The structure successfully resisted the impacts from concrete blocks travelling with 5 MJ and 2 MJ kinetic energies. The deformed shape of the embankment showed that the internal geogrid reinforcements efficiently engaged a large soil volume far from the impact location. A good mobilization of the geogrids' strength was observed through the strain gauges installed on them, which confirmed the validity of the design.

1 INTRODUCTION

Rockfalls occur when rock blocks are detached from their place on the slope and start to roll or bounce downhill. Being on the surface, these blocks are subjected to atmospheric agents, which eventually degrade the weak links that they have with the base rock. The recent climate changes and the thawing of permanent ice in mountain slopes increase the risk of rockfall in these areas (Allen & Huggel 2013; Kellerer-pirklbauer *et al.* 2012).

Reinforced soil embankments are one of the solutions that engineers employ for mitigating the rockfall risk. Several research projects have been carried out for understanding their behavior under dynamic impacts (Lambert & Bourrier 2013; Maegawa *et al.* 2011; Peila *et al.* 2007). The tests were usually performed on trapezoidal embankments, which had different facings and reinforcement designs. Even though the internal geogrid reinforcements played a role in the deformed shape of the embankment (Peila *et al.* 2007; Ronco *et al.* 2009), their contribution in the impact resistance remains uncertain.

The Terre Armée Company recently invested on a research project concerning rockfall protection embankments. The objective was to produce an optimized slender embankment with a relatively narrow foundation footprint and to quantify the role of the geogrid reinforcements during a dynamic impact. Two experimental campaigns were performed in the framework of this project. The reduced scale campaign provided important conclusions (Korini *et al.* 2021) that were used later on to prepare the real scale tests.

2 EXPERIMENTAL SETUP

2.1 *Test conditions*

The impact tests are performed on a remote site near Chambery, France specially equipped for this purpose. This site was equipped with a crane installed at the top of the cliff, which

served to lift the reinforced concrete blocks for carrying out vertical drop tests. Since a horizontal impact is the most unfavorable for a rockfall protection embankment, another device was necessary to be built. In this context, a large scale pendulum was constructed on the vertical rock slope consisting of a steel beam and cables. The concrete blocks were attached to the pendulum cable and then lifted by the crane to the desired drop height. The potential energy of the lifted rock was fully converted to kinetic energy applied horizontally at the lowest part of the pendulum, where the embankment was foreseen to be built. The new device was able to perform horizontal impacts with a kinetic energy of 5 000 kJ, which corresponds to launching a 12.3 tons concrete block from a height of about 41.4 m.

2.2 Rockfall embankment design

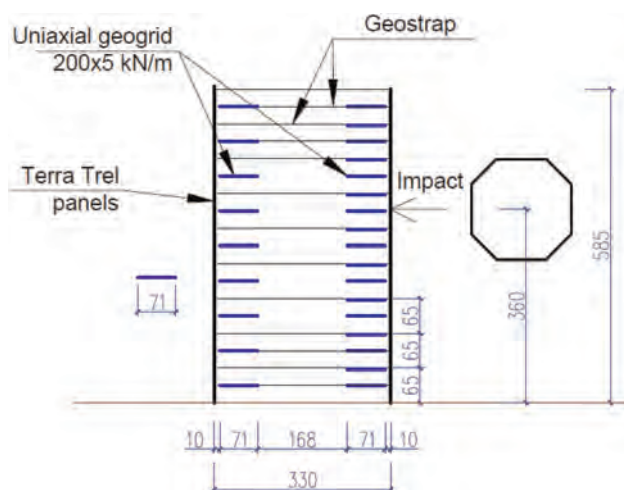
The embankment facings were held vertically by a system of welded steel mesh panels and GeoStrap® reinforcements. The latter were installed in a back to back pattern. For better resistance to the impact, the embankment was equipped with internal geogrid reinforcements. The internal design was chosen after the results of the reduced scale tests (Korini et al. 2021), which showed that the case with geogrids placed horizontally close to the facing had a better performance. For the current tests, the embankment was equipped with additional geogrid reinforcements placed in the back part aiming to reduce the back extrusion during the impact (Figure 1).


Figure 1.   The cross section design of the embankment.

The embankment was constructed using well graded soil backfill. In this way, a proper soil – geogrid interaction is guaranteed as well as an efficient distribution of the impact effect to a larger soil volume. The geogrids were uniaxial with the working direction installed in the longitudinal embankment direction. The role of the geogrids was to spread the impact load in the lateral direction and preserve the integrity of the embankment.

2.3 Instrumentation

The behavior of the embankment during the impact was monitored with several devices and sensors. Rapid cameras were used to record the impact on both front and back faces of the embankment. Accelerometers were used on the impacting block and in several positions in the backfill for measuring the impact force and internal vibrations. Pressure sensors were installed in the base of the embankment to check the variation of the local pressures. The geogrids' mobilization was monitored with the aid of strain gauges that were glued on the main direction strips.

3 TEST RESULTS

The embankment resisted well to the two impacts despite the important deformations. The rapid cameras (500 images/second) gave the possibility to observe in detail the response of the embankment during the test. Due to the high amount of data provided in this study, only part of the visual observations of the embankment and some of the strain gauges data curves will be presented below.

3.1 Visual observations

The first and strongest impact was directed at the longitudinal center of the 15 m long embankment and at about the upper 2/3 of its height (Figure 2). The displacement recorded at the impact position was about 2.1 m, which represents 63% of the embankment width. This value consists of 1.2 m block penetration and 0.9 m of structural deformation.

During the impact, the embankment exhibited a certain flexibility, which is probably due to its slender shape. After the initial penetration of the block, a longitudinal bending deformation followed that brought closer to each – other the front edges. At the end of the bending, the block lost all the kinetic energy, and the embankment continued to move due to the gained inertia. The final movements consisted of a slight back and forth motion of the whole structure similar to a cantilever structure anchored in the ground.

Figure 2. The deformed shape of the embankment after the 5 000 kJ impact.

3.2 Instrumentation measurements

The strain gauges provided important information concerning the geogrids' mobilization in the embankment. The strain curves may be generally split in three parts, i) an initial rapid oscillation, ii) an increase of the strain up to the peak value and iii) a slow decrease until the residual values (Figures 3 & 4). The front geogrid located at the impact height experienced high temporary strains during the initial moments of the impact, but less residual strains afterwards (Figure 3). Some of the strain gauges failed prematurely (e.g., G-2) without providing useful data.
Figure 3. Strain measurements on the front geogrid strip located at depth 0.3 m from the front facing.

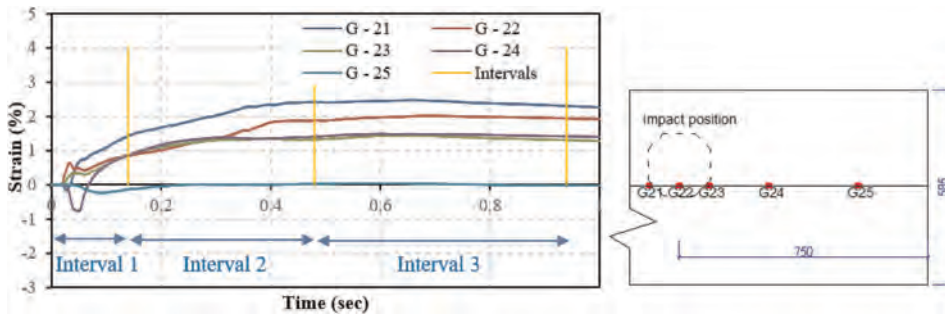
The back geogrid experienced quite different mobilization compared to the front geogrid. The initial oscillations were less sudden (the strain rate was lower) compared to the ones of the front geogrids. Moreover, the initial strains were significantly lower while the residual ones were higher (Figure 4). In both cases the strains remained lower than the geogrid maximal allowable strain of 7%, which is calculated considering the relevant reduction factors.


Figure 4.   Strain measurements on the back geogrid strip located at depth 0.4 m from the back facing.

The intervals yellow lines correspond to the significant moments of the embankment's behavior during the impact. The first interval represents the block penetration phase, the second one is the longitudinal bending and the third one is the backward movement of the whole structure. The front geogrids are mobilized during the first and second interval (up to 0.48 s) and show very low residual strains. On the other hand, the back geogrids remain mobilized after the second interval by showing higher residual strains.

The peak strains recorded by the strain gauges present an important variation around the impact position (Figure 5). The strain gauges measurement was limited to 5.3% due to the physical properties of the special glue that was used to stick them to the geogrids. This prevented the recording of higher strain values that could have been reached close to the impact axis.
Figure 5.   Peak strain measurements of the strain gauges during the 5 000 kJ impact.

The impact caused some of the strain gauges to fail prematurely, mostly at the impact position. This prevents the creation of a clear picture regarding the peak strains on the monitored geogrids. This is the case for G2 placed at H = 3.6 m on the front geogrid (brown line). However, by observing the trend of the geogrid strip that is installed 0.4 m deeper (pink line), it may be deduced that the G2 peak strain could have been about 6 %. Most of the strain gauges failures happened at low or zero strain values, which means that the loading of the geogrid was not the cause of the failure. The cause was probably the sectioning of the acquisition wires due to the rapid loading.
Figure 6.   Determination of the impact wave propagation speed.

4   DISCUSSION OF RESULTS

The embankment dissipated the kinetic energy of the block partly by local plastification at the impact position and partly by structural deformation. During the first moments of the impact the facing steel mesh got quickly disintegrated locally, so its contribution to the impact resistance was not significant. On the other hand, the facing remained intact elsewhere and together with the GeoStrap reinforcements continued to maintain the embankment's structural integrity. This was obvious in the further intervals of the longitudinal and vertical bending of the structure.

The rapid cameras showed the formation of a shear cone in the embankment during the block penetration interval. This is different from the case tested by Peila *et al*. (2007), where horizontal soil layers started to slide at the impact position. The geogrids in Peila's case were continuous sheets that covered all the embankment's width. In our case the internal installation pattern of the geogrids was discontinuous, which prevented the creation of sliding planes and favored a smoother 3D volumetric distribution of the deformations.

The front and back geogrid layers experienced different mobilization (Figures 3 & 4). At the beginning of the impact, most of the strain gauges experienced rapid oscillations with negative sign. This means that they were loaded in compression, which may not seem reasonable for a flexible geogrid. However, these readings could be capturing a physical phenomenon such as an impact (or seismic) wave. Several observations support this claim. Firstly, the negative peaks appear at the initial milliseconds when the block penetration is not significant and the embankment is almost intact. Secondly, the strain gauges continue to measure tensile strains as the block continues to penetrate, which means the gauges were not damaged. Thirdly, the initial peaks have time shifts between them, the oscillation period is higher for the gauges farther from the impact and in some cases the negative peaks have lower amplitude or even switch to positive. The last argument is in line with the seismic waves theory for soils (Kramer 1996).

The impact wave speed may be deduced by the measurements of the strain gauges by considering their initial mobilization time and the distance from the impact position. By plotting these two parameters, a cloud of points is obtained (Figure 6). Considering that a wave has a certain speed in a given medium, a best fit linear curve is proposed. The correlation factor is 0.83, which presents a fairly strong relationship between the plotted parameters. By inversing the slope of the fit curve, it is obtained the average impact wave propagation speed 204 m/s.

5   CONCLUSIONS

An innovative rockfall protection embankment is tested by horizontal impacts with energies up to 5 000 kJ. The embankment behaved as a slender structure due to its low width to

height ratio. Its ability to deform allowed the dissipation of the impact energy by a different mechanism compared to traditional embankments with trapezoidal cross section. Besides the local plastification at the impact position, the structure experienced longitudinal and vertical bending in most of its volume. This structural response was enhanced by the geosynthetic reinforcements, which allowed the distribution of the impact load to a larger soil volume.

The two systems of geosynthetics played a different role in the embankment behavior. The back to back GeoStrap links only guaranteed the structural shape without contributing much to the impact resistance. On the other hand, the geogrid layers got an important mobilization during the impact. The front geogrids contributed more during the initial moments of the impact, while the back ones contributed more after the block penetration interval. The geogrids did not fail during the test due to their ability to deform and also slide in the soil.

The strain gauges installed on the geogrids were able to capture a signal that resembled an impact wave. The rapid initial oscillations presented wave propagation characteristics such as different signal phasing and period depending on the gauge's position. The wave propagation speed was calculated considering the arrival time of the signal for each strain gauge. However, this evaluation needs to be taken with caution since there is the uncertainty whether the wave is transmitted through the soil or through the reinforcement itself.

The impact wave may cause both tensile and compressive strains of the geogrids. If these strains exceed the geogrid's material resistance, they could finally damage it. Consequently, the role of the geogrid in the impact resistance would diminish and the embankment would be more vulnerable. So, the effect of impact (or seismic) waves on geosynthetics is worth investigating in order to prevent undesired situations in relevant engineering applications.

The tested embankment presents an optimized solution compared to traditional rockfall embankments. It may be efficiently used in cases when construction space is limited due to its reduced foundation width.

Biodegradable formwork for reinforced soil structure

D. Palma
Geoflum Engineering srl, Potenza, Italy

ABSTRACT: Reinforced soil structures and their applications currently represent a key point in the field of the geotechnical engineering. They allow reinforcing soils respecting various environmental aspects. Though widely used, this conventional type of reinforced soil structure hides some drawbacks. One of them is the risk of soil pollution due to the degradation and corrosion of the metallic material making up the conventional formwork currently in use. This also applies to the zinc-coated facing elements which nonetheless release harmful particles of rust into the soil, though later than the classic black facing elements (without zinc-coating). The present invention, covered by a patent, concerns a structure for reinforcing soils made up of a formwork made of bio-degradable natural material, which can be combined both with planar reinforcing elements in metal mesh and with synthetic geogrids.

1 STATE OF THE ART

The reinforced soil structure is an engineering solution that allows combining the soil features with those of the reinforcing elements so obtaining a composite structure capable of resisting to tensile stress, so expanding the scope of earthworks.

Reinforced soil structures and their applications currently represent a key point in the field of the geotechnical engineering. They allow reinforcing soils respecting various environmental aspects.

Reinforced soil structure applies to several areas, as for example road and railway infrastructures, soil protection, mitigation of the hydrogeological instability, hydraulic constructions, river works or rock fall protection works, bridge abutments retaining walls, green elements for street furniture and industrial complexes, noise barriers.

Reinforced soil walls or embankments bring wider benefits than the traditional gravity retaining walls or reinforced concrete retaining walls, mainly because they imply a simple technique that does not need any specialized equipment or staff. For doing this works, it is in fact only necessary to use an excavator, a compactor and poor skilled labour. It is furthermore possible to easily construct very high retaining works able to take significant deformations before reaching their serviceability limit state, so needing no deep foundations and so being particularly suitable for stabilizing landslides. If compared to the rigid concrete structures, they can better bear earthquakes, dynamic traffic loads and impacting loads on them.

Using reinforced soil instead of a traditional reinforced concrete wall has a lower environmental impact, especially in consideration of the green grass growing on the front side, and makes it possible to use filling material collected right there a result of excavation, so considerably reducing the construction costs.

It is worth considering that many countries have laws which forbid (or guidelines suggesting to avoid) the use of steel in certain areas, such as for example some natural parks,

rivers and seas, areas in which slowly it will no longer be possible to use the reinforced earth technique, as it is known today, notwithstanding the aforementioned advantages.

1.1 Conventional reinforced soil's elements

As is well known, reinforced soil structures are made of three elements: the first one is the structural soil (the filling material of the structure); the second one is the reinforcing element (usually a geogrid or an hexagonal double twisted wire mesh, having different levels of corrosion protection); and the last one is the formwork (usually a welded wire steel mesh having a variable spacing and cross section diameter usually about 7 to 8 millimeters, mostly having no corrosion protection, combined with a natural or synthetic anti-erosion component.

1.2 Environmental advantages compared to conventional reinforced soil with lost formwork

Though widely used, this conventional type of reinforced soil structure hides some drawbacks. One of them is the risk of soil pollution due to the degradation and corrosion of the metallic material making up the facing element, that is a lost formwork. This also applies to the zinc-coated facing elements which nonetheless release harmful particles of rust into the soil, though later than the classic black facing elements (without zinc-coating).

A second drawback is the high CO_2 emissions into the atmosphere due to the current steel production standards relating to the only formwork currently in use. A third disad-vantage of conventional formwork are Post-production CO_2 emissions for handling and transporting the steel formworks currently in use: large vehicles are required due to their size and weight (cranes/forklifts and trucks respectively); as a result there are also high transport costs due to the size and weight of the current formworks. Finally, there is often poor greening of the front due to poor maintenance that in Italy notoriously unable to be guaranteed over time.

Accordingly, in consideration of the growing worldwide trend towards maximizing the respect for the environment and reducing the various forms of pollution, the principal aim of the present invention is to provide a reinforced soil structure, embankments and excavation faces comprising a facing element (the formwork) made of a biodegradable and natural origin material in order to avoid the risk of soil and groundwater pollution deriving from the steel degradation and corrosion (the systems currently in use include in fact facing elements, connecting parts and stiffening elements made of steel).

The formwork made of biodegradable material can be one of the ways to eliminate this possible source of pollution.

1.3 Comparison with the reinforced soil made with removable formwork

The primordial technique for making reinforced earth is known as the "extractable formwork" technique. This technique provided that the formwork was used only during the construction phase to give shape to the structure and was immediately extracted before creating the upper reinforcing layer. The formwork typically used consisted of a steel structure with the project inclination closed on the front by a single solid wooden panel.

This type of formwork was obviously reusable, but the technique was clearly much slower to implement on site than the disposable formwork technique (with formwork in electro-welded steel mesh described above) in terms of work surface day. In addition, it required at least two types of highly specialized manpower: from the material installer to the excavator operator who had to be able to extract the formwork with extreme delicacy without deforming or damaging the final work, which is remembered it is made of soil.

This technique has therefore been almost completely abandoned in recent times because it is too expensive in terms of labour, in favor of the lost formwork technique in electro-welded steel mesh, which, while involving the additional cost of steel, allows dras-tic reduction in the workforce.

2 ENVIRONMENTAL INNOVATION

In order to maximize the environmental respect of the reinforced soil currently in use, mitigating the possible sources of pollution they produce, a new formwork was designed and patented.

The environmental innovation is that the formwork is made of biodegradable natural material, in order to eliminate the possible pollution of the soil, and of any aquifers, due to the degradation and corrosion of the steel (with which the facings, the connection and stiffening elements are made) of the similar systems currently in use.

The other main characteristics of the formwork are: a) suitable stiffness demonstrated by fem analysis with which the technical and structural checks are satisfied. b) It is able to maintain the initial shape of the work even after the biodegradation process of the formwork. c) It is made up of light pieces and of reduced length compared to the standards to be "joined" on site with rapid interlocking systems. d) It is of a useful size to easily create curvilinear walls becoming a green technology for landscape projects.

Following image represents one of many results of FEM analysis done, where the maximum deformation of patented formwork is less than 10 mm. More details about FEM analysis and their results will described in the next paper.
Figure 1.   FEM analysis results of one of the forms of patented formwork made of biodegradable material. Red represents 8 mm of maximum deformation, and blue is zero mm.

2.1 *About the 17 sustainable development goals of the 2030 agenda and about EU green deal for carbon free*

With the Green Deal, Europe wants to become the first continent with zero climate impact by 2050. One goal is reduce CO_2 emissions by at least 55% by 2030 compared to 1990 levels.

As described in paragraph 2.2, the formwork presented here contributes to the achievement of these objectives.

In particular, it should be noted that the bio-formwork in question allows: a) almost total reduction of CO_2 emissions in the production phase. b) Strong reduction of CO_2 emissions from transport, thanks to the reduced weight and size of the elements, which allow them to be transported not only with trucks, as in the version currently in use, but with small vehicles, even by couriers. c) Zeroing of soil and groundwater pollution following the corrosion of the steel formwork currently in use, because the bio-formwork here presented is made of biodegradable natural material. d) a fertilization contribution to the topsoil layer of the reinforced soil, due to the biodegradation of the formwork over time.

About the SDGs, the bio-formwork described above, contributes in different ways to the achievement of the following Sustainable Development goals: 3) Good Health and well-being; 6) Clean water and sanitation; 9) Industry, innovation and infrastructure; 11) Sustainable cities and communities; 12) Responsible cities and communities; 13) Climate action; 14) Life below water; 15) Life on land.

2.2 *The natural formwork patented*

The formwork presented here is protected by patent in the name of the undersigned. The further environmental innovation offered by the system presented here is to create a structure that combines structural reinforcement needs with naturalistic, environmental and green-related needs, through: a) the construction of soil reinforcement structure with a lost formwork made of natural origin material. b) Creation of an intuitive and fast assembly system through simple joints to facilitate installation and eliminate possible installation er-rors. c) Creation of reinforced earth without risks for workers on site, given the absence of spikes or rusty parts and given their lightness.
Figure 2.   Example of one of the forms of patented formwork with river stone shape.

This formwork is biodegradable and it is made of natural origin material. The material with which it is made is at the same time capable of conferring suitable rigidity to the face itself, so as to guarantee the maintenance of the right shape to the external wall of the work to be done.

3   CONCLUSIONS

Comparing with the conventional techniques for making reinforced soil, it appears quite clear how the use of the formwork made of natural origin material, as described above, can be considered an innovative method and in step with the times, to construct a new green type of reinforced soil.

This natural formwork is able to eliminate environmental pollution of conventional steel formwork and it is able to improve the landscape insertion of the structure. It indeed mitigate CO_2 emissions in production and transport phases and it does not cause soil pollution because is made of natural origin material. In addition, it is able to offer a fertilization contribution to the topsoil layer of the reinforced soil, due to the biodegradation of the formwork over time.

Finally, it is also able to conjugate the above environmental needs with the technical need of to guarantee the shape of the structure over the time; and with the economic need of to carry it out in a short time and with non highly specialized labour.

The present invention, covered by a patent, concerns a structure for reinforcing soils made up of a formwork made of bio-degradable natural material, which can be combined both with planar reinforcing elements in metal mesh and with synthetic geogrids.

Monitoring and warning system including a double stiffness geosynthetic for the reinforcement of cohesive soil on cavities

ABSTRACT: The use of reinforcement geosynthetics to prevent localized cavity collapses is now relatively common. The communication presents a monitoring solution developed as part of the REGIC research project (Reinforcement using Intelligent Geosynthetic over Natural or Anthropogenic Cavities). It is based on an innovative bi-stiffness instrumented geosynthetic and its integrated autonomous acquisition system, specially designed for use by a non-specialist. Suitable for mitigation and management of the risk of localized collapse, it allows early detection of the development of the collapse phenomenon.

1 INTRODUCTION

Numerous experimental and numerical studies have made it possible to understand the behaviour of geosynthetic reinforcement to prevent collapses of structures in areas at risk of cavities; e.g., Rafael (Villard *et al.* 2002) or GeoInov (Delmas *et al.* 2015) projects.

Recently, the REGIC Project addressed the use of coherent fill soils reinforced with geosynthetics above cavities (Delli Carpini *et al.* 2023). It enabled the design and development of a monitoring system specific to geosynthetic reinforcement over cavities. This complete system, which integrates sensors, geosynthetic and monitoring system, will be named as "geo-auscultation" system; by detecting very small deformations, it allows a monitoring ensuring early detection of the collapse. It can then monitor the structure until the end of the service life, while maintaining a high degree of structural safety.

The design of an operational system for auscultation and warning associated with geosynthetic reinforcement on potential soil subsidence, must consider different possibilities of cavity evolution. Underground voids may collapse gradually or abruptly depending on the configuration of the void and the nature of the overlying soil. The main cases are (Al Heib *et al.* 2021):

the subsidence: continuous depression of the ground above the cavity which causes progressive deformation of the ground without brittle fracture; the extension and amplitude are related to the dimensions of the cavity, its depth and the quality of the overlapping strata; localized collapses: due to failure over a natural or anthropogenic cavity at low depths; size and shape of the cavity varies by configuration, e.g. for gypsum and coarse limestone quarries close to Paris, 90% of cavities have a diameter of less than 5 m.

Geosynthetic reinforcement is a recognized solution for treating localized sinkhole of small diameter up to 5 m. Nevertheless, the use of instrumented geosynthetics combined with the appropriate monitoring system can be an interesting solution for detecting, and/or monitoring, a rise in the cavity that leads to a larger subsidence.

2 BACKGROUND AND BASIS FOR THE DESIGN OF THE CAVITY DETECTION AND WARNING SYSTEM

2.1 *Behaviour of geosynthetic reinforced structures on cavities*

The principle of behaviour of a geosynthetic reinforced structure during the ascent of a cavity at the level of the natural ground and then when the cavity opens under the geosynthetic, is presented in the French standard XP G38065: it is possible to analyse the functioning of a geosynthetic reinforced structure over time, to facilitate the design of the detection, monitoring system.

For simplicity, the same assumptions as in the norm are considered: pulverulent fill soil, cylindrical cavity, progressive opening of the cavity at the surface. It is assumed that the design assumptions are valid until the end of the service life and that the design of the reinforcement is correct. Several periods are distinguished: period (I) corresponds to the installation phase of the geosynthetic and the construction of the embankment; during period (II) the cavity gradually rises to the surface and a subsidence occurs; period (III) corresponds to the opening of the cavity until it's nominal diameter under the geosynthetic; in period (IV) the cavity diameter remains unchanged until the end of the service life before a resumption of progressive opening (period V).

Figure 1 shows an example of possible evolution of the maximum horizontal deformation of the ground at the surface during the ascent of the cavity. The estimation of this change in deformation is based on values obtained by the empirical method of NCB (Al Heib *et al.* 2021).
Figure 1.   Schematic diagram of the evolution of horizontal deformations (soil & geosynthetic) and the settlement of the surface of the embankment during the ascent of cavity before opening at the TN.

The absence of slippage between the geosynthetic and the soil is a realistic hypothesis considering the low levels of deformation observed. It is then possible to specify the order of magnitude of the minimum deformation to be measured to allow early detection of the presence of a cavity.

This provides an important criterion for the proper design of instrumented geosynthetics. It should be noted that there was no settlement of the fill surface over this period, which prevents any detection of the cavity using a surface measurement.

The dimensioning methods (XP G38065), and even new modelling tools (Villard *et al.* 2017), make it possible to evaluate the evolution of the deformations of the geosynthetic as well as the settlement observed at the surface during the different phases (III, IV and V). If the geosynthetic is instrumented and its deformation measured, it is possible to deduce the diameter of the cavity and check the level of safety of the structure over time. It should be noted, however, that beyond the maximum measurement threshold of instrumented geosynthetics (limit of sensors), the monitoring of the structure cannot be continued by this technique. This corresponds to a second criterion of the design of the instrumented geosynthetic monitoring system. However, in this phase V, settling at the fill surface is relatively important and allows monitoring of surface settlements.

2.2 *Illustration of the "geo-auscultation" design approach for areas at risk of cavities treated by geosynthetic reinforcement*

As shown in paragraph 2.1, it may be noted that the "monitoring system" and geosynthetic reinforcement are closely linked and must be designed jointly to allow good optimisation.

Solution design begins with the assessment and characterization of the type of potential collapse of the site. This involves specifying whether the cavity location is known or not, whether there is a risk of subsidence or even of sinkhole, and finally assessing the size and shape of the subsidence, or of the sinkhole, and defining the nominal cavity size.

Once these parameters are known and the geotechnical study is finalised, it will be up to the Project Owner (possibly Project Manager) to choose the objectives of the infrastructure's instrumented reinforcement solution:

either a "temporary reinforcement by instrumented geosynthetic" considering that a definitive treatment after detection of the rise of the cavity will be provided;
or a "long-term reinforcement by instrumented geosynthetics": the reinforcement designed (usually for 100 years) is then associated to a "monitoring system" allowing the controlling of the development of the cavity and of the settlement of the surface.

With the definition of these objectives, it is then possible to design the instrumented geosynthetic. It will have to meet the infrastructure stability requirements (mechanical stability, maximum allowable surface settlement) and the monitoring system requirements.

2.3 *Proposal for an innovative "geo-auscultation" system combining monitoring and reinforcement*

It shall be noted that criteria related to design of the monitoring system, mainly those related to the early detection, interfere with the choice of reinforcement geosynthetic.

The requirement to detect at an early stage the subsidence or even the presence of the cavity under the geosynthetic presupposes that the instrumented geosynthetic can deform under very low tensile stresses, which is very often antagonistic with the choice of a high (or even very high) stiffness to meet the reinforcement requirements (low long-term deformations). Even if the measurement accuracy levels of the optical fibre instrumented geosynthetics used are high, they often remain unsuitable for early detection of subsidence during cavity ascent.

To respond to this antinomy, the project has developed a patented innovative reinforcement process based on a "inverted bi-stiffness" geosynthetic. It provides two tensile

stiffnesses that activate one after the other, the first being lower than the second. Combined with a suitable warning system composed by a network of optical fibres, inserted into the geosynthetic during the manufacturing process, this new type of geosynthetic makes it possible to detect small deformations of the soil (thanks to its first lower stiffness) while guaranteeing the same final level of safety as a classical geosynthetic with a single stiffness (the second stiffness more important after the deformation threshold necessary for the detection of movements ensuring this role).

3 DETECTION, AUSCULTATION AND WARNING OF CAVITY BY GEOSYNTHETIC INSTRUMENTED BY "GEO-AUSCULTATION" SYSTEM

Once the preliminary site study has been carried out, with the definition of the cavity type, the knowledge of its possible location or not, the type of expected disorders, their surface extension, and their speeds, it is possible to finalize the design of the solution.

This must consider the temporal objectives of the site Owner (see paragraph 2.3). In order to finalize the specifications of the associated "monitoring system", the following path may be used:

collapse type assessment:
  to be detected, the subsidence, e.g. very progressive opening of a cavity, may require a specific geosynthetic allowing very low deformation measurements (e.g. "inverted bi-stiffness") while a sinkhole with a brutal opening will be less demanding;
  the speed and amplitude of the expected deformations will also be necessary for the definition of the type and frequency of measurements, the processing and the warning system.

spatial location of the collapse in the geometry of the infrastructure:
  the extension of the area to consider will have a major impact on the choice of the type of optical fibres depending if the cavity is located and known, or if potential cavities are not precisely located and may appear under a linear transport infrastructure;
  similarly, the surface extension of the subsidence, or sinkhole, to be detected, will affect the spacing of the optical fibres;

choosing the right optical fibre technology for the site (see types of optical fibres in 3.1).
selection of the geosynthetic product suitable for the chosen optical fibre technology and the type of expected failure;
selection of the appropriate monitoring system (detection/acquisition) for the type of infrastructure, geosynthetic and subsidence type: it depends mainly on the chosen fibre optic technology; an integrated system allowing simple and different auscultation options, is presented in 3.2.

3.1 *Optical fibre sensors used in cavity monitoring*

Distributed (continuous) sensors, Brillouin or Rayleigh are distinguished from the back-scattered signal and distributed (local) sensors, like Bragg sensor. Optical fibres are simultaneously sensitive to temperature and deformation, regardless of the technology used. A fibre not subjected to deformation and placed at the same depth as the geosynthetic allows to realise deformation's measurement corrections.

3.1.1 *Brillouin technology*
Figure 2 shows a schematic drawing of the sensors and the measurement system of the Brillouin technology. The characteristics of the fibre make it particularly suitable for the detection, auscultation, and monitoring of infrastructures where the existence (or presumption) of cavities is known even if they are not localised.
Figure 2. Principle of operation of Brillouin or Rayleigh distributed measure fibres.

3.1.2 *Rayleigh technology*

Although less used in real works than Brillouin technology, this technology can also be used for the detection, auscultation, and monitoring of infrastructure with a limitation, due to its small possible measurement's distance (Figure 2).

3.1.3 *Bragg network technology*

The principle of the Bragg sensors and the associated system are shown in Figures 3 and 4. The use of this technology implies that the wavelengths of each sensor must be chosen

λ_B wavelength reflected by the Bragg sensor
η reflective index
Λ network spacing
Figure 3 Operating principle of the Bragg network system with analyser.

Figure 4. Operating principle of the measurement chain and monitoring of the integrated survey system.

sufficiently spaced to avoid overlapping when the fibre is deformed. As a result, the number of sensors along the same optical fibre is generally limited to about ten. This makes this technology particularly suitable for the detection, auscultation, and monitoring of infrastructures where the location of the cavity is known or of «punctual» structures (of reduced dimensions). However, increasing the size of the area examined is possible by multiplying the fibre optic lines.

A comparison of the technical characteristics is presented in Table 1. Economically Brillouin or Rayleigh optical fibres cost around ten euros per metre, where fibres with Bragg sensors cost more than six times more. On the other hand, the Bragg sensor analyser is about seven times cheaper than the Brillouin or Rayleigh one's.

In conclusion, depending on the failure mechanisms involved, the treatment objectives and the type of surveillance chosen, the designer has a full range of solutions depending on his objectives and the means available.

Table 1. Comparison of fibre optic sensor specifications for cavity monitoring.

Characteristics	Brillouin scattering	Rayleigh scattering	Bragg network
Spatial resolution	1 m	1 m	8 mm & distance between Braggs
Measurement accuracy	10 $\mu\varepsilon$	1 $\mu\varepsilon$	1 $\mu\varepsilon$
Acquisition time	10 min	1ms	1ms
Distance of measurements	20 km	70 m	10 km
Elongation at failure	5 %	(-)	5 %
Maximum measurement strain	3%	(-)	3 %

4 MONITORING SYSTEM

Once the fibre optic sensor technology, the type of geosynthetic and the timing have been specified, the appropriate monitoring system should be designed to acquire the sensor measurements, process them against the defined thresholds and, if necessary, alerts, or alarms.

Optical fibres are woven into the geosynthetic during the manufacturing process.

The tracking system will obviously need to be able to connect to the site's optical fibres via an optical multiplexer for example.

It will:

perform data acquisition (raw measurements): either in periodic acquisition (with manual backup by a technician) or in continuous acquisition with data sampling, filtering and transfer for processing; in parallel an operation check is carried out with automatic alarm.
preliminary data processing with file concatenation, instrumental correction, amplitude calculation; this phase differentiates between unqualified (miscellaneous) and qualified anomalies (geosynthetic movements);
the data corresponding to qualified anomalies (geosynthetic movements) are then subject to advanced processing: location, extension of movements, exceeding thresholds, etc. this processing allows to trigger if necessary:
alerts to the Client with anomaly report which may result; a change in monitoring mode, on-site intervention, etc.

In parallel, the system must provide for the storage of the catalogue of detected anomalies, monitoring reports and graphs as well as equipment maintenance and progress reports.

In order to facilitate the use of this new "geo-auscultation" technology, which may seem relatively sophisticated for neophytes, Afitexinov has developed the integrated monitoring system called PREDITECT© shown in Figure 4.

In its current version, it meets the above requirements for structures monitored by Bragg sensors. Featuring a 16-way multiplexer, it tracks 128 Bragg networks. It's in situ housing allows continuous data acquisition and ensures their transfer to a specific remote server. Its associated solar panel guarantees a minimum autonomy of 6 months. Once the enclosure is connected to the construction site, the measurements can be carried out either on site, by connecting with a computer or remotely by setting up all the data on the digital platform.

On the remote server, the "integrated monitoring system" ensures all preliminary and advanced processing and, if necessary, enables the Client to trigger configurable alerts.

5 CONCLUSIONS

The use of geosynthetic reinforcement to prevent localized cavity collapses is now common and it was important to provide a technique with reliable measurement, detection, monitoring and warning system. This development, as part of the REGIC research project, has enabled the development of the new "geo-auscultation" technology which is supported by its specific integrated tracking system. The development of an innovative reverse bistiffness geosynthetic has made it possible to extend the measurement range to very small deformations allowing the early detection of subsidence above cavities.

The integrated monitoring system, developed in this framework, adapted specifically to the problem of strain monitoring in areas at risk of collapse, offers Project Managers an easy-to-use and easily configurable tool according to the surveillance objectives.

ABSTRACT: The paper refers to one of the largest reinforced soil walls project in Europe, the Bar-Boljari Highway construction project in Montenegro. The highway runs on hilly terrain with high slopes, hence for a large part the soil has to be excavated upslope, while for the valley side high embankments have to be built to support the road. In order to minimize the height of the embankments, to minimize land occupancy, and to minimize the quantity of excavation at the toe and the quantity of required fill, the valley side was supported by reinforced soil walls, with height up to over 30 m. Segmental wall with uniaxial extruded geogrids connected by special connectors to small size precast concrete blocks for facing has been selected as the technology for this impressive project. The paper presents the overall reinforced soil walls project, the design of the walls in static and seismic conditions, the horizontal displacement analysis, and the construction method, with details of the most challenging situations.

1 INTRODUCTION

The paper refers to one of the largest reinforced soil walls project in Europe, the Bar-Boljari Highway construction project, in Montenegro. The Investor (Government of Montenegro–Ministry of Transport and Maritime Affairs) awarded the contract to the company China Road & Bridge Corporation (CRBC), Montenegro Branch. The highway route from Podgorica to Mateševo is divided into 4 parts, each of length of approx. 10 km.

The highway runs on hilly terrain with high slopes, hence for a large part the soil has to be excavated upslope, while for the valley side high embankments have to be built to support the road. In order to minimize the height of the embankments, to minimize land occupancy, and to minimize the quantity of excavation at the toe and the quantity of required fill, the valley side was supported by reinforced soil walls, with heights from few meters to over 30 m.

DOI: 10.1201/9781003386889-101

2 SELECTION OF REINFORCED SOIL WALLS SYSTEM

2.1 *Segmental walls*

The selection of the wall type has been based on the consideration that construction will be on steep hilly terrain, hence all construction elements shall be light and easy to transport and install. Therefore the following type of wall has been selected: reinforced soil segmental walls with uniaxial extruded geogrids reinforcement connected through special connectors to small size precast concrete blocks for facing.

The characteristics of the elements of this reinforced soil wall system are now explained.

2.2 *Concrete blocks*

The segmental concrete blocks for wall facing are shown in Figure 1: the concrete blocks present a tongue on the bottom face and a groove on the top face, which allows the anchorage of uniaxial extruded geogrids through a specially engineered plastic connector, which ensures that the design strength of geogrids is not impaired at the face. This system affords that the full design strength of geogrids can be considered for their whole length, both in static and seismic conditions.
Figure 1.   The concrete blocks: a) Cross section; b) 3-D view; c) Detail of geogrid–block connection.

2.3 *Geogrids*

Geogrids for reinforced soil walls cannot be selected independently from the construction system; in this case geogrids shall fit the connections with the segmental concrete block units. For ensuring that the connection affords 100 % of the design strength of reinforcement, E'GRID uniaxial extruded geogrids (Figure 2.a), produced by BOSTD, were selected. In facts, only this type of geogrid, being an integral product made by drawing a punched HDPE sheet, affords the high junction strength required to be connected to the blocks by the plastic connector through the junctions (Figure 2.a). The geogrids selected for this project afforded ultimate tensile strengths of 60, 95, 125, 170 kN/m, and all geogrids afford a long term design strength > 44 % of ultimate tensile strength.

2.4 *Foundation pad and capping pad*

Reinforced soil walls are inherently flexible structures which can accomodate even differential settlements without impairing their stability. However, the wall system selected for this project presents a segmental concrete blocks facing system, which is in effect a semi-rigid structure. Hence the facing requires a proper foundation to avoid misalignment of concrete blocks which may produce cracking in the facing system. Since the toe of walls is very close

to the slope of the natural terrain, a cast-in-situ concrete foundation pad has been designed, featuring a front upstand which allows simple and firm block alignment and contributes avoiding outward direct sliding of the toe blocks (Figures 2.b and 3.b).

The top of walls has been finished with cast-in-situ capping pads (Figure 3.a), directly on the top row of concrete blocks (Figure 4).

2.5 *Drainage*

A drainage layer has been designed behind the concrete blocks facing for avoiding any water pressure which may impair the stability of the facing system and the connections between geogrids and concrete blocks, as shown in Figure 4.a: a 300 mm wide coarse gravel layer has

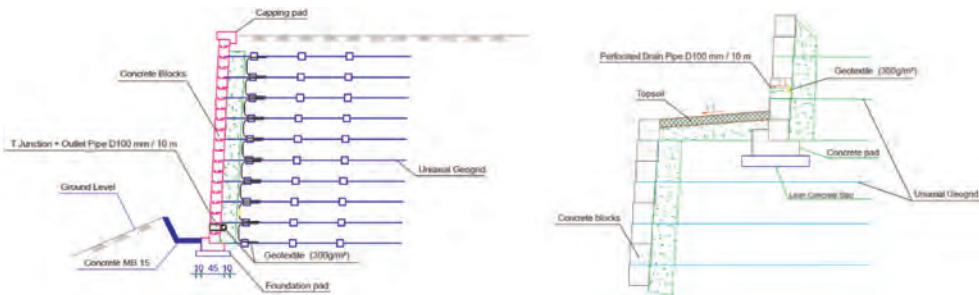
Figure 2.   a) Top view of the concrete blocks with the connectors and the uniaxial extruded geogrids; b) Front view of the first row of blocks placed against the tooth of the concrete foundation pad.
Figure 3.   Detail of cast-in-situ concrete capping pad and concrete foundation pad (all dimensions in mm).


Figure 4.   a) Detail of drainage behind concrete blocks facing; b) Detail of berms.

been specified, with 300 g/m^2 nonwoven geotextiles as filter placed between consecutive geogrid layers. On each berm a horizontal drainage layer has been designed to carry all the rainfall falling on the berm to the vertical drainage layer, as shown in Figure 4.b.

This drainage system and the specification of a self-draining fill allowed to perform the design assuming no pore pressure in the whole reinforced block.

3 OVERVIEW OF PROJECT

The project includes 17 main reinforced soil walls (RSW), with height from few meters to over 30 m. The total length of RSW is 3.5 km, for a total wall face surface of 61,400 m^2; the average wall height is 16.5 m. All walls have been designed with single or multiple tiers: each tier from the top is 6.60 m high and with inclination of 86° on horizontal, with 1.25 m wide berms between tiers. Only the first tier at base has lower height than 6.60 m. Figure 5 shows the cross-section of one of the tallest walls, with height of 30.95 m, composed of 5 tiers; for this wall all geogrid layers have length of 20.10 m.

Geogrid reinforcement is always with the lowest grade (that is 60 kN/m ultimate tensile strength) at top, and increasing strength toward the base. Geogrids are placed every second block, that is with 0.44 m vertical spacing, but for the lower layer of the tallest walls the spacing has been decreased to 0.22 m, as shown in Figure 5.

The highway is always on top of the walls. Whenever possible a shallow embankment has been designed at top, as shown in Figure 5, to move the edge of the highway away from the concrete blocks facing and, in this way, to get the space for placing service pipes and conduits.

For all walls the fill is a selected granular soil with 38° friction angle and high permeability, which allows consideration of the fill as self-draining.
Figure 5. Cross-section of one of the tallest walls.

4 DESIGN OF REINFORCED SOIL WALLS

4.1 *Design approach*

The design process used for designing the reinforced soil structures has been the following:

- Internal stability is first addressed to determine geogrid spacing, geogrid length, and connection to the face, both in static and seismic conditions. This establishes the integrity of the wall.

- External stability against overturning, sliding, and foundation failure is investigated, both in static and seismic conditions, and the internal design is verified or modified accordingly. This establishes that the wall mass will remain stationary.
- Global stability analyses, to ensure that there are no failure mechanisms involving the reinforced soil mass, the soil behind the reinforced fill, and the foundation soil, both in static and seismic conditions. This establishes that the wall mass and the surrounding soil mass will remain stationary.

Eurocode 7 (EN 1997) requires a Limit Equilibrium design approach. A National Annex exists for each Eurocode Part, providing Nationally Determined Parameters. Since a National Annex didn't exist in Montenegro, it was decided to refer to the Italian Norm NTC 2008, since Italian geological, geotechnical, topographical, seismic characteristics are very similar to those in Montenegro.

4.2 *Internal and external stability*

Internal stability analysis addresses the following failure mechanisms: pullout of geogrids; direct sliding along geogrids; geogrids tensile failure; failure of connections between geogrids and segmental blocks. For internal stability of a geogrid reinforced soil wall the tie-back model is assumed, where the failure surface is a straight line starting from the toe and inclined at $(45° + \varphi/2)$, where φ is the friction angle of reinforced fill. To determine the geogrid layers vertical spacing and which grade to use at each level, earth pressures are assumed to be linearly distributed using Rankine active earth pressure conditions for the soil backfill and for the surcharge, even for tiered walls with overall batter $< 20°$. The tie-back model is used also for obtaining the embedment length of geogrid layers in the anchorage zone, L_E, from the pull-out analysis, which is added to the nonacting length of geogrid, L_N, within the active zone for getting the total geogrid length L.

Next, the external stability of the wall mass is considered, which includes overturning, sliding, and bearing capacity analyses. For bearing capacity analysis the Meyerhof distribution of vertical stresses on the foundation (whose width is equal to the geogrids length at base) has been assumed; hence the ultimate bearing capacity has been calculated for each wall height, using the reduced foundation width due to eccentricity, based on the design geotechnical properties of soils.

4.3 *Global stability*

Global stability analyses have been performed as follows:

- Sliding along circular surfaces (rotational stability): for the rotational stability analysis the modified Bishop method (Leshchinsky & Han, 2004) has been used, since this method affords to consider all contribution of forces acting on the slides.
- Horizontal sliding (translational stability): the mass of reinforced soil, and possibly a portion of the soil at its back, can slide as a rigid block along the base or along one of the geogrid layers; hence numerous bilinear surfaces, with a horizontal segment corresponding to increasing portions of each of the geogrid layers and an inclined segment with different angles for each horizontal segment, are therefore investigated; for each bilinear surface the resisting forces and the active forces are calculated, whose ratio provides the Factor of Safety. This is known as the Spencer method (Leshchinsky & Han, 2004).

4.4 *Seismic analyses*

The motion generated by an earthquake at a site depends on the particular local conditions, that is, from the topographic characteristics and stratigraphic deposits of soil and rock masses, and the physical and mechanical properties of the materials. The seismic motion at

the surface of a site, associated with each category of the subsoil, is defined by the maximum acceleration (a_{max}) at the surface. Once the maximum acceleration expected at the bedrock a_g has been defined, it is possible to calculate the seismic coefficients by the following formula:

$$a_{max} = S \cdot a_g = S_S \cdot S_T \cdot a_g \qquad (1)$$

where S_S, S_T are the stratigraphic and topographic amplification coefficients.

The horizontal and vertical seismic coefficients for pseudo-static analyses, K_h and K_v, are:

$$K_h = \beta_m \cdot (a_g/g); \ Kv = \pm 0.5 \cdot K_h \qquad (2)$$

where β_m is the dumping coefficient for reduction of the maximum acceleration at the site.

In the present project the bedrock acceleration a_g varies from site to site, hence from wall to wall, in the range $0.14 \div 0.225$ g.

The definition of seismic parameters was set according to Italian Norm NTC 2008.

4.5 Shear strength of concrete blocks

At the connection between geogrids and concrete blocks the tensile force in the geogrid is resisted by the upstand of the block, against which the plastic connector is butted (Figure 1.c). On the other side of the upstand the fill applies horizontal stresses due to soil thrust.

With reference to Figure 1.c, the base of the upstand is then subjected to shear stresses which may produce breaking of the upstand itself if the shear resistance of concrete is exceeded. Hence the shear strength analysis of concrete blocks is satisfied if:

$$S_{cD} = \tau_{cD} \cdot L \cdot b \geq R1 \cdot S_c \qquad (3)$$

where: S_{cD} is the design shear resistance of concrete (kN/m); S_c is the shear force at the base of the upstand (kN/m); τ_{cD} is the design resisting shear stress of concrete (kPa); L is the length of the upstand = 1.0 m; b is the width of the upstand = 50 mm; R1 is the model factor = Factor of Safety = 1.0,

The shear force S_c at the base of the upstand is:

$$S_c = T_{max} - P_h = T_{max} - \sigma_h \cdot d \qquad (4)$$

where: T_{max} is the maximum tensile strength in the geogrid at connection (kN/m); P_h is the horizontal force applied by soil on the upstand (kN/m); σ_h is the horizontal stress applied by soil on the upstand (kPa); d is the thickness of the upstand = 25 mm.

$$\text{With}: \ \sigma_h = \sigma_v \cdot K_a = \gamma_s \cdot Z \cdot K_a \qquad (5)$$

where: σ_v is the vertical stress applied by soil at the considered elevation (kPa); K_a is the active thrust parameter of fill for factorized friction angle; γ_s is the unit weight of fill = 20.5 kN/m^3; Z is the depth under wall crest.

According to Italian Norm NTC 2008, the shear resistance of concrete is obtained by the formula:

$$\tau_{cD} = 1000 \cdot [1.4 + (R_{ck} - 15)/35]/\gamma_c \qquad (6)$$

where: R_{ck} is the characteristic compressive resistance of concrete blocks (MPa); γ_c is the Reduction Factor for concrete resistance = 1.50.

The maximum tensile force applied to connections is obtained from the stability analyses in seismic conditions carried out for the tallest cross section of each wall.

The calculated Factor of Safety R1 has been always > 1.0 for all walls, thus ensuring that no concrete block of any wall will fail in shear.

4.6 *Horizontal displacements*

The serviceability limit shall refer to post construction displacements, which are equal to the difference between the displacements at 120 years and the displacements at 3 months (at the end of construction); such displacements are due to the tensile creep of the geogrids; hence for the serviceability limit we shall consider:

$$\Delta D_{i,r} = D_{i,k,r}(t = 120 \text{ years}) - D_{i,k,r}(t = 3 \text{ months}) \tag{7}$$

where: $D_{i,k,r}$ is the horizontal displacement of the i-th geogrid layer of tier k; $\Delta D_{i,r}$ is the post construction displacement at the elevation of the i-th geogrid layer of tier k.

According to BS8006: 2010 the serviceability limit for the horizontal strains of the structure of a reinforced soil wall (that is of the whole reinforced block with length L_i, equal to the length of the reinforcing geogrids), with no permanent structural load, is set as:

$$\Delta \varepsilon_{ij \text{ structure, post construction}} \leq 0.01 \, L_i \tag{8}$$

If the differential displacement calculated with Eq. (7) respects the condition in Eq. (8), the serviceability limit on horizontal displacement shall be considered as verified.

The post construction creep strain of the structure, $\Delta \varepsilon_{ij\text{-structure}}$, that is of the whole reinforced block, can be calculated at each geogrid level, by dividing the total post construction displacement (from Eq. 7) by the geogrid length (equal to the width of the reinforced soil block):

$$\Delta \varepsilon_{ij-\text{structure}} = \Delta D_{i,r}/L_i \tag{9}$$

where: L_i = total length of the i-th geogrid (m).

The values of $D_{i,k,\,r}$ (t = 120 years) and of $D_{i,k,\,r}$ (t = 3 months) have been calculated, at each geogrid elevation of each wall, with the method developed by Rimoldi (2018). Figure 6 shows the displacements and strains calculated for a 23.32 m high wall, composed of 4 tiers.

For all walls the condition (8) resulted as satisfied, hence the serviceability limit on horizontal displacement has been verified for all reinforced wall structures of the project.

5 CONSTRUCTION OF REINFORCED SOIL WALLS AND CONCLUSIONS

The construction of the walls was relatively fast and easy, thanks to the modularity and flexibility of the segmental wall system.

Special care had to be applied for the wing walls at the attachment with bridge abutments, where the design layout required either curved or angular connections, as shown in Figure 6. Also widening of the highway at toll stations (Figure 7.a) and the approach to tunnel entrances (Figure 7.b) required specific design details and construction care. The modularity of the construction system allowed to easily address the sudden changes of the wall height, due to the level variability of the hilly terrain (Figure 8.a), and the layout around concrete culverts (Figure 8.b).

The whole project has been completed in July 2022 and the highway was open to the traffic.

All the reinforced soil walls perform very well and their aesthetics has been appreciated, since it merge with the surrounding rocky landscape.

Therefore, this challenging reinforced soil walls project can be considered as completely successful.

ABSTRACT: Kandy, a UNESCO World Heritage Site, is the second largest city in Sri Lanka. The city lies on the 'Kandy' plateau which is mountainous and thickly forested. With the development and population growth in Kandy, it is necessary to construct a wastewater treatment plant which include sludge drying beds. The sludge drying beds which occupy area of about 1.5 acres located in a hilly area on the outskirts of Kandy, namely Gohagoda. To provide the necessary flat platform areas and access road, 250 m length of reinforced soil slopes with slope angle of 65° was constructed on site. The reinforced soil slopes comprise of single tier and two tiers slope with maximum height of 18 m, consisting of gabion facing units with layers of composite reinforcement geotextile. Total 44,000 m^2 of high tenacity composite reinforcement geotextile with characteristic ultimate tensile strength up to 100 kN/m were used in the project.

1 INTRODUCTION

Registered as UNESCO World Heritage Site, Kandy is in the Central province of Sri Lanka and is the second largest city after Colombo. Kandy is both an administrative and religious city housing the Temple of Tooth which is one of the most sacred places of worship in the world. The city is in the Kandy plateau which is mountainous and thickly forested on the island.

Due to city development and rapid increase in population in Kandy, urban issues such as environmental pollution is being concerned. Due to improper disposal of wastewater, the wastewater produced flows through various forms of waterways, deteriorating the water quality that threatens both human beings and environment in Kandy. For example, city's sewerage systems, drainage systems and river are all finally connected to the largest and longest river in Sri Lanka, the Mahaweli River which serves as the main source of raw water locally. To address the water pollution issue in the Mahaweli River, the city of Kandy with collaboration of Kandy Municipal Council (KMC) and National Water Supply and Drainage Board (NWS & DB) together with Japanese International Cooperation Agency (JICA) has introduced a wastewater management project. Figure 1a shows the layout of the overall wastewater management project in Kandy. This project involved the construction of wastewater treatment plant, sludge drying beds, treated effluent disposal system with pipelines, main pump station and maintenance facilities.

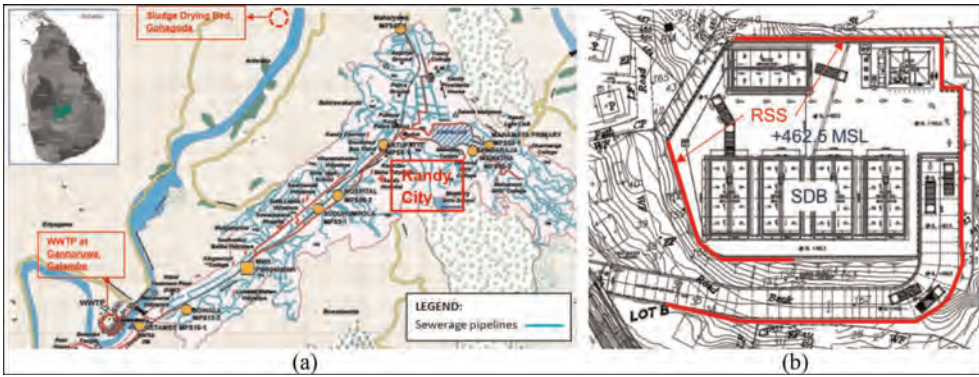
Land utilization is a primary concern in this project due to the challenging terrain with limited flat land and access road for construction. Reinforced soil slope (RSS) was designed to support the sludge drying beds (SDB) and access roads which takes up about 1.5 acres of land in Gohagoda. Approximately 250 m length of RSS was proposed in the project (see Figure 1b). The design height of RSS varies from 5.5 m to 10.0 m for single tier slope and up to maximum 18 m combined height with two tiers of slope due to the uneven existing ground terrain.


Figure 1. The layout of the overall wastewater management project in Kandy (a) and RSS layout (b).

2 SOIL CONDITIONS & SITE TERRAIN

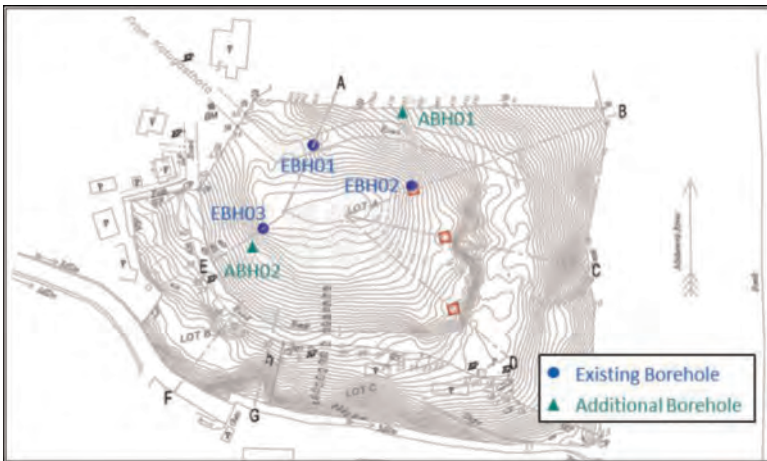
The location where the newly constructed SDB sit on was a landfill area sitting on uphill, with garbage filling activities carried out in the past. With reference to the soil investigation report, three (3) borehole tests were carried out at site initially, with two (2) additional boreholes being carried out later near to the slope area (see Figure 2). The worst soil profile at site consists of about 3.5m depth of garbage fill layer, followed by a very strong completely weathered rock with SPT-N value greater than 50 (see Table 1). Due to the varying soil profile found at site, a different set of soil parameters were input for the slope designs to ensure the designs are safe and economical.


Figure 2. Borehole location and section.

Table 1. Foundation soil properties.

Section	Description	Depth m	Average SPT	Unit weight kN/m^3	Cohesion kPa	Friction angle °
A-A	Highly weathered rock	0.0–5.0	>50	20	10	35

3 REINFORCED SOIL SLOPE SYSTEM

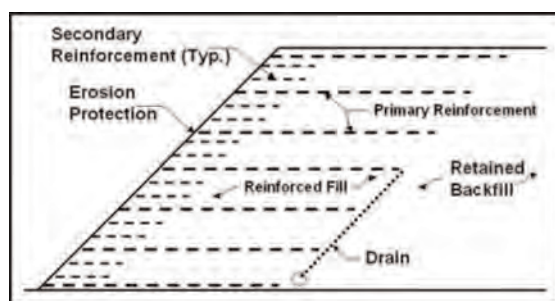
Reinforced soil slope (RSS) is a mechanically stabilized earth structure reinforced with planar reinforcement elements with face inclinations of less than 70 degrees (Berg *et al.* 2009a). Planar reinforcement such as reinforcement geotextiles are typically laid horizontally in multiple layers in a RSS (see Figure 3), providing adequate tensile capacity and stabilizing the slope by transferring destabilized forces from active zone of the slope to resistance zone.


Figure 3. Typical cross section of the reinforced soil slope structure (Berg *et al.* 2009a).

In this project, single tier and two tiers RSS are being constructed with a maximum of 10 m high for the single tier RSS. For the two tiers RSS, a maximum 18 m high with two tiers separated by a 9 m setback distance was constructed. The slope facing angle was formed by stepping each gabion layer approximately half a meter back at each level to create a 65° slope profile.

3.1 Facing system

Gabion facing system is selected for the RSS in this project. The gabion basket is in square size, measuring by 1 m wide by 1 m high by 1 m deep for each basket. The size of rock fills selected to fill up the gabion baskets ranging between 150 mm to 225 mm, with rocks tightly packed into basket to minimize voids.

3.2 Backfill materials

The residual granular soils that are locally available at site are used as the backfill material of the RSS. Utilizing locally available soils not only helps to save cost and time for importing soils, but it also reduces the needs of exporting the excavated soils, especially for a challenging site terrain with difficult access. The selected fills were carefully evaluated to ensure the achievable soil properties meet the project requirements.

3.3 *Reinforcement and filter geotextiles*

Reinforcement and filter geotextiles were used in the construction of the RSS. The reinforcement geotextile used to stabilize the reinforced slope is the Polyfelt® PEC composite reinforcement geotextile made of high modulus polyester yarns knitted to a nonwoven geotextile. The composite reinforcement geotextile combines reinforcement with superior filtration and drainage functionality to enable finer grained soils to be reinforced. The filter geotextile used to wrap drainage aggregates and subsoil pipes is the Polyfelt® TS nonwoven geotextile made of polypropylene continuous filament fibers needle-punched into planar form.

3.4 *Drainage blanket*

The base drain and back drain or often refer as drainage blanket, is designed to collect and remove groundwater from cut slope or behind the reinforced mass and allow infiltration water to preferentially flow toward the back of slope, away from the slope facing (Berg *et al.* 2009a). A typical 300 mm thick drainage blanket is proposed for the RSS. The subsoil pipes are placed within the single size aggregate layer with a nonwoven filter geotextile wrapping both within. To prevent the fines from moving into the subsoil pipes, nonwoven filter geotextile was used to wrap the pipes, protecting it from malfunction due to the potential blockage by the fines. Apart from that, the nonwoven geotextile also protects the subsoil pipes from potential damage from the adjacent aggregates.

4 REINFORCED SOIL SLOPE DESIGN

The design of the RSS using composite reinforcement geotextiles are based on BS 8006-1 (2010). For example, the vertical spacing of the geotextiles and fill material used are proposed according to the strict guidelines stated in the design manual to ensure the structural integrity and workability of the RSS.

4.1 *Soil parameters*

Two soil layers were modelled in the stability analysis, which are the residual granular soil as the backfill soil and weathered rock as the foundation soil. The soil parameters inputted in the analysis are shown in Table 2.

Table 2.   Input soil parameters.

Soil types	Unit weight kN/m^3	Cohesion kPa	Friction angle degrees
Backfill soil	19	0	32
Foundation soil	20	10	35

4.2 *Surcharge loading*

In the design analysis, a uniformly distributed surcharge loading of 20 kPa representing the future traffic loading access to reach the sludge drying bed was adopted on top of the setback platform and the 18 m height finished platform. Dead load such as structure loading was not considered in the RSS design and were taken care by other supporting system.

4.3 *Reinforcement long-term design strength*

Two product grades of the PEC composite reinforcement geotextile were determined and proposed for the RSS based on stability analysis. The lower grade PEC50 was used for the

upper tier whereas the higher grade PEC100 was used for the bottom tier of the RSS. Table 3 shows the long-term design strength of the PEC composite reinforcement geotextile with a design life of 120 years.

Table 3. Long term design strength of PEC composite reinforcement geotextiles used.

Property	Unit	PEC50	PEC100
Characteristic initial strength	kN/m	50	100
Partial factor – creep rupture		1.55	1.55
Partial factor – construction damage		1.02	1.00
Partial factor – environmental effects		1.10	1.10
Long-term design strength (120 years)	kN/m	28.8	58.7

4.4 Stability analyses

Various checking is required to ensure the RSS poses adequate factor of safety against various types of failure. For RSS, the critical design aspects may tend towards internal mode of failures (BS 8006-1 2010). The design was carried out using manual calculation based on BS 8006-1:2010 and with the usage of ReSSA (3.0) software (RESSA 2008). Table 4 shows the various modes of failure considered and the general minimum factor of safety required.

Table 4. Various modes of failure and respective minimum factor of safety required (BS 8006-1 2010, Berg *et al.* 2009b).

Failure mode	Minimum factor of safety
External Stability	
Bearing capacity	1.3
Sliding failure	1.3
Global slip failure	1.3
Internal Stability	
Tensile failure of reinforcement	1.3
Bond failure of reinforcement	1.3
Compound Stability	
Composite slip failure	1.3

4.5 RSS detailing

Figure 4 shows the typical cross section of the single tier maximum 10 m high RSS and two tiers combined maximum 18 m high RSS in this project.
Figure 4. Typical cross section of the proposed single tier RSS (a) and two tiers RSS (b) in Gohagoha.

5 CONSTRUCTION OF REINFORCED SOIL SLOPE SYSTEM

The construction of the RSS began with excavation to form the foundation platform of the RSS at an embedment level of 1.5 m below the base of the RSS. The ground was levelled as flat and smooth as possible for the laying of the first layer of the reinforcement geotextiles. The Polyfelt® PEC composite reinforcement geotextile was precut to length according to the design anchorage length, laid side by side and overlapped with adjacent geotextile panels to ensure the continuity of the reinforcement coverage across the entire slope structure. Once the composite reinforcement geotextile was laid, it was pulled taut and backfill materials were placed over the composite reinforcement geotextile followed by compaction (see Figure 5).

Figure 5.   Placement of backfill soil (left) and compaction of backfill soil (right).

The compaction was carried out with a compaction lift thickness of 0.25 m to achieve a minimum 95% of the optimum dry density based on Standard Proctor method. The composite reinforcement geotextile was installed at 0.5 m vertical spacings. For every unit of gabion baskets installed, a layer of composite reinforcement geotextile is placed under the gabion unit thus creating a frictional connection between the reinforcement and gabion units. At the same time a layer of reinforcement geotextile coincided half-way up the gabion basket was wrapped back towards the backfill materials.

At the base of each tier, a subsurface drainage blanket consisting of single size aggregates wrapped in the Polyfelt® TS nonwoven geotextile was installed (see Figure 6). Along the increased slope height, the drainage blanket was continued up at the back of the slope to intercept any seepage water coming from the back of the slope. A drainage pipe was installed horizontally all the way from the back of the slope to the slope facing. Figure 7 shows the completed RSS with the SDB ready for operation.

Figure 6.   Placement of drainage pipe (left) and drainage blanket at the back of the slope (right).

Figure 7.   Completion of reinforced soil retaining slope.

6   CONCLUSIONS

Without the help of geosynthetics, the slope would have to be constructed at a gentler angle which results in smaller useable land. Geosynthetics reinforced soil slope enables the maximization of land space, and its simple installation allowed the SDB construction to be finished within tight schedule. With the completion of SDB which forms part of the wastewater management project, wastewater can now be processed and cleansed before flowing into the Mahaweli river. Clean water not only improves the health of the public but also assures the sustainability of the environment and natural resources that maintain life forms.

Design and construction of the largest reinforced soil walls project in Cyprus

P. Rimoldi
Civil Engineering Consultant, Milan, Italy

G. Lugli & F. Trovato
Officine Maccaferri Spa, Bologna, Italy

I. Nicolaou
PYS IPSONAS Ltd, Cyprus

ABSTRACT: The paper refers to the design and construction of the largest reinforced soil walls project in Cyprus. The overall project includes reinforced soil wall (RSW) and true bridge abutment structures for the perimeter highway in Lefkosia, the Germasoyeias - Akrountas – Dierona - Arakapa road in Akrounta, the northern bypass of Geroskipou in municipal boundaries Paphos Konia, the Limassol - Saittas Motorway. The project, with a total of 22 RSW with 23,471 m^2 of wall facing, is considered the largest reinforced soil walls application in the country. The walls were designed and built as reinforced fill structures, with precast concrete panel facing elements and polymeric reinforcing strips according to the the Limit Equilibrium design approach and Eurocode 7 (EN 1997). All Cyprus is a seismic area, with peak ground acceleration varying from region to region in the range 0.15–0.25 g. The paper reports the design procedure for the RSW, both in static and seismic conditions. Construction details are introduced and illustrated by photos and sketches.

1 INTRODUCTION

In the last decade the amount of passenger cars per 1000 inhabitants in Cyprus has increased by hundred cars (545 to 645) placing Cyprus on the 7th place among EU, according to Eurostat. Although the amount of passenger cars has increased, the length of motorways and roads in built-up areas has remained almost unchanged over the same period, with increasing traffic problems especially in the capital city Nicosia. This generated the need to build new road infrastructures and improve the existing road network in the island.

For relieving traffic congestion around the city of Nicosia, the Nicosia Orbital Road project is designed to solve the capital's traffic load by creating new roadways. Currently, Phase 1 is under construction and due for completion in 2023, creating 7.5 km of new highway road, 10 km of connecting roads and 3 major junctions.

Limassol - Saittas Motorway is another major project with the aim of expanding the city of Limassol. The project scope is to assist with the suburban development of rural areas and the revitalisation of Troodos Mountain villages and communities. The project is designed in three phases. Phase 1, which is under construction, includes motorway, junctions, and overpasses.

The Germasoyeias - Akrountas - Dierona - Arakapa Rural Road project in Akrounta aims to upgrade 18 km of existing road network to boost the development of the eastern rural communities of Limassol and improve their connection with the city.

In Paphos District, on the west region of the island, the construction of the Paphos – Geroskipou Industrial Area bypass road aims to improve access towards the industrial zone,

previously congested by the merge with the city traffic. The project includes the construction of 6.6 km road network and a bridge overpassing the local stream "Limnaria".

2 THE SELECTED WALL SYSTEM

Retaining structures are heavily demanding in terms of material supplies. Concrete gravity walls, for example, requires large quantities of cement and its production and delivery produce a significant amount of CO_2 emission. Cantilever walls proved to be less demanding than concrete gravity structures, yet not comparable with reinforced soil walls (RSW). The advantages of a reinforced fill structure compared to conventional solutions are even more significant with increasing structure height. The difference among these structures is typically related to the structural components: cast in place walls (CIPW) main element is concrete while RSW rely on reinforcement of soil for supporting loads and superstructures. When possible, in situ soil is used as it is or partially re-worked with selected backfill or chemicals to function as structural fill of the RSW. This entails additional benefits as it represents a further step in achieving circular economy.

When it comes to aesthetics, durability, building installation, and planned settlements, several considerations can lead to the choice of RSW systems. These solutions are often constructed in difficult terrain where massive concrete solutions and traditional construction are not achievable due to site constraints. RSW can withstand extreme loads and mitigate the impacts of high seismic loads thanks to their flexible yet resistant nature. The soil reinforcement elements can be designed to support typical project loads, from traffic to bridge deck, for very long design life (typically 120 years for relevant structures). Once built, the RSW load is spread over a wider foundation area compared to CIPW, therefore RSW can tolerate higher overall and differential settlements, without causing structural damage. RSW walls are versatile, allowing for nearly any geometry and aesthetical customization. Precast concrete panels are relatively thin and can be customized in shape, finishing and colour to fit the architectural requirements. No curing time on site or support structures are needed for these structures, so design and installation are faster than for CIPW. RSW construction does not require skilled labour, even though experience and accuracy are important to guarantee the best results, and the usage of heavy machinery is limited.

The advantages of RSW are also important when it comes to post-construction maintenance. Distress signs can be monitored, and appropriate repair techniques adopted to avoid post-construction concerns and structure instability. Maintenance inspection guidelines detailing expected performance metrics and most appropriate repairs for specific distress observations are often available. Only for shallow RSW costs may become less convenient compared to other wall systems (e.g. CIPW), while significant economic savings has been achieved by using RSW in the construction of retaining walls and bridge abutments (where optimized RSW design leads to shortening the required bridge deck span with clear technical and economic advantages). The polymeric nature and intrinsic flexibility of geosynthetic reinforcement are also a plus when dealing with geometrical obstructions (e.g. pipes, culverts, manholes, etc.), where the geosynthetics layout can be designed to avoid any threat for the structure stability. Moreover, the post-construction deformation of RSW, when subjected to design loads, can be designed to respect the limits indicated by BS8006:2010 guidelines.

Considering all the technical, environmental and economic aspects, RSW has been selected for all the above-described projects in Cyprus. The selected RSW is the MacRes system, developed by Maccaferri, based on precast concrete panel facing elements connected to ParaWeb polymeric geostrips, consisting in discrete bundles of closely packed high strength polyester (PET) filaments, lying parallel to each other, and encased in a tough and durable polyethylene (LLDPE) coating. The geostrips are available in a wide range of tensile strength and width to meet the project design requirements. Geostrips are less demanding than steel reinforcements when dealing with resistivity, water, moisture, chloride ion concentration, temperature, corrosion due to exposure to environment and chemical agents (de-icing salts, etc.).

3 DESIGN OF REINFORCED SOIL STRUCTURES

3.1 *Design approach*

The design process used for designing the reinforced soil structures has been the following:

- Internal stability is first addressed to determine geostrips spacing, length, and tensile strength, and for checking connections to the facing panels, both in static and seismic conditions. This establishes the integrity of the wall.
- External stability against overturning, sliding, and foundation failure is analysed, both in static and seismic conditions, and the internal design is verified or modified accordingly. This establishes that the wall mass will remain stationary.
- Global stability analyses, to ensure that there are no failure mechanisms involving the reinforced soil mass, the soil behind the reinforced fill, and the foundation soil, both in static and seismic conditions.

Eurocode 7 (EN 1997) requires a Limit Equilibrium design approach. A National Annex exists for each Eurocode Part, providing Nationally Determined Parameters. The Cyprus National Annex was integrated with the Italian Norm NTC 2018, since Italian geological, geotechnical, topographical, seismic characteristics are very similar to those in Cyprus.

3.2 *Internal and external stability*

Internal stability analysis addresses the following failure mechanisms: pullout of geostrips; direct sliding along geostrips; geostrips tensile failure; failure of connections between geostrips and concrete facing panels. For internal stability, geostrip are considered as an extensible reinforcement, hence the tie-back model is assumed, where the failure surface is a straight line starting from the toe and inclined at $(45° + \varphi/2)$, where φ is the friction angle of reinforced fill. To determine the geostrips vertical spacing and which grade to use at each level, earth pressures are assumed to be linearly distributed using Rankine active earth pressure conditions for the soil backfill and for the surcharge. The tie-back model is used also for obtaining the length of embedment of the geostrips in the anchorage zone, L_E, from the pull-out analysis, which is added to the length of geostrips within the active zone, L_N, for getting the total geostrip length L. The horizontal spacing of geostrips is varied by increasing or decreasing the number of connections to concrete panel units, ranging from 4 to 6 connections every two panels, that is every 3 m width. Since each geostrip enters and exits the connections at narrow angles, the coverage ratio is calculated considering two geostrips widths for each connection.

Next, the external stability of the wall mass is considered, which includes overturning, sliding, and bearing capacity analyses. The ultimate bearing capacity has been calculated for each wall section, using the Meyerhoff distribution of vertical stresses on the foundation (whose width is equal to the geostrips length at base), using the design geotechnical properties of soils and the design surcharge loads.

3.3 *Global stability*

Global stability analyses have been performed as follows:

– Sliding along circular surfaces (rotational stability): for the rotational stability analysis the modified Bishop method (Leshchinsky & Han 2004) has been used, since this method affords to consider all contribution of forces acting on the slides.
– Horizontal sliding (translational stability): the mass of reinforced soil, and possibly a portion of the soil at its back, can slide as a rigid block along the base or along one of the geostrip layers; hence numerous bilinear surfaces, with a horizontal segment corresponding to increasing portions of each of the geostrip layers and an inclined segment with different angles for each horizontal segment, are therefore investigated; for each bilinear surface the resisting forces and the active forces are calculated, whose ratio provides the Factor of Safety (Leshchinsky & Han 2004).

3.4 Seismic analyses

The motion generated by an earthquake at a site depends on the particular local conditions, that is, from the topographic characteristics and stratigraphic deposits of soil and rock masses, and the physical and mechanical properties of the materials. The seismic motion at the surface of a site, associated with each category of the subsoil, is defined by the maximum acceleration (a_{max}) at the surface. Once the maximum acceleration expected at the bedrock a_g has been defined, it is possible to calculate the seismic coefficients by the following formula:

$$a_{max} = S \cdot a_g = S_S \cdot S_T \cdot a_g \qquad (1)$$

where S_S, S_T are the stratigraphic and topographic amplification coefficients, which were set for each wall according to Italian Norm NTC 2018.

The horizontal and vertical seismic coefficients for pseudo-static analyses, K_h and K_v, are:

$$K_h = \beta_m \cdot (a_g/g); K_v = \pm\, 0.5 \cdot K_h \qquad (2)$$

where β_m is the dumping coefficient for reduction of the maximum acceleration at the site, which was set equal to 0.38 according to Italian Norm NTC 2018.

In the present project the bedrock acceleration a_g varies from site to site, hence from wall to wall, in the range $0.15 \div 0.25$ g.

4 RSW CONSTRUCTION

4.1 Overview

The Cyprus project, with a total of 23,471 m^2 of wall facing, and considering all the 22 RSW that have been built, is considered the largest reinforced soil walls application in the country. This major project has been characterized by the large array of challenges that designers and contractors have tackled for each structure. Different types of RSW were specifically designed to fulfil all the requirements of the sites, space constraints in urban areas, interferences with other infrastructures, and the need of quick and reliable solutions for the many critical geometrical situations; the main types and forms of RSW walls can be classified in 5 categories: simple walls with horizontal or sloping top, trapezoidal walls, back to back walls, true bridge abutments, and overpass and underpass structures. Table 1 presents the inventory for each type of RSW. For this project, the total quantity of geostrips was 778,440 m and the geostrips ultimate tensile strengths were 27 kN; 30 kN; 36 kN; 45 kN; 40 kN; 54 kN; 63 kN; 70 kN. The nominal width of the geostrips vary from 46 to 90 mm and the thickness vary from 1.8 to 2.8 mm.

Table 1. Cyprus project RSW structure inventory.

Wall types	Total facing		Maximum wall height	Geostrip quantity
	m^2	%	m	m
Simple walls [a]	7,007	30%	10.24	227,950
Trapezoidal cross section walls	1,231	5%	7.70	34,460
True abutments [b]	8,220	35%	12.00	306,350
Back-to-back walls	3,711	16%	14.41	92,300
Overpass/Underpass walls	3,302	14%	13.50	117,380

[a]including both horizontal and backslope on top; [b]including the lateral wing wall.

4.2 Simple walls

Simple walls were generally used for the design of highway ramps and retaining walls in Nicosia Orbital Road. The tallest section (H = 9.46 m) with horizontal top was designed for the T6-T7 highway ramp, while the tallest section with sloping top ($H_{backslope}$ = 6.70 m; inclination α = 30°) was reached for the design of the EAC wall (Figure 1). The backslope affected the design, in facts long and closely spaced geostrips with high ultimate tensile strength (UTS) per unit width were required ($L_{geostrip}$ = 13 m; Coverage ratio C = 0.19; UTS = 942 kN/m), according to eccentricity and rotational stability analyses. In addition, a drain channel was provided at the top of the facing behind the top panels, in order to remove water running off the slope and to discharge it at the end of the wall.

Figure 1.   Simple walls: (a) T6-T7 ramp with horizontal top; (b) EAC wall with sloping top.

4.3 Trapezoidal cross section walls

RSW with uneven reinforcement lengths increasing from base to top (known as trapezoidal walls) were adopted for the reconstruction of roadway in Germasogeia – Arakapas area (Figure 2a). This type of reinforcement geometry was the most suitable solution to reduce the amount of excavation works due to the presence of firm ophiolite and dunite rocks (N_{SPT} > 60) encountered after few meters of excavation of the in situ soil. The presence of rock at the back reduces the lateral earth pressure, allowing to shorten the length of the geostrips up to a maximum of L = 0.40 H, where H is the wall height . The flexibility of the polymeric geostrips allowed also to solve some criticalities concerning the presence of large storm drain pipes crossing the wall. Customized panels were designed to fit around the pipe and avoid the washout of the fill through the wall facing. The detail of the drain pipe interference is shown in Figure 2b: a 50 mm thick polystyrene foam was laid around the pipe and the remaining gap between the customized panels and the pipe was filled with concrete or grout.
Figure 2.   Trapezoidal wall in mountain area: (a) strips installation; (b) storm pipe interference detail.

4.4 *True bridge abutments*

True bridge abutments are RSW where the concrete bridge seat is placed directly on the reinforced soil block. The structure is therefore directly bearing the loads from the bridge deck (Figure 3a).

Figure 3.   True bridge abutments in Nicosia orbital road: (a) elevation view; (b) cross section.

True abutments were chosen for the construction of the T4, T10 and T17 structures of Nicosia Orbital road for their strategic importance on the viability, where the needs to have a cost effective solution meet also the requirement to keep a tight construction schedule.

It has to be noted that the bridge imposes an extremely high load on the true abutment: as example, for abutment T17 the vertical component of the load on the bridge seat is equal to 13,800 kN, which produces a linear vertical load of 970 kN/m on the abutment and of 5,050 kN/m on the wing wall; moreover, the horizontal component of the load on the bridge seat, perpendicular to the abutment face, is equal to 850 kN.

Considering also that, due to space constraints, the bridge deck was installed very close to the abutment face, a higher density and higher grade of reinforcement (UTS = 801 kN/m, Coverage Ratio C = 0.30) were designed at the top of the structure, while decreasing with depth as the bearing stresses dissipate (Figure 3b). Also the vertical spacing of the geostrips was reduced to S_v = 0.37 m at the top of the abutment, and then increased to S_v = 0.75 m for the bottom layers.

4.5 *Back-to-back walls*

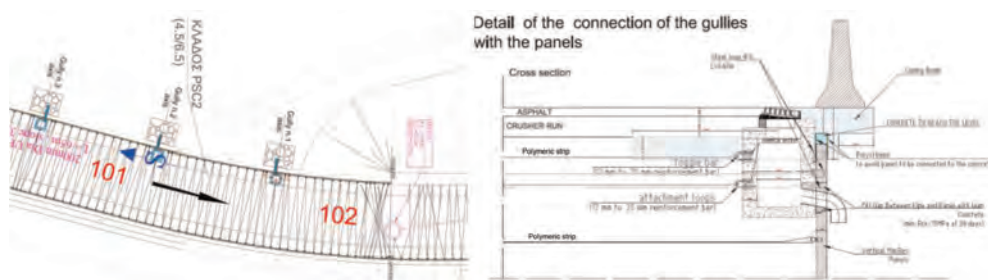
Back to back walls have been mainly used for the design of the long T6A-T6M highway ramp of Limassol – Saittas Motorway. The peculiarity of this application resides in the complexity of the design of a tall and narrow ramp (H_{max} = 14.41 m, width of the ramp = 6.5 m), combined with the presence of horizontal and vertical obstructions, such as manholes, gullies and longitudinal pipes for services. The feasibility of the structure have been made possible thanks to the flexibility of the system and the possibility to lay the geostrips all around the obstruction (Figure 4).


Figure 4.   T6A-T6M ramp: (a) Plan view of geostrips layout; (b) detail of connection of gully with panels.

4.6 Overpass/underpass walls

Overpass and Underpass walls have been mainly designed to allow culverts for pedestrians, cars or water to pass through the structure. The design of these walls was complex because of the height (H_{max} = 13.50 m), high loads and complex geometry of the required panel facing. The Geroskipou Industrial Area bypass is a representative example of such complex geometry: the panels geometry have been designed ad hoc to fit the articulated shape of the culvert while keeping aligned to the curved road alignment (Figure 5).

Figure 5.   Geroskipou bypass road.

5   CONCLUSIONS

The design and construction of the largest reinforced soil walls project in Cyprus has been described, including several types of wall configurations and true bridge abutments in high seismic areas. The RSW were designed and built using a system consisting with precast concrete panel facing elements and polymeric geostrip reinforcements. Construction details have been illustrated by photos and sketches. The construction of the walls has been relatively fast and easy, thanks to the modularity and flexibility of the wall system. All RSW built so far perform very well, therefore this challenging reinforced soil walls project can be considered as completely successful.

ABSTRACT: Mechanically stability earth (MSE) walls have been widely used as bridge abutments due to the advantages of reducing both the construction space saving and the bridge span. This paper presents a case study of an MSE wall with embedded bridge-supporting piles in Anhui, China. Instead of using traditional isolation casing, innovative geogrid treatments were taken to bypass the piles embedded in the MSE wall. The facing deformations, including both lateral displacements and settlement, were monitored for eight months after the completion of construction using a machine vision monitoring system. Monitoring data indicated that both the lateral displacements and settlements of the wall facing increased with time until six months after construction. The rainfall resulted in a small increase of the lateral deformations. In the horizontal direction of facing, both the lateral displacements and settlements at different elevations had an obvious increase from the wing wall to the road centerline. Overall, the deformation of the wall facing was stable and far less than the design limit value, indicating that the MSE wall with embedded bridge-supporting piles showed good service performances after construction.

Keywords: Geosynthetics, Bridge abutment, MSE wall, Pile, Facing deformation

1 INTRODUCTION

Geosynthetic reinforcement has shown great economic benefits in highway, railway and hydraulic engineering applications since its appearance. For the last few decades, due to space constrain t, mechanically stabilized earth (MSE) walls with embedded bridge-supporting piles have been widely used as the transition sections between bridge slabs and approaching embankments. Different from the traditional MSE wall technology, piles are constructed inside the MSE wall to carry the bridge load in this technology. Recent studies show that the use of MSE walls with embedded bridge-supporting piles for highway applications can bring significant savings for the reduction of both bridge span and construction space. (Han *et al.* 2018; Tatsuoka *et al.* 2016). In this technology, the piles are inevitably laterally loaded due to either the thermal expansion of the bridge girders or the active earth

---

pressures of the retained soil behind the piles. As a retaining structure, the MSE wall itself could limit the lateral deformation of the embedded piles. The interaction mechanism between piles and reinforced soil is still unclear, resulting in a conservative design of the pile diameter. Therefore, researchers have conducted full-scale tests (Pierson *et al.* 2009, 2011; Rollins *et al.* 2022), model tests (Jawad *et al.* 2020, 2021) and numerical analyses (Huang *et al.* 2013, 2014) to investigate the effects of different influencing factors on the responses of MSE walls with embedded piles subjected to lateral loads. However, few cases existed in literature regarding filed monitoring data of MSE walls with embedded piles under service load conditions. As a result, further studies were necessary to have a comprehensive understanding of this special type MSE for further applications.

In this study, a MSE wall with embedded bridge-supporting piles was constructed and monitored in the field. This MSE wall with embedded piles served as a bridge abutment for the Mingguang to Chaohu Highway located in Anhui province in China. This study investigated the facing deformation characteristics of the MSE wall with embedded piles under service loads. This study analyzed the monitored facing deformation of the MSE wall within eight months after construction. Conclusions from these monitoring data could provide references for the design and construction of similar projects in the future.

2 PROJECT DESCRIPTION

2.1 *Site conditions and geometry*

The Mingguang to Chaohu (Ming-Chao) Highway runs through the middle east of Anhui Province in China with a total length of 131 km. The highway has four traffic lanes (two lanes per traffic direction). The mainly geomorphic units crossed by the highway are valley plains and hills. The instrumented MSE wall in this study is located in the section K120 + 173 of the Ming-Chao Highway in Suwan Town in City Hefei. According to the geological survey, the foundation soil mainly consists of three soil stratums. The top layer is Quaternary Holocene silty clay with a bearing capacity of 160 kPa, which is less than the required bearing capacity of the foundation soil (i.e., 200 kPa). The middle layer is Quaternary Upper Pleistocene silty clay with a bearing capacity of 220 kPa. The bottom layer is gravelly argillaceous sandstone with different degrees of weathering. Therefore, the top layer soil was excavated and replaced with 7% lime soil and geogrid reinforced soil cushion. The thickness of the reinforced cushion was 0.6 m with the reinforcement spacing of 0.3 m. The bearing capacity of the treated soil foundation satisfied the design requirement.

The MSE wall had a width of 27 m and a height of H = 5.3 m. The wall facing was composed of modular blocks with dimensions of 0.4 m long × 0.2 m wide × 0.19 m thick. The batter of the wall facing was 2.86° (i.e., the slope ratio of the wall facing was 1:0.05 (vertical: horizontal)). Four steel reinforced concrete piles construed using C35 concrete were embedded inside the MSE wall. Each pile had a diameter of 1.5 m (D = 1.5 m). The distance from the back of the facing top to the center of the pile was 4.05 m. The reinforcement layers used in this project were 9 m long and 1.3 m wide. The vertical spacing of the reinforcement layers was 0.38 m.

2.2 *Materials*

A uniaxial high-density polyethylene (HDPE) geogrid was used as the reinforcement material in the MSE wall and the mechanical properties of the geogrid are listed in Table 1. Graded crushed stones were selected as the backfill material. The maximum particle size of the crush stones was 0.1 m and the friction angle was no less than 35°. Concrete modular blocks with a compressive strength of 107 MPa were used as the facing material of the MSE wall.

Table 1. Mechanical properties of the uniaxial HDPE geogrid.

Item	Value
Ultimate tensile strength (kN/m)	81
Tensile strength at 2% strain (kN/m)	23.2
Tensile strength at 5% strain (kN/m)	41
Ultimate tensile strain (%)	10.5

2.3 Construction

Construction of the MSE wall started on September 12, 2021 and ended with the placement of the bridge girders on late December of 2021. The construction process mainly consisted of ground improvement, the construction of the strip footing, MSE wall, cap beam, and approach roadway, and the placement of the bridge girder. The concrete piles were cast in-place and cured to reach the design strength before the ground improvement. The foundation soil was then excavated and replaced with 7% lime soil and geogrid reinforced soil cushion to improve the bearing capacity. A strip footing using C30 concrete, as shown in Figure 1(a), was cast on top of the reinforced soil cushion before placing modular facing blocks to provide horizontal alignment and to support the modular facing blocks. The strip footing had a thickness of 0.3 m and a width of 0.9 m. The MSE wall was then constructed layer by layer. The bottom layer of the modular blocks was placed on top of the strip footing and levelled with cement mortar. For each layer, the modular facing blocks were placed first, followed by the placement of the backfill soil behind the modular blocks. Before placing the geogrid in each layer, the backfill soil was compacted to a minimum relative compaction of 96% using a large-sized roller compactor and a plate compactor for zones behind the pile shown in Figure 1(b) and near the modular facing blocks respectively.

When placing the geogrid layers into the backfill soil, instead of using traditional isolation casing, innovative geogrid treatments were taken to bypass the piles embedded in the MSE wall as shown in Figure 1(c). Two pieces of geogrid layers were cut into a semi-circle shape to embrace the pile and then connected together using zip-ties. U-nails were used to anchor the geogrid layers with the backfill soil for the purpose of better pre-tensioning. By using plastic connectors to fix the geogrid layers with the sub grooves of the modular facing blocks, all the geogrid layers were mechanically connected with the wall facing as shown in Figure 1(d). At the MSE wall corner where two wall facing intercepted, staggered placing was used to avoid
Figure 1. Construction of the MSE wall: (a) Strip footing; (b) Large-sized roller compactor; (c) Geogrid bypass the pile; (d) Connection between geogrid and blocks; (e) Filtration drainage layer; (f) Photo of the bridge supported by the MSE wall with embedded piles after the completion of the construction.

overlapping of geogrid in the same layer. A 0.5 m thick layer composed of geotextile wrapped gravel was set behind the facing as shown in Figure 1(e) to serve as a drainage layer.

After construction of the MSE wall, the cap beam with steel reinforced concrete was cast in-place. The bridge beam and the approach roadway were constructed after the strength of the cap beam concrete reached the design requirements. Figure 1(f) shows a photo of the completed bridge supported by the MSE wall with embedded piles.

2.4 *Instrumentation layout*

In this study, the wall facing deformation was monitored using a machine vision monitoring system, which could achieve a high-precision automatic measurement of the facing deformation. This system mainly composed of a machine vision measurement instrument installed at a stable foundation, a number of targets installed at the surface of the wall facing, a solar power supply system, and a software for data collecting and processing. When the targets changed their coordinates along with the deformed wall facing, the machine vision measurement instrument could process the target image automatically and both the horizontal displacements and the settlements of the facing were measured simultaneously.

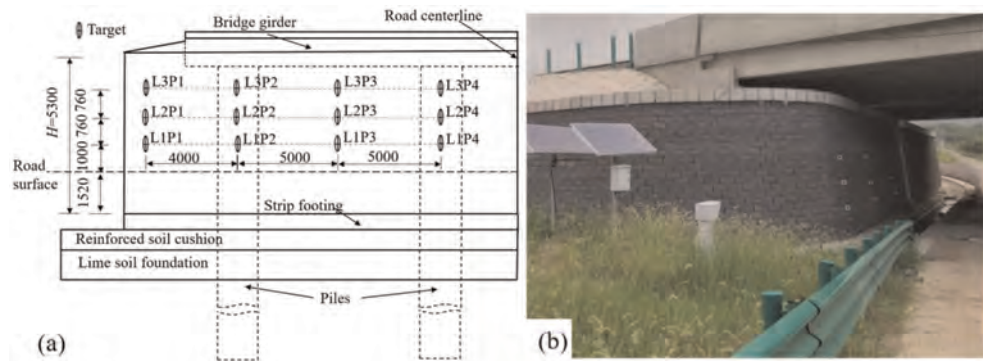
Considering the site condition as well as the symmetry of the two walls at different ends of the bridge slabs, the MSE wall located at East was chosen as the monitoring section and targets were installed at this MSE wall. A total of 12 targets (3 rows and 4 columns) were installed on the facing by using expansion screws. Figure 2(a) shows the location of each target. In Figure 2(a), the letters "L" and "P" represent the monitored layer and the position respectively. L1 is located at the bottom of the MSE wall while L3 is located at the top. P1 is located at the position close to the corner of the MSE wall while P4 is located at the road centerline. After the debugging of the monitoring system, the field monitoring of this project started from January 7, 2022. Figure 2 shows the instrument layout and filed installation.


Figure 2. Instrumentation layout: (a) Schematic of the instrument layout (Unit: mm); (b) Filed installation.

3 PRELIMINARY RESULTS

3.1 *Lateral facing displacement*

Figure 3 presents the distributions of lateral facing displacements within eight months after construction. As shown in Figure 3, the lateral facing displacement had an obvious increase within three months after the completion of the construction and then tended to become stable. However, the measured values of the lateral displacements increased again at five

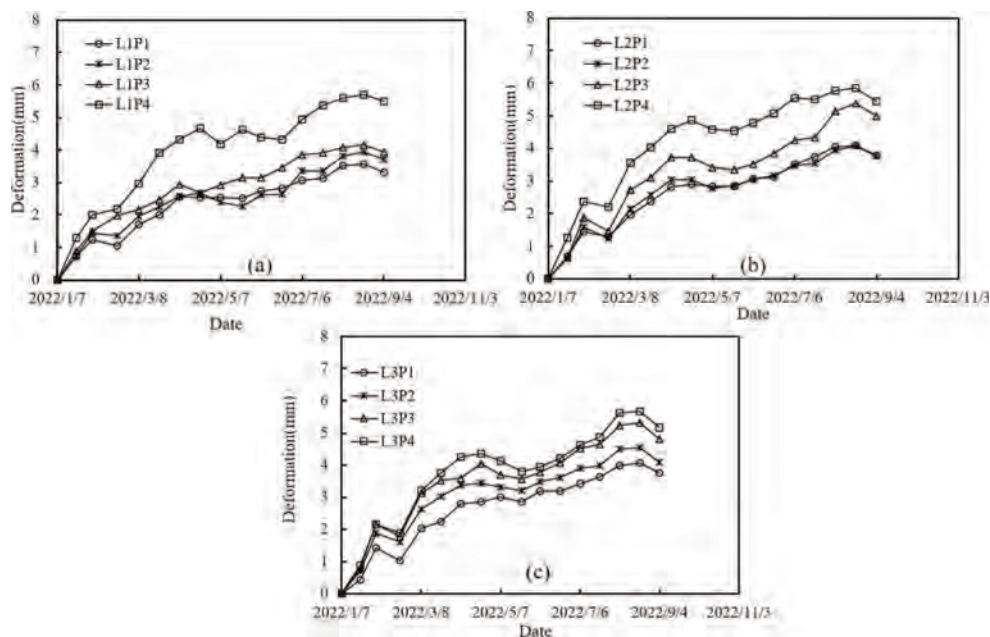
months after construction due to the coming of the rainy season and the rising of air temperature. After the rainy season, the maximum lateral displacement increased approximately 1 mm. Meanwhile, Figure 3 also indicates that the lateral facing displacements increased significantly from the wing wall (i.e., P1) to the road centerline (i.e., P4) in the horizontal direction. The maximum lateral displacements were 5.69mm, 5.84mm, and 5.67mm from the bottom to the top layer respectively, which were less than 0.12% of the wall height and were far below the design limit value. These small lateral displacements indicated that the MSE wall was stable and the use of the geogrid could effectively limit the lateral facing deformation.


Figure 3.   Distributions of the lateral facing displacements along elevation with time: (a) $z/H = 0.47$; (b) $z/H = 0.62$; (c) $z/H = 0.76$.

3.2   Settlement of the facing

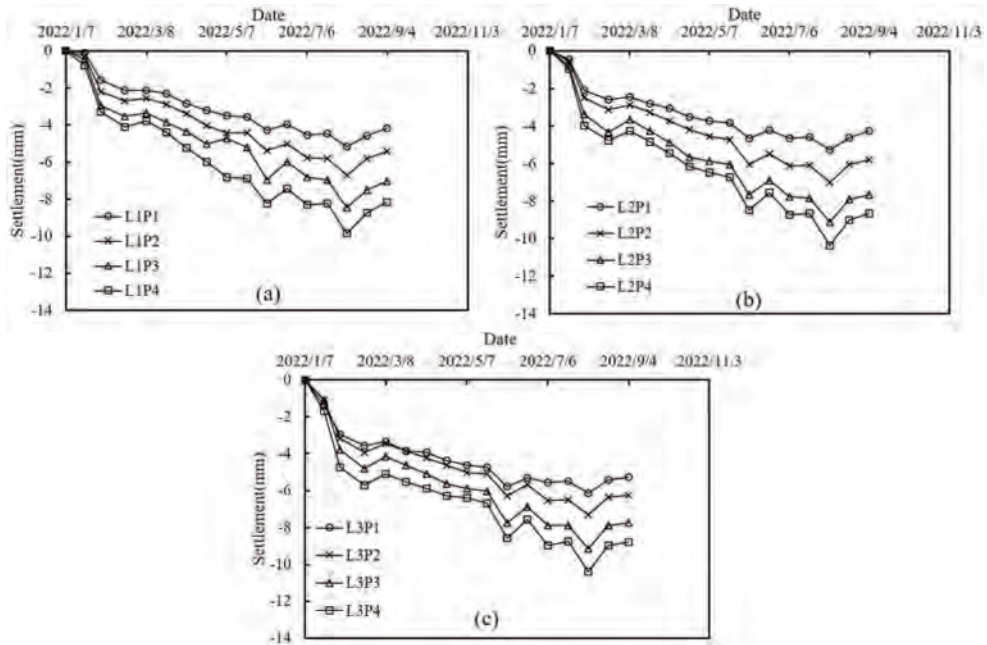
Figure 4 presents the measured facing settlements at different elevations with time. As shown in Figure 4, within the first month after the completion of construction, the facing settlements increased significantly at all measurement points, and then the increments gradually decreased during the following five months. The settlements trended to become stable six months after construction. The maximum settlement at different elevations were approximately the same, which indicated the compression of modular blocks could be ignored and the adjacent block layers were in close contact without large gaps. The measured facing settlements increased significantly from the wing wall to the road centerline in the horizontal direction, which was the same as the distributions of the lateral facing displacements. The maximum facing settlements were 9.8mm, 10.3mm, and 10.4 mm from the bottom to the top layer respectively, which were 0.18%, 0.19%, and 0.19% of the wall height, indicating the bearing capacity of the treated foundation was enough and the strip footing as a supporting structure performed well.


Figure 4. Distributions of facing settlements along elevation with time: (a) $z/H = 0.47$; (b) $z/H = 0.62$; (c) $z/H = 0.76$.

4 CONCLUSION

This study presented field instrumentation and preliminary evaluation of a mechanically-stabilized earth (MSE) wall with embedded bridge-supporting piles serving as a bridge abutment. Instead of using traditional isolation casing, innovative geogrid treatments were taken to bypass the piles embedded in the MSE wall. The wall facing deformations, including both lateral displacements and settlements, were analyzed within eight months after the completion of construction. The following conclusions could be drawn based on the monitoring data:

(1) Overall, the MSE wall with embedded bridge-supporting piles showed good service performance after eight months of the completion of construction. No obvious deformations of the facing were observed, which indicated that the innovative geogrid treatments did not produce an obvious effect on the facing deformation.
(2) The lateral displacements and settlements of the wall facing gradually increased within six months after construction of the MSE wall. In the horizontal direction, both the lateral displacements and settlements of the wall facing increased from the wing wall to the road centerline. Approximately eight months after construction, the maximum lateral displacement of the wall facing was 5.84 mm, which was 0.11% of the wall height. After a rainy season, the lateral displacements had an increment of 1 mm. The maximum settlement of the wall facing was 10.4 mm. The facing settlements at different elevations did not show significant differences.

ABSTRACT: To investigate the geogrid reinforcement mechanisms in the reinforced soil retaining walls, discrete element modeling has been carried out based on the model tests under strip footing loads. The mechanical and deformation behavior of the reinforced soil retaining wall was analyzed at a mesoscopic scale during construction and under strip footing loads. With increasing heights of the retaining wall during the construction period, the strains of geogrids increased. Before applying the footing loads, the contact forces in the retaining wall showed a realistic distribution under gravity and the geogrid strains of lower layers were slightly larger than those of the upper layers. With increasing loads of the strip footing, the vertical settlement of the footing increased gradually. The horizontal deformation of the upper part of the wall facing was larger than the lower part. With increasing footing loads, the strains of geogrids increased, but the increment of geogrid strains was relatively small under the loading conditions in this study. The discrete element modeling results in this study visualize the load transfer between geogrid and soil and quantify the deformation behavior of geogrids in the reinforced soil retaining wall during construction and under strip footing loads.

1 INTRODUCTION

As a kind of flexible retaining structure, the geogrid reinforced soil retaining wall, which has the advantages of saving land, being friendly to the environment, and being low cost, has been widely used in practice (Yang *et al*. 2014). To illustrate the geogrid reinforced mechanisms in reinforced soil retaining walls, many researchers have conducted a series of model tests and field tests (Jia *et al*. 2021; Jiang *et al*. 2016; Sun *et al*. 2019; Santos *et al*. 2014; Viswanadham *et al*. 2017; Yazdandoust & Taimouri 2022).

Numerical simulation is an important supplement to experimental studies. Many researchers also carried out lots of numerical simulations to describe the working mechanisms of reinforced soil retaining walls (Lees & Dobie 2021; Ma *et al*. 2020). Compared to the finite element method (FEM), the discrete element method (DEM) has particular

advantages of capturing detailed insights into the interlocking and interaction between soil and geogrid (Wang *et al.* 2020).

Therefore, this study established a DEM model of a geogrid reinforced soil retaining wall based on laboratory model tests. The horizontal deformation and vertical settlement of the retaining wall were analyzed quantitatively as well as the development of geogrid strains during the construction period and the loading process. The contact force and tensile force chains inside the retaining wall were visualized from a mesoscale level. This study is expected to improve the understanding of the mechanical and deformation behavior of geogrid reinforced soil retaining walls, which provides some theoretical support for the design optimization of reinforced soil retaining walls.

2 EXPERIMENTAL BACKGROUND AND DISCRETE ELEMENT MODELING

The schematic diagram of the reinforced soil retaining wall model in the laboratory tests is shown in Figure 1. The dimensions of the model were 3 m × 1 m × 1.8m (L × W × H) with a slope ratio of 1: 0.05. The vertical spacing of the geogrids was 0.3 m and the length of the geogrid was 2 m. A rigid plate with a width of 0.505 m was placed on top of the reinforced retaining wall. The vertical strip footing loads were applied from 10 kPa to 60 kPa with an increment of 10 kPa. The experimental data such as the horizontal deformation of the wall facing, the vertical settlement of the rigid plate, and the geogrid strains were recorded automatically.
Figure 1. Sketch of reinforced soil retaining wall model test (unit: mm) (after Wang *et al.* 2016).

In the DEM investigations of reinforced soil retaining walls, it is necessary to first determine the mesoscale parameters of geogrid and soil. Based on the experimental data, the mesoscale parameters for geogrids and soils were calibrated by the DEM modeling of geogrid tensile tests and soil direct shear tests, respectively. The corresponding mesoscale parameters were used to establish the DEM model of the reinforced soil retaining wall. A multi-layer compaction method was used in the DEM investigations to build the reinforced soil retaining wall. The 1st layer of soil particles was generated at the bottom of the retaining wall and then the 1st layer of geogrid until the 6th layer of geogrid and the 7th layer of filling soil. In each generation process, the unbalance forces were eliminated after several cycles. A string of vertical bonded particles was used to simulate the facing of the retaining wall and a

rigid wall with a width of 0.505 m was generated on top of the retaining wall as the loading plate. The modeling process was consistent with the construction process of the reinforced soil retaining wall in the model tests. The DEM model of the reinforced soil retaining wall before applying the vertical loads is shown in Figure 2.
Figure 2.   DEM model of reinforced soil retaining wall before applying the vertical loads.

3   RESULTS AND ANALYSES

3.1   *Accumulated horizontal displacement of wall facing*

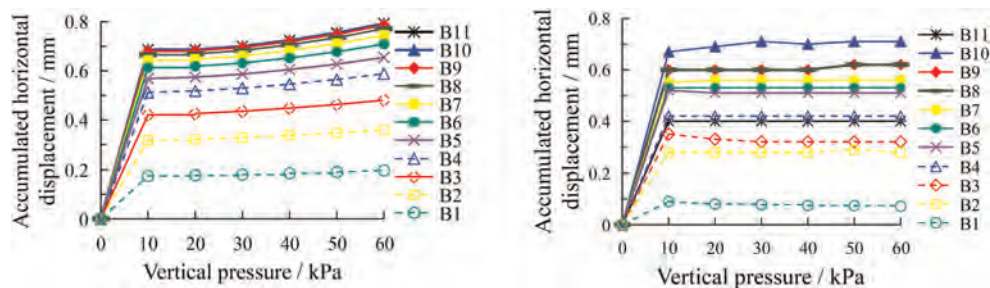
The horizontal displacement of facing particles along the vertical height of the retaining wall was recorded and the accumulated horizontal displacement of the wall facing in the DEM simulation is shown in Figure 3a. The corresponding model test results are shown in Figure 3b for comparison. It can be seen from the figure that the horizontal displacements obtained from the DEM simulations were quite similar to those obtained from the laboratory model tests. The horizontal deformation at the upper part of the wall facing was larger than that at the lower part. The accumulated horizontal displacement changed greatly during the initial loading process, while the overall increase amplitude was small in the subsequent loading process. This was mainly due to the sudden vertical pressure on top of the retaining wall, which destroyed the original stability of the structure. Hence, the deformation of the retaining wall was large. With increasing vertical pressure, the reinforcing effects of geogrids were mobilized and the lateral movement of soil particles was restrained by the geogrids, which caused the increase of the accumulated horizontal displacement to be relatively small.


Figure 3.   Accumulated horizontal displacement of wall facing. (a) DEM simulation results (b) Model test results (after Wang *et al.* 2016).
Figure 4.   Comparison of vertical pressure and settlement relations.

3.2   *Vertical settlement of strip footing*

Figure 4 compares the vertical pressure and settlement relations obtained from experimental and DEM investigations. The DEM simulation results showed a linear relationship between the vertical pressure and the settlement, which was different from that obtained from the model tests. Such observation can be explained by the liner model used for soil particles in this study. Nevertheless, the trend of the DEM investigation was the same as that of the model test, i.e. the accumulated vertical settlement increased with increasing vertical pressure and the accumulated vertical settlements at the ultimate pressure of 60 kPa in both experimental and DEM investigations were quite similar. Therefore, it is believed that the DEM models and the mesoscale parameters were rational and further DEM analyses were carried out to investigate the mechanical and deformation behavior of the geogrid reinforced soil retaining wall under strip footing loads.

3.3   *Development of geogrid strain*

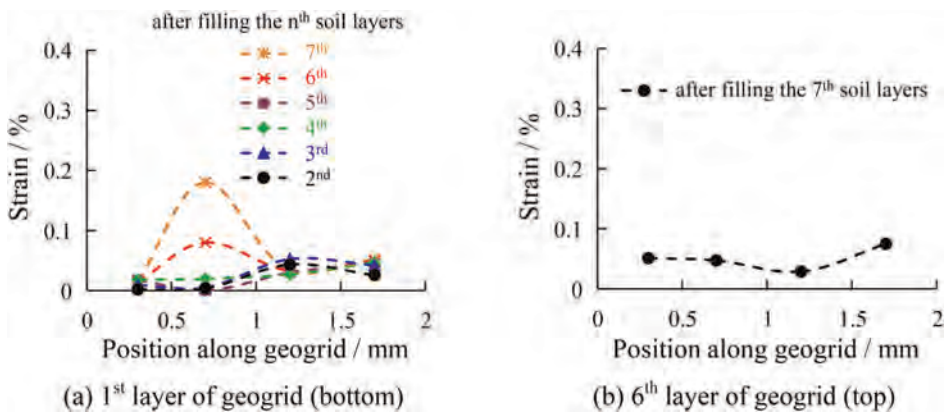
3.3.1   *Geogrid strain during the construction period*
The strains of each geogrid layer can be recorded in the DEM investigations during the construction period and the loading process, respectively. Figure 5 shows the strain distribution of the 1st and 6th layers of geogrids during the construction period. The 1st layer of geogrid (bottom) was placed at the lower part of the retaining wall and it experienced 6-times


Figure 5.   Distribution of geogrid strain during the construction period. (a) 1st layer of geogrid (bottom) (b) 6th layer of geogrid (top).

892

compaction of the upper soil layers, while the 6th layer of geogrid (top) was placed at the upper part of the retaining wall and it experienced only one-time compaction of the 7th soil layer. It can be seen from the figure that the strain distributions of the 1st layer of geogrid were almost the same under different compaction times of the above soil layers. With increasing compaction times, the geogrid stains increased, as shown in Figure 5a. The geogrid strains in the lower part of the retaining wall (Figure 5a) were larger than those in the upper part (Figure 5b). Such phenomena can be explained by the action of gravity and compaction.

3.3.2 *Geogrid strain during the loading process*

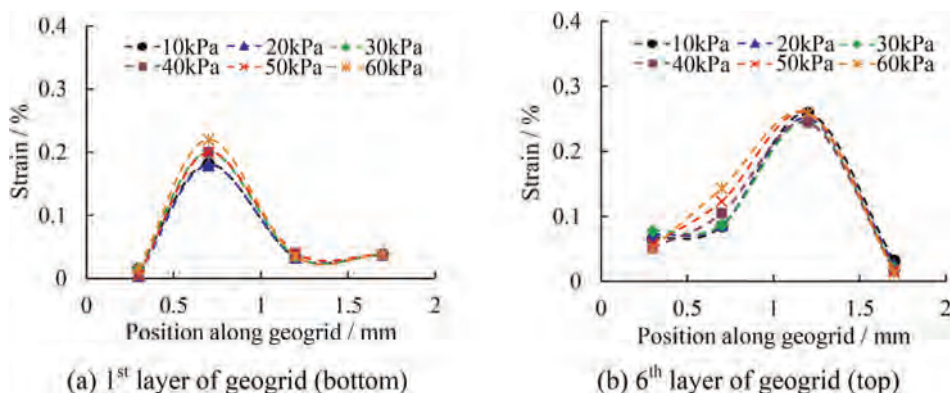
Similarly, the strain distributions of the 1st and 6th layers of geogrids during the loading process were obtained in the DEM investigations, as shown in Figure 6. It can be seen from the figure that the geogrid strains increased with increasing footing pressure. However, the overall increment of the geogrid strain was relatively small, which was less than 0.1 % under the action of each load increase. The vertical loads selected in this study have little influence on the geogrid strains. Since the 6th layer of geogrid (top) was close to the loading plate, the strain increment of the 6th layer of geogrid (top) was greater than that of the 1st layer of geogrid (bottom) during each loading process, especially after the first footing load of 10 kPa by comparing the curves in Figures 5b and 6b. Compared with Figures 5a and 6a, the strains of geogrids in the lower part of the retaining wall mainly occurred during the wall construction period.


Figure 6. Distribution of geogrid strain under vertical loading. (a) 1st layer of geogrid (bottom) (b) 6th layer of geogrid (top).

3.4 *Development of contact force and tensile force*

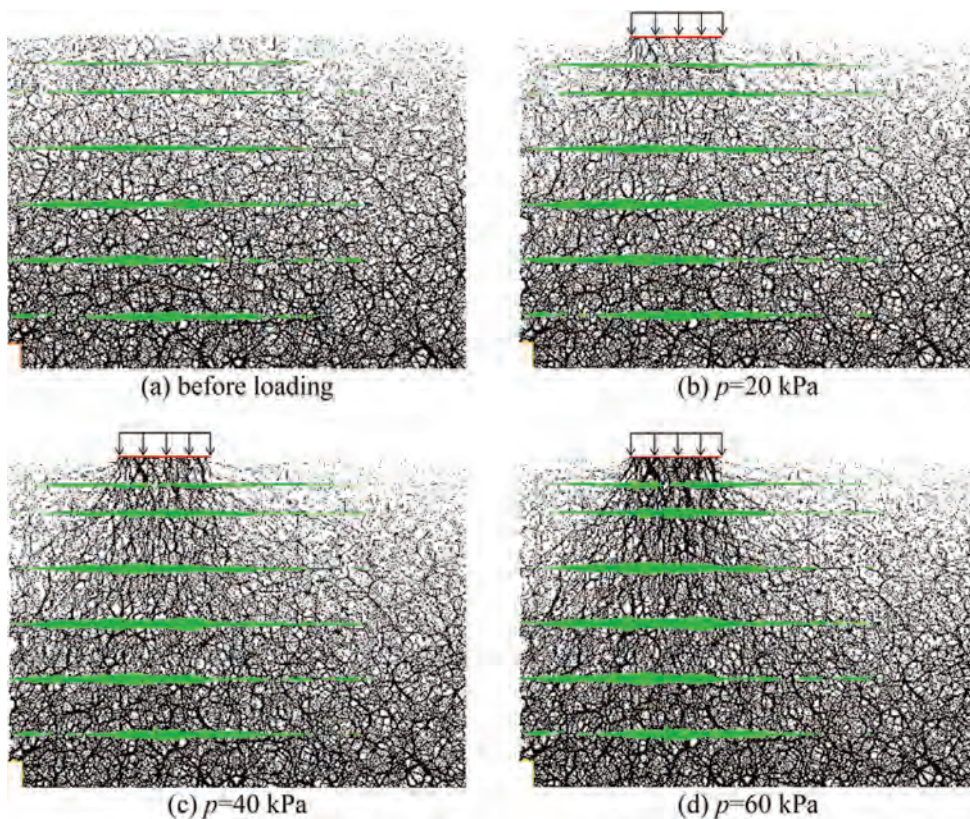
Figure 7 shows the development of contact forces among the soil particles and the development of tensile forces along the geogrids in the reinforced soil retaining wall under different vertical loads. The black lines represent the contact forces among the soil particles, while the green lines indicate the tensile forces along the geogrids. The thicknesses of the lines are proportional to the magnitudes. Before applying the vertical load, the distribution of contact forces among the soil particles was following the distribution along gravity, i.e. the contact forces in the lower parts were larger than those in the upper parts as well as the tensile force distributions along the geogrids (Figure 7a). With increasing vertical loads, the contact forces among the soil particles and the tensile forces along the geogrids in the retaining wall increased gradually, especially those below the loading plate. The


Figure 7. Contact force and tensile force distributions under different loading conditions. (a) before loading (b) p = 20 kPa (c) p = 40 kPa (d) p = 60 kPa.

development of contact forces among the soil particles and tensile forces along the geogrids in this study visualized the load transfer behavior in the geogrid reinforced soil retaining wall under strip footing loads.

4 CONCLUSION

Based on the model tests of geogrid reinforced soil retaining walls, a DEM model was set up and further DEM analyses were carried out to illustrate the mechanical and deformation behavior of the reinforced soil retaining wall under strip footing loads. The main conclusions are as follows:

(1) The horizontal displacements of the wall facing were obtained based on the DEM simulations as well as the vertical settlement of the loading plate on top of the retaining wall. The DEM investigation results showed good agreement with the experimental data, which validated that the DEM models and the corresponding mesoscale parameters were rational.
(2) In the DEM modeling, a multi-layer compaction method was used to build the geogrid reinforced soil retaining wall. With increasing numbers of filling soil layers, the geogrid strains increased. The strains of the geogrids in the lower parts of the retaining wall were mainly generated during the construction period.

(3) Before applying the vertical load, the distribution of contact forces in the retaining wall showed a realistic distribution under gravity. The strains in the lower part of the geogrids were larger than those in the upper parts. With increasing vertical loads, the contact forces below the loading plate increased as well as the tensile forces along geogrids. The vertical loads mainly affected the upper part of the retaining wall in this study.

Case study. The geotextile materials application for reinforcing the man-made coastal slopes in the Prymorske village area (Crimea)

O. Trofymchuk & I. Kaliukh
Institute of Telecommunications and Global Information Space, National Academy of Science of Ukraine, Kyiv, Ukraine

ABSTRACT: The boathouses construction in Prymorske village (Crimea, Ukraine) caused the need to undercut the existing Black Sea coastal slopes. It required some additional measures to stabilize the man-made slopes, which were formed as an undercutting result. There was not enough space to make the slopes not steep, so it was recommended to use geotextiles to reinforce them. The PLAXIS software package and the simplified LANDSLIP software with the Bishop and Spencer model were used. The PLAXIS package allowed to perform the direct dynamic calculations of the initial and undercut slopes. Calculated accelerograms of the 7 and 8 points earthquakes were used for calculations. The required breaking strength was provided by geotextile materials with the 130–170 g/m^3 density. The man-made slope reinforcement with synthetic materials should be carried out in layers in every 0.75 m using backfilling with cohesive soil from undercutting the slope with a specific gravity and without compression.

1 INTRODUCTION

The tasks of increasing the slopes stability become increasingly important in the world and in Ukraine (Lacasse 2015), (Jenner *et al.* 2015), (Robertson & Gilchrist 1987). The main reasons for this are the ever-expanding development of landslide territories for construction caused by a shortage of free land areas, as well as the existing landslides activation and the new man-made landslides emergence (Kaliukh *et al.* 2013), (Kaliukh *et al.* 2018), (Voloshkina E. *et al.* 2021)The slopes strengthening is intended to stabilize the soil erosion processes and prevent the soil collapse under its dead weight or sliding due to inertia forces under dynamic effects from industrial explosions during the minerals development, vehicles, seismic and other phenomena (Slyusarenko *et al.* 2009, 2010), (Trofymchuk *et al.* 2018, 2019), (DBN V.1.1-3-97. 1998). The slopes strengthening projects should be chosen taking into account such factors as the slope steepness, loads, the presence or absence of vibrations, as well as the composition of the physical and mechanical characteristics of the slope soil layers. A wide variety of methods have been used to solve the problem of strengthening the embankment slopes, roadbeds or slopes sides and the special synthetic materials (geosynthetics) have been developed for soils reinforcement. The first attempts to increase the soils strength by means of the reinforcement with the use of steel strips, geogrids and geomeshes were undertaken at the beginning of the 20th century, and in the 1960s, with the chemical industry progress, non-woven geotextiles began to be used, and late on the high strength geogrids and geotextiles appeared. In foreign construction practice, the term "geosynthetic materials" was put into practice in the 1990s as a notion that replaced the "geotextile" term (Oliver & Younger 1988). Geotextiles were the first technical textiles and fabrics used in the construction and geotechnics. Geogrids became the next representatives of technical materials. The research of the French scientist A. Vidal

resulted in the development of a new type of material for geotechnics - reinforced soil. Currently, the geosynthetic materials use in construction practice is rapidly increasing, because they have a number of advantages, such as water resistance, biostability, resistance to acid and alkaline environments, resistance to ultraviolet radiation, mechanical resistance, environmental friendliness (due to reducing the natural resources use). Besides, such a property of geosynthetic materials as durability is worth of a special mention.

2 PROBLEM FORMULATION

The execution of works on the boathouses construction in the area of the Vertolit Research Center in Prymorske village, Feodosia district, Autonomous Republic of Crimea, Ukraine, required the existing slopes undercutting. So, it was necessary to provide additional measures to stabilize man-made slopes formed as a result of existing slopes undercutting.

It is known that the slope stabilization works can be performed in various ways, and the expediency of each of them is determined based on the available spaces, reliability and economic feasibility. Making a slope gentle and stable after its undercutting can be recommended as the first and most economical measure. As the Contractor did not have the necessary space to make the slope gentle and stable after undercutting, the use of geosynthetic materials (the second method) was proposed for reinforcing the man-made slopes and ensuring their necessary stability.

The geosynthetic materials could significantly reduce the cost of the initial working project, which provided for the installation of a strengthened landslide protection retaining wall of reinforced concrete. It was assumed that the retaining wall would absorb the landslide pressure and ensure the necessary stability of the new man-made slope. The use of geosynthetic materials envisaged the landslide pressure transfer from the retaining wall to geosynthetic materials. In this way, the effect of "bags with soil placed on top of each other" could create a reinforced wall. This method has obtained a wide application in construction practice, for example, in Pakistan, where an embankment with a vertical slope up to 40 m high was built using geosynthetic materials without any additional reinforced concrete structures. In compliance with this plan, at the first stage the slope stability assessment was carried out in the form of a calculation of its reserve factor, and on that basis the necessary number of interlayers was selected.

3 APPROXIMATE CALCULATIONS

As the first stage, a slopes stability analysis at the boathouses construction site in the area of the Vertolit Research Center in the Prymorske village was performed. The input data for the LANDSLIP software (Trofymchuk *et al.* 2018) consisted of the geometric, physical and mechanical characteristics of the slopes at the construction site provided by the Contractor. Based on the preliminary analysis of the cross-sections of the slopes at the construction site, it was determined that the most serious problems due to the landslides hazard could arise during the existing slopes undercutting along the defined cross-sections. The cutting height just along these cross-sections would be the biggest and reach 6 - 7 m. With this in mind, the further calculations should be carried out for the worst cross-section with extrapolating the results to other cross-sections. Moreover, the recommendations based on the worst calculated cross-section should go into reserve for other cross-sections. First, the initial stability of the existing slope along the worst cross-section was analyzed using the LANDSLIP software. The slope geometry according to that cross-section is presented in Figure 1. As a result of the calculations, the coefficient of the initial slope stability for the cross-section was 3.67. Thus, before the undercutting start, the initial slope was completely stable, which was really observed. In Figure 2 the landslide pressure distribution along the calculated slope width is shown.

According to the geotechnical boring data provided by the Customer, in the cross-sections calculated for the slope soils there are 2 predominant types of the physical and mechanical characteristics of the soils to be cut:

1. Yellowish-brown, greenish, hard-plastic, lumpy clay, strongly swelling, with inclusions of pebbles (ancient landslide deposits) and with the soil density of 1.91 kN/m^3; specific adhesion of 3.24 kN/m^2; internal friction angle of 11°;
2. Yellowish-brown, semi-hard clay with gypsum pockets, strongly swelling with the soil density of 1.93 kN/m^3; specific adhesion of 5.6 kN/m^2; internal friction angle of 21°.

The further calculations are carried out for the case of the first type physical and mechanical characteristics (obtained with a probability of 95%, since they are worse than the indicators obtained with a probability of 85%). These results will be reserved for the case of the second type physical and mechanical characteristics.
Figure 1. The slope geometry in the boathouse construction area, Prymorske village.
Figure 2. The landslide pressure distribution along the calculated slope width.

That is, a deliberately worse option is assumed. Thus, the sliding slope consists of soil with the following physical and mechanical characteristics: the soil density of 1.91 kN/m^3; specific adhesion of 3.24 kN/m^2; internal friction angle of 11°. Using the Maslov-Berrer and Shahunyants engineering methods (the Bishop and Spencer methods) and the LANDSLIP software package (Trofymchuk *et al.* 2018) the calculations were performed and, in accordance with the requirements of (DBC 49-86. 1988), the minimum tensile strength Rp of geosynthetic materials was determined for one their layer (n = 1):

$$Rp = [3000 - 4000] \text{ N/m}$$

As the geosynthetic materials relative strength under a long-term loading is lower than the nominal value of Rp (depending on the geosynthetic materials type), this lowering can be up to 60%. Therefore, a suitable reserve by Rp is necessary. According to the given breaking load of geosynthetic materials Rp = [3000–4000] N/m, in the discussed case the geotextiles with the density of 150–200 g/m^3 will be the most suitable. The laid material length must be at least 2 m. After the drainage prism is installed, the geosynthetic materials rolls of required length (taking into account the overlap onto the reinforced layer) are rolled out. The residual material is left in a roll on the wall. The rolls should be sewn by width with a stapler. The overlap must be at least 0.1 m. Then the backfilling is carried out with the cohesive clayey soil of a 1910 kg per m^3 bulk weight obtained from slope undercutting and leveling. The reinforced layer is covered with the residual part of the roll at least 2 m from the wall and the cycle is repeated up to an elevation below 1 m from the design soil elevations (Figure 6).

4 REFINED CALCULATION

Due to the fact that in the LANDSLIP software package (Kaliukh *et al.* 2018) the issues of reinforcing the steep slopes and retaining walls are considered on the basis of the approximate formulas and analytical dependencies using the engineering methods of Maslov-Berrer and Shakhunyants (Bishop and Spencer methods), the seismic loads for the slopes stability calculations were taken into account in the form of the appropriate seismic coefficient μ (the supplementary static loads addition according to the Bishop and Spencer methods).

The issue of the calculations improvement based on the more accurate mathematical models and the use of a direct dynamic calculation method with the real accelerograms of the construction site for landslide protection measures (slopes and retaining walls reinforcement design) acquire a national importance. This is due, first of all, to the scale of the phenomenon in Ukraine and the world, and, secondly, to the issues of saving limited resources allocated for landslide protection measures in the country.

Considering these facts, the direct dynamic calculation using the accelerograms based on seismic microzoning of the boathouses construction site in the Vertolit Research Center area, Prymorske village, Feodosia, Autonomous Republic of Crimea, Ukraine, is applied for the existing slopes undercutting based on the software package PLAXIS (2022). The PLAXIS software package is certified in the EU and meets the requirements of the relevant normative documents (Eurocode 7. 2004.). The accelerograms of 7 and 8 points earthquakes are used for the calculations. The preliminary calculations and analysis of the slopes and their undercutting geometry taking into account the physical and mechanical characteristics and seismicity of the construction site show that the greatest landslide hazard can arise when the slope is undercut along a specified cross-section (Figure 1). The further direct dynamic calculations of the stability coefficient of the man-made slope reinforced with geosynthetic materials are carried out using the PLAXIS software (PLAXIS 2022). Two geometric models of the initial and undercut slopes in the PLAXIS software package are shown in Figures 3 and 4.
Figure 3.   The initial slope geometric model in the PLAXIS software package.
Figure 4.   Geometric model of undercut reinforced slope in the PLAXIS software package.

The calculations were carried out using the preliminary physical and mechanical characteristics. As a result of calculations according to the second group of limit states, the minimum tensile strength Rp of geosynthetic materials is specified for one layer of synthetic materials (n = 1) as Rp = [2500–3500] N/m, which allows to reduce the geosynthetic materials minimum strength up to 30% if compared with the previous case. This made it possible to reduce the minimum density of the geotextile to 130–170 g/m^3, taking into account the appropriate reserve according to Rp.

5   DESIGN AND PRACTICAL EXECUTION OF WORKS

The calculation data were used in the design and arrangement of a landslide protection structure in the area of the boathouses location in Prymorske village, Feodosia city. The step-by-step project for the construction of the landslide protection wall is shown in Figures 5 and 6. The initial and final stages of the landslide protection structure construction are shown in Figure 7(a & b).

6   CONCLUSIONS

1. In the course of the conducted research, modern geosynthetic materials are analyzed in part of their application for ensuring the stability of the man-made soil slope formed as a result of cutting the existing slope. For its reinforcement, it is proposed to use the high strength geosynthetic materials allowing to increase the landslide resistance of soil structures, thereby ensuring the necessary soil stability.
2. Based on the choice of the area most vulnerable to landslide deformations, a graphic model of the slope near the boathouses location in the area of the Vertolit Research

Center, Prymorske village, Feodosia, Autonomous Republic of Crimea, Ukraine, is developed and later on used in the LANDSLIP engineering software for the calculations of the landslide pressure and slope stability coefficient. The calculations show that the undeformed slope is safe with regard to landslides.
Figure 5.   Stages of the landslide protection wall. construction from geosynthetic materials: 1- sealing roll (2 m); 2 – drainage prism; 3 – reverse filling of the next layer; 4 – drainage pipe; 5 – unrolling of the sealing roll; 6 – the next work section of rubble masonry.
Figure 6.   The final view of the landslide protection. wall reinforced with geosynthetic materials: 1-foundation reinforced concrete pad; 2 – decorative wall of quarry stone; 3 – asbestos cement drainage pipe; 4 – drainage tray; 5 – storm drain.

As a result of serial calculations of various options and their analysis, it is found that for the undercut slopes at the site of boathouses construction, the minimum tensile strength Rp of geosynthetic materials varies in the range of [3000–4000] N/m for one layer of synthetic materials (n = 1). According to the breaking loads given in (DBC 49-86. 1988), geotextiles with the 150–200 g/m^3 density will provide required strength.

3. In the PLAXIS software package a slope graphic model is developed for the most vulnerable to landslide deformations area, Figures 3 and 4. The graphic model is used for the direct dynamic calculations of the landslide pressure and stability coefficient, taking into account the results of construction site microseismic zoning (using real accelerograms). According to refined calculations carried out with the PLAXIS software package, the required tensile strength Rp varies in the range of [2500–3500] N/m. Geotextile having the 100–150 g/m^3 density with one layer of geomaterial meets these requirements. The more advanced model of the PLAXIS software package allows to reduce the geosynthetic material cost due to its density reduction.

4. The man-made slopes reinforcement with geotextile materials should be carried out layer-by-layer in every 0.75 m with the use of backfilling with cohesive soil from undercutting

Figure 7.   The initial and final stages of the landslide protection structure construction during the 2013 summer in the area of the Vertolit Research Center boathouses location (Prymorske village, Feodosia, Autonomous Republic of Crimea, Ukraine): a) – natural slope: b) undercut slope fixed according to the project. The planned monitoring of the reinforced wall was not carried out due to the annexation of Crimea by the Russian Federation in the spring of 2014.

the slope without any compaction, since the backfill soil will be compacted during construction under the weight of the reinforced layers located above. The backfill reinforcement must be carried out up to 1 meter below the design soil levels. The length of geosynthetic material laid in the slope should be at least 2 m (Figure 7).

5. The presented research results define that for the optimal and economical choice of geosynthetic material the need arises for a comprehensive assessment of such factors as the construction site engineering and geological conditions, the type of the erected structure soil material, the loads nature and the environmental conditions. Microseismic zoning is mandatory for the construction sites in earthquake-prone zones.

ABSTRACT: The failure of a historical dry laid masonry gravity wall on a tertiary road in Hereford provided difficulties for the local authority in maintaining traffic access along the existing road with a guaranteed level of stability whilst enabling the retaining wall to be reconstructed with minimal visual impact and upgrading the original vehicular restraint system to meet more exacting modern standards.

This paper will look at the design, construction and detailing of the solution proposed to the client's Engineer WSP by Huesker and Dywidag as well as exploring similar historical solutions to highlight the variety of face finishes achievable and demonstrating the clear advantages hybrid solutions offer to geotechnical asset owners. The paper will also review the limited design advice available for such hybrid solutions and make recommendations for the expansion of existing design codes to specifically address the use of hybrid anchored and reinforced soil solutions.

1 STONE COTTAGE, HEREFORD CASE STUDY

1.1 *Background*

Hereford is a rural County in the West Midlands of England on the border with Wales, it is sparsely populated with the principal businesses being agricultural in nature. The B4224 is a winding rural road linking Hereford to the Forest of Dean, these rural roads are scarcely wide enough for 2 vehicles to pass in places and are generally lined by dense vegetation and mass masonry structures.

On the 16th of February 2020 the aftermath of Storm Dennis following immediately after flooding caused by Strom Ciara caused two slip failures along the road closing it completely between Holme Lacy Bridge and Fownhope. The second of these slip failures at Stone Cottage led to the partial collapse of an unreinforced mass masonry retaining wall approximately 70m long by 5m in height. These failures led to a complete closure of the road to through traffic, requiring lengthy diversions particularly for larger vehicles causing widespread traffic congestion in the area backing up into the county town of Hereford.

1.2 *Developing a solution and facing novel problems*

WSP who had a framework agreement with Hereford Council and Balfour Beatty, their term maintenance contractor were required to develop a solution for the wall failure at Stone

Cottage. In addition to the access constraints posed by the failure itself and the subsequent congestion, the surviving portion of the existing road housed local water, gas and tele-communication services whilst the surviving portions of the masonry parapet wall would clearly not meet modern highway design standards for vehicle containment.

The decision was made to replace the whole 70m length of the partially failed structure including the installation of a reinforced concrete cantilever parapet wall designed to meet current standards. The initial structural options for a wall solution consisted of embedded structures (sheet pile or king post and panel) or in-situ structures (RC cantilever, mass wall such as gabion or reinforced soil). Whilst the embedded structures met the main criteria of retaining the existing services the logistics of accessing the site with the heavy piling equip-ment required made the solutions unsuitable. In situ structures were easier in terms of plant access but the depth of excavation required would have meant the removal of the services and required significant temporary works to facilitate the construction.

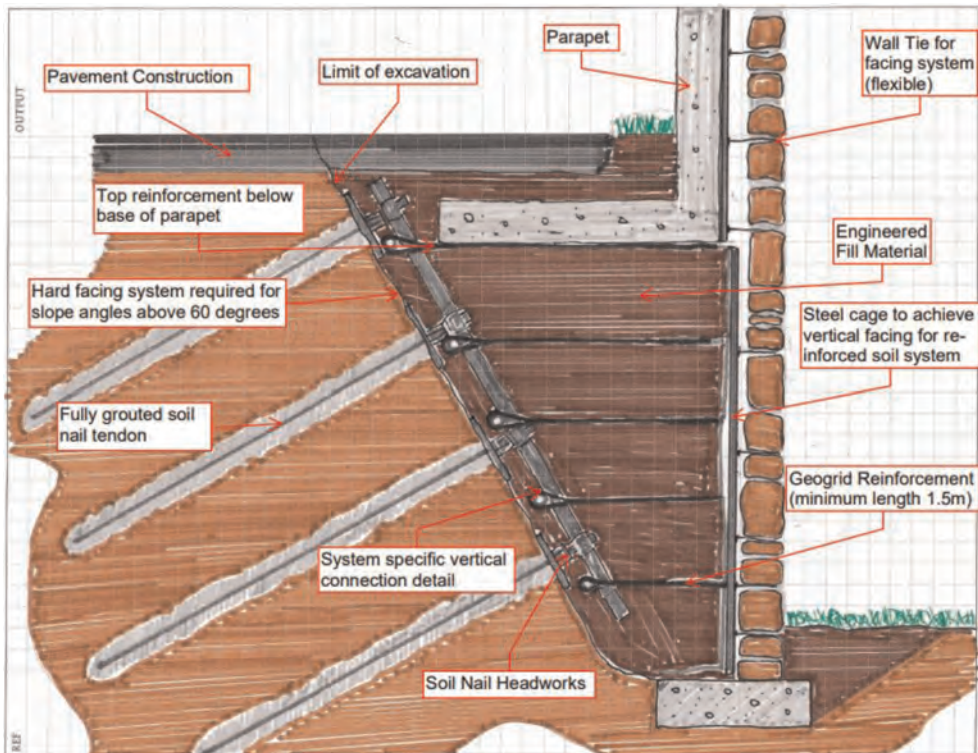
A further "novel" problem was becoming apparent during the initial design feasibility stage as the Covid 19 virus took hold in the UK and our first lockdown was announced. Whilst alleviating much of the traffic congestion problem and giving an ideal window to carry out the repair works if a solution could be found the lockdown meant that design meetings were now confined to video conference calls. Through discussions with Huesker Ltd and Dywidag a hybrid solution was proposed which offered the advantages of preser-ving the existing road surface and services with the aesthetic finish of a reinforced soil solution that could be combined with a full reinstatement of the existing masonry facing. A first Teams meeting in mid-April fleshed out this solution resulting in an initial sketch of the solution.


Figure 1. Initial design sketch of hybrid wall concept.

1.3 *A new way of working*

Five remote meetings between of the tripartite design team were required to come up with a final approved solution. For the size and scale of the project had these meetings been face to face involving multiple parties travelling 100s of kilometres the cost implication would have been significant and may have rendered the solution less workable. The new way of remote working however meant that details could be quickly discussed and amended with designs checked so that a final solution could be put forward.

Although a detailed design was agreed relatively quickly approvals and the procurement process meant the construction of the solution did not begin until the start of the UK's third lockdown in January 2021. The construction consisted of removing the failed section of the wall, retaining the masonry for later reuse, and the diversion of the telecom services from the wall edge to the other side of the road and the marking and protection of the existing gas and water services whilst maintain local pedestrian access to the adjacent properties. The road surface and slope was cut back to the construction profile and progressively stabilized by nailing as the works progressed downwards.

A sliding scaffold system was then erected onto the face of the nails along with the normal steel mesh and textile facing to prevent spalling. A vertical reinforced soil structure (RSS) was then built up at a 1.5m offset from the toe of the nailed profile with a vertical galvanized steel mesh formwork to the front face contained a wraparound of geogrid and non-woven textile whilst the tails of the reinforcement were wrapped around 16mm bars located behind the scaffold facing. This "towel rail" connection detail was seated beneath the nail heads so that any movement of the fill during compaction would allow the grids to tension and restrain the RSS face and pass the tensile force into the nails without introducing potential shear forces or moments and without the risk of the towel rail locking out above the nail heads and over tensioning the reinforcement.

This attention to detail produced a flush vertical face to the RSS block to which galvanized sliding masonry anchors were fixed. The RC parapet wall was then cast in-situ above the RSS block with similar masonry anchors cast into the facing. A narrow concrete levelling pad was cast in front of the RSS facing and the existing stone from the failed wall were fixed onto the masonry anchor system to finish the wall in a manner that matched the original structure. The construction by Alun Griffiths was completed ahead of schedule in 13 weeks and the road reopened to traffic 13 months after the initial failure at a cost of £124,000.

The first time the design team physically met was for the interview stage of the Ground Engineering Awards 2022 where the project was nominated in the projects under £500k category and then again for the Awards dinner where the project won its category.

2 HYBRID STRUCTURES

2.1 *Active and passive reinforcement systems*

The concept of reinforced soil is well understood within the field of geotechnical engineering having first been postulated by Casagrande in 1938. When talking of reinforced soil we normally refer to the horizontal layering of strips or sheets of geosynthetic or metallic material within a compacted engineered fill where the reinforcement goes into tension as the fill material is compacted increasing the lateral restraint of the material and reducing the soil's natural tendency to dilate under normal stress. Since the reinforcement is tensioned during compaction it is seen as active reinforcement.

Where an existing soil mass needs stabilising and removal and replacement is impractical or logistically impossible reinforcement can be introduced into the soil either through drilling and grouting or through dynamic insertion of steel bars or carbon or glass fibre rods. In principal soil nails of this nature differ little from soil reinforcement although they are generally inclined downwards from the horizontal. Since the nails will only generate tension through skin friction along the nail/soil or grout/soil interface as the soil begins to move their reinforcement is seen as passive.

The main constraint on the feasibility of reinforced soil solutions in cuttings is insufficient space to excavate and place the reinforced fill mass, this is particularly evident in failed walls and slopes supporting services or access routes, on sites requiring walls and slopes close to boundaries or on sites seeking an aesthetic facing over weathered rock. Similarly when founding reinforced soil slopes or walls on existing shallow embankment slopes to facilitate highway widenings it may be preferable to nail the existing slope rather than excavate significant volumes of fill to place the reinforcement. In such situations it is possible to combine a permanent passive means of stabilising the cut face such as soil nailing, rock bolting or sheet piles with a narrow reinforced soil facing.

2.2 *Design and detailing of hybrid solutions*

Design of both the active and passive reinforcement is typically done by considering the reinforcement affect beyond a series of postulated failure surfaces defined by single or multipart wedges, slip circles or log spirals with partial factors applied to soil and reinforcement properties, interface friction coefficients and applied loads. In the UK this design is generally done in accordance with *BS 8006 Part 1. 2010. Code of practice for strengthened/reinforced soils and other fills* and *BS8006 Part 2. 2011. Code of practice for strengthened/reinforced soils Part 2: Soil nail design.*

Whilst the two design documents explain the design methods for their respective types of reinforced soil well there is no attempt to combine both active and passive reinforcement into a hybrid solution. Some reference to this had previously been included in *Highways Agency. HA68/94. 1994. Design methods for the reinforcement of highway slopes by reinforced soil and soil nailing techniques.*

The approach suggested in HA68/94 consisted of mechanically joining or overlapping the nails and geosynthetic reinforcement at the active/passive interface and matching the vertical spacing of the two systems for simplification of the analysis by the proposed two part wedge method and would apply only to reinforced soil faces shallower than 70°.

Whilst the benching detail and connection shown in HA68/94 suit a steeper RSS built above an existing shallow slope, it is likely that, logistics permitting, the toe of the shallow slope would normally be over-steepened locally to permit the construction of full width reinforced soil rather than nailed whilst the matching of nail and reinforcement layers is generally impractical due to the significant differences in strength between the HT steel bars used for nailing and geosynthetic reinforcement whilst spacings for nails are normally in excess of 1.0m whilst vertical spacings of geosynthetic reinforcement should rarely exceed 0.5m.
Figure 4.   Detail of nail head connection and "towel rail" geogrid connection behind scaffold bar.

The typical application area for hybrid solutions is usually in far steeper situations against very steep top down nailed or anchored faces. This steeper face lends itself well to a vertical scaffold system fixed to the nail/anchor heads which can then be connected to the reinforcement of the RSS facing with a sliding detail so that moments and shear forces are not transferred into the nail heads but such that the full tensile force from the horizontal reinforcement is transferred via the scaffold facing into the soil nails, this also obviates the need to match the nail and reinforcement spacing enabling them to be designed independently to suit the system.

Initial designs are most simply done using standard single or multi wedge analysis or slip circle analysis for the reinforced soil as if it were a full width normal RSS and similarly the soil nail design should be done independently to stabilize the required cut face. A supplementary check can then be done to ensure the total design load from the geosynthetic reinforcement at the interface does not exceed the total capacity for the soil nails whilst a more detailed global stability analysis can be carried out using staged construction for both the top down nailing process and for the combined nails and reinforced soil facing.

In creating a hybrid facing the narrow reinforced soil zone is typically 1.5m minimum width to facilitate compaction of the fill and a safe working platform, similarly for safety reasons nail heads should be capped to protect workers in close proximity to the face. Since the passive zone with the soil nails is already fully consolidated and the active zone of the reinforced soil block is liable to undergo some vertical compression during compaction, in the order of 5cms for the lowest grid layer decreasing as the wall progresses, the physical connection should be designed to permit sufficient vertical movement to avoid a concentration of forces at the interface and potential shear failure at the nail head. The vertical spacing of the reinforcement is unlikely to coincide exactly with the nail or anchor heads or any lugs connected to a sheet pile facing a vertical bar/ scaffold system attached to the retained face can be created with horizontal connections to the reinforcement formed so that they are capable of sliding vertically without focusing stress in the reinforcement or inducing shear or bending moments at the nail heads.

Ideally the scaffolded face to the nail cutting and the finished face of the reinforced soil should be close to parallel to avoid slackening of the reinforcement during compaction but given the inherent flexibility of the cages and the geogrid/soil interaction the difference between the 70°–80° cut and the vertical cage face produced no perceptible discrepancy from vertical during post construction whilst any minor tolerance issues could have been taken out in the masonry application on the sliding masonry ties to the face to ensure the outer face of the wall was vertical.

2.3   *Pros and cons*

The principal advantages gained through soil nailing the existing soil is the ability to stabilize the face as the works progress in a top-down fashion ensuring existing services and access above the failure are not further jeopardised as the works progress whilst minimizing the need to remove fill from site and import new material for the reconstruction.

The aesthetic finish to a nailed slope is not ideal however usually consisting of exposed nail heads and plates with a retention mesh or textile facing which is typically covered either through the establishment of vegetation or by the application of shotcrete. Since the reinforcement is passive in nature some localized movement of the facing is expected as the earth moves prior to generating skin friction with the nails.

Reinforced Soil Systems offer a wide range of face finishes from grassed or hand planted facings, gabion finishes, modular concrete blocks or panels or masonry which can be used to effectively tie in seamlessly with adjacent structures.

Reinforced Soil Systems require a relatively large footprint in comparison to their height which whilst not a problem when building a new embankment can pose logistical issues when building in cutting supporting existing fill or adjacent to existing site boundaries. With this in mind a hybrid system offers the logistic advantages of nailing in stabilizing the existing fill combined with the aesthetic versatility of the RSS facing for interfacing with other structures.

The introduction of multiple disciplines in the construction process could potentially pose problems but on this scheme the contractor, Alun Griffiths had a geotechnical drilling team and civils team under one company. The sequence of construction is such that the drilling contractor installs the soil nails, temporary mesh and plates and nuts which stabilizes the slope in a temporary as well as permanent state. The slope can in theory, then be left to stand until the civils or earthwork contractor arrives on site. This means there is no real interface problem between the drilling and the earthworks team & the attendant risks of standing time claims usually associated with many trades working closely together in a tight space. The one interface will be in the first excavation of the slope which will need to be done in stages or lifts using an excavator, usually the earthworks contractor followed by the soil nail drilling contractor. This is normal however on all soil nailing schemes requiring co-ordination and management.

2.4 Ageing infrastructure in a changing climate

Innovative solutions like this are likely to become increasingly necessary particularly in countries where their infrastructure is approaching or exceeding original design life and service conditions and the increased frequency of severe weather events risk partial or complete failures of earth retaining structures. The increasing need for resiliant structures to withstand the changing environment and meet modern standards whilst still fitting in alongside existing infrastructure is likely to see more retrofitted repair solutions like the one discussed here being used to minimize the disruption the works cause, reduce the amount of imported material and associated traffic movement and ultimately to create more robust structures.

2.5 Other examples and aesthetic finishes

Reinforced Soil Systems offer a wide range of face finishes from grassed or hand planted facings, gabion finishes to modular concrete blocks or panels or masonry which can be used to effectively tie in seamlessly with adjacent structures.

For steep sloping finishes whilst a simple wraparound with an external demountable formwork might be feasible the ability for sacrificial or galvanized integral mesh falsework to concertina accommodating any vertical compression of the fill lends itself well to the compaction limitations due to the narrow construction zone available when applying a RSS skin to a steep nailed or anchored face and reduces the risk to workers posed by using demountable falsework from a relatively narrow working platform.

The same steel mesh facings can be taken to vertical or near vertical with a galvanized finish to create gabion finished stone facing or provide a facing for post-fix application of masonry or brickwork to match existing structures. Alternatively modular concrete blocks or concrete panels can be constructed as an integral facing to the RSS structure.

Lateral earth pressure against geosynthetic reinforced soil-integrated bridge abutment block wall

B. El Refai & P.J. Naughton
Atlantic Technological University Sligo, Sligo, Ireland

ABSTRACT: The deformation and magnitude of the coefficient of earth pressure at locations in a Geosynthetic Reinforced Soil – Integrated Bridge System subjected to self-weight and external vertical and horizontal loads was investigated using Plaxis 2D. The soil mass was found to move outward at all locations under all loading conditions. The application of the external loads increased the outward movement over the full height of the wall. The magnitude of the coefficient of earth pressure varied significantly. Over the middle two-thirds of the wall height the coefficient was close to the active value or between the active and at rest values. At the top and bottom of the wall it was closer to the at rest value. Directly beneath the bank seat the application of the external loads significantly increased the magnitude of the coefficient to higher than the at rest condition.

1 INTRODUCTION

Bridges are essential elements in modern infrastructure. Bridges, in their simplest form, consist of two abutments supporting the bridge deck spanning over an obstacle. In conventional bridge construction, expansion joints and bearings were installed between the bridge deck and the supporting abutments to accommodate relative movement resulting from expansion and contraction of the bridge deck due to temperature changes. Expansion joints require maintenance due to damage from de-icing salts leaking through the deck joints, leading to corrosion and damage of the bridge joints and bearings.

Given the problems with conventional bridges, the concept of physically and structurally connecting the superstructure and abutments to create an integral bridge have become very popular (Carder & Card 1997). For integral bridges the problems associated with joints and bearings are avoided. However, because of the integral connection between the superstructure and the abutment, the abutments are forced to move away from the retained soil when the temperature decreases in winter and the superstructure contracts and move towards the soil when the temperature rises, and the superstructure expands in summer (Horvath 2000).

Geosynthetic Reinforced Soil – Integrated Bridge Systems (GRS-IBS) is an amalgamation of reinforced soil and integral bridge technology with the explicit aim of overcoming several inherent problems with conventional abutment arrangements. These problems include high construction costs, long construction periods, durability and maintenance issues due to water ingress to bridge bearings and joints including differential settlement with the adjoining road construction and low stability in high seismic areas (Abu-Farsakh *et al.* 2018). Unlike conventional integral abutment systems, GRS-IBS involves the placement of the bridge deck directly onto a reinforced soil structure, which is typically a segmental block wall, without the use of vertical piles or bridge bearings.

The Federal Highways Administration (FHWA) (Adams *et al.* 2011) have developed a dedicated design method for GRS-IBS. However, Adams *et al.* (2011) showed that this method was heavily empirically based and provided a 'recipe' for design.

The determination of the tension in the geosynthetic reinforcement is a key design requirement for any GRS. Geosynthetic reinforcement works in tension and creates a

composite material with the surrounding backfill. Current design codes (BS 8006-1 2016; FHWA 2009; NCMA 2020; NF P94-270 2009) tend to use either the coherent gravity or tie back wedge methods to estimate the tension in the geosynthetic reinforcement.

Abu-Farsakh *et al.* (2018) argued that the failure envelopes outlined in BS 8006-1 (2016) failed to cover the true failure patterns within GRS-IBS. Both the BS 8006-1 (2016) and the allowable stress design (ASD) method also disagree on the limit states which occur within a GRS-IBS, (Adams *et al.* 2011).

This study investigated the deformations and lateral earth pressures mobilized in a GRS-IBS abutment.

2 METHODOLOGY

Plaxis 2D, Version 20, (2021) was used to conduct a parametric study investigating the lateral earth pressures in the reinforced soil block of a GRS-IBS abutment subject to both vertical and alternating horizontal load. The GRS-IBS abutment investigated consisted of a reinforced soil segmental block wall with a bridge bank seat resting directly on top of the structure.

The Plaxis 2D model was initially validated against data from a full-scale instrumented GRS wall and GRS-IBS abutment reported by Hatami & Bathurst (2005) and Zheng & Fox (2017) respectively to ensure that the Plaxis 2D model adequately captured the deformational response of GRS-IBS. The validation model was discussed in detail by El Refai & Naughton (2022).

2.1 *Parametric study and geometry*

The model geometry consisted of a 6m high segmental wall with a vertical face. The vertical boundary in the model was 15m both in front of the wall and behind the end of the reinforcement layers. The concrete facing blocks were 0.15m high and 0.3m thick. The blocks were arranged in 40 vertical courses supported on a steel plate. The primary reinforcement had a length of 7m and was spaced every 0.6m vertically, corresponding to every 4th block. In addition, two secondary geogrids of length 4.8m, were installed midway between the topmost geogrid layers in the structure, Figure 1. This reduced the vertical spacing to 0.3m over the top 1.5m of the wall. The wall supported an abutment bank seat which was 2m wide, and 1.4m deep located at 2.5 m from the back of the facing block. The properties of the blocks, bank seat and backfill soil used in the model are presented in Table 1. An interface was created between the blocks themselves, and the blocks and the soil, Table 2. The stiffness, EA, of the geogrid reinforcement was 1500kN/m, corresponding to a polyester geogrid with a short-term strength of approximately 150kN/m.

Table 1. Model parameters for the backfill and facing blocks used in the Plaxis 2D analysis.

Material	γ (kN/m^3)	E_{50}^{ref} (MPa)	E_{oed}^{ref} (MPa)	E_{ur}^{ref} (MPa)	ν	c (kPa)	φ_p (°)	ψ (°)
Backfill	22	50	28	100	0.15	1	44	11
Facing block	16	100	–	–	0.15	–	–	–

Table 2. Backfill – facing block and facing block – facing block interface properties used in the Plaxis 2D model.

Interface	E (MPa)	c (kPa)	φ_p (°)	ψ (°)	Kn (MN/m^3)	Ks (MN/m^3)
Backfill–facing block	50	0	44	11	100	1
Facing block–facing block	100	46	57	0	1000	40
Figure 1. Schematic of GRS-IBS investigated in this study.

The bank seat was supported by a fixed anchor plate at the top of the bank seat representing the bridge beams and was required to restrain the abutment from unconditional outward movement when the bridge loading was activated in the model. The axial stiffness of this fixed anchor plate was 16MN/m, which was selected to limit the horizontal displacement of the bridge beams to 1cm. Without this anchor the GRS wall would have no restraint to horizontal displacement.

2.2 *Model construction and calculation of bridge loads*

Each parametric model was constructed in phases within Plaxis 2D, with an analysis undertaken at each stage. A detailed discussion of each phase is given in El Refai & Naughton (2022).

The vertical and horizontal loads used in this study are shown in Table 3 and were determined from the analysis of a single lane bridge deck, 15m long, supported on a 2m wide and 1.4m high bank seat and were previously discussed by El Refai & Naughton (2022).

In this paper only the results of Phases 2, 9 and 10 are discussed. Phase 2 was the construction phase, where only the facing blocks, the backfill, and the geogrids were activated. Phase 9 applied all the vertical loads (Table 3) together with all the inward, towards the abutment, horizontal loads (Table 3) to the top of the wall. Phase 10 applied all the vertical loads (Table 3) together with the outward, away from the abutment, horizontal loads (Table 3) to the top of the wall.

Table 3. Magnitude of loads used in the analysis.

Load	Self-weight	Variable traffic load	LM1[*]	Shrinkage	Creep	Temperature	Braking force
Vertical (kN)	185.3	31	72	0	0	0	4.3
Horizontal (kN)	123.4	36.6	10.5	−100	−44.2	±73.5	±23

Notes
[*]LM1 model is for tandem axle and general uniformly distributed case in accordance with the design standard for traffic loads on bridges, BS EN 1991-1-1 (2002).

3 RESULTS

The displacement and the coefficient of lateral earth pressure were investigated at three locations in the model during Phases 2, 9 and 10. The first plane was directly behind the facing blocks, the second plane was a vertical section starting at the midpoint of the bank seat base, and the third plane was along the line of maximum tension in the reinforcement layers. The

coefficient of lateral earth pressure, K, was defined in this study as the ratio of the vertical and horizontal stresses extracted from the Plaxis 2D model at each location investigated.

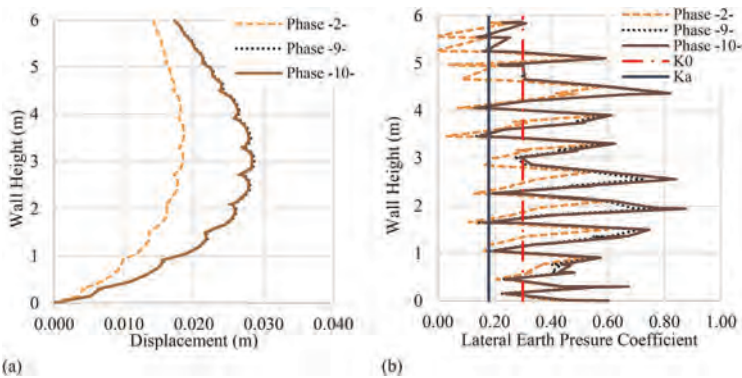
In Phase 2, with just the self-weight of the wall considered, the wall facing bowed outward, with a maximum deflection occurring two-thirds the way up the wall face, Figure 2(a). The application of the vertical and inward horizontal loads, Phase 9, increased the outward movement of the wall. Reversing the direction of the horizontal load, Phase 10, did not impact the deformation of the wall facing. Outward movement of the wall facing was observed during all three phases examined. The magnitude of K immediately behind the wall is shown in Figure 2(b) and was found to be highly variable. The variation of K was almost identical for Phases 2, 9 and 10, with the magnitude of K slightly higher for Phases 9 and 10 following application of the external loads. The magnitude of K was greater than 0.5 at each layer of reinforcement. Between layers of reinforcement the magnitude of K tended towards the coefficient of active earth pressure, K_a. This was in keeping with the outward displacement of the wall observed at this location. Near the top and bottom of the wall between layers of reinforcement, the magnitude of K tended towards the coefficient of earth pressure at rest, K_0. This was contrary to the observed displacement, where outward displacement of the face was observed at the top and bottom of the wall, Figure 2(a).


Figure 2. (a) Displacement directly behind the wall & (b) Lateral earth pressure coefficient directly behind the wall.

The displacement at the second plane, a vertical line from the midpoint of the bank seat base, showed outward displacement of the soil mass over the full height, Figure 3(a). In general terms, the displacement increased proportional to the height of the wall, with the maximum displacement observed at the top of the wall in Phases 2, 9 & 10, (18.2mm, 38.8mm & 35.9mm respectively). The application of the vertical load and inward horizontal load, Phase 9, followed by the outward horizontal load, Phase 10, increased the deformation over the full wall height at this location. The value of K at this location is shown in Figure 3 (b), with almost identical values for Phases 2, 9 & 10. The magnitude of K was close to K_a over the middle two-thirds of the wall height and approached K_0 at the very top and very bottom of the wall. The magnitude of K at the top and bottom of the wall was contrary to what was expected based on the predicted displacement at this location, i.e. outward movement of the soil mass.

The displacement along the line of maximum tension is shown in Figure 4(a). Again, outward displacement was observed over the full height, with a maximum value occurring at the top of the wall in Phases 2, 9 & 10 (13.8mm, 31.8mm & 29.9mm respectively). The application of the external loads in Phase 9, followed by Phase 10 resulted in a significant increase in deformation at this location. Very little change was observed in the deformations when the direction of the horizontal load was reversed, Phase 9 followed by Phase 10. The value of K at this location is shown in Figure 4(b), with reasonably good agreement between the magnitude of K over the

bottom two-thirds of the wall height. In the top third of the wall, the magnitude of K for Phases 9 and 10 was approximately double that for Phase 2. The value of K over the bottom two-thirds of the wall height was between K_a and K_0 and approached K_0 at the bottom of the wall. Like the other two locations examined; the magnitude of K was consistent with the predicted displacement over the bottom two-thirds of the wall height. However, at the top and bottom of the wall, the predicted value of K was contrary to the predicted displacement.

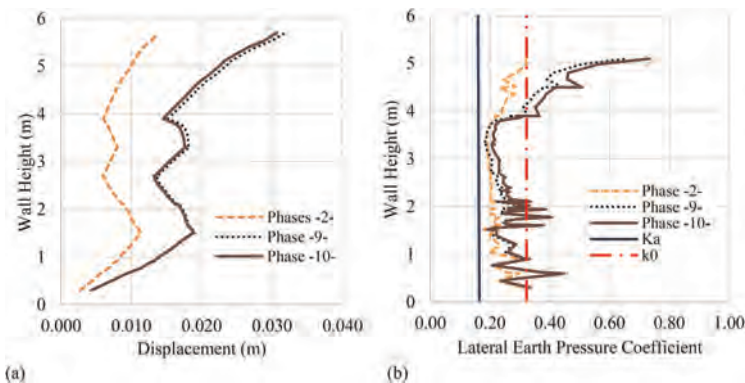

Figure 4. (a) Displacement at line of maximum tension and (b) Lateral earth pressure coefficient at line of maximum tension.

4 CONCLUSIONS

Plaxis 2D was used to predict the behaviour of a GRS-IBS abutment under self-weight of the segmental block wall and the addition of externally applied loads from the bridge deck. The magnitude of displacement and the magnitude of the coefficient of earth pressure were investigated at three locations, behind the wall facing, directly beneath the bank seat and along the line of maximum tension.

The backfill deflected outward at all three locations under all load combinations. The application of the external loads significantly increased the outward displacement. No significant change in displacement was observed when the direction of the external horizontal load switched direction, initially acting towards and then away from the abutment.

913

No consistency was found in the magnitude of K at the three locations examined. Immediately behind the wall face, K was very erratic and had a maximum value at each reinforcement layer, with the magnitude of K > 0.5. In between the reinforcement layers, over the central height of the wall, the magnitude of K tended towards the coefficient of active earth pressure. Near the top and bottom of the wall, K tended towards the at rest coefficient of earth pressure. The magnitude of K when the external loads were applied increased slightly over the case with just the backfill self-weight.

Directly beneath the bank seat, good agreement was found in the magnitude of K. Over the middle two-thirds of the wall height K tended towards the active coefficient, while at the top and bottom of the wall, K tended towards the at rest condition.

Along the line of maximum tension, the value of K, over the lower two-thirds of the wall height was between the active and at rest coefficients. In the top two thirds of the wall height, K tended towards the at rest coefficient of earth pressure for the self-weight only and exceeded the magnitude of K_0 when the external loads were applied.

ABSTRACT: The paper presents the results of two methods applied to the impact of fast landslides against an artificial barrier reinforced by geosynthetics. The first approach consists in simulating either the fast-moving landslide or the movable barrier through a single mathematical model based on inelastic collision formulation. In a second approach, the maximum expected impact pressure is estimated from the geometric and kinematic features of the impacting landslide mass by using literature impact formulations, and hence a FEM (Finite Element Method) dynamic analysis is performed to assess how the barrier is damaged and/or displaced during the impact. In such a case, a very detailed geometry of the barrier is considered and there is the chance of simulating the local/internal yielding of the structure. The latter is made of granular soil reinforced through geogrids wrapped around the facing, and it is free to move along the contact with the base soil. The landslide is constituted by a rectangular-like shaped volume of saturated soil moving at some meters per second at the impact stage. However, the height of the impact material is necessarily assumed as constant during the landslide-structure impact interaction. Globally, the two approaches provide consistent results as it concerns the Landslide-Structure Interaction (LSI) problem, with some discrepancies depending on the initial landslide velocity and type/geometry of the protection barrier structure.

1 INTRODUCTION

Recent research has outlined the feasibility of geosynthetics reinforced embankments as protection measures against flow-like landslides, especially in the case of debris avalanches, which are unchannalised flows capable to spread laterally upon hitting a rigid-like barrier. The field application has been also verified by means of landslide propagation analyses considering or not the presence of such structure (Cuomo *et al.* 2019).

The geosynthetic reinforcements improve the efficiency of the Deformable Geosynthetics-Reinforced Barrier (DGRB) to withstand the impact forces since they distribute the load in the longitudinal direction (Peila *et al.* 2007). Specifically, the deformation of the barrier nearby the impacted zone causes a tension in the layer oriented along the longitudinal axis of the structure. Moreover, the reinforced layers contain the displacement of the backside facing and thus increases the capability to withstand the impact while the impact force is increased (Lambert & Bourrier 2013). However, geosynthetics can reach the ultimate shear resistance (T_u) bringing the barrier to failure for excessive relative sliding of the layers along the soil-reinforcement interface. Elasto-plastic frictional interfaces are inserted between the granular backfill soil and the geogrids, with strength properties reduced to 80% of those of soil.

Nowadays, the crucial point consists of elaborating methods and procedures to (1) quickly individuate their geometry in the case where different locations for installation can be considered or (2) accurately design such works in the case when the location has been already established.

2 METHODS

2.1 Analytical method

An analytical model is set up where the landslide and the barrier are considered as two colliding bodies (Figure 1). At impact (t = t_{imp}), the approaching flow has mass m_1, length $L_{1,0}$, depth h, unitary width, density ρ_m, and initial velocity $v_{1,0}$. During impact ($t_{imp} < t < T_2$), flow velocity and length change to v_1 and L_1, respectively. The barrier is rigid, with its own mass m_2 and it is free to slide along the base. The frictional contact at the base is equal to $\tan(\delta_b)$, which can be set as the 80% of the strength properties of the subsoil base material (Cuomo *et al.* 2020). The impacted side of the barrier is usually inclined of $\beta = 60° - 80°$. The landslide-barrier interaction is schematized by an inelastic collision. After the impact, the two bodies reach the same velocity v_{CM}, applied in the centre of mass (CM) of the system and can be derived from the conservation of momentum.
Figure 1. Conceptualization of the impact according to the analytical method.

The impact force F is a spatio-temporal function since the approaching volume of the landslide increases with time until T_1 (Eq. 1) and then diminishes due to the dissipation of flow energy until T_2 (Eq. 2).

$$F(t) = \frac{1}{2}\frac{q_1^2}{K_1}\left(\frac{t}{\tau}\right) \qquad 0 < t \leq T_1 \tag{1}$$

$$F(t) = \frac{1}{2}\frac{q_1^2}{K_1}\left(\frac{T_2 - t}{1 - \tau}\right) \qquad T_1 \leq t < T_2 \tag{2}$$

The quantity s_1 represents the change (shortening) in landslide body after the impact (i.e., $L_{1,0} - L_1$) and it is computed as positive in the direction opposite to the flow movement. Being the impacting mass saturated, the expected behaviour is that a part of the landslide mass will overtop the barrier and the remaining volume will interact with the barrier. The maximum value of s_1 (i.e., $s_{1,max}$) is reached when the impact force is equal to the peak value. This means that only a part of the total volume of the landslide contributes to the interaction with the barrier.

The mathematical steps are reported in Cuomo *et al.* (2022), while the main equations are written below. For more readability, let introduce the quantities K_1 (Eq. 3) and q_1 (Eq. 4). In particular, K_1 is related to the body 1 (landslide) and resembles a change in momentum over space, while the quantities q_1 and T_2 (Eq. 5) are the model primary unknows. For $t_{imp} = 0$, as T_2 and T_1 can be achieved by fixing the ratio $\tau = T_1/T_2$ (e.g., from experimental evidence), the impact dynamics description is complete.

$$K_1 = \left(\frac{m_1 m_2}{m_1 + m_2}\right) \cdot \left(\frac{v_{1,0}}{s_{1,max}}\right) \tag{3}$$

$$q_1 = \frac{3}{4} \frac{K_1 v_{1,0}}{\sqrt{s_{1,max}}} \tag{4}$$

$$T_2 = \frac{8}{3} \frac{s_{1,max}}{v_{1,0}} \tag{5}$$

The barrier acceleration starts growing at $t = t^*$ (Eq. 6) and changes over time, being controlled by the frictional force along the barrier base and by the inertial forces instantly developed in the landslide and in the barrier during sliding. After reached the peak force at $t = T_1$, both landslide and barrier accelerations begin to decrease. It entails that the velocity $v_2(t)$ (Eq. 6) and the displacement $\Delta x(t)$ (Eq. 7) trends over time for the barrier can be approximately computed (if landslide shear stresses along the impacted side of the barrier are neglected). The final displacements of the barrier can be computed through Equation 8.

In this analytical model, two quantities $s_{1,max}$ and τ must be evaluated. From numerical calibrations performed by Cuomo *et al.* (2022) for a set of cases, it emerges that the ratio $\lambda = s_{1,max}/L_{1,0}$ was equal to 0.72 for barriers fixed to the base ground and 0.41 for unfixed barriers. Suggested values for τ are 0.17 (fixed) and 0.25 (unfixed).

$$v_2(t) = \begin{cases} \dfrac{AC}{2}\left(\dfrac{t^2 - t^{*2}}{\tau}\right) - B(t - t^*) & t^* < t \le T_1 \\[2ex] \dfrac{AC}{2}\left(\dfrac{t^2 - 2T_2 t + T_1 T_2}{1 - \tau} - \dfrac{t^{*2}}{\tau}\right) - B(t - t^*) & T_1 < t \le T_2 \\[2ex] t^* = \dfrac{B\tau}{AC} \end{cases} \tag{6}$$

$$\Delta x(t) = \begin{cases} \dfrac{AC}{6}\left(\dfrac{t^3 - 3t^{*2}t + 2t^{*3}}{\tau}\right) - \dfrac{B}{2}(t - t^*)^2 & t^* < t \le T_1 \\[2ex] \dfrac{AC}{6}\left(\dfrac{(T_1 - t)^2(3T_2 - 2T_1 - t)}{1 - \tau}\right) - \dfrac{B}{2}(T_1 - t)^2 - v_2(t = T_1)(T_1 - t) + \Delta x(t = T_1) & T_1 < t \le T_2 \end{cases} \tag{7}$$

$$\Delta x_f = \frac{AC}{6}\left[\frac{(T_1 - t^*)^2(T_1 + 2t^*)}{\tau} + \frac{2(T_2 - T_1)^3}{1 - \tau}\right] - \frac{B}{2}\left[(T_1 - t^*)^2 + (T_2 - T_1)^2\right] \tag{8}$$

where $= \frac{q_1^2}{2K_1 m_2}$; $B = g \tan \delta_b$; $C = \sin \beta + \cos \beta \tan \delta_b$.

2.2 A finite element method approach

Different types of barriers were considered and employed in a numerical model implemented in the Plaxis 2D code.

Barrier B1, whose FEM model is shown in Figure 2, is 6 m high and equipped with 10 geogrids, 0.6 m vertically spaced and wrapped around the facing. This barrier has an equilateral trapezoidal shape with the facing 60° inclined, a top width of 4 m and the base 11 m large. Barrier B2 is 7.5 m high and equipped with 12 geogrids, 0.6 m vertically spaced and wrapped around the facing. This barrier has an equilateral trapezoidal shape with the facing 72° inclined, a top width of 3.63m
Figure 2. An example of computational domain for FEM analyses (barrier B1).

and the base 8.38 m large. Lastly, barrier B3 is 6 m high and equipped with 10 geogrids, 0.6 m vertically spaced and wrapped around the facing. This barrier has an equilateral trapezoidal shape with the facing 80° inclined, a top width of 6.50 m and the base 8.50 m large. The control point in the core of each structure is individuated for tracking the computed displacements and it is located at the barrier mid-height. The analyses are performed for a unitary width of the barrier, in plane strain conditions.

3 EXAMPLES

3.1 Input data

Some landslide typologies (impact scenarios) are chosen as examples for the analysis of the protection structure. Table 1 reports the geometric features of different types of landslides and barriers for several impact scenarios. In the engineering practice, all these quantities are accurately estimated through specific analyses of landslide triggering and propagation (Cuomo *et al.* 2019, 2021a). The concept of the analyses is to apply the temporal trend of the impact force (obtained from Eqs. 1-2-3-4) along the impacted side of the DGRB modelled in a FEM framework. The pressure distribution along the barrier side simulated in the FEM analyses is assumed as constant. The mechanical properties of the materials employed in the FEM analysis are listed in Table 2.

3.2 Results and discussion

For the nine examples proposed in Table 1, the temporal trend of displacements obtained through the two methods are in many cases in very good agreement (Figure 3).

Table 1. Impact scenarios considered in the analyses.

ρ is the density of granular soil; c' is the cohesion; φ' is the friction angle; ψ is the dilatation angle; K_0 is the earth pressure coefficient; ν is the Poisson's ratio; E is the Young modulus; T_u is the ultimate tensile strength of the geogrid; EA is the extensional stiffness; EI is the bending stiffness; α and β are the Rayleigh's coefficients.
*Interface friction assumed equal to 0.8 tan(φ') of the confining material

The numerical method considers the elasto-plastic soil behavior, and the interaction between the filling soil and the geogrids. These features are not considered in the analytical method. However, due to the similarity between the analytical and the FEM displacements, the composite barrier can be schematized as a homogeneous rigid body for the assessment of the final displacements. However, it is worth noting that the influence of pore-water pressure at the impact, recognized as an important factor of LSI (Cuomo et al. 2021), is not considered in these analyses.

The final configurations and the entities of deformations within the barriers are related to the soil-geogrid interaction, which deserves further investigation.

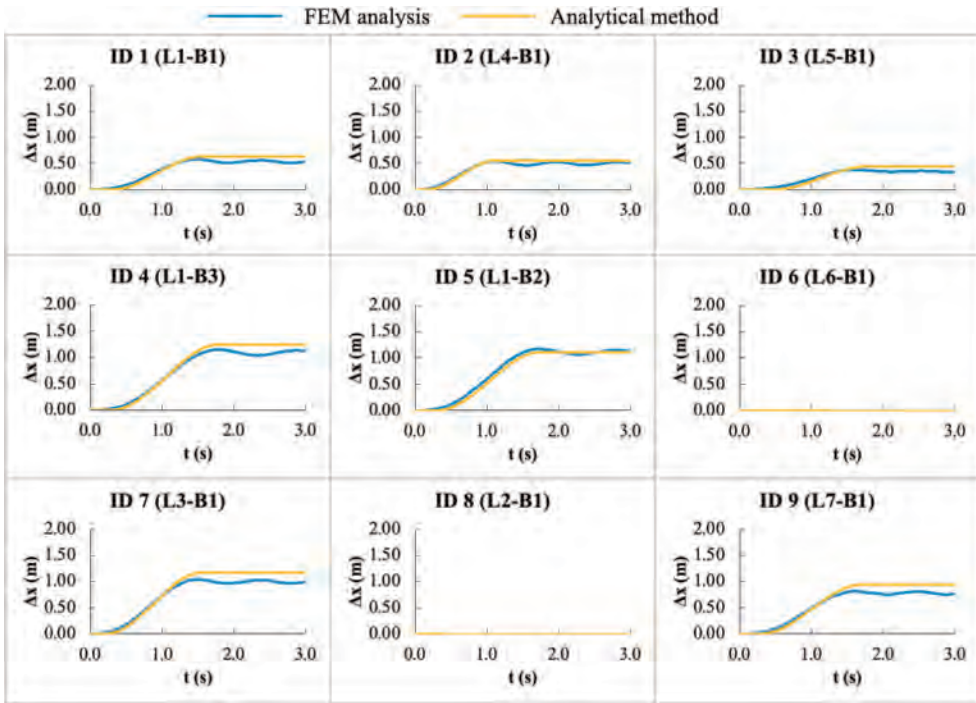
The axial forces (N) along the geogrids have been computed for simulation ID 1 (L1-B1) in Figure 4a and for simulation ID 5 (L1-B2) in Figure 4b. When the peak impact pressure is


Figure 3. Displacements temporal trend of the DGRB computed with FEM and analytical method.

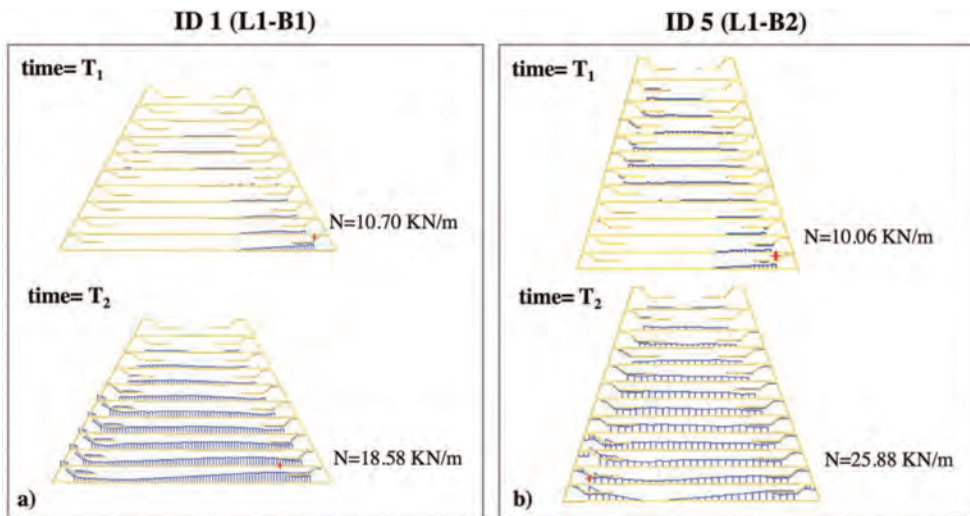
reached (time equal to T_1), the highest value (N = 10 kN/m) is measured on the valley side (beyond the barrier). Then, the axial forces increase more at time equal to T_2 (N = 18.58–25.88 kN/m). These values are far from the ultimate strength of the geogrids. In both simulations, the occurrence of the peak tensile stress of the geogrids is not the same of the application of peak impact pressure (T_1). This means that the structure is mostly compressed


Figure 4. Axial force inside the geogrids: a) ID1; b) ID 5.

until T_1, and the tensile stress within the geogrid is limitedly mobilized; then, the barrier is sheared more and more during the decreasing of the external pressure. Specifically, the peak tensile stress in the bottom geogrid is reached at the rear of the barrier for both configurations, with decreasing values towards the core. This entails that the barrier is mostly compressed at the impact front, and so the geogrids are not pulled out from the base corner where very small tensile stress is mobilized due to the geometrical configuration and the wrap of the geogrid. On the other hand, the rear of the barrier is mostly sheared and so the base geogrid undergoes an extension.

However, more investigation would be needed to understand whether, and in which cases, global stiffness of the barrier may play a role despite the stress in the geogrids still being far from the ultimate state.

4 CONCLUSIONS

Two approaches have been proposed to examine the problem of the interaction of a fast-moving flow-like landslide upon hitting a protection barrier made of geosynthetics reinforced coarse-grained material. The analytical approach fully describes the landslide energy release process and the movement of the barrier. The numerical approach allows including the very detailed layering of the structure and the presence/features of the geosynthetics which contribute to the stiffness of the work. Indeed, the two approaches are complementary rather than alternative, and usable at different stages of the design procedure.

ABSTRACT: Retaining structures are one of the most common applications of geosynthetic-reinforced soil (GRS). Most design approaches assume a multi-body failure mechanism below a quasi-monolithically reinforced block for the loss of bearing capacity in the foundation soil. Preliminary small-scale model tests showed that these assumptions are well justified and provided fundamental insights in the bearing capacity failure of GRS walls. However, the small-scale tests suffered from scale effects because the mechanical similarity was not completely fulfilled. Therefore, large-scale tests are additionally presented in this paper using regular geogrids. For this purpose, a 1.2 m high and 1.0 m wide geogrid-reinforced wall with a wrapped-around facing was installed on 2.0 m loose sand as subsoil. Then, a vertical load was applied on top of the reinforced structure. Horizontal and vertical wall deformations were recorded and the kinematic behaviour of the wall footprint at the bottom reinforcing layer was observed through a transparent side window using digital image analysis. Finally, the experimental data are compared to the results of analytical bearing capacity equations, revealing that the reduction of the reinforcement length needs to be considered to conservatively predict the load-bearing capacity.

1   INTRODUCTION

Retaining walls using geosynthetic-reinforced soil (GRS) have proven advantageous performance compared to conventional cantilever or gravity walls in terms of differential settlements, particularly during seismic events due to relatively ductile and flexible behaviour (e.g. Huang B. *et al.* 2010; Tatsuoka *et al.* 1997). On top of the mechanical benefits of GRS to increase load-bearing capacity and reduce deformation, structures with geosynthetics are flexible in geometry, resource-efficient, durable, sustainable, ecologically and economically favourable.

However, the behaviour of GRS retaining walls needs to be carefully considered to enable a safe and economical design (e.g. Allen & Bathurst 2002; Mirmoradi & Ehrlich 2019; Ziegler 2017). For instance, Y. Xie and B. Leshchinsky (2015) confirmed that bearing capacity and overall failures of GRS walls involve complex mechanisms which depend on several factors, e.g. surcharge, reinforcement properties and soil conditions. For the calculation of the load bearing capacity, the design approaches assume a multi-body failure mechanism below a quasi-monolithic reinforced block

(coherent unit) (e.g. British Standard BS 8006; German Standard DIN 4017 in connection with EBGEO 2010). As a result, geogrid-reinforced soil walls are treated similarly to strip foundations and the influence of the reinforced block above the wall footing is not considered. Therefore, a review of the mode of bearing capacity failure is required. For this purpose, small- and large-scale 1g model tests of geogrid-reinforced soil walls have been carried out at the Institute of Geomechanics and Underground Technology (GUT) in RWTH Aachen University under plain strain conditions.

2 MATERIALS

A dry sand was used as a subsoil, fill and backfill material. The particle size distribution is shown in Figure 1a. The uniform graded sand with $d_{50} = 0.5$ mm is classified as "SP" according to the unified soil classification system (ASTM D2487). In the experiments, the subsoil and backfill were installed with approximately 91 % and 100 % of proctor's density (1.725 g/cm^3). In these conditions, the peak friction angle of the sand was determined in triaxial tests for the subsoil as $\phi'_c = {}_0 \approx 34.9°$ and for the backfill to $\phi'_c = {}_0 \approx 43.7°$. The failure envelopes are presented in Figure 1b. Real scale geosynthetic reinforcements were used for the large-scale tests.

The woven biaxial geogrid with an aperture size of 30×30 mm in Figure 1c was made of polyester (PET). The tensile strength and stiffness were determined by the manufacturer to $T_{ult} = 47.9$ kN/m and $J_{0-2\%} \approx 510$ kN/m, respectively.
Figure 1. Particle size distribution (a) and triaxial test results (b) of the sand, woven biaxial geogrid (c).

3 PRELIMINARY SMALL-SCALE ANALYSIS

Preliminary small-scale experiments were conducted to analyse the performance and behaviour of GRS walls during bearing capacity failure qualitatively. For this purpose, the geometric scaling factor was chosen to 1/10, whereby a 2 m high prototype wall was represented by 0.20 m high model wall. The reinforcement length was 70 % of the wall height according to common design practice, such as recommended by EBGEO (2010). The wall was constructed with five reinforcement layers, which were wrapped-around the facing. To provoke bearing capacity failure, the wall was seated on a 0.6 m thick layer of subsoil and increasingly loaded on top of the structure.

During the experiment the deformation of the specimen was captured with photographs of a digital camera through the transparent side wall. The displacement field in Figure 2a was calculated by comparing patterns of subsequent taken pictures. Additionally, the changes in direction of the displacement vectors were evaluated, whereby the development of shear bands can be visualized in Figure 2b for a vertical strain $\varepsilon_v = 10\%$, defined as vertical settlement to wall height.
Figure 2.   Total displacements vectors (a) and failure surface (b) in small-scale test.

The mode of failure was characterized by a slip surface running externally around the rein-forced soil block. The retaining wall was pushed into the subsoil and the soil mass in front of the wall was uplifted. The failure was characterised by the loss of bearing capacity of the subsoil that turned into a global failure. The multi-body failure mechanism below the base of the wall con-sisted of an active and passive wedge connected by a transition zone, as illustrated in Figure 2b. The failure pattern in the subsoil was characterised by angles of active and passive failure surfaces of $v_a = 45 + \phi'/2$ and $v_p = 45° - \phi'/2$, corresponding to the assumptions for rigid foundations.

However, the bottom reinforcement layer of the GRS deformed in a curved shape. This flexibility enabled the capability of the structure to mobilize the bearing capacity of the subsoil instead of failing due to overturning or sliding, as observed for comparable con-ventional gravity and cantilever retaining structures, as shown in Derksen *et al*. (2022).

The uniform orientation of the vectors and the shape retention of the wall indicate that the geogrid-reinforced fill acted as a quasi-monolithic, coherent unit. It should be noted that the quasi-monolithic behaviour is expected to suffer when the geogrid spacing becomes too large or the geogrid length too short. Then internal failure modes with shear bands running through the structure are more likely than external modes like bearing capacity failure.

Although the preliminary small-scale tests provided important insights into the bearing capacity failure of GRS walls, the experimental setup suffered from scale effect because the mechanical similarity was not completely fulfilled. For instance, the stress level was by a factor of 10 smaller than for the prototype, influencing the shear strength and in turn also the bearing capacity of the subsoil. Moreover, the small-scale GRS wall was over proportionally stiffer than real scale walls due to the challenge to scale the geosynthetic tensile properties appro-priately. To overcome these drawbacks, large-scale experiments were additionally performed to quantify the ultimate load-bearing capacity and to observe the failure at a larger scale.

4   LARGE-SCALE TESTS

4.1   *Experimental setup*

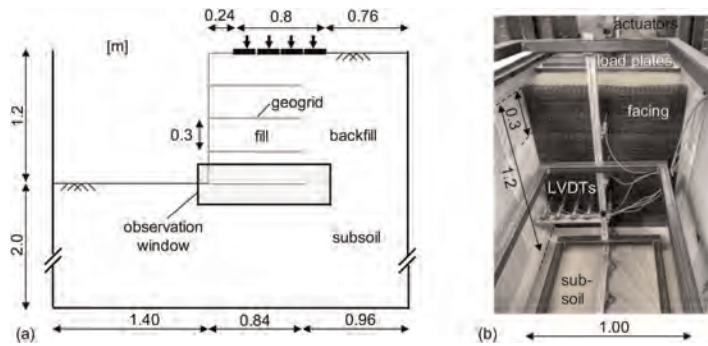
Figure 3 shows the dimensions of the large-scale experiment for which a geometric scaling factor of 1/1.67 was used, resulting in a wall with a height of 1.2 m that was installed on 2.0 m loose subsoil. The 1.0 m wide wall was constructed using four geogrids with an anchoring length of 0.84 m (70 % of wall height) and a vertical spacing of 0.3 m, corresponding to 0.5 m at prototype scale. Following the small-scale test, the wall was constructed with a wrapped-around facing. A thin nonwoven was used at the face to prevent the sand from running through the geogrid apertures. To minimize friction effects, two layers of Polytetrafluoroethylene (PTFE) foil were installed at each side wall of the testing apparatus. During the test, a vertical load was applied by four actuators, each loading steel plates in a pressure-controlled manner on top of the structure. Linear variable differential transformers (LVDTs) measured the displacements of the wall and the movement of subsoil ground surface in front of the wall. Moreover, photos were taken from the bottom reinforcement layer through the observation window for digital image analysis.


Figure 3.   Experimental setup: sketch of side view (a) and frontal view of wall (b).

4.2   Results

4.2.1   Load-bearing capacity

The load-settlement curve of each of the four actuators and their mean is plotted in Figure 4a. In this paper, the vertical strain $\varepsilon_v = u_y/H_W$ is defined as the ratio of vertical displacements to the initial wall height. Additionally, Figure 4a contains the load-settlement curve of a repetition test of the same wall configuration. The results proved the reproducibility of the large-scale experiment as similar structural response was observed. The curves represent the characteristic load-settlement response of a medium-dense sand in which local failure occurred. In the initial compression stage, all load plates followed the same linear trend. However, larger deviations between the load plates occurred as the vertical strain increased. The vertical stress and deformation gradually increased because the bearing capacity of the subsoil progressively increased during compaction.

Due to the difficulty of determining the ultimate load-bearing capacity at failure, approaches A and B are subsequently presented. Vesic (1963) considered ultimate load-bearing capacity for the local shear mode when the maximum settlement rate was reached. There, the non-linear part of the load-settlement curve turned into a straight line, indicated as point (III) with a failure load of $\sigma_{f,A} = 293$ kN/m^2 in Figure 4a. Moreover, the intersection of the two tangential lines T_1 and T_2 in Figure 4a was used to pinpoint failure following the approach by Adams and Collin (1997). The tangent T_1 described the initial slope of the curve, and tangent T_2 corresponded to the part of the curve where a constant strain rate during shear failure was reached. According to this procedure, bearing capacity failure occurred at vertical load of $\sigma_{f,B} = 249$ kN/m^2 at point (III) in Figure 4a.
Figure 4.   Load-settlement displacement curve (a) and displacement sketch (b) of large-scale test.

4.2.2 *Wall and subsoil displacements*

The displacement of the wall face was measured with LVDTs for each of the four wrapped-around layers in the centre line of wall. It was observed that the horizontal displacement increased from the top to the bottom layer with increasing load on top of the structure. In conclusion, the geogrid-reinforced block turns backwards to the backfill during failure, as illustrated in the displacement sketch in Figure 4b. At the same time, the subsoil surface in front of the wall was uplifted. The results confirmed that the reinforced block works as a quasi-monolithic, coherent unit what was also found also in the small-scale experiment.

Moreover, Figure 5 presents the results of the DIC analysis in terms of total displacements vectors (a) and failure surface (b). Confirming the findings of the small-scale GRS wall, the failure initially developed at the end of the bottom geogrid layer in Figure 5a, corresponding to a vertical load of $\sigma_{f,B} = 249$ kN/m^2 in Figure 4a. When the reinforced soil block was pushed into the subsoil, the shear bands manifested their presence and were fixed at the end of the bottom geogrid. However, at a vertical load of $\sigma_{f,A} = 293$ kN/m^2 additional shear bands formed, intersecting the bottom geogrid and shortening the reinforcement length relevant for bearing capacity by about 10 % to 0.755 m. It should be noted that the effective reinforcement length relevant to the bearing capacity of the foundation soil was reduced by the intersecting failure line, but the pullout resistance at the rear end of the reinforcement was mobilised as a self-healing process.
Figure 5.   Total displacements vectors (a) and failure surface (b) in small-scale test.

5   ANALYTICAL CONSIDERATION

The failure pattern in the small-scale and large-scale experiments has revealed that the assumption of a multi-body failure mechanism is justified. Therefore, the bearing capacity was analysed analytically based on the limit-equilibrium equation derived for rigid foundations, as given in equations (1–3). It should be noted that the effect of the reinforcement, e.g. tensile strength and stiffness, are not taken into account because the GRS wall is considered as a monolithic, coherent unit.

$$q_u = i_c \cdot c' \cdot N_c + i_s \cdot s \cdot N_s + i_\gamma \cdot \gamma \cdot B \cdot \frac{1}{2} \cdot N_\gamma \tag{1}$$

$$N_\gamma = 2 \cdot \left(e^{\pi \cdot \tan\phi'} \cdot \tan^2\left(45 + \frac{\phi'}{2}\right) - 1 \right) \cdot \tan\phi' \tag{2}$$

$$i_\gamma = (1 - \tan\delta_{li})^{m+1} \tag{3}$$

To compare the experimental results of the large-scale tests with the analytical approach (without safety factors), the vertical top load, at which limit equilibrium was reached, was determined. It should be noted that for the situation investigated, the eccentricity was shifted towards the backfill. However, the calculation was performed for different effective widths of the reinforced block to illustrate the importance of adequate consideration.

For the initial reinforcement length (B = 0.84 m), the analytical solution ($\sigma_f = 309.1$ kN/m^2) was in good agreement with the experimental capacity obtained with approach A ($\sigma_{f,A} = 293$ kN/m^2) but was 24 % higher than determined with approach B ($\sigma_{f,B} = 249$ kN/m^2). However, when the effective width was reduced to B = 0.755 m according to the experimental observation, the analytically predicted failure ($\sigma_f = 254.1$ kN/m^2) matched with the results of approach B ($\sigma_{f,B} = 249$ kN/m^2). For the width reduced by analytical eccentricity (B = 0.705 m), the analytical solution

underestimated the experimental bearing capacity by 16.8 % and 29.3 % following approaches A and B, respectively. These results show that reducing the reinforcement length to an effective width is crucial to determine a rather conservative load-bearing capacity with the analytical solution.

6 CONCLUSIONS

In this paper, small-scale (1/10) and large-scale (1/1.67) 1g experiments were performed under plain strain conditions to investigate the bearing capacity failure of geogrid-reinforced soil walls. The small-scale model was used to visualize the mode of failure qualitatively. The test results show that the assumption of the geogrid-reinforced soil body as a quasi-monolithic, coherent unit is well justified and that a failure mechanism similar to that of strip foundations occurs below the footing of the wall. However, the small-scale test suffered from scale effects. Therefore, additionally large-scale tests were performed to determine the ultimate load bearing capacity quantitatively. The evolution of shear bands at the base of the wall has shown that the failure surface was initially fixed at the rear end of the reinforced zone, resulting in an effective reinforcement length equal to its full length. However, the effective reinforcement length relevant to the bearing capacity of the subsoil was reduced due to the intersecting failure line. The analytical analysis has shown that a rather conservative load-bearing capacity is predicted by the analytical solution when the reduced reinforcement length is considered.

ABSTRACT: A series of small-scale experiments on geogrid-anchored sheet pile walls (SPWs) under strip footing surcharge loading was conducted at the Deltares laboratory. From the experiments, the following was concluded. Two slip surfaces develop, starting at the edges of the strip footing. These slip surfaces divide the soil behind the SPW into three zones. The paper analyses the contributions of each of these zones to the failure load of the structure. The location of the strip footing surcharge load, the length of the geogrids and the number of geogrid anchors all affect the failure load of the structure. Furthermore, it was found that the slip surface reorients at the intersection with geogrids, and that even very short geogrid anchors contribute to the total resistance.

1 INTRODUCTION

A geogrid-anchored sheet pile wall (SPW) is a relative new application of geogrids (van Duijnen *et al.* 2022; Wittekoek 2020; Wittekoek *et al.* 2022). The system is closely linked to a retaining wall of reinforced soil with a full-height facing as well as to a traditional anchored SPW. However, there are notable differences. The geogrid-anchored SPW has less embedment than a retaining wall of reinforced soil. And contrary to a traditionally anchored SPW, a geogrid anchor is also effective within the active soil wedge when the SPW deforms. This paper looks at small scale experiments, to get a feeling for how the system works. Schoen *et al.* (2023) present numerical analyses on the same structure-type.

2 SMALL SCALE EXPERIMENTS

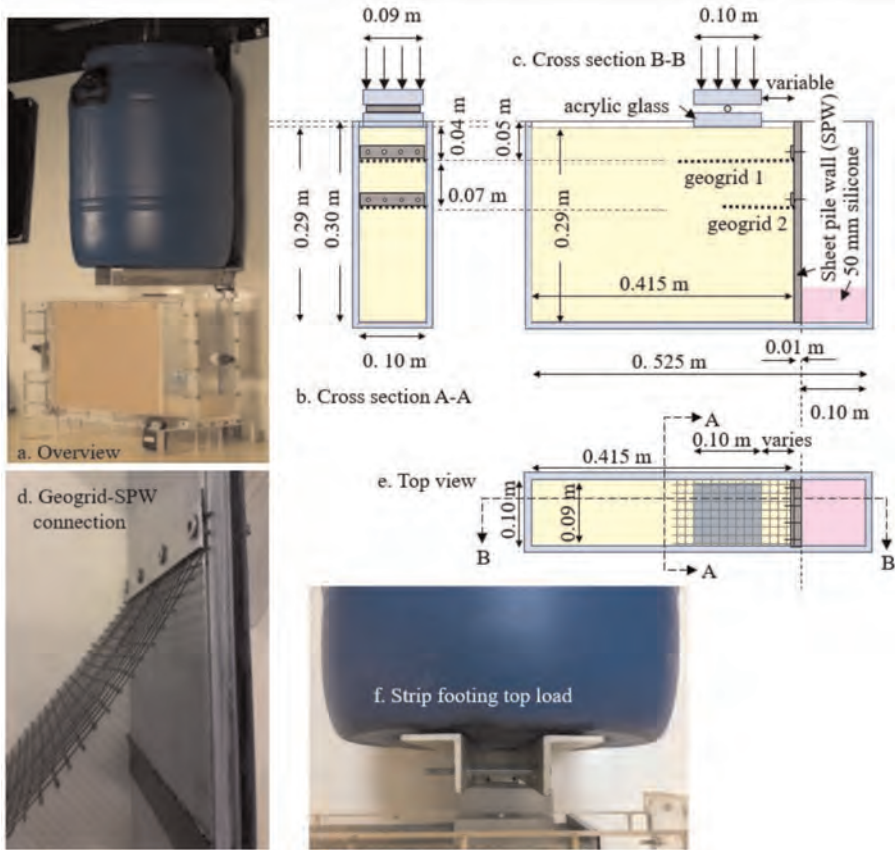
Figure 1 shows the test set-up of the small-scale experiments. The 10 mm thick aluminium model-SPW models only the upper part of the embedded part of the SPW. Therefore, the SPW was free to slide along the box bottom. The polypropylene (PP) model-geogrid had a short-term stiffness of 191 kN/m at 2% axial strain and a short-term tensile strength of 16.2 kN/m at a maximum strain of 13.5%. The fill at the active side of the SPW consisted of Baskarp B15 sand. This is a poorly graded sand, densified to a relative density of ~70%. Table 1 lists its properties.


Figure 1.   Test set-up.

A 0.1 m wide silicon block models the passive side. It has a stiffness of 159 kPa up to a strain of at least 8% (8 mm). The strip surcharge load is applied by loading a 0.1 m wide footing with a blue barrel that is filled with water during the test. The soil-wall friction was minimized with a lubricated thin (< 1mm) transparent silicone sheet. Wittekoek *et al.* (2022) analysed how the limited width (100 mm) of the test box and the soil-wall friction affect the results, by, among other things, comparing the results with tests in an eight times wider test box. They found similar slip surfaces, proving that the narrow box results were sufficiently reliable to analyse qualitatively. The movement of the soil and the SPW was tracked using digital photographs, which were acquired with a rate of 0.2 Hz. Soil displacements and strains were subsequently calculated by applying the Particle Image Velocimetry (PIV) technique to the test photos, using the program GeoPIV-GR (Stanier *et al.* 2015). The results matched a number of manually tracked displacements of a number of subsets well.

3 RESULTS SMALL-SCALE EXPERIMENTS

3.1 *The location of the strip surcharge load*

Figure 2 shows how the location of the surcharge load determines the failure mechanism. Two slip surfaces develop from the inner and outer edge of the strip footing towards the SPW. These divide the soil into three different zones. Zone I is enclosed between the SPW and the secondary slip surface 1B and characterized by rigid soil body motions. The active zone II slides along the
Figure 2. Slip surfaces for a surcharge load of ∼4 kN/m. Test 19. 1A: critical slip surface and 1B: secondary slip surface. The slip surfaces divide the soil in three zones: active zone II between zones I and III.

critical slip surface 1A. Zone III is stable and is located outside the critical slip surface 1A. The third slip surface in Figure 2 only occurred in Test 19, not in duplicate Test 18 or any other test.

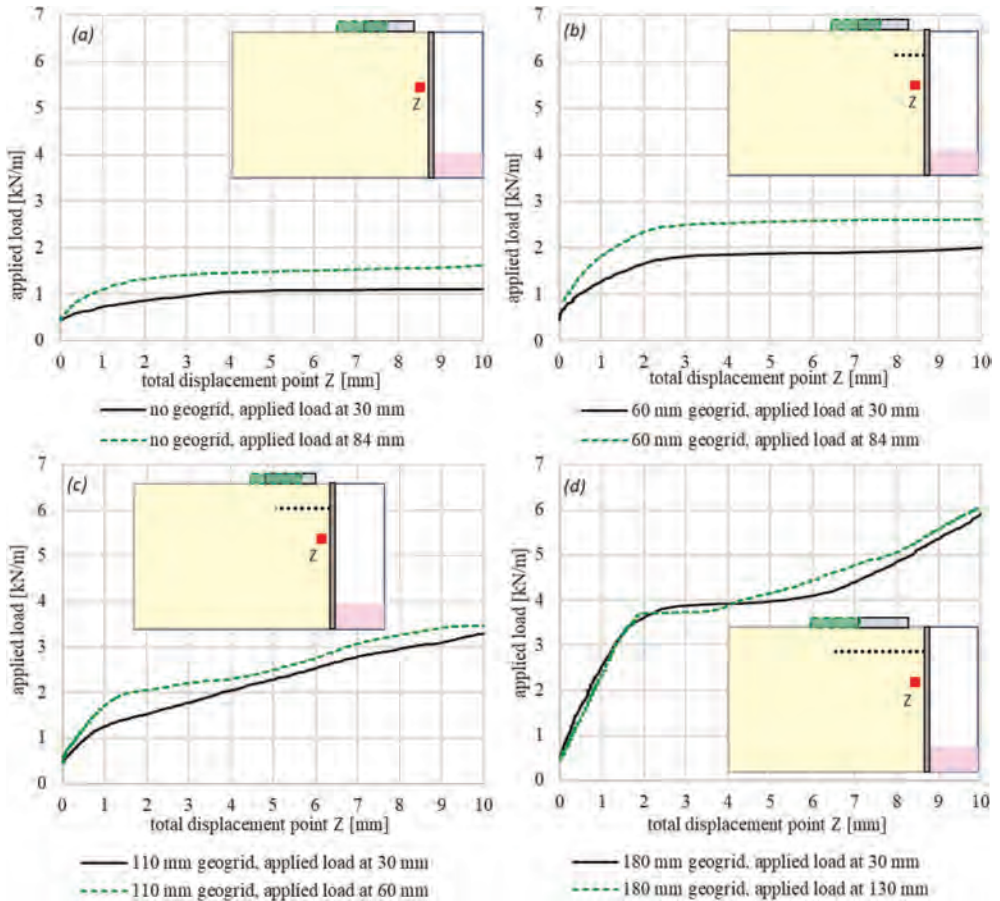
Figure 3 shows how the location of the surcharge load affects the total soil displacements close to the SPW. A greater distance between load and SPW results in stiffer behaviour, which is twofold: the wider slip surfaces mobilize more shear resistance and the load is distributed to deeper soil. The difference between Figure 3a and b is remarkable. If the surcharge load is on 84 mm from the SPW, the 60 mm geogrid falls within zone I. Nevertheless, the bearing capacity increases compared to the situation without geogrid. The geogrid therefore has a contribution, although it is located fully in zone I. The position of the surcharge load seems to have less influence for tests with longer geogrids, as shown in Figure 3c and d.


Figure 3. Influence of the location of the surcharge load (a) without geogrid (b) 60 mm geogrid (c) 110 mm geogrid and (d) 180 mm geogrid.

3.2 *Geogrid anchor length*

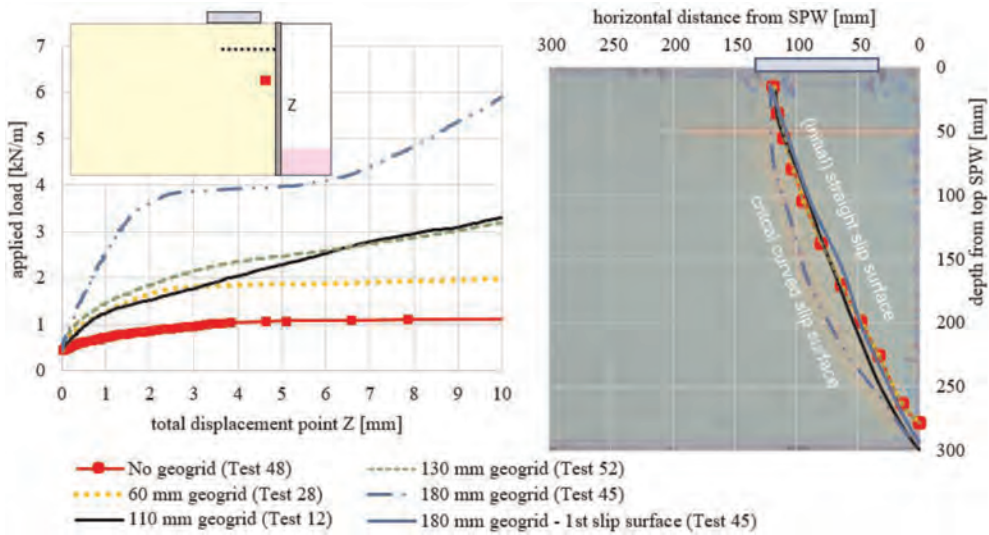
Figure 4 shows that longer geogrids provide more resistance and therefore the entire system has a higher bearing capacity. The longest geogrid initially behaves stiffer than the shorter geogrids. Figure 4b shows a straight slip surface for all geogrids. Only for the longest geogrid of 180 mm (Test 45), the slip surface crosses the geogrid and a second curved slip surface develops. The initial straight slip surface is therefore not the critical one. The geogrid is activated more efficiently, and the orientation of the slip surface at the intersection with the


Figure 4. Influence of the geogrid length. Surcharge load on 30 mm from the SPW. The background of the right-hand figure is Test 45 (180 mm geogrid).

geogrid changes. The slip surface therefore becomes longer and curved. This was also found by Ziegler (2010).

3.3 A second geogrid anchor

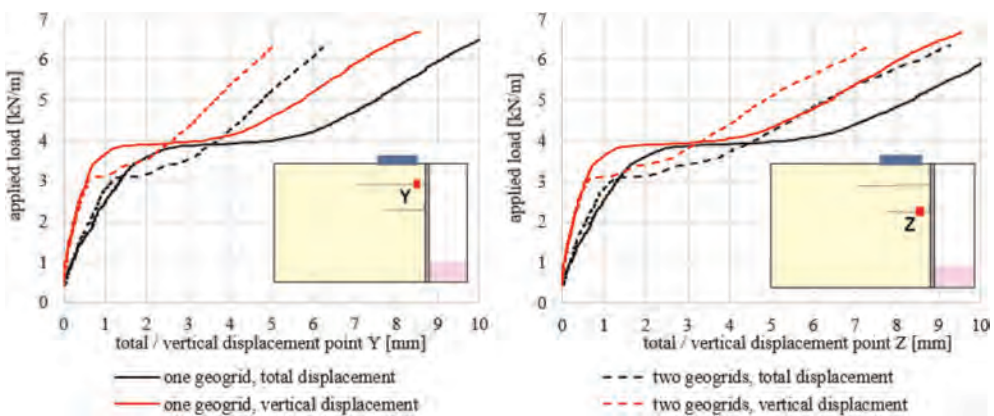
Figure 5 compares the deformations for the situation with 1 or 2 geogrids. Up to a surcharge load of 3.0 kN/m, the deformations are equal. Above 4.0 kN/m, the SPW slides along the box bottom in both tests. This failure mode is triggered by the relatively high resistance of the geogrid anchor(s). For this higher surcharge load, the second geogrid limits the deformations when the vertical pressure on the geogrids (and therefore the soil-geogrid interface friction) increase. This is in line with the findings of Schoen et al. (2023): they found with 2D FEM calculations that the geogrid anchor is more effective when installed at a lower level. Contrary to expectations, point Z settles more than point Y. The second geogrid increases


Figure 5. Load-displacement behaviour for 1 or 2 geogrids. Surcharge load on 30 mm from the SPW. Tests 45 and 22. Both tests have a 180 mm geogrid at the same position, Test 22 has a second geogrid (110 mm).
Figure 6. Slip planes for 1 or 2 geogrids.

this difference. Obviously, the geogrids limit the settlement of the soil above. Figure 6 shows how the second geogrid changes the slip surface: it becomes slightly wider and therefore longer as it circumvents the second geogrid.

3.4 Connection geogrid – sheet pile wall

The geogrid was not connected to the SPW in four tests, see Figure 7. We conclude the following:

– Connecting the geogrid increases the failure load.
– Short non-connected geogrids ≤ 130 mm do nearly not contribute to the failure load.
– Short connected geogrids ≤ 130 mm increase the failure load, although they are located in zones I and II only. So, zones I and II are only activated when the geogrid is connected to the SPW and the geogrid has moved downwards with the soil in zone II.
– Short geogrids ≤ 130 mm do not reinforce the soil, because in that case, the situation with short non-connected geogrids would provide more failure load than the situation without geogrid.
Figure 7. Difference between geogrids that are connected or non-connected to the SPW.

- The increase in failure load due to connecting the geogrids ($\leq$ 130 mm) indicates the presence of the membrane effect.
- The 180 mm geogrid, even if not connected to the SPW, contributes to the total resistance. The failure load results from the pull-out resistance in zones I and III.
- Connecting the 180 mm geogrid activates the rear part of the geogrid (zone III) more effectively and increases the failure load. However, the rear part contributes most to the total resistance at higher load levels while the geogrid is being pulled out by the sliding soil mass in zone II.
- The total resistance of a connected geogrid anchor consists of contributions of the membrane effect (zone I), frictional resistance (zone II) and pull-out resistance (zone III).

4 CONCLUSIONS

A series of small-scale tests of geogrid-anchored SPWs was conducted, leading to the following conclusions. Two slip surfaces develop, starting at the edges of the strip footing. These slip surfaces divide the reinforced fill behind the SPW into three zones: the active zone II, zone III behind the active zone and zone I between SPW and active zone. The paper analyses the contributions of each of these zones to the failure load of the structure. It is concluded that the location of the strip footing surcharge load, the length of the geogrids and the number of geogrid anchors affect the failure load of the structure. Notable findings are the reorientation of the slip surface at the intersection of the critical slip surface with the geogrids and the contribution of a very short geogrid anchor to the total resistance.

ABSTRACT: Scaled experiments were compared on geosynthetic-reinforced soil walls with a full-height facing (GRSWs) and geogrid-anchored sheet pile walls (SPWs).

A strip footing surcharge load was applied. PIV analyses showed that, in both test series, two slip surfaces developed under the strip footing load: one from the inner edge, the other one from the outer edge of the strip footing. In the GRSWs, the slip surfaces were straight, and the angle with the horizontal was approximately $\pi/4 + \varphi/2$. For the SPWs, the slip surfaces reoriented at the intersection with the geogrids and did not always remain straight.

The GRSW model behaved stiffer than the geogrid-anchored SPW model for relatively high surcharge loads. The SPW-system behaviour was also stiffer when an extra geogrid anchor was installed at a lower level. This indicates that the soil-reinforcement interface frictional behaviour determines the system behaviour more than for example the reinforcement stiffness.

1 INTRODUCTION

In many situations, strip footings are located on the backfill of retaining structures. This paper compares scaled experiments with footings on geosynthetic-reinforced soil walls with a full-height facing (GRSWs) and footings on geogrid-anchored sheet pile walls (SPWs).

The behaviour of GRSWs under a strip footing load has been studied through many full-scale physical models and laboratory model tests, including Ahmadi & Hajialilue-Bonab 2012; Ahmadi & Bezuijen 2018; Allen & Bathurst 2019 and Ahmadi 2020. These studies show that the failure mechanism of a GRSW depends on a number of factors (Ahmadi & Hajialilue-Bonab 2012; Ahmadi 2020 and Ahmadi *et al*. 2021), including: (1) the location of the footing in relation to the wall facing; (2) the type of reinforcement; (3) the number of reinforcement layers; (4) the depth to the first reinforcement layer below the footing; (5) the spacing between reinforcement layers; and (6) the dimensions of the reinforcement compared to the dimensions of the wall.

Research on geogrid-anchored SPWs is scarce. Experiments on scaled models were recently presented by Wittekoek (2020) and Wittekoek *et al*., (2022, 2023).

Geogrid-anchored SPWs are closely linked to geosynthetic-reinforced soil retaining walls with a full-height facing, as well as to traditionally anchored SPWs. However, there are notable differences causing different soil-structure behaviour. An important difference is that geogrid-anchored SPWs have more passive soil resistance than GRSWs, due to the SPWs' deeper embedment. Furthermore, SPWs have less geogrid layers compared to GRSWs.

Traditional anchors and geogrid-anchors have a different active anchor length, along which resistance is mobilised. Wittekoek (2020) and Wittekoek *et al.* (2022, 2023) proved that a geogrid anchor is also effective within the active soil wedge, when the SPW deforms or moves. This differs from what is normally assumed for traditional anchors.

Purpose of this research is to see how these two systems work. The paper analyses the slip surfaces and load-deformation behaviour of the two construction types.

2   SCALED MODELS FOR THE EXPERIMENTS

2.1   *Geogrid-anchored Sheet Pile Wall (SPW) model*

Figure 1a shows the test set-up of the small-scale experiments for the geogrid-anchored SPW. It has a scale factor of 1/16 compared to the Windpark Krammer project (Van Duijnen *et al.* 2021).

The 10 mm thick aluminium model-SPW modelled only the upper part of the embedded part of the SPW. Therefore, the SPW was free to slide along the box bottom. The polypropylene (PP) model-geogrid had a short-term stiffness of 191 kN/m at 2% axial strain and a short-term tensile strength of 16.2 kN/m at a maximum strain of 13.5%. The backfill at the active side of the SPW consisted of Baskarp B15 sand. This is a poorly graded sand, densified by manual tamping. Table 1 lists the sand properties.

A 0.1 m wide silicon block modelled the passive side. It had a stiffness of 159 kPa up to a strain of at least 8% (8 mm). The strip surcharge load was applied by loading a 0.10 m wide footing with a barrel that was filled with water during the test.
Figure 1.   Test set-up for the small-scale tests considered in this paper: (*a*) geogrid-anchored sheet pile wall (SPW), (*b*) geosynthetic-reinforced soil wall (GRSW).

Table 1. Soil and reinforcement parameters in the geogrid-anchored sheet pile wall (SPW) tests and the geosynthetic-reinforced soil wall (GRSW) tests.

Parameter	Symbol	SPW tests	GRSW tests
Coefficient of uniformity	C_u	1.6 (D_{60}/D_{10})	1.32

Short term stiffness reinforcement (kN/m)	J	191 (ε = 2%)	15 (ε < 40%)
Ultimate tensile strength reinforcement (kN/m)	T_u	16.2	8
Flexural rigidity of facing panel (kNm^2/m)	EI	5.8	28 × 10^{-3}

[*]Plane strain value as derived from triaxial test ($^{11}/_9$ · triaxial value)
[**]Plane strain value as derived from direct shear test ($\tan^{-1}(1.2\tan\varphi_d)$).

The soil-wall friction was minimized with a lubricated thin (< 1mm) transparent silicone sheet. Wittekoek *et al*. (2022, 2023) analysed how the limited width (0.1 m) of the test box and the soil-wall friction affected the results. Among other things, by comparing the results with tests in an eight times wider test box. They found similar slip surfaces, proving that the narrow box results were sufficiently reliable to analyse qualitatively.

The movement of the soil and the SPW was tracked using PIV, using the image analysis module for MATLAB, GeoPIV-GR (Stanier *et al*. 2015). The PIV results matched a number of manually tracked displacements of a number of subsets well.

2.2 Geosynthetic-Reinforced Soil Wall (GRSW) model

The GRSW experiments were done on small-scale models. They had a scale factor of 1/5 compared to the full-scale structures evaluated by Ahmadi and Bezuijen (2018). Figure 1b shows the test set-up. The models were 0.8 m high, 0.6 m long and 0.8 m wide. A surcharge load was applied with a hydraulic plunger up to 100 kN/m on a 0.2 m wide strip footing behind the facing of the models.

Table 1 lists the properties of the materials considered in this paper. Sand layers were placed every 0.025 m and compacted by a hand-held electric compactor (a Wacker vibrating plate). Reinforcement layers were placed on the surface of the compacted sand layers, at predetermined depths. Three different reinforcement types were used in this study: a highly extensible nonwoven geotextile, a less deformable geogrid and a woven geotextile. The authors are aware that a nonwoven as this one is not applicable in practical application. Nevertheless, the nonwovens were applied in these experiments to get relatively large deformations and to be able to compare different reinforcement stiffnesses.

3 COMPARING THE SLIP SURFACES FOUND IN THE EXPERIMENTS

3.1 Geogrid-anchored SPW

For the comparison between SPW and GRSW, we focus on SPW-Test 19 of Wittekoek *et al*. (2022, 2023). This test only has one 180 mm geogrid. This maximizes the difference between both systems.

Figure 2 shows the slip surfaces found in the SPW test. Figure 2a shows the soil shear strains after two-third of the test, at a surcharge load of 4 kN/m. The figure shows the general failure mechanism that was found in most geogrid-anchored SPW tests of Wittekoek et al. (2022, 2023). These tests were all subjected to a strip footing surcharge loading. It consists of two slip surfaces which develop from the inner and outer edge of the footing. The outer slip surface goes to the toe of the SPW and does not necessarily have an angle of $^\pi/_4$ $+^\varphi/_2$. It is possible that this would have been different if the SPW had been longer.

The soil first starts to slide along the critical slip surface (labelled 1A in the figure). Then, the secondary slip surface (1B) develops between zones II and I. The unstable soil mass II moves downwards and sideways due to the strip footing load. Soil mass I is enclosed by the unstable soil mass and the SPW. Wittekoek (2020) and Wittekoek et al. (2022, 2023) concluded that the slip surfaces reorient at the intersection with geogrids. This is in line with the findings of Ziegler (2010). In that case, the slip surface does not remain straight, but it becomes more curved and wider as well.

Figure 2b shows that the slip surfaces divide the soil domain behind the wall into three different strain zones:

  I.   a zone with rigid soil body motion between the wall and secondary slip surface;
 II.   an active zone below the strip footing enclosed by the secondary slip surface and the critical slip surface;
III.   the stable soil zone behind the critical slip surface.

The third small slip surface, between 1A and 1B, has been excluded from further analysis since this slip surface was seen in this specific test configuration only. Furthermore, the SPW system was approaching a state of failure prior to the development of this slip surface.

Wittekoek et al. (2022, 2023) analyses in detail the differences in behaviour between zones I, II and II. One of their conclusions is that even very short geogrid anchors, that are located in zone I only, contribute to the failure load of the system. This is because these reinforce the soil at the active side of the wall.

3.2   Geosynthetic-Reinforced Soil Wall (GRSW)

Figure 3 shows shear strains of one of the GRSW tests from Ahmadi (2020) study, which had eight nonwoven geotextile layers and a flexible facing panel. The footing was placed
Figure 2.   Slip surfaces in a geogrid-anchored SPW test: (a) soil shear strains (created using PIV) for a test with one 180 mm geogrid anchor and the load positioned 130 mm from the SPW, (b) schematisation of the general failure mechanism and the development of three different strain fields in the backfill behind the SPW. Further explanations in Wittekoek et al. (2022, 2023).
Figure 3. Slip surfaces in a GRSW test, soil shear strains in % obtained from PIV. Test set-up with a flexible facing panel and eight layers of nonwoven reinforcement: (*a*) end of backfill construction step and after releasing struts in front of the wall, (*b*) end of first series of loading steps (Ahmadi 2020).

100 mm from the facing. The pictures show the development of the slip surfaces, that eventually divide the soil into several distinct zones, including the same zones I, II and III as found in Figure 2.

Figure 3a shows the shear zones after removing the struts in front of the wall. Small strains occurred close to the facing, with peaks between the lowest reinforcement layers. This shows the confinement effect of the reinforcement layers, which is in line with the findings of Ruiken *et al*. 2010.

In Figure 3b, after applying a load of 300 kN/m^2, two failure surfaces developed. Similar to the SPW tests, these surfaces originate from the outer and inner edges of the footing. However, in this case, the surfaces are straight and consistently have an angle of $\pi/4 + \varphi/2$, as delineated by the white dashed lines. Also, the slip surfaces both intersect the facing. This shows that the full facing is high enough for the slip surfaces are free to find their location. This is different from the SPW test in Figure 2, as mentioned before.

Figure 3b shows an extra slip surface, on the left-hand side of the footing, over the second layer of reinforcement. The failure pattern is similar to the general shear failure pattern as found under shallow foundations.

4 LOAD-DEFORMATION BEHAVIOUR

Figure 4 compares the measured load-displacement behaviour of the geogrid-anchored SPW and the GRSW. This should be considered as a qualitative comparison to show how the soil-geogrid interface mechanism works between these two different models. The tests are not similar enough to compare quantitatively. However, the scale factor effects should only have limited influence, because the surcharge-induced stresses dominate the stresses in the soil mass and especially under the strip footing load.
Figure 4.   Comparison load – displacement behaviour of the geogrid-anchored SPW and the GRSW.

The figure indicates that the initial stiffness behaviour of the SPW and the GRSW is comparable. But for higher loading, the GRSW behaves much stiffer than the SPW. Ahmadi (2020) concluded that the stiffness of the reinforcement affects only to a limited extend the stiffness behaviour of the structure, as, the soil-reinforcement interface friction appeared to have more influence.

In addition to that, Wittekoek *et al.* (2022, 2023) found in their test series, that a second geogrid at a lower level only affects the stiffness behaviour for relatively high surcharge loads. These two findings match: the interface friction, and therefore, the vertical pressure on the geogrid apparently is of leading importance. This is also in line with the 2D FEM calculations of Schoen *et al.* (2023), who found that the depth of the geogrid anchor has a large influence on the stiffness behaviour, due to the larger vertical load on the geogrid anchor.

5   CONCLUSIONS

Scaled experiments were compared on geogrid-anchored SPWs and geosynthetic-reinforced soil walls (GRSWs).

For both systems, two slip surfaces developed under the strip footing load: one from the inner and another from the outer edge of the strip footing. The inclination and shape of the slip surfaces differed for the two systems. In the GRSWs, the slip surfaces were straight, with an angle of approximately $\pi/4 + \varphi/2$. For the SPW, the slip surfaces reoriented at the intersection with the geogrids and did not remain straight. The two slip surfaces divide the soil into zones I, II and III. For the SPW, even only one very short geogrid anchor, located fully in zone I, contributed to the failure load of the system.

In the considered scaled experiments, the GRSW behaved stiffer than the geogrid-anchored SPW for relatively high surcharge loads. For lower loadings the difference is less. This confirms the finding that the soil-reinforcement interface friction is leading in the system behaviour, and that this plays a more important role than for example the reinforcement stiffness. So, installing more reinforcement layers increases the ultimate strength of the construction considerably, but has a limited influence on the stiffness behaviour for small deformations.

Bearing capacity and stability analysis of geocell-reinforced slopes subjected to the footing loading

M.R. Harirsaz
Department of Civil, Environmental and Architectural Engineering, University of Padova, Padova, Italy

A. Ghanbari & Gh. Mehrjardi
Department of Civil Engineering, Faculty of Engineering, Kharazmi University,Tehran, Iran

ABSTRACT: In many cases, the foundations of structures are constructed near the edge of slopes, which may cause a lack of bearing capacity. In recent years, several studies have been carried out on the application of geocell reinforcement to enhance the global stability of slopes. However, there are limited studies on the effect of geocell reinforcement on a slope's stability when the reinforced slope is subjected to footing loadings. In this study, the positive impact of geocell reinforcement on the bearing capacity of strip footings on slopes is discussed. Also, limit equilibrium analysis has been conducted to better investigate the effect of the reinforcement on the potential slip surfaces and factors of safety. The results of the study suggest that geocell reinforcement not only enhances the bearing capacity of the footing located on the slope, but it will also improve the whole stability of the system by forcing the failure planes deeper into the underlying soil.

1 INTRODUCTION

In many cases, the foundations of structures are constructed in marginal ground conditions, which may bring about a lack of bearing capacity. This can include the construction of buildings, roads in hilly regions, and bridge abutments on the top of slopes. The improvement of the bearing capacity of these types of slopes is consequently one of the fundamental issues in foundation engineering practice since such structures are prone to slope failure. Many investigations have indicated that geosynthetic reinforcements can enhance both the ultimate bearing capacity and the settlement characteristics of the foundations located near the slope. (Alamshahi & Hataf 2009; Bathurst *et al.* 2003; EL Sawwaf 2007; Halder & Chakraborty 2018; Kakrasul *et al.* 2020; Moradi *et al.* 2019; Tavakoli Mehrjardi *et al.* 2016).

However, geocell confinement in three dimensions better minimizes the lateral and vertical movements of the soil particles compared to the geogrids and geotextiles. Several studies have investigated the mechanisms and failure modes of geocell-reinforced retaining walls and slopes. Mehdipour *et al.* (2017) and Khorsandiardebili and Ghazavi (2021) provided an analytical approach to calculate the safety factor of geocell-reinforced slopes. Also, Ardakani and Namai (2021) performed a numerical study to evaluate the behavior of geocell-reinforced slopes using FLAC 3D. Chen and Chiu (2008) investigated the behavior of geocell-reinforced retaining walls. Chen *et al.* (2013) showed that the failure modes of the gentler geocell-reinforced walls consist of a few slides passing along the interface between geocell layers, while that of the steep vertical walls revealed both modes of interlayer sliding and overturning failure. Song *et al.* (2018), via centrifuge model tests, found that when the slope inclination is relatively large, the sliding wedge propagates near the slope crest.

Kazemi *et al.* (2022) indicated that the optimum depth of the placement of the first geocell layer for both single and double-layer geocell reinforced slopes was found to be independent of the length of the geocell. Although several studies have been conducted to evaluate the behavior of the geocell-retaining walls under self-weight or surcharge, there are few studies on the effect of footing loading on the stability of the geocell-reinforced slopes. In this study, the positive impact of geocell reinforcement on the bearing capacity of strip footings on slopes is discussed. Also, a numerical study has been conducted to investigate the effect of the reinforcement on the potential slip surfaces and factors of safety.

2 EXPERIMENTAL STUDY

2.1 *Backfill material*

The soil used in this study as backfill material was uniformly graded gravel (GP) with a specific gravity of 2.64 and maximum and minimum dry density of 16.64 and 13.32 kN/m^3. The medium particle size of grains (D_{50}) and effective particle size (D_{10}) are 7 and 3.52 mm respectively. Moreover, the coefficient of uniformity (C_u) and the coefficient of uniformity (C_c) are 2.12 and 1.13.

2.2 *Geocell*

The Geocell used in the tests, made of heat-bonded non-woven geotextile, had a pocket size of 110mm × 110mm and a height (H) of 50 mm, respectively. The pocket size (d_g) is defined as the diameter of an equivalent circular area (d_g = 110mm). The geocell used in the study is made of non-woven polyethylene. The density of the geocell is 0.47 g/cm3. The tensile strength of the strip is 13 kN/m^3 and the elongation is 55% at maximum strength. Figure 1 illustrates a prototype view of the backfill materials and geocell.

2.3 *Performing experiments*

Figure 2(b) shows the schematic of the physical test setup and its attachments consisting of a testing tank, loading system, and data measurement system. The load was transferred to the footing through the hand-operated hydraulic jack and pre-calibrated load cell mounted on the base plate with dimensions of 650 × 150 × 30 mm. In this study, the edge distance (D) of 0.5 B was selected. The hydraulic jack applied the loading via a pre-calibrated load cell with a capacity of 10000 kg and an accuracy of ±0.02% of full scale. All the model-footing tests were performed with a relative density of 70%. In all tests, firstly, soil embankment with the

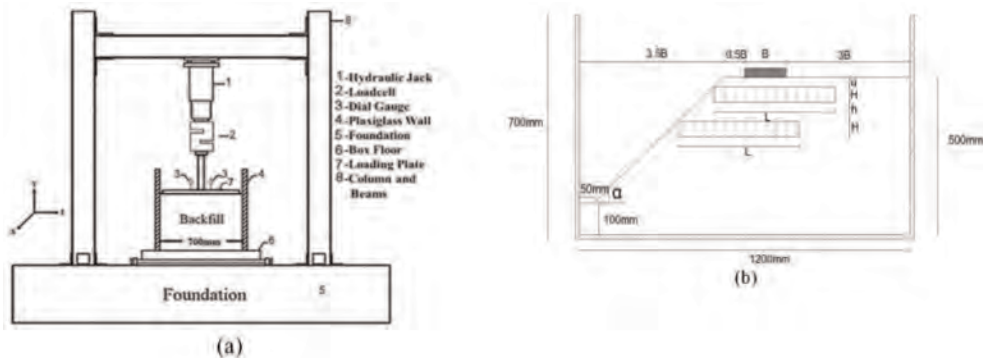
Figure 1.   A view of installed geocell in the backfill.


Figure 2. Schematic representation of the test setup (a) Y-Z section, and (b) X-Y section (Not to scale).

plane surface was constructed in layers of 50 mm thickness to reach 500 mm height. Figure 2 (a) shows the geometry of the slope backfill. The embankment was trimmed to achieve a slope backfill with an angle (α) of 40°. Throughout the tests, to investigate any possible rocking or tilting of the footing, settlements were monitored by two dial gauges with an accuracy of 0.01% of the full range (50 mm), located on opposite edges of the loading plate.

3 RESULTS AND DISCUSSION

3.1 *Experimental modeling*

To investigate the impact of geocell reinforcements on the response of the strip footing situated on the sloped backfill, a testing program was established. In this regard, two reinforced experimental tests were performed to examine the behavior of geocell-reinforced slopes using one and two layers of reinforcement in addition to the unreinforced slope condition and a test on the plane surface (plain condition). It should be clarified that the burial depth(u) of the first layer is 0.1B and the vertical distance between the first and the second layer (h) is 0.2B. Also, the length (L) of the geocell in the both single-layered geocell reinforced slope and the double-layer reinforced slope is 3B. In order to consider how much the improvement technique is effective in enhancing slope stability, the factor of slope influence I_f is defined by Equation 1. In this equation $(q)_r$ and $(q)_{un}$ are the bearing pressure of "reinforced" and "slope" backfills for the equivalent settlement ratio, respectively.

$$I_f = \left(\frac{(q)_r}{(q)_{un}} \right) \tag{1}$$

As can be seen in Figure 3 the diagram related to the slope reinforced with one layer of geocell has a significant vertical distance from the unreinforced slope. Table 1 shows the variation of I_f for different settlement ratios for slope reinforced with one and two layers of geocell reinforcement.

As it is indicated in Table 1, for the slope reinforced with one layer, I_f yields the value of 1.41 for S/B = 5% whereas it climbed to 2 for S/B = 15%. It is worth noting that due to the presence of coarse soil grains inside geocells, in larger settlements, the dilation of soil particles will result in better confinement of soil particles, leading to higher relative improvement in bearing capacity.

According to Figure 3 arguably there is a significant gap between the response of the reinforced slope and the plane condition. To lessen this gap, double-layer geocell reinforcement was examined. Figure 3 shows that the double-layer geocell reinforced slope diagram intersects with the plane condition for the range of settlements up to approximately 9 percent indicating
Figure 3. Bearing capacity diagram of geocell reinforced with one and two geocell layers.

Table 1. Improvement factors of the geocell slope reinforced slopes.

Settlement	Single-layer reinforced slope	Double-layer reinforced slope
(I_f) $S/B = 5\%$	1.41	1.73
(I_f) $S/B = 10\%$	1.59	1.84
(I_f) $S/B = 15\%$	2	2.29

that the response of the double-layer system has considerably improved in comparison with the single-layered reinforcement. Table 1 shows that in the case of the double-layer geocell reinforced slope the I_f values for S/B = 0.1 and S/B = 0.15 are 1.84 and 2.26, which are significantly higher than the equivalent values for single-layer reinforced slope. In the case of using two layers of reinforcement, the first layer exerts pressure on the second layer which spread the pressure on the bottom layers. This results in preventing the formation of shallow failure planes, leading to a meaningful increase in the bearing pressure capacity of the slope.

3.2 Limit equilibrium analysis

In order to compare the factor of safety in reinforced and unreinforced conditions a limit equilibrium analysis of the slope condition has been done using the Spencer method. To evaluate the factor of safety of unreinforced slope and single-layer and double-layer geocell reinforced slope, it is necessary to model the geocell layer as a layer with the same friction angle as the granular material and the equivalent cohesion. Madhavi Latha *et al.* (2006) calculated the membrane stresses developed in the walls of the geocell ($\Delta\sigma_3$) using the hoop tension theory (Henkel & Gilbert 1952) to estimate the apparent cohesion. Equation 2 shows the formula to calculate the apparent cohesion due to confinement provided by geocell where K_p is the coefficient of passive earth pressure.

$$C_r = (\Delta\sigma_3/3)\sqrt{K_p} \tag{2}$$

The geocell layer has a friction angle of 43° and equivalent cohesion of 17.33. A surcharge of 200 kN/m^3 was applied on the footing. Figure 4 shows the failure wedge for the unreinforced slope, the reinforced conditions, and also the factors of safety. The factor of safety for the

unreinforced slope is 1.19 which shows medium stability. As can be seen, for reinforced slopes failure wedge tends to form at greater depth compared to unreinforced slopes, which is consistent with previous findings. (Bathurst *et al.* 2003; Mehdipour *et al.* 2013; Tavakoli Mehrjardi *et al.* 2016). Figure 4 depicts that the potential failure surface has been expanded horizontally and vertically for the case of the double-layer geocell reinforced slope yielding a factor of safety of 4.19. This notable increase in the factor of slope stability is because the presence of two geocell-reinforced layers can have a more significant effect on the shear strength characteristics of the slope. To better illustrate this, according to Figure 3 when the double-layer geocell reinforced slope is subjected to the surcharge of 200 kN/m^3 the load bearing capacity of the slope is similar to the plane condition which indicates noticeable stability is predictable in this case.

Considering the fact a small-scale experimental model has been used in this study, it is important to note that in general, small-scale models tend to experience higher stresses than full-scale models which is due to the phenomenon called scale effects. However, for granular soils, the difference in soil stress between a small-scale and full-scale model is less pronounced due to the nature of the soil compared to cohesive soils.
Figure 4. limit equilibrium analysis of the experimental models under the surcharge of 200 kN/m^3. a) Unreinforced slope b) Single-layer reinforced slope c) Double-layer reinforced slope.

4 CONCLUSION

In this article, the behavior of the slopes reinforced with one and two layers of geocell under a surcharge was investigated. The main objective of the experiments was to investigate the effect of using the geocell to improve the bearing capacity and reduction of the settlement of footing located near the slope edge. Also, a numerical study has been conducted to investigate the effect of the reinforcement on the potential slip surfaces and factors of safety. The results of this study are as follows.

Geocell provides anchorage length behind the failure wedge and increases the bearing capacity of soil by reducing the lateral movement of soil particles surrounded by the geocell pockets.

The relative positive impact of the geocell reinforcement in improving the load-bearing behavior of the granular slope increases as the settlement ratio rises due to the mobilization of dilation characteristics of granular backfill material and better lateral confinement of soil grains by geocell in larger pressures.

In the case of the double-layer geocell reinforced slope, the redistribution of pressure over deeper layers of soil causes the load-bearing capacity diagram to intersect with the load-bearing capacity of a plane condition in low settlements.

Geocell reinforcement redistributes the pressure over deeper layers of soil, causing the failure wedge to expand and increasing the factor of safety compared to unreinforced slopes.

As with other studies, the results of this research were influenced by experimental conditions. For instance, the results were obtained for only one type of reinforcement, one type of soil, and one width of the footing. Specific applications should only be made after considering the above limitations. Nevertheless, this study provided insight into the basic mechanism that establishes the behavior of slope reinforced by geocell under static loads, which may be used to guide further studies.

Influence of geometric configuration on the interaction of back-to-back MSE walls under static loading

F. Li, W. Guo & Y. Zheng*
Wuhan University, Wuhan, China

ABSTRACT: Back-to-back mechanically stabilized earth (MSE) walls are commonly used for ramp ways and bridge approaches. The behavior of back-to-back MSE walls is significantly influenced by the geometric configuration, especially the horizontal distance (i.e., width-to-height ratio) of the wall. This paper presents a numerical study on the behavior of back-to-back MSE walls to investigate the influence of horizontal distance on the interaction. Numerical simulations were conducted with different width-to-height ratios. Results indicate the horizontal distance has significant influences on the static behavior of back-to-back MSE walls. The lateral soil thrust behind the reinforced soil zone, the required reinforcement strength, and the vertical toe load generally increase with increasing horizontal distance up to a critical value. The Federal Highway Administration (FHWA) simplified method significantly overestimates the required reinforcement tensile strength, but underestimates the lateral soil thrust for the range of horizontal distances involving interaction between the back-to-back MSE walls.

1 INTRODUCTION

As an important derivative structure of mechanically stabilized earth (MSE) walls, back-to-back MSE walls consist of two opposing MSE walls in a back-to-back configuration. Back-to-back MSE walls can save more space than traditional embankments and are commonly used for ramp ways and bridge approaches (Anderson *et al.* 2018).

The behavior of back-to-back MSE walls is significantly influenced by the geometry. The geometrical configuration of back-to-back MSE walls is typically described in terms of the horizontal distance (D) between the back of the reinforced soil zone of the two MSE walls or the width-to-height ratio (R_{WH}) of the system, which is defined as the system width W divided by the wall height H. In the Federal Highway Administration (FHWA) design guidelines (Berg *et al.* 2009), two cases are considered based on the horizontal distance of the two MSE walls. For Case I, the distance between two MSE walls is large enough so that the two walls do not affect each other and can be designed independently assuming the full active soil thrust could be mobilized. The theoretical critical distance is $D_t = H\tan(45°\text{-}\phi/2)$, which corresponds to the theoretical critical width-to-height ratio $R_t = 1.4 + \tan(45°\text{-}\phi/2)$. For Case II, when the overlapping reinforcement length is greater than $0.3H$, no active soil thrust needs to be considered for external stability. For horizontal distances between Case I and Case II, the active earth thrust can be linearly interpolated from the full active condition to zero. However, no justification is provided for this assumption. Therefore, research is needed to investigate the interaction of back-to-back MSE walls with different horizontal distances.

Several numerical studies have been performed on the static behavior of back-to-back MSE walls (Benmebarek & Djabri 2017; El-Sherbiny *et al.* 2013; Han & Leshchinsky 2010). Han & Leshchinsky (2010) conducted numerical study of back-to-back MSE walls with

---

*Corresponding Author: yzheng@whu.edu.cn

width-to-height ratios R_{WH} ranging from 1.4 to 3.0, and the results indicate that the FHWA design guidelines underestimates the interaction distance. El-Sherbiny *et al*. (2013) found that the interaction effect on failure surface is not significant for horizontal distance greater than $0.5H$. Benmebarek & Djabri (2017) found that the factor of safety increases significantly with increasing overlapping reinforcement length. The above numerical studies generally indicate that ignoring the interaction effect between the back-to-back MSE walls would result in overestimation for the design; however, no quantitative evaluation is provided regarding the interaction of back-to-back MSE walls.

This paper presents a numerical study of the interaction analysis of the static behavior of back-to-back MSE walls. A parametric study is conducted to investigate the effect of width-to-height ratio. Results provide insights regarding the interaction of back-to-back MSE walls in terms of lateral soil thrust, required reinforcement strength, vertical toe load, and factor of safety.

2 NUMERICAL MODEL

A parametric study is performed to evaluate the effect of width-to-height ratio R_{WH} on the static behavior of back-to-back MSE walls with modular block facing. For all the models, the back-to-back MSE walls have a height of $H = 6.0$ m, reinforcement length of $L = 0.7H = 4.2$ m, and vertical spacing of $S_v = 0.6$ m. Only the horizontal distance between the two MSE walls changes, as shown in Table 1, and the corresponding width-to-height ratios range from 0.9 to 4.0.

Table 1. Geometrical configuration of back-to-back MSE walls for baseline case series.

Geometrical Parameter	Value									
Width-to-Height Ratio[1], R_{WH}	0.9	1.1	1.25	1.4	1.65	1.9	2.2	2.5	3.0	4.0
Horizontal Distance, D (m)	−3.0	−1.8	0.9	0	1.5	3.0	4.8	6.6	9.6	15.6

[1]defined as the width of back-to-back MSE walls divided by wall height, W/H.

2.1 *Finite difference grid and boundary conditions*

The finite difference program FLAC was used to investigate the behavior of back-to-back MSE walls at the end of construction. Figure 1 shows the finite difference grid and boundary
Figure 1. Finite difference grid and boundary conditions of back-to-back MSE walls.

conditions of the back-to-back MSE walls with width-to-height ratio $R_{WH} = 1.9$. The back-to-back MSE walls have a total width $W = 11.4$ m and horizontal distance $D = 3.0$ m between the two opposing MSE walls. The foundation was 12 m ($2H$) depth. The bottom boundary of foundation was fixed in both the horizontal and vertical directions. The left and right sides were fixed in the horizontal direction but free in the vertical direction.

2.2 *Materials interfaces*

The modular blocks were modeled as a linear-elastic material with Young's modulus $E = 31.5$ GPa and Poisson's ratio $\nu = 0.2$. Geogrids were modeled using linearly elastic-plastic cable elements with tensile stiffness $J = 1000$ kN/m. The foundation soil was simulated using a linear elastic-plastic model with $E = 160$ MPa and $\nu = 0.3$, friction angle $\phi = 40°$, and cohesion $c = 0$ kPa. The backfill soil was modeled as a nonlinear elastic-plastic material with the Duncan-Chang hyperbolic relationship and the Mohr–Coulomb failure criterion. This approach has been used successfully in many previous studies on geosynthetic reinforced soil structures (e.g., Zheng & Fox 2016; Zheng *et al.* 2018). The hyperbolic parameters for the backfill soil were selected based on data of granular soils reported by Duncan *et al.* (1980) are listed in Table 2.

The interaction between different materials (e.g., soil-block and block-block) was modeled through interface elements considering Coulomb sliding behavior. The soil interface strength was related to the shear strength parameters of the backfill soil using a strength reduction factor, and the block-block interface parameters were selected based on reported data in the literature. This approach and the parameters were reported by Zheng *et al.* (2018).

Table 2. Parameters for backfill soil.

γ (kN/m^3)	K	K_{ur}	n	R_f	K_b	m	c (kPa)	ϕ (°)	ψ (°)
21.9	1780	2136	0.39	0.67	1300	0.16	0	34	4

2.3 *Modeling procedures*

The numerical model of the back-to-back MSE walls was constructed in stages. The foundation soil was first solved to an equilibrium state under gravitational forces. The walls were constructed in lifts with each lift consisting of facing blocks, soil layer, reinforcements, and interfaces.

3 RESULTS AND DISCUSSION

3.1 *Lateral soil thrust*

Figure 2(a) show the effect of width-to-height ratio R_{WH} on profiles of the lateral soil stress behind the reinforced soil zone. Lateral stresses generally increase with increasing depth, and the maximum values occur near the bottom of the wall. For $R_{WH} \geq 1.9$, lateral soil stresses are essentially similar. The active failure wedge could be fully developed for these cases with large horizontal distances, and the interaction effect between the back-to-back MSE walls is negligible.

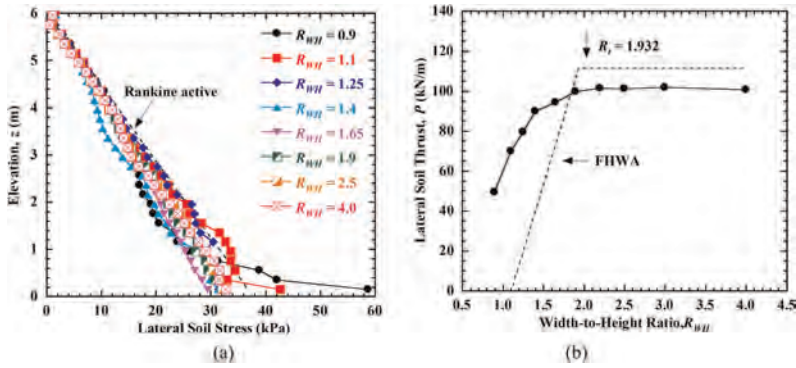
Figure 2(b) shows the lateral soil thrust behind the reinforced soil zone. Lateral soil thrust increases significantly from 49.3 kN/m at $R_{WH} = 0.9$ to 89.8 kN/m at $R_{WH} = 1.65$. For these cases, the overlapping reinforcement layers result in strong interaction effect between the two opposing MSE walls. As longer reinforcement layers could provide more anchorage resistance, which would reduce the lateral soil thrust. With increasing horizontal distance, lateral soil thrust further increases mildly to 99.7 kN/m at $R_{WH} = 1.9$, and then remains nearly constant at approximately 100 kN/m for larger distances. The failure wedge could be fully developed for $R_{WH} \geq 1.9$, and the full active soil thrust could be mobilized. Therefore, the interaction effect of the two opposing MSE walls on lateral soil thrust could be ignored for these conditions.


Figure 2. Effect of width-to-height ratio on lateral soil stresses behind reinforced soil zone: (a) lateral soil stress profiles; (b) lateral soil thrust.

3.1 Vertical toe load

The vertical toe load is important for the external stability of MSE walls. The vertical toe load factor is defined as the ratio of the total vertical load divided by the self-weight of wall facing. Figure 3 show the vertical toe load factor for different width-to-height ratios. The vertical toe load factor first increases significantly from 1.85 to 2.02 when the width-to-height ratio increases from 0.9 to 1.65, and then the factors are close to 2.02 for larger ratios. For width-to-height ratio $R_{WH} \leq 1.65$, vertical toe load factors generally increase with increasing distance, but the effect becomes less significant. As the overlapping reinforcement layers could provide anchorage resistance when the horizontal distance is small, which reduce the shear stress on the back of facing and the down drag forces from the connected reinforcements. For the back-to-back MSE walls with $R_{WH} > 1.65$, the vertical toe load factors are nearly constant.
Figure 3. Effect of width-to-height ratio on vertical toe load factor.

3.2 Required reinforcement strength

Figure 4(a) shows the effect of the width-to-height ratio on the maximum reinforcement tensile force profiles, and the reinforcement tensile forces calculated using the FHWA simplified method are also presented for comparison. The maximum tensile force profiles for different width-to-height ratios have similar shapes. The maximum value increases gradually from the top of the wall to the highest value at approximately $z = 1.5$ m, and then decreases slightly toward

the bottom. In addition, the maximum tensile forces generally increase with increasing distance, but the effect becomes less pronounced. The maximum tensile forces are essentially the same for the cases with $R_{WH} \geq 1.65$, and the interaction between the MSE walls has little effect on the internal stability. Simulated maximum tensile forces are close to the calculated values using the simplified method in the upper section but have increasing deviations toward the bottom.

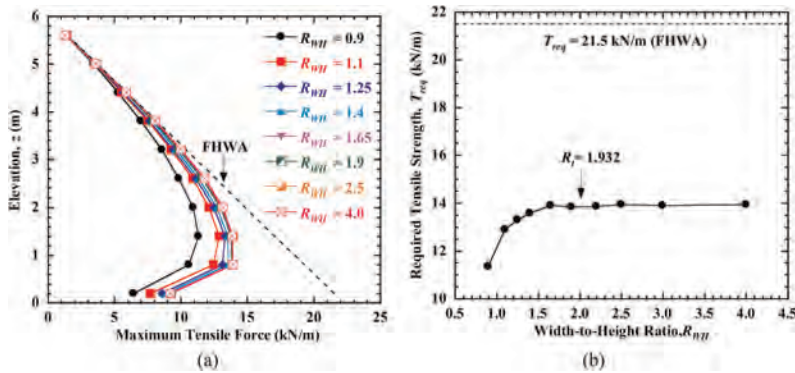
The required reinforcement tensile strength T_{req} is the maximum value of each maximum tensile force profile and is plotted versus the width-to-height ratio in Figure 4(b). The required reinforcement strength increases nonlinearly from 11.3 kN/m to 13.9 kN/m when the width-to-height ratio increases from 0.9 to 1.65, and then remains nearly constant at approximately 14 kN/m for larger ratios. The critical width-to-height ratio for constant required reinforcement strength of the back-to-back MSE walls is approximately 1.65. The calculated required tensile strength using the simplified method is 21.5 kN/m, which is much larger than the simulated maximum values. In addition, the simplified method does not account for the interaction of the back-to-back MSE walls, which would result in even larger overestimation for the cases with smaller width-to-height ratios that involve strong interaction. In general, the simplified method is overconservative for the internal stability design of back-to-back MSE walls.


Figure 4. Effect of width-to-height ratio on reinforcement tensile force: (a) maximum tensile force profiles; (b) required tensile strength.
Figure 5. Effect of width-to-height ratio on factor of safety.

3.3 Factor of safety

Figure 5 shows the effect of width-to-height ratio on the factor of safety. The factor of safety against shear failure was obtained using the strength reduction method. The factor of safety

decreases nonlinearly from 3.193 to 1.748 when the width-to-height ratio R_{WH} increases from 0.9 to 1.65, and then remains nearly constant at approximately 1.72 for larger ratios. For the cases with $R_{WH} \leq 1.4$, the overlapping reinforcement layers result in strong interaction effect between the back-to-back MSE walls, and longer overlapping reinforcement could provide more anchorage resistance, resulting in a greater factor of safety. In general, the effect of interaction becomes smaller with increasing horizontal distance, and the interaction could be ignored for horizontal distance greater than a critical value.

4 CONCLUSIONS

This paper presents a numerical study of the interaction analysis of back-to-back MSE walls under static loading. A parametric study was conducted to investigate the effects of horizontal distance on the back-to-back MSE walls. Simulation results indicate that the lateral soil thrust behind the reinforced soil zone, the required reinforcement tensile strength, and the vertical toe load increase nonlinearly with increasing horizontal distance to a critical value, and then remain nearly constant for larger distances. The FHWA simplified method is overconservative for the required reinforcement tensile strength, but underestimates the lateral soil thrust involving interaction of back-to-back MSE walls.

ABSTRACT: In the last decades, geosynthetic reinforcement has been widely used in geotech-nical applications. Recently, geogrid has also been used to back-anchor sheet pile walls. However, this system has not received sufficient attention neither in research nor in construction. Due to the complex interactions between soil, geogrid and sheet pile wall, the applicability of common design guidelines for conventionally back-anchored walls to this particular system has to be proven. To develop a fundamental understanding about the influence of various components of the system on its behaviour, numerical investigations have been conducted within this study. In this paper the influence of geogrid inclination, design of geogrid-sheet pile connection including prestressing and geogrid position on the earth pressure distribution and wall deformation is discussed. The numerical results revealed that the position of geogrid and design of geogrid-sheet pile connection significantly affect the earth pressure distribution. The wall deformations are mainly influenced by the geogrid position.

1 INTRODUCTION

For many years, sheet pile walls have been key construction elements in the design of excavation pits and any types of marine constructions such as ship lock, cofferdams or wharfages. Sheet pile walls can be designed as unsupported walls with fixation in the soil. The use of unsupported sheet pile walls for large retaining heights often leads to large deformations, high embedment depths and thicker sheet pile profile, thus to uneconomical solutions. Therefore, the use of a support system e.g. anchors is selected to obtain a more economical designs. Depending on the boundary conditions, different types of support-systems are possible.

In the case of excavation pits, grouted anchors are often used. In bank construction with backfilled sheet piles, steel anchors with anchored plates or similar constructions are used. A newly alternative to this is the support with a geogrid (Detert *et al*. 2022; Van Duijnen *et al*. 2020, 2022). In this case, individual geogrids are inserted into the soil during backfilling and connected to the sheet pile wall, thus increasing the load-bearing capacity of the sheet pile wall. The advantages of this method are the easy installation as well as the support acting all along the wall, not like punctual support every few meters with anchors. Therefore, it is an economical alternative to other support systems and was therefore used in 2018 in the Netherlands at the Kramer wind park.

However unlike e.g. conventional anchor systems, the geogrid interacts with the soil along its full length. This results in complex interactions that need to be investigated in detail. The aim of this research is to develop a numerical model that can simulate these interactions with the use of the finite element method and can be used to better understand the whole support system. Furthermore, the influence of different design variables, such as anchor length, on the earth pressure distribution and wall deformation will be analyzed in the following chapters.

2 NUMERICAL MODELLING

For a better understanding of the sheet pile wall geogrid system, small-scale tests (Wittekoek *et al*. 2023) and full scale test (Van Duijnen 2022) have been performed. These tests have been simulated using Plaxis 2D and the system behaviour detected from the numerical model was in a good agreement to the laboratory observations (e.g. in Wittekoek *et al*. 2022). Based on these observation, the creation and the main features of the finite element simulation in prototype scale are described in the following section.

2.1 *Finite element model*

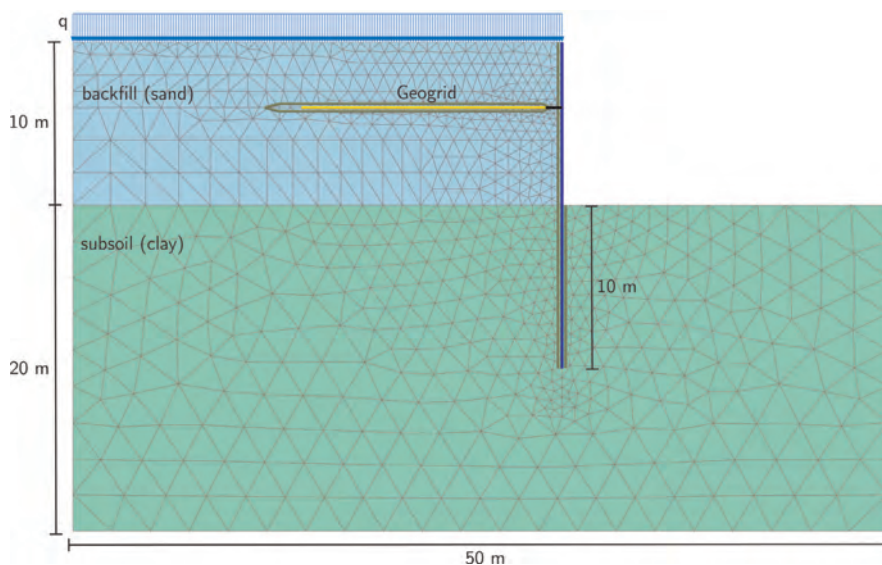
Since sheet pile constructions are line structures, a 2D finite element simulation in plain strain is sufficient, wherefore the numerical model was created in finite element code Plaxis 2D. As shown in Figure 1 the sheet pile wall is embedded in a clay soil layer and is supporting a 10 m thick backfill layer of sand. The geogrid is located in this backfill and connected to the wall. The selection of the model dimension was based on the recommendation from EANG (2014). Thus, twice the backfill height was chosen for the lateral distances from the sheet pile wall to the model boundaries. The distance between the bottom of the excavation pit and the bottom edge of the model was also chosen accordingly. The sheet pile wall was modeled as a plate element and the soil as a volume element. An interface was placed between the wall and the soil to allow a realistic sheet pile wall-soil interaction as well as between geogrid and soil. In Plaxis geogrids exist as a structural element, which is a 5 node line element with two degrees of freedom *(ux,uy)* in each node. The only material constant is the elastic axial stiffness *EA*. To realistically account for the membrane effect of the geogrid, the finite element mesh must be updated during the simulation.


Figure 1.   Finite element model of sheetpile wall with geogrid.

Table 1. Constitutive parameters of hardening soil model used in finite element simulation.

Name	Parameter	Sand	Clay
E_{50}^{ref} (kPa)	Secant stiffness	35000	52500
E_{Oed}^{ref} (kPa)	Tangent stiffness	35000	52500
E_{ur}^{ref} (kPa)	Unloading/reloading stiffness	105000	157500
m (-)	Power coefficient	0.5	0.5
ν_{ur} (-)	Poissons's ratio	0.20	0.20
K_0^{nc} (−)	K_0 value for normal consolidation	0.5	0.6580
R_f (-)	Failure ratio	0.9	0.9
p^{ref} (kPa)	Reference stress for stiffness	100	100

The hardening soil model (Schanz 1998) was used to obtain a more realistic stress-strain behavior of the soil. The hardening soil model has a double hardening yieldsurface, stress-dependent stiffnesses and Mohr-Coulomb (MC) failure criterion. An important detail of the finite element model is the prestressing of the geogrid. On the construction side the geogrid will be inserted and covered with soil, except 1 m close to the sheet pile wall to allow the prestressing. The geogrid is then pulled towards the sheet pile wall using an excavator, where it the wall, creating a prestress. A slight pre-stressing is needed in-situ to allow a force-fit connection to the sheet pile wall, which should prevent the geogrid from slipping under load. In the finite element model two types of geogrid-sheet pile wall connections were simulated. First the installation and the prestressing of the geogrid was performed close to the reality and is shown in Figure 2. Instead of pulling the geogrid, which showed unrealistic results, a spring element between geogrid and sheet pile wall is used to apply the prestressing. Note, along the length of the spring element no interaction between the reinforcement and the soil takes place. Secondly, the geogrid is directly connected to the wall without prestressing.

The construction of the sheet pile wall as well as the installation and prestressing of the geogrids is modeled by the following 12 construction stages/phases:

Phase 1: Applying geostatic pressure on initial soil (clay)
Phase 2: Activation of sheet pile wall and interface
Figure 2. Phases of prestressing of the geogrid in finite element model (Description see text).

Phase 3: Backfilling from -10.0 m to -8.0 m

Phase 4: Backfilling from -8.0 m to -6.0 m

Phase 5: Activation of geogrid with interface and spring (s. Figure 2)

Phase 6: Placing of backfill on the geogrid with a thickness of 1.0 m (Figure 2)

Phase 7: Generate a prestressing force $p = 20$ kN/m in the spring element (Figure 2)

Phase 8: Backfilling the spring - entire area behind the wall is backfilled up to -5.0 m (Figure 2)

Phase 9: Backfilling from -5.0 m to -4.0 m

Phase 10: Backfilling from -4.0 m to -2.0 m

Phase 11: Backfilling from -2.0 m to -0.0 m

Phase 12: Activate uniform load q = 10,0 kN/m

3 RESULTS AND DISCUSSION

The influence of geogrid inclination, geogrid-sheet pile wall connection and the geogrid depth on the resulting earth pressure and wall deformation will be analysed in the following subsections.

3.1 Influence of geogrid inclination

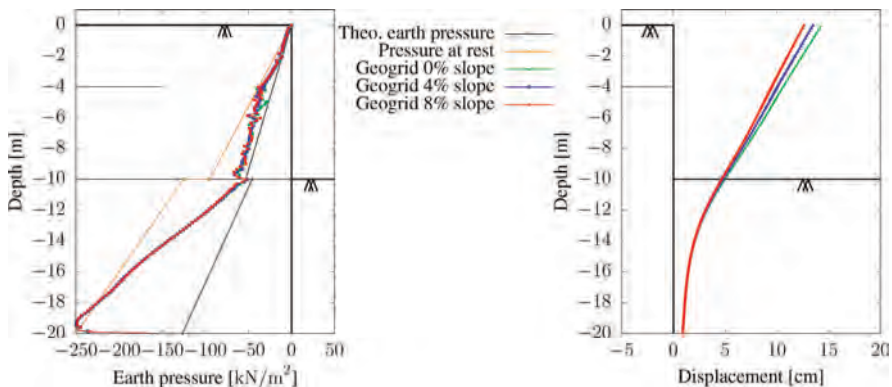
The influence of geogrid inclination in retaining a sheet pile wall is investigated in the following. Therefore, the geogrid position is kept constant at -4 m and only the inclination is varied. Figure 3 shows both, the earth pressure distribution and the related sheet pile deformation for three exemplary geogrids with different inclinations (0%, 4% and 8%) and all prestressed with 20 kN/m. It can be seen that for all three inclinations an almost identical earth pressure develops over the entire height. The magnitude of this is slightly higher than the active theoretical earth pressure within the backfilled area and increases in the area of the sheet pile confinement, so that at the base of the wall the earth pressure generated is as great as the theoretical earth pressure at rest. If the associated displacements of the sheet pile wall are compared, a noticeable difference can be seen. The fact that the use of a geogrid with a greater.


Figure 3. Earth pressure distribution on active side (left) and resulting wall deformation (right) for variation of the geogrid angle in vertical direction.

3.2 Influence of numerical solution for the wall connection

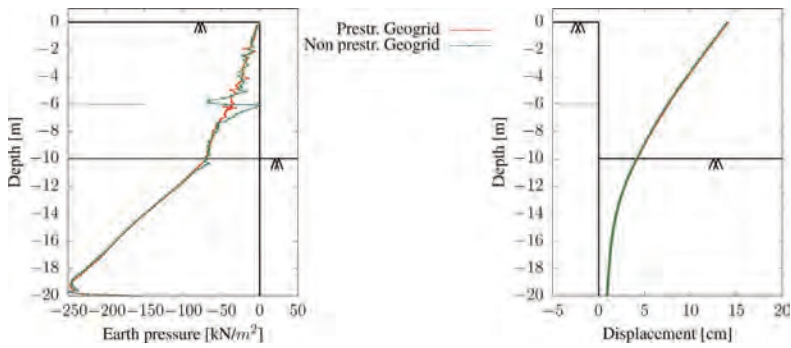
As mentioned before, the pre-stressing on site is needed to connect the geogrid perfectly straight and force-fit to the sheet pile wall. Since this is not necessarily needed for finite element modeling, the influence of the wall connection on the earth pressure distribution as well as on the wall deformation was investigated. As shown in Figure 4, the earth pressure distribution and the wall deformation are very similar. However, it is noticeable that the


Figure 4. Effect of wall connection for a geogrid at -6 m on earth pressure distribution on active side (left) and resulting wall deformation (right).

calculation without pre-stressing gives jumps in the earth pressure distribution at the height of the geogrid connection. This can be explained by the shielding effect of the geogrid below the connection point. Above the connection point an increase of the earth pressure is visible, which can be explained by local arching effects. The use of a spring eliminates this shielding and arching effects and therefore these jumps are not visible in the earth pressure distribution of the model with prestressing. Which of these wall connection types should be used depends on the in-situ connection of the geogrid to the wall. In the following it is assumed, that the geogrid is installed close to the wall and only a short construction for the connection is designed, so the variant with direct connection is used for further simulations.

3.3 Influence of geogrid position

In order to analyze the influence if the geogrid position, different finite element models of the sheet pile walls retained by geogrids were created, in which the depth of geogrid placement was varied. In this publication only three exemplary variants, with the depths of -6.0 m, -4.0 m and -2.0 m are presented. Figure 5 shows the calculation results of the three models with different insertion depths of the geogrid. The earth pressure distribution in the clay layer is nearly identical in the section between -15.0 m and -20.0 m. In the upper 5 m of clay layer, higher earth pressure occurs for deeper geogrid position, which also occurs in the backfilled area from -7,0 m to -10 m. Above this depth, all three variations generally exhibit an identical earth pressure distribution. When comparing the three variations, it can be seen that the
Figure 5. Earth pressure distribution on active side (left) and resulting wall deformation (right) for variation of the geogrid position in vertical direction.

geogrid positions -4 m and -6 m provide an almost identical displacement at the top, whereas the geogrid position -2 m has a significantly higher deformation. To explain this, the wall displacement for all calculation phases of the three variations is shown in Figure 6. Comparing the geogrid positions -4 m and -6 m, shows that the initial deformation prior activating the geogrid in the case of the geogrid at -6 m is lower than at -4 m. As a result, the geogrid with deeper geogrid position is also more loaded, so the maximum geogrid stress for the geogrid at a depth of -6 m is 270.7 kN, 201.2 kN for geogrid at -4 m depth and only 99.7 kN for geogrid at -2 m depth. Nevertheless, in the case of the geogrid position at -4 m, the wall does not deform so much after activation. This can be explained by the more favorable position of the geogrid with respect to the lever arm. In the case of the geogrid position of -2 m, the initial wall deformation is already so high that the geogrid can only reduce the wall deformation to a very limited extent.
Figure 6. Sheet pile wall deformation for all backfilling phases for Geogrid at -6 m (left), at -4 m (middle) and at -2 m (right).

4 SUMMARY AND OUTLOOK

In the framework of this publication, a finite element model was created that can simulate the behavior of a sheet pile wall back-anchored with geogrids. Different geogrid positions as well as different angles of the geogrids were analyzed. The geogrid position in particular has a great influence on the wall deformation. For a further reduction of the wall deformation, other geogrid positions could be considered in future research.

ABSTRACT: Rapid landslides are commonly mitigated by artificial embankments that can be constituted of granular material reinforced by geosynthetics. For their design, the evaluation of debris flow impact force against the structure is a crucial issue. The paper focuses on determining the forces transmitted over time to a geosynthetic reinforced structure and on analyzing its response to the impact in terms of horizontal displacement. The impact force has been evaluated adding the static component, depending on the flowing mass height, to the dynamic component, depending on both the flowing mass height and its velocity. In the analyses of the geosynthetic reinforced structure response, two cases have been considered regarding the soil – geogrid interaction: the first one considers a constant soil shear strength angle along the height of embankment the second one considers the variation of soil shear strength angle along the height.

1 INTRODUCTION

In the last decades, the attention of several scientists focused on debris flow hazard assessment and risk management (Ciurleo *et al.* 2019, 2021, 2022) with a special focus on the design of risk mitigation measures such as sheltering structures. The use of these structures (deformable or rigid) allows to deviate or stop the flow reducing debris flow run-out distance and velocity and, as consequence, its residual destructive power.

In the case of deformable structures, such as geosynthetics reinforced embankments, the design is strictly related to the calculation of the debris flow impact force against the structure and on its response to this force.

Several approaches and empirical formulas are available in scientific literature for the calculation of the impact forces acting on embankments (Armanini 1997; Arattano & Franzi 2003; Calvetti *et al.* 2017; Gioffrè *et al.* 2017; Suda *et al.* 2010). Independently on the adopted approaches and used formulas, only few papers consider the evolution with time of the impact force (Gioffré *et al.* 2017). Gioffrè *et al.* (2017) proposed the evaluation of the impact force adding the static component, which depends on the flowing mass height, to the dynamic component, that depends on both the flowing mass height and its velocity.

Different impact features will result in different response mechanisms of the embankment. In the paper, considering a typical prismatic shape of geosynthetics reinforced embankment,

the impact force according to Gioffrè *et al.* (2017) over the time against the structure has been evaluated. Subsequently, the influence of soil-geogrid interaction properties on the deformative response of the geosynthetics reinforced structure has been analyzed. To do this, FEM numerical analyses have been carried out considering two different cases related to the variation of shear strength angle of the soil along the earth reinforced embankment. The first one with a constant shear strength angle (one layer) along the height and the second one with a variable shear strength angle along the height (four layers).

The deformative response of the structure for these two different configurations has been analyzed and discussed in terms of horizontal displacements.

2 MATERIALS AND METHODS

The evaluation of debris flow impact force with time has been carried out considering a simplified relationship of a fluid-based model proposed by Gioffrè *et al.* (2017). The authors evaluate the impact force with time (F) by adding the static force (F_{stat}) to that dynamic (F_{dyn}). Particularly, F_{stat} and F_{dyn} are respectively calculated as follows:

$$F_{stat}(t) = \frac{1}{2}\gamma K_p S_{stat}^2 w \tag{1}$$

$$F_{dyn}(t) = k\rho v^2 S_{dyn} w \tag{2}$$

where γ is the soil unit weight, K_p is the passive earth pressure coefficient under critical state conditions, and S_{stat} is the static debris flow height, w is the width of storage area, k an empirical coefficient, ρ is the density of the flowing mass and v is the flow velocity, S_{dyn} is the current debris flow height.

Figure 1a shows the trend of debris flow height over the time characterized by a flowing mass that has a height of 1 m at t = 0, increases from t = 0 to t = 18 s with a linear increment and then it increases at t = 18 s. A linear increment of debris flow height has been assumed from 18 s to 30 s when debris flow is over and a debris flow height of 3 m is deposited.

Figure 1b shows the assumed trend of debris flow velocity that is characterized by two peaks of velocity at t = 0 s and t = 18 s respectively equal to 10 m/s and 6 m/s.

The total force (Figure 1) is given by the sum of the two components F_{stat} and F_{dyn} that have been calculated by equations 1 and 2 and considering the trends of debris flow height
Figure 1.   Debris flow height and velocity trends and total impact force.

and velocity discussed above. The total force shows two peaks of 917 kN and 262 kN respectively at t = 0 s and t = 18 s.

Considering the trend of total impact force so obtained, the points of application of this force over the time on the structure have been evaluated assuming the scheme of accumulation of material behind the earth reinforced embankment without obstacle overtopping shown in Figure 2.

The dynamic component of the total force was assumed to have a rectangular stress distribution and was located at different points in different impact times (t_0 = first impact, t = impact at generic time and t_f = final condition), at t_f the contribution of the dynamic component is equal to 0 (Figure 2).

The static component of the total force was assumed to have a triangular stress distribution that is clearly equal to 0 at t = 0 and gradually increases as the amount of material accumulates beyond the obstacle reaching 3 m (the highest assumed value) at t_f when all material is accumulated (Figure 2).
Figure 2. Scheme of static and dynamic force distributions behind the earth reinforced structure.

To evaluate the response of the earth reinforced structure, a typical shape has been considered. Particularly, the structure has a prismatic geometry, the height (H) is equal to 5 m, the top (b) is 6 m large and the base (B) is 8.5 m large, the upstream side slope is 90° (α) and the valley side slope is 63° (β).

The soil that constitutes the earth reinforced structure is a gravel with sand and the geogrid used is a HDPE extruded geogrid with a tensile modulus about equal to 1200 kPa wrapped around the face with 0.50 m vertically spacing.

The characteristics of soil and geogrid are summarised in Tables 1 and 2. Two different cases have been considered (Figure 3) regarding the soil – geogrid interaction, the first one considers a constant soil shear strength angle along the height of embankment (C1 – Table 1) the second one considers the variation of soil shear strength angle along the height (multilayers configuration) (C2 – Table 2). The soil – geogrid interaction has been taken into account in terms of apparent interface coefficient of friction (μ) according to Moraci et al. (2014) and the related assumptions of two cases are reported in Tables 1 and 2. The soil initial shear modulus G_0 has been assumed equal to 280 kN/m^2.

Where γ is the unit weight of soil; c' is the cohesion; φ is the friction angle; ν is the Poisson coefficient; and μ is the apparent interface coefficient of friction.

It is worth to nothing that in C1, only a value of shear strength angle φ and consequently only a value of apparent interface coefficient of friction μ has been considered. In the case

Table 1. Characteristics of soil and geogrid for case C1.

Depth [m]	γ [kN/m^3]	c' [kN/m^2]	φ [°]	v [-]	μ
0–1.25	21	0	48	0.3	0.9
1.25–2.50	21	0	48	0.3	0.9
2.50–3.25	21	0	48	0.3	0.9
3.25–5.00	21	0	48	0.3	0.9

Table 2. Characteristics of soil and geogrid for case C2.

Depth [m]	γ [kN/m^3]	c' [kN/m^2]	φ [°]	v [-]	μ
0–1.25	21	0	52	0.3	1.2
1.25–2.50	21	0	50	0.3	1.0
2.50–3.25	21	0	47	0.3	0.9
3.25–5.00	21	0	44	0.3	0.7
Figure 3. Schematization of the two cases. a) C1 case (Table 1), b) C2 case (Table 2).

C2, different values of shear strength angle φ and so several apparent interface coefficients of friction μ, from the top to the bottom of the structure, have been considered.

The deformative response of the considered earth reinforced structure in C1 and C2 cases has been analyzed by 2D FEM analysis using RS2 – Geoscience (2022).

3 ANALYSES AND RESULTS

The earth reinforced structure has been discretized by triangular elements of about 0.25 m which thicken around geosynthetics and the upstream face (Figure 4).

The FEM analyses have been performed considering drained conditions, a linear elastic-perfectly plastic behavior of the soil and the soil strength parameters and G_0 values reported in Tables 1 and 2. Geogrids have been modelled by means of linear elastic and isotropic elements considering one value or several values of μ depending on the modelled cases as reported in Tables 1 and 2.

FEM results are drawn in terms of horizontal displacements (Figure 5). Figure 5 shows that the maximum horizontal displacement occurs in the downstream top of the structure independently on the analyzed case (one layer – C1; multilayers – C2) and it is equal to $1.3 \cdot 10^{-1}$ m for C1 configuration and $1.8 \cdot 10^{-1}$ m for C2 configuration.

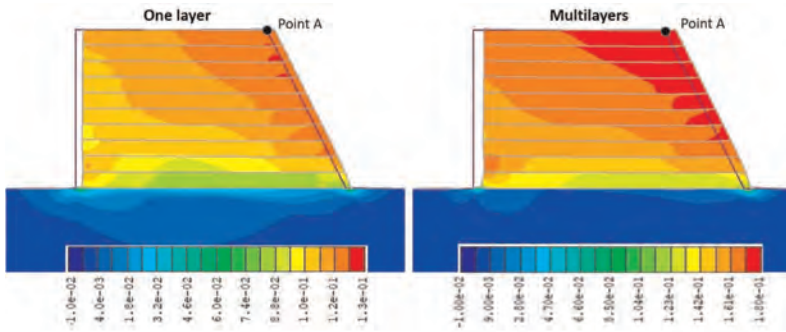
In both cases, the earth reinforced structure slides over the base soil. Particularly, for C1 configuration, the entity of sliding over the base soil assumes values going from 0.093 m (upstream point) to 0.079 m (downstream point) with an average value of 0.088 m. For C2 configuration, the sliding over the base soil assumes values ranging from 0.14 m to 0.11 m (from upstream to downstream points) with an average value of 0.12 m.
Figure 4.   FEM model.


Figure 5.   Horizontal displacements and the control point (point A) used to compare the horizontal displacement vs time.

The maximum horizontal displacement versus time at control point A (located in the downstream top of embankments - Figure 5) for C1 and C2 configurations is shown in Figure 6.
Figure 6.   Point A horizontal displacements vs time.

It worth nothing that, in both cases the trend is characterized by two peaks. The first one appears immediately after the first impact when an instantaneous increase of horizontal displacement has been recorded. The second peak has been recorded around t = 18 s according to second impulse that impacts the earth reinforced structure.

The highest horizontal displacements occur in the C2 configuration that is when the variation of shear strength angle along the depth has been considered (multilayers configuration) (red line in Figure 6).

4 CONCLUSIONS

The obtained results showed that not considering the effect of the variation of soil shear strength angle along the height of an earth reinforced embankment leads to underestimations of horizontal displacements of the structure. So, the design of these structures considering constant the interaction parameter for the overall reinforced soil structure is not precautionary. The knowledge of soil-reinforcement interaction parameters and their evolution over time, that depend on the interface conditions is very important in the design of geo-synthetics reinforced structures. Further investigations are in progress to study in-depth these results assuming values of shear modulus function of applied vertical effective stress, using different soils and geogrids.

ABSTRACT: Polyester (PET) materials have become more common as reinforcement solution in reinforced soil walls (RSW). It has been shown that strength and stiffness of geosynthetics products, including PET, is load-, time-, and temperature-dependent. Consequently, the mechanical response of these materials is influenced by in-soil conditions. The present study describes visco-elastic and visco-plastic constitutive formulations used to model PET strap reinforcement layers in thermo-mechanical finite element models. The models are demonstrated using an idealized 15-meter high RSW with concrete facing panels, including loading due to a road at the top of the structure. Reinforcement model parameters were calibrated using laboratory measured data. Analyses include temperature boundary conditions representing a Mediterranean climate for a 1-year period following end of construction. Calculated stress and strain values were in accordance with values found in the literature. The results of this study are a precursor for the long-term modelling of RSWs under operational conditions subjected to changing atmospheric boundary conditions.

1 INTRODUCTION

Numerical models are being routinely used to predict the behaviour of reinforced soil walls (RSWs) constructed with metallic or geosynthetic reinforcements (e.g., Damians *et al.* 2014; Huang *et al.* 2009; Yu *et al.* 2015, among others). Usually, reinforcement elements are modelled using a single stiffness value. In the case of extensible polymeric reinforcement (Miyata *et al.* 2018), such as polyester (PET), stiffness has proven to be load-, time- and temperature-dependent. Consequently, great care must be taken when choosing a unique stiffness value. Common practice in both numerical and analytical solutions is to obtain a stiffness modulus corresponding to (say) 2% strain and 1000 hours (Allen & Bathurst 2019). This value can be obtained from isochronous stiffness curves based on laboratory measured creep curves as described by Bathurst & Naftchali (2021).

Numerical models typically consider only the in-isolation mechanical behaviour of polymeric reinforcement materials and disregard the effect of hydraulic and thermal in-soil conditions on the mechanical performance of these materials. Temperature dependency implies that under different in-soil conditions, long-term mechanical behaviour of a polymeric reinforcement can vary.

The present work describes visco-elastic and visco-plastic constitutive formulations with temperature and water saturation dependencies used to model PET strap reinforcement

materials. Model parameters were first calibrated using measured creep master curves, followed by a generalization of parameter values using simple power functions. A 2D thermo-mechanical RSW numerical model was used to predict, as a first approach, the short-term behaviour of the structure when subjected to operational (in-service) loading conditions and varying temperature atmospheric conditions. Numerical simulations were carried out using the finite element program CODE_BRIGHT (CODE_BRIGHT 2021; Olivella *et al.* 1996)

2 NUMERICAL MODELLING

2.1 *PET strap reinforcement modelling*

Short-term mechanical behaviour of PET strap reinforcement materials can be approximated using a linear-elastic model. However, because these materials are temperature and moisture dependent, the long-term behaviour requires more complex formulations. The long-term rate of deformation ($d\varepsilon/dt$), or creep, was modelled with a visco-elastic (VE) constitutive model (Eq. 1), and a visco-plastic (VP) constitutive model (Eqs. 2–4).

$$d\varepsilon^{VE}/dt = \left[1/\left(2B(T)\sqrt{S_l}\right)\right](\sigma' - p'I) \tag{1}$$

$$d\varepsilon^{VP}/dt = [\Gamma_0 \exp(-Q/RT)]\langle\Phi(F)\rangle \quad \partial G/\partial\sigma' \tag{2}$$

$$F = \alpha(\eta^*)p' + \left[\cos(\theta) - \alpha(\eta^*)\sin\theta/\sqrt{3}\right]\sqrt{J_2} - \alpha(\eta^*)\delta(\eta^*) \tag{3}$$

$$G = \cos(\theta)\sqrt{J_2} \tag{4}$$

For the VE model, σ' is effective stress, p' is mean stress, I is the identity matrix, S_l is degree of saturation, and B(T) is the elastic fluidity as a function of temperature (T), the universal gas constant (R), and activation energy (Q). In the case of the VP model, Γ_0 is a reference plastic fluidity, F is a function of mean stress (p'), a frictional parameter (δ), a adhesion parameter (α), the lode angle (θ), and the second invariant of the deviatoric stress (J_2), and G is a function of θ and J_2. Parameters δ and α are controlled by a hardening parameter (η^*).

Numerical results were compared with laboratory data reported by Hang-Won & Je-Goo (2020) for different PET strap reinforcement products manufactured by a single manufacturer. Parameters were first calibrated using measured creep master curves constructed from the step isothermal method (ASTM D6992-03 2003) together with simplified 2D axial load model of a single PET strap. Samples were subjected to constant loads ranging from 66% to 80% of the ultimate tensile strength (UTS) for specimen (and grades) rated at 34.2 (i.e., grade 30), 52.9 (grade 50), and 78.2 (grade 70) kN/strap. From the calibration outcomes, simple power functions were used to estimate parameter values and model reinforcement behaviour when subjected to low magnitude axial tensile loads anticipated for PET strap RSWs under operational conditions. Power functions were based on reinforcement grade (UTS) for parameters E, δ, and α, while parameters B and Γ_0 considered reinforcement grade and applied load (as a percentage of UTS). Table 1 shows the range of parameter values depending on reinforcement grade and load conditions using the power functions.

Figure 1 shows the fitted power functions value for elastic modulus E (Figure 1a) and fluidity Γ_o (Figure 1b). E values for each grade are in agreement with those obtained by Allen & Bathurst (2019) and Bathurst & Naftchali (2021) for PET strap reinforcement products after the proper unit conversion (i.e., MPa to kN/strap, considering the proposed geometry). Figure 1c compares the axial strain of measured creep master curves with model (predicted) creep master curves for the grade 50 PET strap reinforcement using the power functions. Results show small discrepancies between measured and modeled results. Axial strain values are underestimated at an earlier stage and present better agreement at a later stage. Parameters were extrapolated for lower axial load conditions to obtain a wide array creep master curves.

Table 1. PET strap reinforcement model parameters based on power law function.

Constitutive model	Parameter	PET strap reinforcement grade		
		Grade 30	Grade 50	Grade 70
Linear-elastic (LE)	Elastic modulus, E [MPa]	211	356	567
	Poisson's ratio, ν [-]	0.2	0.2	0.2
Visco-elastic (VE)	Fluidity, B [$s^{-1}MPa^{-1}$]*	2.70×10^{-43} to 1.60×10^{-13}	1.39×10^{-56} to 3.36×10^{-12}	4.43×10^{-46} to 3.02×10^{-13}
Visco-plastic (VP)	Fluidity, Γ_0 [$s^{-1}MPa^{-m}$]**	1.83×10^{-15} to 2.48×10^{9}	6.24×10^{-14} to 3.89×10^{8}	1.22×10^{-23} to 1.51×10^{8}
	Activation energy, Q [$Jmol^{-1}$]	1.0×10^{5}	1.0×10^{5}	1.0×10^{5}
	Peak and residual parameters for adhesion, α_{peak} and α_{res} [MPa]	2 and 6.8	4.2 and 13.5	6.7 and 21.3
	Peak and residual parameters for friction, δ_{peak} and δ_{res} [°]	0.1 and 1.0	0.1 and 1.0	0.1 and 1.0

*Range of values for a reference temperature of 20°C and loads of 10% to 82% of UTS.
**Range of values corresponding to loads of 10% to 82% of UTS load.

Based on the available experimental data, extrapolating fluidity values using a power law function, values decrease as load decreases, reaching almost zero values, meaning that close to no creep should be expected for lower loads, even after extended periods of time.

Using modelled and measured creep master curves, isochronous stress-strain curves were calculated for 30 and 60 days, and 1, 10, 60, 100, and 120 years. Figure 2 shows isochronous curves for a grade 30 PET strap reinforcement. For loads over 66% of UTS, modelled isochronous curves present an adequate adjustment to laboratory obtained curves for 30- and 60-days, while strains are underestimated for longer periods of time. Measured and modelled isochronous curves did not present any suitable relation from 0 to 60% of UTS. As no measured data was available for loads under 66%, experimental data was approximated by a linear function with respect to the origin. In the case of modelled isochronous curves, extrapolating fluidity values using a power law function results in almost zero values at low loads, meaning that negligible creep can be expected at low load levels.
Figure 1. Model parameters for (a) elastic modulus E, (b) fluidity Γ_0, and (c) predicted/measured axial strains comparison.

2.2 RSW numerical model

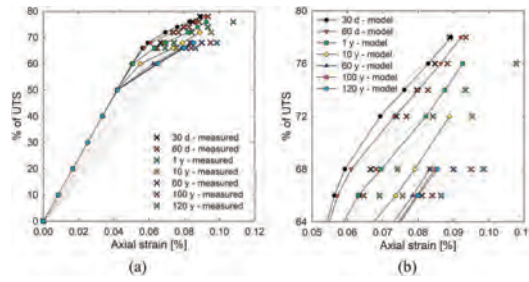
An idealized 2D, 15-meter-high RSW with PET strap reinforcement layers and concrete facing panels was modelled. A thermo-mechanical (TM) formulation was used. Boundary conditions consisting of daily in-air temperature measurements of a Mediterranean climate (Barcelona, Spain) taken from a weather database (WeatherOnline Ltd.), were applied at all surface boundaries. The dataset mean annual temperature was 17°C. Model geometry includes all relevant structural components, such as the levelling pad at the base of the structure, discrete concrete facing panels, bearing pads between panels, toe front embedment, and equivalent PET strap reinforcement layers (Figure 3). A two-lane road, including a concrete safety barrier was included at the top of the structure. Based on the work of Damians et al. (2022), equivalent continuum interface elements were considered between the reinforced soil and facing elements as


Figure 2.   (a) Measured and predicted stress-strain isochronous curves for grade 30 PET strap reinforcements, and (b) detail for 64% to 80% of UTS curves for 30 and 60 days (d) and 1, 10, 60, 100, and 120 years (y).

well as between soil and reinforcement layer elements. Strength reduction factors of 0.6 and 0.52 were considered for the soil-facing and soil-reinforcement interfaces, respectively.

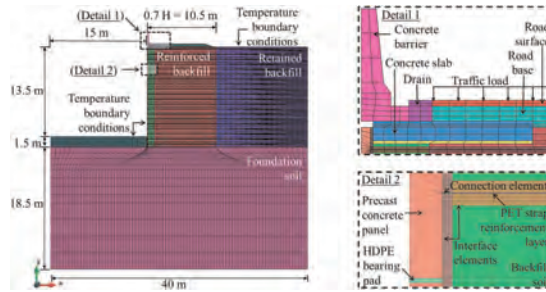
The soil materials were modelled using a Mohr-Coulomb constitutive model with dilatancy. Parameter values are shown in Table 2 based on the work of Yu *et al.* (2015) and Damians *et al.* (2021), considering plane strain conditions with an equivalent width of 1 m. For numerical stability purposes a small amount of cohesion was considered for all soil materials. The soil within 1 m of the vertical facing was assigned reduced stiffness to account for poorer compaction that is often observed during construction of these types of structures.


Figure 3.   RSW 2D model domain and finite element mesh geometry detail.

Table 2.   Parameters for mechanical properties of soil materials.

Parameter	Reinforced soil (<1 m)	Reinforced soil (>1 m)	Retained soil	Foundation	Soil-facing interface	Soil-reinforcement interface
Unit weight, γ_n [kN/m³]	19	19	19	19	19	19
Young modulus, E [MPa]	10	20	20	100	4.02	10.20
Poisson's ratio, ν [-]	0.3	0.3	0.3	0.3	0.45	0.45
Cohesion, c [kPa]	1	1	1	5	0.6	1
Friction angle, ϕ [°]	44	44	44	36	30.1	26.6
Dilatancy angle, ψ [°]	14	14	14	6	0	14

Concrete elements used a linear elastic model with E = 32 GPa and $\nu = 0.3$. The road base properties were the same as the reinforced soil (>1 m). The road surface was considered as concrete.

Modelled PET strap reinforcement layers have a coverage ratio of 0.142 (two connections every 2.5 m of wall face in the running length of the wall, two straps per connection, 89 mm-wide straps) including eight grade 30 layers, two grade 50 layers and ten grade 70 layers, from top to bottom of the wall.

Each incremental vertical panel was constructed separately, followed by a 1.5 m-thick soil layer zone, including reinforcement layers, every 10 days. A transient compaction surcharge of

10 kPa was applied over every soil layer during construction to simulate the influence of compaction equipment (see Hatami & Bathurst 2005). The front toe embedment was constructed once the structure achieved a height of 4.5 meters (total of three panels). After construction, a constant vertical pressure of 15 kPa was applied over the road surface for one year.

Thermal dispersion was modelled by Fick´s law, with a horizontal and vertical dispersivity of $d_l = 5$ m and $d_t = 0.5$ m, respectively. Thermal conductivity was modelled using Fourier´s law, with dry and saturated conductivity values of $\gamma_{dry} = 0.5$ W/mK and $\gamma_{sat} = 1$ W/mK for the soil and $\gamma_{dry} = 0.88$ W/mK and $\gamma_{sat} = 1.41$ W/mK for the concrete materials. Solid phase specific heats (c_s) of 1000 $Jkg^{-1}K^{-1}$ and 900 $Jkg^{-1}K^{-1}$ were used for soil and concrete, respectively.

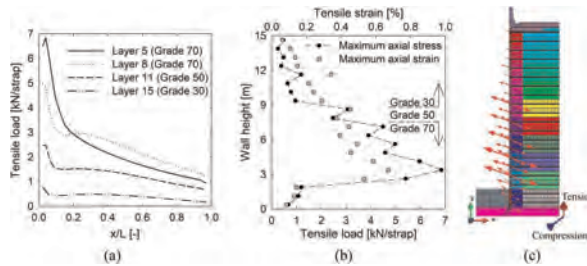
Figure 4a shows the axial tensile loads along the length of layers 5, 8, 11, and 15 (numbered from toe to top of the wall). Maximum loads are obtained near the connection elements. Tensile loads at the free end of each layer approach zero. Figure 4b shows the maximum axial strain and load in each reinforcement layer with respect to wall height. Model outcomes showed tensile loads of up to 8% of UTS. Maximum strains do not exceed 0.8%, which is in agreement with measured maximum reinforcement strain under operational conditions in monitored PET strap field walls (Miyata *et al.* 2018). Tensile loads and strains follow similar distributions, increasing with depth until the two bottom panels. Due to the influence of toe embedment, the lowest reinforcement layers generated attenuated tensile load and strain. Figure 4c shows the maximum load vector for each reinforcement layer, which present a downward direction, attributed to the relative movement of the reinforced backfill with respect to the facing elements. The result is an increased vertical load at the connection and facing elements (see Damians *et al.* 2013, 2016). Computed horizontal facing displacements were less than 5 cm.


Figure 4. Numerical results after 1 year of service of (a) tensile load in reinforcement layers 5, 8, 11, and 15, (b) maximum tensile load and strain values for all reinforcement layers, and (c) principal stress (load) vector plots in the reinforced soil section.

3 CONCLUSIONS

The present study gives some details of the implementation of visco-elastic and visco-plastic constitutive formulations used to model PET straps reinforcements in an idealized 2D RSW thermo-mechanical finite element model. The constitutive models include temperature and saturation dependencies. Based on calibrations using quality control tensile test records of reinforcement specimens, model parameters were extrapolated to different load levels. The idealized RSW model includes temperature boundary conditions from daily registries of a Mediterranean climate database (Barcelona) and a service traffic load of 15 kPa. The main findings are as follows:

Stiffness values for the numerical model obtained based on laboratory results were in accordance with values in the literature.

Stress-strain isochronous curves were obtained from creep testing and simulated numerically. Long-term (over 1 year) model predictions tended to underestimate measured strain values. Short-term predictions presented an adequate adjustment with measured values over 60% UTS. A lack of data for loads under 60% of UTS resulted in extrapolated fluidity values close to zero, meaning that no creep behaviour will occur. Measured data was extrapolated with respect to the

origin for comparison purposes. For low load values, no suitable relationship between measured and model results was possible.

After 1 year of service, model results are in agreement with similar cases reported in the literature. Reinforcement strains increased with depth up until the four lower-most layers. Maximum reinforcement strains did not exceed 0.8% and axial tensile loads were less than 10% of UTS.

Further work is required in order to predict the long-term behaviour of PET-strap RSWs during service life, along with the influence of hydraulic dependencies in the numerical formulations.

M.V. Pham
Pukyong National University, Busan, Korea

Y.T. Kim*
Professor, Pukyong National University, Busan, Korea

ABSTRACT: Reinforced soil retaining wall (RSW) frequently collapses due to various causes such as drainage problems owing to heavy rainfall and increase in earth pressure owing to surface load. Therefore, we need technology that can continuously monitor the behavior of the retaining wall. In general, since a depth image between an image and an object cannot be extracted from an image taken from a monocular vision, it is not possible to accurately analyze the three-dimensional behavior of the real space. The behavior of the reinforced soil retaining wall is defined as facing displacement and settlement based on the collapse mechanism of the reinforced soil retaining wall. Mask R-CNN was applied to detect and track the RSW block before and after the behavior, and performances of matching and displacement calculation were evaluated. The errors were distributed in 2.12 mm in laboratory RSW experiment.

1 INSTRUCTION

1.1 *Background*

RSW which is widely used in the world were basically composed of block, geosynthetics, backfill material. Several direct sensors such as displacement sensor, tilt meter, strain gauge were installed to monitor safety of retaining wall, however, it causes lots of control fee, and it can only analyze around the sensors. Therefore, behavior of RSW, which is effected by conditions of geosynthetics and backfill, can be monitored with the movement of blocks. Vision-based technology has strength of low price and possibility of constant monitoring of RSW. The vision-based technologies are not only analyzing behavior but also directly monitoring a RSW in a far distance. The stereo camera system based on two or more cameras or takes images from various location of view. The proposed single camera system processes images from a monocular vision. Many researchers were studied to analyze displacement of slope, retaining wall, and bridge based on three dimensional coordinates with the stereo camera system (Esmaeili *et al.* 2013; Jiang & Jauregui 2010; Oats *et al.* 2017; Sun *et al.* 2022; Zhao *et al.* 2018). However, additional costs were inquired to maintain and process lots of cameras in a stereo camera system. The camera system based on monocular vision has been limitedly studied in analyzing a simple behavior that perpendicular with optical axis. The in-plane displacements were analyzed for the structures such as building, bridge, two-story steel frame, and masonry specimen. (Choi *et al.* 2011; Feng *et al.* 2015; Lee & Sinozuka 2006; Wang *et al.*

2021). In this study, we pro-posed the single camera system that detect blocks and calculates displacement of RSW using mask R-CN with different type of RSW structure.

1.2 *Mask R-CNN*

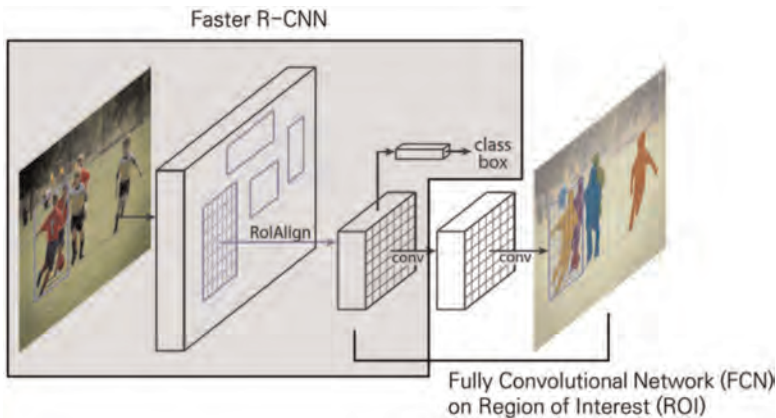
Vision-based technologies have been gradually developed into image classification, object detection, semantic segmentation, and instance segmentation with the development of deep learning algorithms, Various studies have been conducted to analyze the location of a specific object in an image, such as fast R-CNN, faster R-CNN, sementic segmentation, and instance segmentation based on a convolution neural network (CNN). Mask R-CNN performs fully convolutional networks (FCN) based on the bounding box and classification information estimated by Faster R-CNN, a widely used object detection technique, and performs instance segmentation by estimating the mask without loss of location information. Figure 1 shows the mask R-CNN framework for instance segmentation. Decoupling via per-class binary masks (sigmoid) gives large gains over multinomial masks (softmax). Based on subcell and bilinear interpolation, ROI alignment was used to increase the accuracy compared to ROI pooling. FCNs improve results as they take advantage of explicitly encoding spatial layout than multi-layer perceptrons (MLP, fully-connected) for mask prediction (He *et al.* 2017). Through these various advantages, Mask R-CNN is being used in various fields. Xu *et al.* (2022) conducted comparison study based on faster R-CNN and Mask R-CNN, Performances were compare with different learning rate and figure out optimal learning rare for each case. Tiede *et al.* (2021) made a dwelling map with different type of roof based on mask R-CNN. Jeong *et al.* (2020) utilized the 3D Mask R-CNN approach to localize and segment the high- and low-grade brain tumors from dynamic MRI perfusion images. Wang *et al.* (2020) detected open-pit mines based on improved mask R-CNN and transfer learning. Wang *et al.* (2022) conducted Rural Building roof type recognition from UAV high-resolution Images. Tian *et al.* (2020) suggest road marking detection method based on mask R-CNN Instance Segmentation Model. Mask R-CNN is being used in various fields based on the advantage of being able to detect the exact location of a target based on high-accuracy mask and segmentation information. Therefore, in this study, it is used to detect individual facings of RSW where multiple objects exist in order to detect blocks that are difficult to detect due to changes in conditions during RSW monitoring.


Figure 1.   Mask R-CNN framework for instance segmentation (modified from He *et al.* 2017).

2   EXPERIMENT

2.1 *Laboratory RSW experiment*

The laboratory RSW experiment was performed to evaluate the performance of matching and displacement calculation under controlled conditions in a laboratory. Figure 2 shows an

experimental setup of RSW (650 mm x 270 mm) consisting of 121 blocks. the reference displacements were measured from a total station (Sokkia 510k). The camera was installed with an incident angle of 43 degrees, and distance of 1267 mm. cumulative displacement such as facing displacement and settlement were alternately occurred and analyzed.
Figure 2. Experimental setup and equally distributed targets in RSW.

3 EXPERIMENTAL RESULT

3.1 *Detection and displacement calculation of block*

Figure 3 shows an example of the blocks trained and detected for the laboratory RSW experiment. 9 images were used for validation, and 2 images are shown in the figure. Each column represents the original image, ground truth, and predicted mask. Table 1 shows the
Figure 3. Detection results of mask R-CNN for laboratory RSW experiment.

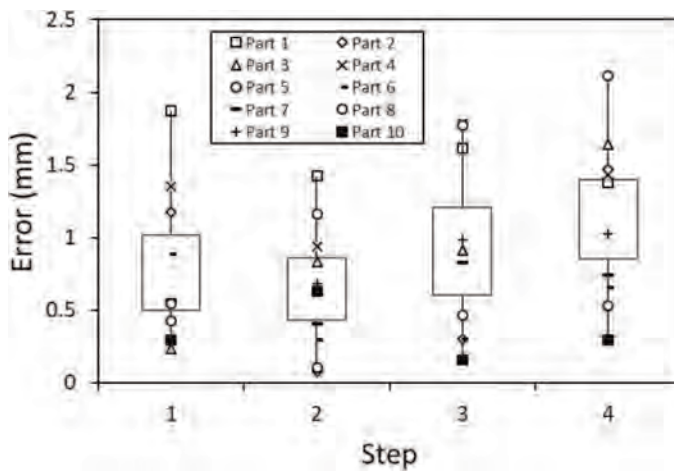
9	47,923	3,832	2,203	207,895	0.9260	0.9561	0.9408
Average					0.9226	0.9187	0.9196


Figure 4. Results of displacement calculation error for laboratory experiment.

precision, recall, and f1 scores for 9 images used for validation. Although blocks could not be detected for some sections for each image, laboratory RSW blocks were detected with precision of 92.28%, recall of 92.51%, and f1 score of 92.31%. Figure 4 shows the results of calculating the behavior based on the detected blocks. In case of using mask R-CNN, since transformation by behavior is not considered, the error does not increase significantly for each behavior step. In addition, the overall performance is excellent with an error within 2.12mm.

4 CONCLUSION

The result based on mask R-CNN showed high performance of detection. However, these results were trained and validated only for laboratory RSW blocks, we need to train and validate for various types of RSW blocks considering the conditions of fields. Regarding displacement calculation performance, the average MREs were 1.39 % in the laboratory RSW experiment, indicating an excellent displacement calculation performance. Based on this result, if more types and behaviors of RSW were considered, the proposed single-camera system can be improved to monitor the behavior of the RSW.

ABSTRACT: Back-to-Back Mechanically Stabilized Earth (MSE) walls can sustain significant loadings and deformations due to the interaction mechanisms which occur between the backfill material and the reinforcement elements. These walls are commonly used in embankments approaching bridges, ramps and railways. The performance of a reinforced wall depends on numerous parameters, including the ones defining the soil, the reinforcement and the soil/reinforcement interaction behavior. The focus of this study is to investigate numerically the behavior of back-to-back mechanically stabilized earth walls considering synthetic and metallic strips. A two-dimensional finite difference numerical modeling is considered. The role of the soil friction angle, the Soil material quality and the wall width to the height ratio are investigated in a parametric study. Their effects on the soil/strip shear displacements and tensile forces on the reinforcements are presented. The behavior of the reinforcement strips in back-to-back reinforced walls strongly depends on the distance between walls and on the soil parameters.

1 INTRODUCTION

The soil resists well to compressive stresses but is less able to resist to shear strength solicitations. Therefore, tensile elements are often used to compensate this weakness. The concept of soil reinforcement was initially expressed by Vidal (1969). Reinforced soils are used in the construction of many geotechnical structures such as retaining walls, embankments, slopes and shallow foundations. The reinforced walls can be integrated in the category of flexible walls, which usually contain three elements an embankment generally made of granular soils, reinforcement elements which can be metallic or synthetic and the wall face usually made of concrete. Utilizing Back-to-back mechanically stabilized earth (MSE) walls are especially prevalent in raising elevation of bridges, ramps and railways. However, these walls are demanding regarding their design, since they require complex geometries like in the FHWA Demonstration Project 82 (Elias & Christopher 1997). In Figure 1, two cases are analyzed regarding the two

Figure 1. Schematic view of a back-to-back reinforced wall.

back-to-back walls distance. The walls can be designed independently if D (distance between the reinforcements from each other) is greater than H tan (45°-φ/2) where H is the wall height and φ is the backfill friction angle. The effect of the distance, D, between walls (width to height ratio) on the internal and external stability of MSE walls under static conditions was explored. Han & Leshchinsky (2010) conducted back-to-back walls investigations. They indicate that when the two back-to-back walls are far from each other, they perform independently. While, if they are close to each other, they interact with each other. When the ratio is less than one the two walls interact with each other and the earth pressure behind the wall decreases because the failure wedge behind the wall is not fully developed. Thus, the geosynthetic reinforcement tensile forces decrease with decreasing the spacing between walls (El-Sherbiny et al. 2013).

Previous researches on two back-to-back geosynthetic-reinforced soil walls revealed that these walls perform independently when they are far apart and interact with each other when they are close. The location and shape of the critical failure surface would be changed depending on their interaction. Moreover, the distance between the back-to-back walls would affect the maximum geosynthetic tension. Accordingly, the required maximum reinforcement tensile strength slightly decreases in the case of decreasing the distance of the two back-to-back walls (Djabri & Benmobarak 2016). An investigation on the spacing ratio between the two walls to the wall height (W/H) was done (Sasanka et al. 2019). Numerical analysis of the behavior of a reinforced wall using different types of synthetic and metallic strips showed that parameters like the soil friction, the shear interface and the elastic modulus of strips, have an effective role in the wall behavior (Abdelouhab et al. 2009). Numerical studies less considered back-to-back walls, especially when considering two types of reinforcements: Metallic Strips (rigid) and Geosynthetic Strips (flexible). In this article, a stability analysis of back-to-back reinforced walls is carried out using a two-dimensional finite difference code. A parametric analysis considering two types of reinforcements (metallic and synthetic), the effect of the soil friction angle and reinforcement elements distance on the wall displacements, soil/strip shear displacements and reinforcement tensile forces are investigated. In addition, it is shown that for the wall construction that involves static loading conditions, the modified Plastic Hardening model is a good compromise. A full description of this work can be found in the paper by Lajevardi et al. (2021).

2 STUDIED CASE

2.1 Geometry of the wall

The wall is 6 meters high. For both sides of the wall, a concrete face cruciform geometry divided in panels, with 16 reinforcement strips (metallic or synthetic) of 4 m length is used.

The concrete face panels allow to homogenize the displacements of such structures. Using the assumptions of Figure 2, it is possible to consider a 2D model which is representative of the 3D behavior of such structure (Abdelouhab *et al*. 2010). In each wall side, 4 concrete panels in the vertical direction of dimension 1.5 × 1.5 m, are used in the transverse direction. To simplify the model geometry, the three-dimensional shape is converted into a two-dimensional one. The cruciform parts of the concrete parts are then considered as square ones (dimensions of 1.5 × 1.5 m).
Figure 2.   Three-dimensional view of a back-to-back reinforced wall.

2.2   *Soils*

The system is composed of two types of soils: a reinforced backfill and the soil foundation. In this study, the reinforced backfill soil behavior is simulated by using the Plastic Hardening (PH) constitutive model (Schanz *et al*. 1999). This constitutive model is a shear and volumetric hardening model. The stress-strain relationship is hyperbolic, and a power-law describes the stress-dependent elastic stiffness. Moreover, a shear hardening, a volumetric hardening law and the Mohr-Coulomb failure criterion are included (Itasca Consulting Group 2017). The reinforced backfill soil's parameters for the PH constitutive model (Table 1) were deduced from triaxial tests (Abdelouhab *et al*. 2010).

Table 1.   Reinforced backfill PH input parameters.

Parameter	Value
Volumic weight (kN/m^3)	1580
E_{50} ref[1] (MPa)	50
E_{oed} ref[2] (MPa)	60
E_{ur}[3] (MPa)	145
Failure Ratio	0.7
Cohesion (kPa)	0
Dilatancy angle (°)	6
Friction angle (°)	36

[1]Secant stiffness at half of the ultimate deviatoric stress at the reference pressure; [2]Tangent stiffness in an oedometer test at the reference vertical stress; [3]Elastic unloading-reloading Young's modulus.

2.3   *Concrete face and foundation soil*

The foundation soil (concrete slab) is assumed to behave elastically to minimize the foundation influence on the reinforced soil behavior. The wall face is made up of concrete in the numerical model. This concrete face is simulated using beam structural elements. These elements are resistant to tensile and compressive stresses and to bending moments. They behave as a linear elastic material (Table 2).

Table 2. Parameters for the concrete and the foundation soil.

Parameter	E^1 (MPa)	v^2	Volumic weight (kN/m³) γ
Concrete panel	15000	0.2	2500
Soil foundation	200	0.25	2200

[1]Young modulus; [2] Poisson's ratio

2.4 Concrete panel/soil interface

To simulate the soil/structure interaction, an interface between the concrete panel and soil is defined. The interface elements parameters are related to the soil parameters. The interface shear strength (φ_{int}) is calculated by using a strength reduction factor (R_{int}) Equation 1:

$$tg\varphi_{int} = R_{int} \times tg\varphi_{int} \qquad (1)$$

The interface adhesion (C_{int}) was related to the backfill soil cohesion (C_{Soil}) Equation 2:

$$C_{int} = R_{int} \times C_{soil} \qquad (2)$$

A constant value of R_{int} = 2/3 was assumed (Yu *et al.* 2015). The shear stiffness, normal stiffness and friction angle of this interface are presented in Table 3.

Table 3. Characteristics of the concrete panel/soil interface.

Parameter	Normal stiffness (MPa)	Shear stiffness (MPa)	Interface friction Angle
Concrete panel/soil interface	1000	1000	24

2.5 Reinforcements

Two types of strips reinforcement: a metallic and synthetic strip reinforcement are considered (Lajevardi *et al.* 2021) (Table 4).

Table 4. Reinforcement's characteristics.

Reinforcement	Geosynthetic (GS HA)[1] strip	Metallic strip
Elastic modulus (GPa)	2.5	210
Width (m)	0.1	0.05
Thickness (mm)	3	4
Strip tensile yield-force limit (kN)	70	100
Tensile failure strain limit of the strip (%)	12	10

[1]New geosynthetic strips (GeoStrap High Adherence) used in MSE Walls

The strip structural element implemented in Flac2D is used in the following simulations for the two kind of strip reinforcements. This element has a tensile strength limit. The shear behavior of the soil/reinforcements interface is defined by a nonlinear shear failure envelope, which changes based on the confining pressure.

3 NUMERICAL MODELLING

3.1 *Parametric analysis*

In this section, the behavior of back-to-back walls considering two width to height (W/H) ratios for the two types of strips reinforcement is investigated. The wall height (H) and the reinforcement length (L) are fixed and are respectively equal to 6 and 4 meters. The horizontal distance between the reinforcements from each other (D), which is the variable parameter of this study, is determined by the proposed equation of the FHWA design guideline (FHWA 2007). In this study, the influence of the distance between the reinforcements in the horizontal direction is considered by using two cases. D equal to 0 which is a lower value than the proposed one of the FHWA design guideline and D equal to 10 m which is greater than the FHWA proposed value (Figure 3).
Figure 3.   Geometry of the back-to-back reinforced walls considering different ratios of width (W) to height (H).
Figure 4.   Soil/strip shear displacements for two strip types and different W/H ratios.

3.1.1 *Influence of the width to height ratio (W/H)*

3.1.1.1 *Soil/strip shear displacements*

The soil/strip shear displacements for the two considered strips started to increase from the bottom of the wall (Figure 4). As the wall height increases, they decrease so that the greatest displacement occurs between the fourth and fifth strips and the lowest between the seventh and the eighth strips.

981

As the reinforcement strip distance (D) increase the values of the soil/strip shear displacements decrease. The distance between reinforcements and the soil/strip shear displacements are directly linked.

3.1.1.2 Tensile force

As shown in Figure 5, the maximum tensile forces occur at the first 2 m of the wall, and then decrease and reach the lowest value at the wall top. In addition the tensile forces on strips decrease with increasing the distance between reinforcements (D).
Figure 5.   Tensile force variations on the two strip types and different W/H ratios.

3.1.2 Influence of the friction angle (φ)

The results indicate that the friction angle has a significant influence on the displacement amplitude and on the safety factor of MSE Walls. The results showed that the decrease of the friction angle leads to a wall displacement increase. On the other hand, it leads to a safety factor reduction. The higher safety factor and the lower displacements were related to D = 0. While increasing the distance between strips (D) leads to reduce the safety factor and increases the displacements (Table 5).

Table 5.   Influence of the friction angle.

					% Decrease Fs		% Increase |U|	
Strip	W[1]/H[2]	φ (°)[3]	Fs[4]	|U|[5] (cm)	(36-30)	(30-25)	(36-30)	(30-25)
Metallic	3	36	1.7	1.38	21	19	31.3	35.8
		30	1.3	2.01				
		25	1.1	3.13				
	1.33	36	2.2	0.61	20.6	19	3.2	1.6
		30	1.7	0.63				
		25	1.4	0.64				

[1]width of the wall; [2]Height of the wall; [3]Soil friction angle (°); [4]Factor of safety; [5]Maximal displacement of the reinforced backfill.

4   CONCLUSION

The numerical results show that back-to-back walls with geosynthetic strips have more flexibility than with the metallic ones. This flexibility leads to higher soil/strip interface shear displacements. This is due to the lower rigidity of the geosynthetic strips.

The results of back-to-back reinforced soil walls considering different ratios of width to height indicate that this ratio is directly connected to the tensile forces and it is inversely related to soil/strip interface shear displacements

The results show that the soil friction angle has a significant effect on the behaviour of the back-to-back walls. As this friction angle decreases, the stability of the wall decreases, and the soil/strip shear displacements and the tensile forces on the reinforcement increases.

The role of rainwater infiltration on the tensile load in unsaturated geosynthetic reinforced soil layer

M.C. Santos & F.H.M. Portelinha
Federal University of Sao Carlos, Sao Carlos, Sao Carlos, Brazil

ABSTRACT: The comprehension of rainwater infiltration effect into Geosynthetic Mechanically Stabilized Earth (GMSE) walls is required to precisely predict the mobilized tensile loads in design analyses. A laboratory-testing device that simulate a geosynthetic-reinforced layer was used to assess the water infiltration effects in tensile loads mobilized by the reinforcement. The experimental device allows applying a controlled infiltration rate over a reinforced layer and capture the mechanical response from backfill soil to geosynthetic during infiltration. Water content profile, horizontal pressure variations, reinforcement tensile load and strain were provided by the monitoring program. The results demonstrated that the infiltration led to reinforcement strains and loads up to 15% of the ultimate tensile load. In addition, the rates of increases were found to be directly related to the average matric suction of the reinforced-layer.

1 INTRODUCTION

The geotechnical standards guidelines recommend the use of granular soils as backfill material in Geosynthetic Mechanically Stabilized Earth (GMSE) walls. However, the high cost associated with collection and transport of such materials has led to the use of local soils, specifically in tropical areas where lateritic fine-grained soils are abundant (Koerner & Koerner 2011; Ren *et al.* 2022). The main concern about the use of fine-grained materials is the possible strength reduction and large deformations due to decreases in matric suction within the reinforced zone induced by rainwater infiltration. Usually, fine-grained soils are applied in GMSE walls compacted at the optimum moisture content leading to high initial values of matric suction (Portelinha & Zornberg 2017; Vibha & Divya 2021). The unsaturated soil condition improves soil properties, such as strength stiffness and compressibility, as well as the soil-geosynthetic interface shear strength. The unsaturated condition can persist for a long time, depending on the local rainfall events and evaporation rates (Nunes *et al.* 2022; Yang *et al.* 2019). On the other hand, soil condition can be drastically changed by rainfalls, which depends on the intensity, duration and frequency.

Many studies reported the effects of rainfall events on GMSE walls behavior (Wu & Chou 2013; Yoo & Jung, 2006; Yang *et al.* 2018). Vahedifard *et al.* (2017) observed that the infiltration effect is more pronounced in soils with a high initial suction value. Still, the upper part of the soil structure is mostly affected by the rainfall intensity, where the reinforcement loads increased about 60% after an extreme rainfall event. A similar conclusion was assessed by Razeghi *et al.* (2019). The authors reported that the location of maximum reinforcement strains along the wall height followed the progress of infiltration front until a certain depth, which after this point increased for all layers. A large-scale reinforced wall subjected to a moderate rainfall infiltration was investigated by Portelinha & Zornberg (2017) to evaluate the soil structure mechanical response. The authors observed that that the maximum reinforcement strain can significantly increase when infiltration front reached the middle height of the wall. Moreover, the average matric suction measured along the entire wall height was a suitable parameter to assess the infiltration effect in the unsaturated reinforced soil performance.

Here, there is a clearly gap in quantifying the tensile load and strain induced by rainfall events in GMSE walls with unsaturated backfill soils. This paper aims to investigate the hydro-mechanical response of a geogrid reinforcement layer subjected to a rainwater infiltration. The objective is achieved by monitoring the response of an experimental device that properly reproduces the GMSE walls working conditions. Such experiment allows the tensile load-strain quantification in an unsaturated reinforced layer subjected to an infiltration process.

2 EXPERIMENTAL PROGRAM

2.1 *Experimental device*

The experimental device reproduces a reinforced layer of a GMSE wall. The geogrid is indirectly mobilized by the surrounding soil under working stress and plane strain conditions. The geosynthetic reinforced soil system consists in placing a geogrid between two compacted soil layers in a rigid box with internal dimensions of 600 mm × 750 mm × 700 mm (width × length × height), as can be seen in Figure 1.
Figure 1.　Geosynthetic reinforcement layer experimental device.

The working principle of the experimental device is applying a vertical surcharge on the top of the reinforced soil system and induces a horizontal stress. While the geosynthetic is strained the internal clamp tends to restrict the movement. The front wall can move freely in the horizontal direction through ball bearings running over rails at the base (plane strain condition). The back and lateral walls are stationary and lubricated with grease to minimize friction along the center plane of the geogrid layer. The vertical surcharge is applied with hydraulic pistons and plates with bearings are used at the base to allow internal soil-geogrid straining.

A Linear Variable Differential Transformer (LVDT) transducer placed outside the front moving wall records the displacement and allows the geogrid strain calculation. The geogrid is attached to a load cell through an internal clamp that measures the reaction force as the front moves. The load cell is connected to a frame attached to the front wall and the relative movement between the front wall and the front geogrid clamp allow the mobilized tensile load to be recorded. A total pressure cell measures the horizontal pressure at the contact between the soil and the front wall. The detail testing apparatus and instrumentation was reported by Portelinha *et al.* (2021).

To simulate a rainfall event an irrigation system was installed over the soil-geogrid layer. The system includes supplying pipes and a 100 mm-thick sand drainage blanket placed on the top. Water was provided by a reservoir with a float switch used to maintain a constant hydraulic

head and the water flow rate was controlled by measuring the output volumetric flow. A vertical display of Volumetric Water Content (VWC) sensors was placed in order to obtain the infiltration process through the unsaturated soil using frequency domain deflection sensors. The location of each VWC sensor is present in Figure 1. Front-wall displacements, geogrid tensile loads, horizontal pressures and VWC were simultaneously measuring during the entire test.

2.2 Materials

The soil used in the experimental test was a high plastic clay with 68% of fines classified as CH according to the Unified Soil Classification System. Consolidated-drained direct shear tests and soil water retention curve (ASTM D5298) for the wetting process were conducted in samples compacted at the optimum water content and at 98% relative to the maximum dry unit weight using the standard Proctor effort. The soil water retention curve experimental data was fitted using the van Genuchten's model (van Genuchten 1980) and the fitting parameters were $\theta s = 0.49$, $\theta r = 4.15 \times 10^{-7}$, $\alpha = 0.016$ and $n = 3.7 \times 10^{-7}$. Figure 2 present the soil water retention curve and Table 1 summarizes the soil characteristics. The reinforcement used was a polyester woven geogrid and Table 2 summarized the physical and mechanical characteristics.

Table 1. Soil characteristics.

Properties	Standard	Value
Clay fraction	ASTM D422	56%
Silt fraction	ASTM D422	12%
Sand fraction	ASTM D422	32%
Specific gravity of solids	ASTM D 7263	2.95
Liquid limit	ASTM D4318	52%
Plastic limit	ASTM D4318	28%
Maximum dry unit weight	ASTM D1557	17.5 kN/m^3
Optimum water content	ASTM D1557	25%
Cohesion (at optimum content)	ASTM D3080	52 kPa
Friction angle (at optimum water content)	ASTM D3080	26°
Saturated hydraulic conductivity	ASTM D5856	3.4×10^{-7} m/s
Figure 2. Soil water retention curve and VWC for the initial and final infiltration test conditions.

Table 2. Geogrid characteristics.

Properties	Standard	Value
Thickness	ASTM D5199	1.3 mm
Ultimate tensile strength	ASTM D4595	42 kN/m
Elongation at failure (at 2%)	ASTM D4595	13 %
Tensile strength (at 2%)	ASTM D4595	20 kN/m
Secant tensile strength (at 2%)	ASTM D4595	440 kN/m
MD yarn width	–	3.0 mm
CMD yarn width	–	8.5 mm
MD aperture size	–	27 mm
CMD aperture size	–	19 mm

2.3 Testing procedure

The soil was placed in 50 mm-high layers at 98% relative to the maximum dry unit weight and at optimum water content of 25% compacted with a manual hammer. The initial conditions (void ratio, dry density and water content) were controlled during the compaction phase. The geogrid was embedded between 150-mm-thick soil layers. Then, the upper wheels and a distribution plate were positioned over the top closed the system prior to the application of vertical surcharge.

A conditioning phase was conducted to simulate the operational condition in a GMSE wall before the infiltration test. Vertical surcharges of 30 kPa were applying for 5 min until reaching the final stress value of 180 kPa, which remained constant during the entire experiment. Thus, a water flow rate (q) of 1.3×10^{-7} m/s was applied uniformly over the soil-geogrid layer. The irrigation rate was selected to simulates a moderate rainfall event of 10 mm/day, which represent a ratio with the soil hydraulic conductivity (q/k_s) of 0.38. The experimental test occurred under consolidated drained conditions of soil to simulate rainfall events after the wall construction.

3 RESULTS

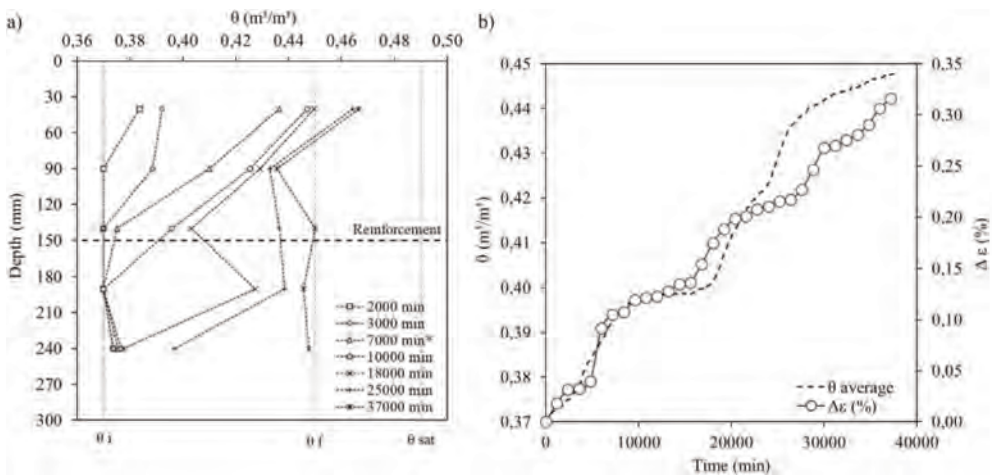
The VWC profile is a key factor to determine the hydraulic behavior of geosynthetic-reinforced layers. The sensor readings for the imposed water flow rate of 1.3×10^{-7} m/s is present in Figure 3a. The VWC corresponding to the initial (θ_i), final (θ_f) and saturation


Figure 3. a) VWC profile during the infiltration process in an unsaturated geogrid layer (*infiltration front reached the reinforcement); b) Progression of average VWC and geogrid strains during the infiltration test.

(θ_{sat}) are also plot for comparison reasons. The sensors evidenced a constant infiltration rate over the entire test indicating that the geogrid layer did not affected the infiltration process thanks to the geogrid openings. This fact can be evidence by the sensor located above the geogrid layer after the infiltration front reached the reinforcement depth (7000 min), which registered similar readings to the other sensors. The saturation water content was not reached because the imposed water flow rate was lower than the saturated soil hydraulic conductivity ($q/k_s < 1$).

The coupled hydro-mechanical performance of a geosynthetic-reinforced layer is related to the soil unsaturated condition. Based on the VWC readings, the geogrid-layer hydraulic behavior was evaluated by the average VWC (θ average). Still, the mechanical variations were assessed through the geogrid strain, calculated from the moving front wall displacement divided by the reinforcement length. Figure 3b relates the coupled behavior during the infiltration test. As the infiltration front advanced the geogrid strain increases over the test following the θ average rises. The results demonstrated a correlation between both parameters, since the curves exhibited similar trends. Similar behavior was reported by Portelinha & Zornberg (2017).

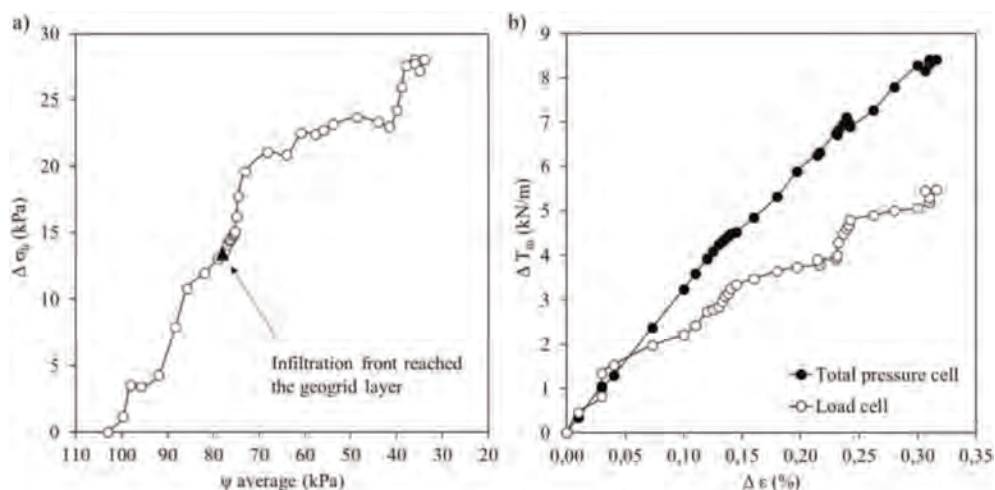
The mechanical response of GMSE walls with unsaturated fine-grained soils depends on the earth pressures values. The horizontal pressure variation ($\Delta\sigma_h$) plotted against the average matric suction (ψ average) changes due to the infiltration process is present in Figure 4a. The ψ average was obtained by using the VWC values in the soil water retention curve present in Figure 2. Note that in Figure 2 is plotted the θ_i and θ_f values. Notably, the horizontal earth pressure increased with the progressive reduction in the average matric suction since the begging of the infiltration test. A variation of 28 kPa were registered with a final matric suction of 35 kPa. This behavior can be attributed to the soil stiffness reduction due to the progressive decreases in the matric suction as the infiltration advances. Still, the variation rate in the horizontal earth pressure were higher when the infiltration front advanced from the top to the reinforcement depth, as reported in previous works (Portelinha & Zornberg 2017; Vahedifard *et al*. 2017).


Figure 4. a) Relation between the horizontal pressure variation and average matric suction; b) Tensile load-strain variation relation during the infiltration test.

Figure 4b relates the geogrid strain variation to the tensile load recorded during the infiltration test calculated from the total pressure cell and directly measured by the load cell.

The final tensile load value mobilized by the geogrid was approximately 5.5 kN/m, which corresponded to 15% of the ultimate resistance and it was lower than the back calculated value from the soil response. This fact indicates that the reinforcement did not mobilized the entire horizontal pressure variation caused by the water infiltration. Moreover, the tensile load increment occurred with lower reinforcement strains. This can be possible attributed to the elevate geogrid stiffness combined with the geosynthetic opening, which allowed the surround soil remains continuous even with a reinforcement inclusion. The curves plotted in Figure 4 indicate a relation between the matric suction reduction and the geogrid tensile-strain response under an infiltration state.

4 CONCLUSIONS

An experimental device that simulates the stress transference in GMSE walls was used to evaluate the rainfall infiltration effect in an unsaturated geogrid-reinforced layer. The test was conducted with a constant vertical surcharge and water infiltration rate. The following conclusions can be expressed:

- The infiltration process caused hydraulic-mechanical responses in the unsaturated soil-geogrid layer. The water content elevation generates an increase in the tensile load mobilized by the geogrid (up to 15%) following the matric suction reduction.
- The tensile load increment rate due to the infiltration process was higher when the water front advanced from the top to the geogrid depth. The linear trend of load increases was attributed to the high initial matric suction value (approximately 100 kPa) and to the pattern along the soil water retention curve primary transition (θ_i to θ_f);
- The geogrid did not demonstrated changes in the water flow into the unsaturated backfill soil. This phenomenon can be attributed to the geogrid openings which allowed the surround soil remains continuous even with the reinforcement inclusion.

Numerical analysis using FEM on the behavior of reinforced fill structure having geogrid and steel wire mesh as a reinforcing element

Ahsan Rehman Khan & Gemmina Di Emidio
Laboratory of Geotechnics, Department of Civil Engineering, Ghent University, Belgium

ABSTRACT: Nowadays, installation of geosynthetics is an effective and economical way to cater soil stability problems. It also helps in designing reliable, constructible, eco-friendly, cost-effective geotechnical structures. Numerous infrastructures resting on these stabilized soil structures is prone to failure due to collapse which result in financial loss, loss of life and disturbance in the services which may take few years to rebuilt. The aim of this paper is to highlight the importance of geogrid and wire mesh as a reinforcement method in reinforced fill structure. To assess the performance of this soil reinforcement, finite element method analysis was adopted. The geometry model of this reinforced fill structure has dimensions as 10 m height, 20 m wide. The type of geogrid used consist of high tenacity polyester fibers coated with a polyethylene sheath. This research paper explores the use of reinforced fill structures incorporating geogrids and wire mesh as an economical, eco-friendly, and adaptable alternative to conventional methods. These structures offer advantages in terms of minimal labor, low manufacturing costs and easy to install that can be customized to fit the specific requirement of any project. The study concludes that reinforced fill structures using geogrids and wire mesh represent a promising alternative solution for construction projects.

Keywords: Geogrids, Wire mesh, Reinforced fill structure, Soil, Eco-friendly

1 INTRODUCTION

The parameter that effects the tensile loads in MSE walls is the stiffness of a reinforcement (Allen & Bathurst 2019) . By inserting the reinforcing elements in the soil, the stiffness of the soil can be enhanced (Sulovska & Stacho 2021). The effect of soil reinforcement on horizontal and vertical deformation is shown in Figure 1. The behavior of retaining structures is influenced by the various factors that affect their construction, such as the type of compaction, and the degree to which it is applied. In order to avoid failure, proper guidelines are established during the construction process (Koerner & Koerner 2013, 2018). Different case studies have shown that poor or inconsistent compaction can lead to the failure of MSE walls (Mahmood 2009; Tarawneh & Siddiqi 2014).
Figure 1. Effect of reinforcement on soil deformation.

Gabion walls, due to their weight, show dominating strength against hydraulic and active soil pressure. The gabions with wire mesh boxes are built by welding or twisting wires and the boxes are filled with course soils (Lin *et al.* 2010). The Gabion walls considered the best stabilization method having 50% less cost (Chikute & Sonar 2019). The reinforced fill structures are also more cost-effective when compared to traditional walls (Uray 2022). Wire mesh has been widely used as a secondary reinforcement for stabilizing earth structures in combination with units that can provide a stone-facing surface for the past few years (Lelli *et al*. 2015). These rectangular boxes are usually manufactured from a combination of steel mesh and stones at the worksite. These materials are commonly used in various infrastructure projects such as airports and roads. Besides stabilization, they can also be utilized for the construction of riverbanks, erosion control measures, and landslide mitigation. Compared to gravity-type retaining structures, reinforced fill boxes offer various economic advantages. They can be used as the wall's height increases (Rimoldi & Scotto 2012). A reinforced fill structure can be constructed using a combination of wire mesh and geogrids, which are commonly used as primary and secondary reinforcement materials respectively. Geogrids, as primary reinforcements, help to prevent the structure from experiencing any potential rupture surfaces. While wire mesh acts as a secondary reinforcement to offer the strength at the facing.

This paper contains the initial part of author's research work. In general, the whole research work is structured around three phases. The initial phase assesses the effectiveness of geogrid and welded wire mesh in terms of stability. The step-by-step procedure of how to model a reinforced fill structure in a simplified way is elaborated. In the second phase of the research, the author aims to predict the long-term performance (creep) of geogrids using finite element method and validate these values with the monitored field data. In the third phase of the research, the author will investigate the long-term pullout test (sustained loading) to predict the performance of geogrid under confined loading based on its design life.

2 METHODOLOGY

Finite element software Plaxis 2D was used here. The model with 15 node elements with plain strain condition was used for the analysis. The stratigraphic feature of the soil can be defined by using the borehole feature. The water table and the location of the soil layers can also be determined by using boreholes. A geogrid was used as a primary reinforcement as it is a slender structure with axial stiffness and axial force and can withstand tension. The gabions with wire mesh were used as a secondary reinforcement to provide erosion control and retention of earth. Also, double twisted wire mesh configuration guarantees the minimum occurrence of strength reduction. The typical steps involved in the analysis of the reinforced fill structure (Edition 2020) are as follows:

- Representation of a Conceptual model
- Specifying boundary, initial, and loading conditions
- Defining geometry
- Specifying the soil, reinforcement, and backfill properties
- Designate specific material model and parameters
- Generation of mesh
- Staged construction development
- Running & verification of the model
- Evaluation of the findings with engineering judgement

2.1 *Constitutive model and material properties*

For the analysis and design of complex geometries, finite element analysis software Plaxis 2D is frequently used nowadays. The tool has the power for the detailed soil response towards construction procedures, boundary conditions & simulating primary loading stiffness, initial stiffness, and unloading/reloading stiffness as per model requirement.

The material properties of the foundation soil & backfill are shown in Table 1, while for geogrid, gabion & wire mesh are listed in Tables 2, 3 and 4 respectively. The model was made using a highly refined mesh.

Table 1. Properties of soil.

Properties	Units	Foundation soil	Backfill soil
Saturated unit weight	kN/m^3	18	18
Unsaturated unit weight	kN/m^3	18	18
Angle of internal friction	Degree	30	35
Cohesion	kN/m^2	1	1
Poisson's ratio	–	0.3	0.3
Reference elastic modulus			
Eref$_{50}$	MPa	60	30
Eref$_{oed}$	MPa	60	30
Eref$_{ur}$	MPa	180	90

Table 2. Properties of geogrid.

Properties	Units	Value
Axial Stiffness (EA)	kN/m^2	3000
Maximum Axial force N$_p$	kN/m	300
Material Type	–	Elastoplastic

Table 3. Properties of gabion.

Properties	Units	Value
Unit weight	kN/m^3	18

Maximum axial force	N$_p$	kN/m	135
Cohesion	C	kN/m^2	27

2.2 Model geometry in Plaxis-3D

The reinforced fill structure modelled in this study has the height of 10 m and base of 20 m as shown in Figure 2, comprises of the following materials components:

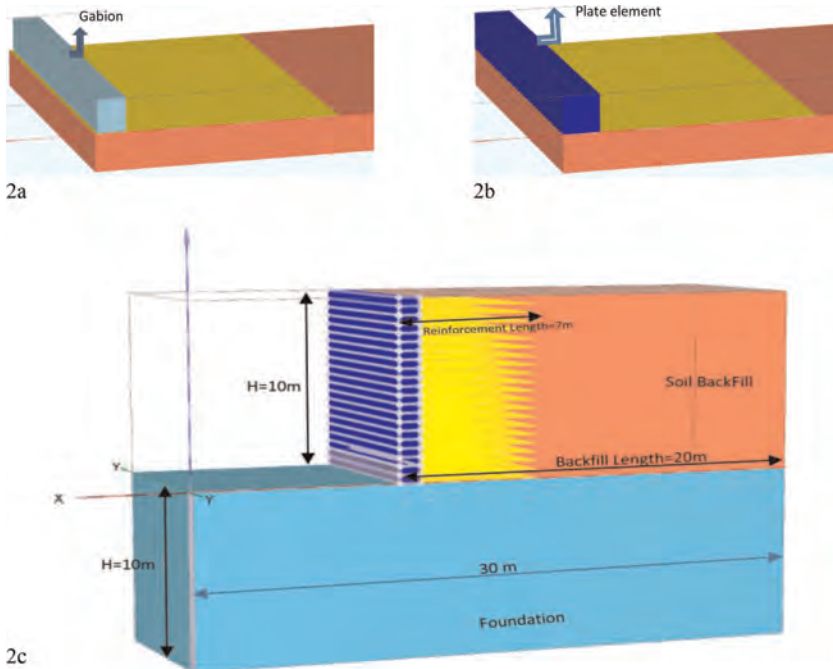
- Gabions modelled as soil clusters as shown in Figure 2a
- Welded wire mesh panels modelled as plate elements as shown in Figure 2b
- Geogrids modelled as Elastoplastic (N-ε) geogrid elements as shown in Figure 2c


Figure 2. (a and b) Plaxis-3D geometry model and MSE wall components. (c). Plaxis-3D Geometry model and MSE wall components.

2.3 Interface modeling

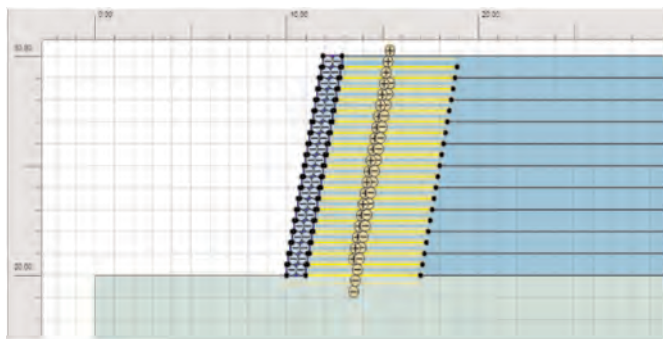
One of the features of Plaxis 2D is the use of interfaces for modelling soil-structure inter-action. Without an interface the soil & structure are tied together having no relative dis-placement between them. By using an interface, node pairs are introduced at the interface of soil & structure as shown in Figure 3. The interaction is modeled by the various interface elements that are used in the construction process. Here, Table 5 represents the coefficients of friction between the soil & wire mesh and soil & geogrid.


Figure 3. Interaction between soil and reinforcing elements.

994

Table 5. tan δ / tan φ friction coefficients for wire mesh & geogrid.

Soil	tan δ / tan φ (Wire mesh)	tan δ / tan φ (geogrid)
Clay	0.3	0.4
Silt	0.4	0.7
Sand	0.65	0.9
Gravel	0.9	0.9

3 RESULTS AND ANALYSIS

Modeling & analysis was executed using the software known as Plaxis 2D. For the stability assessment of the reinforced fill structure, the base soil and the embankment soil was generalized to be homogeneous with the physical properties. The maximum wall displacement is computed to be around 23 cm as shown in Figure 4. Horizontal and vertical displacement was obtained as 6.3 cm & 23 cm respectively as shown in Figures 5 & 6.

The phi/c reduction method was used for estimating the factor of safety. Both the strength parameters phi (φ) and c are gradually reduced until failure occurs in the soil. The FOS was determined as 1.2 as shown in Figure 7. The required length and spacing of the geogrids used were 7m and 0.5m respectively.
Figure 4. Total displacement.
Figure 5. Horizontal displacement.
Figure 6. Vertical displacement.
Figure 7. Factor of safety.

4 CONCLUSION

This study is a preliminary research based on first year PhD, about the stability of a reinforced fill structure with geogrids and wire mesh as a reinforcing unit. The reinforcement layer helps spreading the load over a wider area and provides the necessary tensile strength to the surrounding soils. It can be concluded that the use of geogrid and wire mesh can reduce horizontal movement and increase stability in slopes. These reinforcing materials distribute stresses evenly, mitigating the risk of failure. A reinforced fill structure with geogrids and wire mesh are an alternative and economic solution as compared to other conventional solutions as they are easily buildable, adaptive with nature, durable, ecofriendly, and flexible structure.

Probabilistic back analysis of a high geosynthetic-reinforced slope failure

J.F. Chen, R. Sun, M. Peng & N. Bao
Department of Geotechnical Engineering, College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: This paper presents a probabilistic back analysis for a geosynthetic reinforced soil slope (GRSS) at Yeager airport considering the uncertainty of statistical parameters of random variables based on the Bayesian network. The response surface method was used to develop the input-out relationship between the random variables and the safety factor of the GRSS. The Markov chain Monte Carlo (MCMC) simulation was used to update the statistical parameters of random variables. The results show that the soften soil strength of soil-rock interface is the main reason of failure of the reinforced soil slope at Yeager airport.

1 INTRODUCTION

The use of reinforcements in the form of geosynthetic materials makes the geostructures (like embankments, retaining walls, engineered landfills and soil slopes) perform well under both static and seismic conditions (Chen *et al*. 2014; Peng *et al*. 2020, 2021; Tatsuoka *et al*. 1997; Yoo & Jung 2004). Even though the geosynthetic-reinforced soil structures (GRSS) have good performance, there are still some failure cases (Koerner & Koerner 2013). Among the reasons to cause failure of the GRSS, the uncertainty of soil and reinforcement parameters is one major reason cannot be ignored. Therefore, it is of great necessity to perform the reliability analysis of the GRSS.

The existing studies on the reliability analysis of the GRSS are composed of reliability analysis under static condition and reliability analysis under seismic condition. In term of reliability analysis of GRSS under static condition, the internal stability reliability analysis (Alhajj *et al*. 2022; Chalermyanont & Benson 2004; Bathurst *et al*. 2020) and external stability reliability analysis (Chalermyanont & Benson 2005; Kim & Salgado 2012; Yang *et al*. 2011) considering the uncertainty of soil and reinforcement parameters was carried out in recent decades. In term of reliability analysis of GRSS under seismic condition, reliability analysis considering the uncertainty of earthquake, soil and reinforcement parameters based on pseudo-static method (Basha & Babu 2010, 2014; Sayed *et al*. 2008) and pseudo-dynamic method (Agarwal *et al*. 2021; Basha & Babu 2009, 2011).

The above studies on the reliability analysis of GRSS ignore the uncertainty of estimated statistical parameters, causing uncertain failure probability or reliability index. Bayesian network provides a probabilistic graphical model representing a set of random variables and their conditional dependencies (e.g. F_S) via a directed acyclic graph (Jensen 2001). It has been proven to be a robust method for reliability analysis to update the random variables (Mahadevan *et al*. 2001). Bozorgzadeh & Bathurst (2019a) used a Bayesian approach to perform internal stability reliability analysis of reinforced soil retaining walls considering the uncertainty in failure probability or reliability index. Bozorgzadeh & Bathurst (2019b) also used Bayesian approach to carry out statistical analysis of load and pullout model bias data for steel strip mechanically stabilized earth walls. The mention-above studies have been investigated clearly the internal stability reliability

analysis of GRSS considering the uncertainty of reliability index (or failure probability) based on the Bayesian method. The overall stability reliability analysis of GRSS considering the uncertainty of reliability index (or failure probability) needs to be further investigated.

In this paper, we constructed a Bayesian network considering F_S to conduct the probabilistic back analysis of a reinforced slope at Yeager airport considering the uncertainty of statistical parameters of random variables. First, the numerical model of reinforced slope at Yeager airport was developed to perform deterministic analysis using the GeoStudio 2018 software (2018). Second, the probabilistic back analysis was conducted based on the Bayesian network considering F_S.

2 DETERMINISTIC ANALYSIS OF A REINFORCED SLOPE AT YEAGER AIRPORT

2.1 *Numerical model*

The geosynthetic-reinforced slope at Yeager airport near Charleston, West Virginia, was constructed in 2007 to support the extension of Runway 5 of the airport. In 2015, the slope failed after 8 years in-service. A GRSS model based on the work of Collin *et al.* (2021) is developed using the GeoStudio 2018 software (2018), as Figure 1 shown.
Figure 1.   Geometry of geosynthetic-reinforced soil slope at Yeager airport (adapted from Collin *et al.* 2021).

Table 1.   Inputs of GRSS in the numerical model.

Parameter	c^* (kPa)	ϕ^* (°)	γ^* (kN/m^3)	E^* (MPa)	v^*	A^* (m^2)	H^* (m)
Reinforced soil	0	36	21.2	50	0.3	–	67
In situ retained soil	0	36	21.2	50	0.3	–	67
Bearing soil at slope toe	0	36	21.2	50	0.3	–	67
Soil-rock interface$_1$	0	36	21.2	30	0.3	–	67
Soil-rock interface$_2$	0	36	21.2	30	0.3	–	67
Sandstone	–	–	25	1000	0.3	–	67
Shales	–	–	25	1000	0.3	–	67
Geogrid^1	–	–	–	300	–	0.005	67
Geogrid^2	–	–	–	750	–	0.005	67

Note: $^*c$ is cohesion, ϕ is friction angle, γ is unit weight, E is elastic modulus, v is poison's ratio, A is area, H is the groundwater level.

The soil and the interface between soil and rock was modelled as the Mohr-Coulomb elastic-plastic model and the rock was model as elastic model. The thin soil layer (e.g. Soil-Rock Interface$_1$ and Soil-Rock Interface$_2$ as shown in Figure 1) is used to model the soil-rock interface to evaluate the influence of interaction between the reinforced soil and the sandstone and shales. In the GRSS, two types of uniaxial geogrids were used in the reinforced zone, they were modelled as beam element without moment of inertia. The basic parameters of the soil, and reinforcements are given in Table 1. The cohesion, friction angle, unit weight and poisson's ratio of soil including reinforced soil, in situ retained soil, bearing soil at slope toe and soil-rock interface are 0 kPa, 36°, 21.2 kN/m^3 and 0.3 respectively. The Young's modulus of soil including reinforced soil, in situ retained soil, bearing soil at slope toe and soil-rock interface are 50 MPa and 30 MPa respectively. The unit weight, Young's modulus and poisson's ratio of rock including sandstone and shales are 25 kN/m^3, 1000 MPa and 0.3. The Young's modulus of two types of geogrids are 300 MPa and 750 MPa and the area of geogrid is 0.005 m^2. The groundwater table level is 67 m.

2.2 *Parametric analysis*

Figure 2 illustrates the sensitivity analysis of parameters of soil-rock interface$_1$ and soil-rock interface$_2$ and groundwater table level on the safety factor of GRSS. To make a clear comparison of different factors, the parameters are normalized by the Equation (1).

$$y = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \qquad (1)$$

where y = the normalization parameter; x = the original parameter; $x_{\min}$ = the minimum parameter of original parameters; and $x_{\max}$ = the maximum parameter of original parameters.

It can be seen that the friction angle of soil-interface$_1$ is most sensitive on the F_S of GRSS. The unit weight of soil-interface$_1$ and soil-interface$_2$ have almost no effect on the F_S of GRSS.
Figure 2. Sensitivity analysis of GRSS at Yeager airport.

3 PROBABILISTIC BACK ANALYSIS OF A REINFORCED SLOPE AT YEAGER AIRPORT

3.1 *Constructing a Bayesian network*

Based on the sensitivity analysis, the friction angle of soil-interface$_1$ and soil-interface$_2$ and the water table level are set as random variables. The friction angle of soil-interface$_1$ and soil-interface$_2$

Table 2. Prior statistics of random variables.

Parameter	$\phi_1(°)$	$\phi_2(°)$	H (m)
Mean	36	36	67
COV	0.1	0.1	0.03
Standard deviation	3.6	3.6	2

is considered to follow lognormal distributions with means and standard deviations of 36° and 3.6°, respectively (Collin *et al.* 2021; Phoon 1999). The groundwater level is important but its location is unclear. In this study, the water table level is considered to follow normal distribution with means and standard deviations of 67 m and 2 m, respectively (Shadabfar *et al.* 2020).

A Bayesian network by considering F_S is constructed to carry out the probabilistic back analysis of the GRSS in this study, as Figure 3 shown. Three random factors are considered, namely the friction angle of soil-rock interface$_1$ (ϕ_1) and soil-rock interface$_2$ (ϕ_2) and the groundwater level (H). The F_S can be calculated by SIGMA/W and SLOPE/W in the GeoStudio 2018 software (2018). The stress-strain relationship is obtained first using SIGMA/W considering the effect of groundwater and the interaction between the soil and reinforcement. The obtained stress of GRSS is then imported into the SLOPE/W to calculate the F_S based on the limit equilibrium method.
Figure 3. The Bayesian network ϕ_1, ϕ_2 and H of GRSS and F$_S$.

3.2 Response surface function of F_S of GRSS

To improve the efficiency of probabilistic back analysis of GRSS, altogether 125 combinations of ϕ_1, ϕ_2 and H are considered to develop the response surface function of F_S. The F_S model can then be approximated by the following equation:

$$F_S(\phi_1, \phi_2, H) = 0.2425 + 0.0077\phi_1 - 0.0024\phi_2 + 0.0258H + 0.0002\phi_1^2 + 0.0001\phi_2^2 - 0.0003H^2 \tag{2}$$

To check the accuracy of the response surface functions, 25 more points are randomly drawn from the space of θ and the F_S corresponding to these parameters are evaluated with both the numerical simulation and with the response surface function, as shown in Figure 4. It can be seen that the results from the two approaches are close but not exactly the same. Hence, the response surface model error, ε_1, is introduced to characterize the difference between the response surface method and the numerical simulation. The ε_1 is considered to be followed standard normal distribution with mean and standard deviation of 0 and 0.3455, where the standard deviation is estimated by statistical methods. The numerical simulation error ε_2 is also concerned in this study, which is also be modeled as a normally distributed random variable with a mean of 0.05 and a standard deviation of 0.07, according to Christian *et al.* (1994) and Zhang *et al.* (2010).

3.3 Probabilistic back analysis of GRSS based on Bayesian framework

If the F_S is larger than 1, the GRSS is in the safe state, and if F_S is smaller than 1, the GRSS is in the failure state. When the F_S is unity, the GRSS is in the limit state. The F_S is considered
Figure 4. Comparison of F_S calculated using the response surface with those calculated using the numerical simulation.

to be unity in this study as the GRSS failed in the back analysis, which is also be adapted by Zhang *et al.* (2010) and Wang *et al.* (2013) in the back analysis when the slope failed.

The Markov chain Monte Carlo (MCMC) simulation is used to update the random factors in the probabilistic back analysis. It can be seen that the posterior mean values of ϕ_1 and ϕ_2 are much smaller than the prior value from Figure 5, particularly the posterior mean values of ϕ_1, which is
Figure 5. Comparison of distribution of ϕ_1, ϕ_2 and H considering F_S.

0.75 times of the prior value. The posterior mean value of H is larger than the prior value. The standard deviation values of ϕ_1, ϕ_2 and H are a little smaller than the prior values. The prior mean F_S and failure probability of GRSS is 1.27 and 0.16% respectively based on the prior distribution of ϕ_1, ϕ_2 and H. The posterior mean F_S and failure probability of GRSS is 0.98 and 67.89% respectively based on the posterior distribution of ϕ_1, ϕ_2 and H, which is unacceptable level for the safety status of GRSS. It can be found that the decrease of ϕ_1 and ϕ_2 make the posterior failure probability of GRSS significantly increase, which contributes to failure of GRSS.

4 CONCLUSION

This paper conducted a probabilistic back analysis of GRSS considering the uncertainty of statistical parameters of random variables based on the Bayesian network. The uncertainty of friction angle of soil-rock interface and groundwater table level of the reinforced soil slope was considered. Based on the probabilistic back analysis results, the weaken strength of soil-rock interface of the reinforced soil slope at Yeager airport caused significant increase of failure probability of GRSS, making the reinforced soil slope fail. Therefore, the soften soil strength of soil-rock interface is the main reason of failure of the reinforced soil slope at Yeager airport.

Seyed Hamid Lajevardi & Seyed Mohammad Mirhosseini
Department of Civil Engineering, Arak Branch, Islamic Azad University, Arak, Iran

ABSTRACT: Stone column technique is well established to improve soft soil performance. However, an alternative material is proposed to enhance the soft soil performance by reinforcing with geofoam materials. Expanded Polystyrene (EPS) geofoam is a super-weighted geosynthetic material used in various geotechnical engineering applications. This study deals with the innovative use of geofoam as a column material in soft soils to improve bearing capacity. This method has been developed in small-scale laboratory tests and a series of loading tests have been performed on different single floating geofoam columns with two different diameters and a length to diameter ratio of 5. Then, a comparison was made with the results of ordinary stone columns and reinforced stone columns to obtain the advantages of geomofume columns. By considering the bearing capacity, it was found that geofoam columns could be a suitable alternative material to improve the bearing capacity of soft soils. The results showed that the efficiency of geofoam columns is almost similar to ordinary stone columns and geofoam is easy and economical to use.

Keywords: Geosynthetics, Geofoam, Stone Column, Ground Improvement, Laboratory Study

1 INTRODUCTTION

There are various techniques available for improving the soft soil capacity. One of these, is stone columns. Most studies summarized the failure mechanisms of stone columns, including bulging failure, shear failure, and punching failure. However, stone columns may not work well in very soft soil due to the bulging of columns. Encasement materials have been used to minimize the bulging of stone columns and improve their performance (Van Impe 1986). Many studies deal with the stone columns encased with geosynthetics (Murugesan & Rajagopal 2007).

Despite those mentioned above, due to the increasing demand for conventional materials such as stone aggregates as well as the equipment required for construction of stone columns, the use of alternative materials seems necessary. Further, the technique of soil-improvement using geosynthetics is extensively used in the construction of stone columns (Lajevardi *et al*. 2018a, 2018b). In the case of alternative materials, researchers proposed different materials for the construction of columns. The use of a steel bar as reinforcement has been investigated in laboratory studies. The findings show that reinforced stone columns with bars have more stiffness in comparison with ordinary stone columns. (Rezaei *et al*. 2019a).

*Corresponding Author: sbazazian@tvu.ac.ir

The newest type of geosynthetics is expanded polystyrene (EPS) geofoam blocks, which is a superlight weight material used for construction purposes. EPS geofoams have been used consistently in roads and as a compressible inclusion behind soil retaining structures as well as a method for protecting buried pipelines (Bartlett *et al.* 2015). It is an elastoplastic hardening material with plastic contractive volume changes under compressive loading, whose behaviour is dependent on the density and confining stress. Further, it has been shown that the volumetric strain and axial compression strain have a linear relation. The growth of both geofoam density and thickness affects the reduction of settlements. However, the changes in the thickness factor of geofoam are more effective than the alteration of the density factor on reducing settlements. Selvakumar and Soundara (2018) conducted one-dimensional swell experiments to evaluate the efficiency of the EPS geofoam column (GC) on the swelling behaviour of expansive soil (Selvakumar & Soundara 2018). The results revealed that by the increase in the diameter of the column, there is a significant reduction in the swelling potential.

The crushed stone aggregate is the most common material used for the construction of the stone column. However, little research has been done on the use of alternative materials as a column material. The previous experimental study as mentioned above has been performed on end-bearing geofoam column using small circular tank (typical CBR sample) and the results were not compared with the other types of columns like ordinary stone columns to obtain its performance. In this study, to introduce a geofoam column as a suitable alternative material to other columns, some laboratory experiments were conducted on floating columns in a large tank. The primary purpose of the study is to evaluate the efficiency of geofoam columns (GCs) with different arrangements. Also, to show the effectiveness of this new approach, the tests were compared with the ordinary stone columns (OSCs) and vertical encasement stone columns (VESCs).

2 LABORATORY MODEL TESTS

2.1 *Material used*

The kaolin clay soil was used as a soil bed. Table 1 represented the properties of kaolin clay soil and stone aggregates features. The properties of geotextile were shown in Table 2. The EPS geofoam blocks with a density of 18.4 kg/m3 (EPS19), were used as a column material. In this case, the geofoam blocks were cut into cylindrical cross sections. Then, one of the geofoam cylinders became a hollow cylinder (Figure 1a), while the other was used as a normal cylinder as shown in Figure 1b. A hollow cylindrical geofoam column had a hole at the middle filled with stone aggregates where a normal solid cylindrical geofoam column had not any hole and it was used without any modifications. As shown in Figure 1c, a cylindrical geotextile was constructed with an overlap of 15 mm geotextile in the length for encasing the column.

Table 1. Properties of the kaolin clay soil and crushed stone aggregates.

Parameter	Kaolin clay	Stone aggregates
Maximum dry unit weight (kN/m^3)	15.5	16.9
Unconfined compression strength (kPa)	30	–
Specific gravity	2.6	2.7
Liquid limit *(%)*	48	–
Plastic limit *(%)*	25	–
Bulk unit weight at 23% moisture content (kN/m^3)	19.1	–
USCS classification symbol	CL	GP

Table 2. Properties of geotextile.

Parameter	Value
Yarn material	Prolypropylene
Ultimate tensile strength (kN/m)	10
Secant stiffness at ultimate Strain (kN/m)	15
Thickness (mm)	1.4
Mass per unit area (gr/m^2)	150

2.2 Experimental model

Similar to some researches (Hamidi *et al.* 2018; Rezaei *et al.* 2019b), a large steel tank with steel rigid loading frame was made. The system of loading was based on displacement control, which contained a hydraulic jack and a rigid loading plate. To achieve the minimum boundary effects on the results of the tests, the steel tank was built in a 1.2 m × 1.2 m × 1 m (Figure 2).

Figure 1. Reinforcement materials: (a) Hollow Geofoam, (b) Normal Geofoam, (c) Geotextile.
Figure 2. Test tank.

2.3 Experimental procedure

The kaolin clay soil was mixed with a water content of 23% in a container to obtain a homogeneous mixture (corresponding to the unconfined compression strength of 30 kPa). The technique of column construction in the present study is the replacement method. In the case of geofoam columns, after making a borehole in the kaolin clay bed, the geofoam column was simply located into the hole. Moreover, in the case of using a hollow geofoam, the stone aggregate was used to fill the borehole of geofoam column. For encasing vertical geotextile, a thin-walled tube with a diameter equal to the diameter of the geotextile sock

was driven into the hole. Then, the geotextile was located in to the casing and filled with stone aggregates by considering the procedure which was discussed above for OSCs. After that, the casing pulled up while the geotextile left in the place (Bazzazian Bonab *et al.* 2021).

2.4 *Tests conducted*

The columns, which formed in the kaolin clay bed, were subjected to vertical loading through a loading plate displaced at a constant strain rate of 1 mm/min up to a settlement of 50 mm. The loading plate was 2 times larger than the diameter of the columns and had a thickness of 30 mm. The experiments were performed on an unreinforced kaolin clay bed, OSCs, VESCs and GCs (Figures 3 and 4). To evaluate the efficacy of the columns, 11 tests were conducted on two different diameters with the length of 5D, which were installed in kaolin clay bed without ground water level.

As shown in Figure 3, in OSCs, the tests were applied on two diameters (D) and lengths (L), D = 80 mm and L = 400 mm (OSC1) and D = 100 mm and L = 500 mm (OSC2). In VESCs, as the OSCs, two tests were conducted on the stone columns with full-length geotextile encasement with two diameters and lengths (VESC1 and VESC2). The GCs consist of two groups. The first group includes four different tests which were performed using different length of the normal geofoam columns; GC-N1 (D = 80 mm and L = 400 mm), GC-N2 (D = 80 mm and L = 200 mm), GC-N3 (D = 100 mm and L = 500 mm), and GC-N4 (D = 100 mm and L = 250 mm). The second group includes two different tests which were conducted using hollow geofoam columns; GC-H1 (D = 80 mm, L = 400 mm) and GC-H2 (D = 100 mm, L = 500 mm). In this case, there was a hole at the middle of the column with a diameter of 0.5D, which was filled with the aggregates material.
Figure 3.   Schematics of different types of columns testing.
Figure 4.   Different types of column: (a) OSC, (b) VESC, (c) GC-H, (d) GC-N.

3 RESULTS AND DISCUSSION

3.1 *Load-settlement behaviour*

Figures 5(a) and (b) demonstrated the load-settlement behaviour for the columns with the diameter of 80 and 100 mm, respectively up to the settlement of 50 mm. As seen, OSCs, VESCs, and GCs increased the bearing capacity of clay soil. The increase of the bearing capacity for OSC1 (D = 80 mm) and OSC2 (D = 100 mm) were 25.6% and 44.4%, respectively. Also, using VESC1 and VESC2 led to an increase in bearing capacity by 84.8% and 103.7%, respectively. In the case of using geofoam, GC-N1 (D = 80 mm) and GC-N3 (D = 100 mm) led to increase the bearing capacity of the kaolin clay by 33.0% and 40.7%, respectively. The magnitudes of this increase for GC-N2 and GC-H1 (D = 80 mm) was 32.1% and 33.0% while for GC-N4 and GC-H2 (D = 100 mm) was 35.8% and 38.9%, respectively.
Figure 5.   Variation of load-settlement of kaolin clay bed, OSCs, VESCs and GCs.

According to the results, by using OSCs or GCs instead, the bearing capacity would increase. Encasing OSCs via vertical geotextile reinforcement resulted in a further increase in the bearing capacity of kaolin clay soil. It was because geotextile provides additional confinement, which led to more stiffness of the column. Moreover, the comparison between Figures 5a and 5b for OSCs showed that, by increasing the diameter, the bearing capacity of the clay soil increased by 15.0%. Also, comparing VESC1 with VESC2 showed that upon elevation of the diameter, the bearing capacity rose by 10.3%. Further, the average value of this increase was 4.3% for GCs. The results showed that the increase in the bearing capacity with increasing diameter in VESC is more than twice that of GCs. This is because geotextile has more stiffness, which leads to more confinement than geofoam. Application of VESC1 and VESC2 increased the bearing capacity of the OSC1 and OSC2 by 47.2% and 41.0%, respectively. Therefore, with an increase in the column diameter, the benefit of the encasement decreases. It is because the lateral stresses mobilized in encased stone columns are higher for smaller diameter columns. Based on the experimental study, Bazzazian Bonab *et al.* 2020 also observed that the encasing the stone columns with geotextile, led to increase in the bearing capacity of the stone column by 38% and 32%, respectively for D = 80 and 100 mm. This showed that, encasing the stone columns resulted in more increase in the bearing capacity. Also, the results of the study demonstrated that increasing the column diameter reduced the efficiency of geotextiles as discussed above for the present study.

The effect of the geofoam length was studied for two different lengths. It was seen that with the increase in the length of geofoam from half-length (GC-N2 and GC-N4) to full-length (GC-N1 and GC-N3), the variation of the bearing capacity was negligible. This was because of the deformation mode of OSCs in the form of bulging changes to the small bulging with elastic shortening in both lengths. Therefore, the use of shorter geofoam columns seems sufficient. As observed in Figure 5, the performance of the GC-Hs was almost the same as that of GC-Ns. In other words, filling GCs with stone aggregates did not lead to more increase in the bearing capacity. It might be because GC was not a good element for encasing the stone aggregates.

Comparison of OSCs and GCs showed that the variations of the bearing capacity of the columns for both diameters were negligible. Therefore, the use of GCs instead of OSC led to almost the same results in the bearing capacity of the kaolin clay. From another perspective, the geofoam columns are very easy to install and save both cost and time by eliminating compaction operations. Also, there is not any soil distribution in installation in such cases. Also, the lightness of the geofoam makes it easy to work with and reduces the cost of transportation.

The parameter of the ratio of the area replacement (AR) is defined which offers the percentage of soil replaced by the column materials and obtains from dividing the column area to the loaded area. In order to compare the benefits of geofoam material and geotextile encasement with OSC, the dimensionless parameter (β) is defined, which explained as the ratio of the bearing capacity of the reinforced column (GCs or VESCs) to unreinforced stone column (OSCs). The variations of β with AR for different columns diameters presented in Table 3. As seen, the variation of the β was almost the same for GCs. Thus, by considering the bearing capacity, the performance of the GCs was similar to that of OSCs. In addition, it was found that the β values for VESCs vary within the range of 1.41–1.47. In this case, the elevation of AR leads to decreases in β. So, it means that increasing the column diameter led to a decrease in the efficiency of the reinforcement. Also, as stated for VESCs, in geofoam columns, the column efficiency decreases with increasing the column diameter. As seen in Table 4, with the increase of the AR, the stiffness of the column increases and as a result, the bearing capacity of the column increases.

Table 3. Variation of β with AR.

Diameter (mm)	80	100
AR%	16	25
GC-N1	1.06	–
GC-N3	–	0.97
GC-N2	1.05	–
GC-N4	−0.94	
GC-H1	1.06	–
GC-H2	–	0.96
VESC1	1.47	–
VESC2	–	1.41

Table 4. Details of tests conducted.

	AR	
Type of column	16	25
GC-N1	1.82	–
GC-N3	–	2.24
GC-N2	1.67	–
GC-N4	–	2.05
GC-H1	1.80	–
GC-H2	–	2.28
VESC1	2.79	–
VESC2	–	3.29

4 CONCLUSIONS

- The bearing capacity of geofoam columns (GCs) is almost equal to the bearing capacity of ordinary stone columns (OSCs). However, this amount is smaller than vertical encasement

stone columns (VESC). This shows that the stiffness created by the stone aggregates is the same as the stiffness created by the geofoam materials.

- In VESCs, the reinforcing stone column with geotextile provides additional confinement. Thus, the bulging reduces and the bearing capacity increases. This indicates that the geotextile encasement increases the stiffness of the column.
- The value of β varies in the range of 0.94–1.06 and 1.41– 1.47 for GCs and VESCs, respectively. Therefore, it is concluded that the increase of the area replacement ratio (AR) in the GCs and VESC, lead to decrease in the benefits of the geofoam and geotextile materials.
- The geofoam columns could be a good alternative material because they have the same performance with the ordinary stone columns and are very easy to install and save both cost and time. However, the technique of using geofoam columns is in the beginning and requires additional studies on a real scale condition to understand its behaviour.

ABSTRACT: Geosynthetics are widely used on improving embankment stability. However, limited studies have focused on the stability and failure modes of geosynthetic-reinforced embankments with various layers and stiffness of geosynthetics. In this paper, a finite difference approach is used to analyze the ultimate surcharge of embankments and failure mechanism. The results show that the stiffness and layers of geosynthetic both have a positive influence on the embankment stability. A deep-seated failure occurs when the geosynthetic stiffness and layers are low. When the stiffness and layers increase to a certain value, the failure mechanism changes to lateral sliding failure.

Keywords: Numerical analysis, Geosynthetics, Failure mode, Embankment, Stability

1   INTRODUCTION

Embankments on soft clays are often required for building expressways and railways (e.g., Chai *et al.* 2013; UIC 2018; Zhou *et al.* 2020, 2023). The stability of embankments over soft soil has attracted considerable attention (e.g., Sharma & Bolton 1996; Mohapatra & Rajagopal 2017). The application of geosynthetic reinforcements serves as an economical solution for increasing global stability when stabilizing an embankment (e.g., Chai *et al.* 2002; Miao *et al.* 2014; Zheng *et al.* 2021).

The failure mechanisms of embankments reinforced by geosynthetics can be divided into two categories: deep-seated failure (global failure) and lateral sliding failure (surface failure) (Abusharar & Han 2011; Smith & Tatari 2016; Zheng *et al.* 2020). Smith & Tatari (2016) conducted parametric studies of single layer geosynthetic reinforced embankment, the major failure modes were determined and design envelopes of overall stability were presented. However, varying stiffness and layers of geosynthetic reinforcements may have a significant influence on the associated failure mechanism and the embankment's overall stability.

In this study, finite difference numerical modelling is performed to explore the influence of various layers and stiffness on the critical failure modes. The ultimate failure height and the transition of the failure mechanism of the embankment are analyzed.

2 NUMERICAL MODELLING

Numerical modelling of the geosynthetic reinforced embankment (GRE) over soft soils is established using the finite difference method implemented through the software FLAC3D (Itasca, 2006; Zheng *et al.* 2018, 2019). A typical numerical modeling section is shown in Figure 1. Embankment with a slope of 3(*H*):2(*V*). The thickness of the soft layer is 15m and the thickness of the silty layer is 5m. One half of the embankment was modeled, and symmetrical boundary conditions were applied along the lateral boundaries, while both the horizontal and vertical displacements were fixed along the bottom boundary.

Soil constitutive models and their baseline material properties are listed in Table 1. The silty clay layer and embankment were represented as linear elastic and perfectly plastic with the Mohr-Coulomb failure criterion. The soft clay layer was modeled with Modified Cam Clay (MCC) model. According to the MCC model and along undrained triaxial compression stress paths, the undrained shear strength (s_u) was determined by the MCC model as shown in Eq. (1) (Chai *et al.* 2013; Liu *et al.* 2007; Zhou *et al.* 2021):

$$c_u = \frac{p'}{2^{1+\Lambda}} M \left(\frac{M^2 + \eta^2}{M^2}\right)^\Lambda (\text{OCR})^\Lambda \tag{1}$$

where $\Lambda = 1-\kappa/\lambda$; $\eta = q/p'$ and overconsolidation ratio (OCR) of 1 in this study.

Geosynthetics were modeled using orthotropic linear elastic structural geogrid elements of the constant strain triangle type (Abusharar & Han 2011; Zheng *et al.* 2019). The geogrid elements can sustain membrane stress but not bending, which reasonably simulate the behavior of the geosynthetic reinforcement layers. A friction coefficient of 0.8 was adopted for geogrid-soil interfaces and the shear stiffness $k_{s,geo}$ between the geosynthetic layer and the surrounding soil was considered as 1/10 of the elastic modulus of the geosynthetic material (Liu *et al.* 2009; Yu *et al.* 2021; Zheng *et al.* 2020, 2021). The properties of the geosynthetic reinforcement are exhibited in Table 3.

The embankment construction process was simulated by placing embankment structure elements layer by layer until the global failure occurs. The thickness of each layer was 0.25m.
Figure 1.   The configuration of the numerical model.

Table 1. The configuration of the numerical model.

Material	v	c_u(kPa)	E(MPa)	φ (°)	γ(kN/m^3)	λ	κ	M	e_1	σ'_p(kPa)
Embankment	0.3	10	30	32	18	–	–	–	–	–
Soft clay	0.37	–	–	–	18	0.26	0.05	1.02	2.57	σ'_v
Silty clay	0.25	20	37.5	35	19	–	–	–	–	–
Geosynthetic	J = 800, 2000,6000,8000,10000,12000kN/m, v_{geo} = 0.3, c_i = 0.8, t = 2mm, $k_{s,geo}$ = Variable									

Note E = elastic modulus, v = Poisson's ratio of soil, c_u = undrained shear strength, φ = friction angle, γ = unit weight (saturated unit weight for the soil below the ground water table), c_i = interaction coefficient between geosynthetic and the surrounding soil, J = tensile stiffness of geosynthetics, v_{geo} = Poisson's ratio of geosynthetics, t = the thickness of geosynthetics and $k_{s,g}$ = interface shear stiffness between the geosynthetics and the soil.

3 PARAMETRIC STUDY

Figure 2 shows the variation of embankment center settlement with filling height for various geosynthetic tensile stiffnesses. A non-linear variation of foundation settlement can be observed for all the cases. Besides, with the increase in the geosynthetics stiffness from 800kN/m to 12000kN/m, the foundation settlement has decreased from 1.3 to 2.7 times compared with the unreinforced case.
Figure 2. Histories of the vertical settlement of the foundation with various geosynthetic stiffnesses.

Figure 3 illustrates the influence of the number of geosynthetic layers on the settlement of center of the soft foundation (J = 2000kN/m). With an increase in the number of geosynthetic layers, the vertical settlements located at the embankment center are reduced. However, the settlement discrepancy is relatively small at the beginning of the construction process (e.g., $H<6$m) and gradually becomes significant as the embankment height increases. For example, the difference of subsidence between J = 800kN/m and J = 12000kN/m is increased for 16.2% (H = 6m) to 84.9% (H = 9m). This result indicates that compared to adding the number of geosynthetic layers, increasing geosynthetic stiffness is more effective in limiting the global deformation under embankment loading conditions.
Figure 3. Histories of the vertical settlement of the foundation with numbers of geosynthetic layers.

4 TRANSITION OF THE FAILURE MECHANISM

In this study, the ultimate height of embankment (H_u) is selected as the stability metric. Figure 4 shows the ultimate height corresponding to different stiffness values of single layer geosynthetic. There are two failure mechanisms occurred under embankment loading, which can be described as deep-seated failure and lateral sliding failure (Smith & Tatari 2016; Zheng *et al*. 2019). For a low tensile stiffness reinforcement, a deep-seated failure mechanism is found in the embankment system, and the stability of embankment increases with the increase in the tensile stiffness. Once the tensile stiffness exceeds a certain value ($J = 10000$kN/m), the failure mechanism changes from the deep-seated failure mode to the lateral sliding failure, indicating that the shear strength of the embankment on global stability becomes dominant. In turn, the ultimate height remains constant, representing that the effect of the geosynthetic stiffness is negligible.
Figure 4. Variation in embankment failure height with geosynthetics stiffnesses.

To further elaborate on the failure mechanisms transition of various geosynthetic tensile stiffnesses, a different number of geosynthetic layers are considered, as shown in Figure 5. It can be seen that in the deep-seated failure mechanism, increasing reinforcement layers effectively improves the global stability. Besides, the threshold value (tensile stiffness J) for the failure mechanisms transition is smaller in the two layers of reinforcements. Similarly, in the lateral sliding failure mechanism, the effect of the number of geosynthetic layers is negligible.
Figure 5. Transition of the critical failure mechanism with different numbers of geosynthetic layers.

5 CONCLUSIONS

A numerical model is adopted to investigate the failure mechanisms and performance of geosynthetic reinforced soft foundations under an embankment load. Various layers and stiffnesses of geosynthetics are considered and discussed. The following conclusions can be drawn:

1. Increasing tensile stiffness and the number of geosynthetic layers result in a better performance to reduce the amount of settlement located at the center of the embankment. Compared to adding the number of geosynthetic layers, increasing geosynthetic stiffness is more effective in limiting the global deformation under embankment loading conditions.
2. The ultimate height of the reinforced embankment increases nonlinearly with the tensile stiffness of geosynthetic, and the deep-seated failure changes to lateral sliding failure as tensile stiffness increases up to a certain critical value. In the lateral sliding failure mechanism, the effect of geosynthetic reinforcement is negligible.
3. Increasing reinforcement layers effectively improve the global stability under the deep-seated failure mechanism. Meanwhile, it reduced the critical value of the failure mechanism transition.

ABSTRACT: A wide range of treatments has been proposed to improve soft soils. However, increasing construction costs and combining with today's environmental considerations will undoubtedly make the need for alternative materials. Expanded Polystyrene (EPS) geofoam is a superlight weight geosynthetic material used in various geotechnical engineering applications. This study deals with the innovative use of geofoam as a column in the soft soil for improving the load-carrying capacity. A series of numerical analysis was carried out on the various single floating geofoam columns with diameters of 80 mm and 100 mm and the length of 400 mm and 500 mm, respectively. Then, the results of the analysis were compared with the results of ordinary stone columns and vertical encasement stone columns with the geotextile to obtain the benefits of geofoam columns. The load-carrying capacity of the geofoam column is almost equal to the load-carrying capacity of an ordinary stone column. However, this amount is smaller than vertical encasement stone columns. The lateral deformation of the columns was investigated for all types of columns. The bulging in geofoam columns is smaller than the ordinary stone column.

Keywords: Geosynthetics, Geofoam, Stone Columns, Ground Improvement, Numerical Analysis

1   INTRODUCTION

There are various techniques available for improving the load-carrying capacity of soft soils. One of these is stone columns. However, due to increasing demand of conventional materials such as stone aggregates as well as the equipment required for construction of stone columns, the use of alternative materials seems necessary. Further, the technique of soil-improvement using geosynthetics is extensively used in the construction of stone columns (Lajevardi *et al.* 2018a, 2018b; Malarvizhi & Ilamparuthi 2007). The newest type of geosynthetics is expanded polystyrene (EPS) geofoam blocks which is a superlight weight material used for construction purposes. EPS geofoams have been used consistently in roads (Beinbrech & Hillmann 1997) and as a compressible inclusion behind soil retaining structures (Ram Rathan Lal *et al.* 2014) as well as a method for protecting buried pipelines (Bartlett *et al.* 2015). It is an elastoplastic hardening material with plastic contractive volume changes under compressive loading (Leo *et al.* 2008) whose behavior is dependent on the density and confining stress. Further, it has been shown that the volumetric strain and axial compression strain have a linear relation (Chun *et al.* 2001). The growth of both geofoam density and thickness affects reduction of settlements. However, the changes in the thickness factor of

---

*Corresponding Author: m-mirhoseini@iau-arak.ac.ir

geofoam are more effective than the alteration of the density factor on reducing settlements. (Abdelrahman & Kamash 2014). Selvakumar and Soundara (2018) have performed a series of one-dimensional swell tests to study the performance of the EPS geofoam column (GEC) on the swelling behavior of expansive soil. The results revealed that by increasing the column diameter, there is a significant reduction in the swelling potential.

There are very limited studies on geofoam columns. In this study, some small-scale laboratory tests were carried out on single floating columns with various diameters. In these tests, columns were installed in kaolin clay bed with no ground water table. The main objective of this study is to investigate the efficiency of geofoam columns (GECs) with various arrangements. Also, to show the effectiveness of this new approach, the tests were compared with the ordinary stone columns (OSCs) and vertical encasement stone columns (VESCs) with geotextile. It was then extended to real columns by performing numerical analyses.

2 LABORATORY MODEL TESTS

2.1 *Material used*

The kaolin clay soil was used as a soil bed. Table 1 represented the properties of kaolin clay soil and stone aggregates features. The EPS geofoam blocks with a density of 18.4 kg/m3 (EPS19), were used as a column material (Bazzazian Bonab et al. 2020).

Table 1. Properties of the kaolin clay soil and crushed stone aggregates.

Parameter	Kaolin clay	Stone aggregates
Maximum dry unit weight (kN/m^3)	15.5	16.9
Minimum dry unit weight (kN/m^3)	–	14.3
Optimum moisture content *(%)*	19	–
Unconfined compression strength (kPa)	30	–
Specific gravity	2.6	2.7
Liquid limit *(%)*	48	–
Plastic limit *(%)*	25	–
Plasticity index *(%)*	23	–
Bulk unit weight at 23% moisture content (kN/m^3)	19.1	–
Bulk unit weight for test at 70% relative density (kN/m^3)	–	16
Internal friction angle at 70% relative density (degree)	–	46
Uniformity coefficient (Cu)	–	2.25
Curvature coefficient (Cc)	–	1.62
USCS classification symbol	CL	GP

2.2 *Experimental model*

Similar to some researches (Hamidi *et al.* 2018; Rezaei *et al.* 2019b), a large steel tank with steel rigid loading frame was made. The system of loading was based on displacement control, which contained a hydraulic jack and a rigid loading plate. More information about the test setup was described by Bazzazian Bonab et al. (2021).

3 NUMERICAL STUDY

The kaolin Numerical modeling is often used to develop and complete experimental modeling, through which engineering problems can be solved and the behavior of materials could

be predicted in both real and field conditions. In this section, axisymmetric finite element model was developed on Plaxis 2D to achieve this purpose. It was calibrated to match the actual laboratory measured response of the column. Then, another series of finite element (FE) models was done to describe the behavior of the columns in real condition (Mohammad Rezaei et al. 2019).

The analyses simulate the same geometry and boundary conditions as in the laboratory tests. Numerical modeling is performed in an axisymmetric form in the half-plane using 15-nodded unstructured mesh. The vertical boundaries were released in the vertical direction with the bottom boundary being fixed.

For loading element, the plate element was placed on the top of the columns and the entire analysis was considered by the displacement control where the maximum settlement was 50 mm. Since the plate was modeled as rigid, the settlement remained uniform beneath the loaded area. The soft soil behavior and Mohr–Coulomb failure criterion were adopted for soil and the crushed stone aggregates, respectively. Also, the elastic-plastic method based on Mohr–Coulomb failure criterion was adopted for geofoam. The material properties used for modeling kaolin clay bed, crushed stone aggregates, geotextile encasement and geofoam are presented in Table 2.

Table 2. The number of officially reported plague cases in the world.

Parameter	Kaolin clay	Crushed stone aggregates	Geofoam	Geotextile
Model type	Soft soil	Moher-column	Moher-column	–
Friction angle, φ (degree)	28	46	2	–
Dilation angle, ψ (degree)	0	16	0	–
Cohesion, C (kPa)	15	1	21	–
Poisson's ratio, v	0.33	0.30	0.10	–
Young's modulus, E (kPa)	–	40000	4000	–
Unit weight, γ (kN/m^3)	19	16	0.18	–
Logarithmic hardening constant for plasticity, λ	0.134	–	–	–
Logarithmic bulk modulus for elastic material behavior, κ	0.40	–	–	–
Secant stiffness, J (kN/m)	–	–	–	15

3.1 Verification

To verify the numerical model developed, a comparison was made between the results of experimental tests and the numerical analysis for 100 mm stone columns (Figure 1) (Bazzazian *et al*. 2020). The comparison showed a good agreement between experimental and numerical results.

3.2 Lateral deformation of the columns

After completion of each test, slurry of plaster was poured into the stone column and allowed to settle for 24 hours to harden. This would prevent dissipation of stone aggregate. Then, the surrounding kaolin clay was removed carefully and whereby a deformed shape of the stone column was obtained where the bulge depth was visible. Figure 2 demonstrates the deformed shapes of OSC and VESC indicating bulging failure mechanism occurring at the depth of D to 2D from top of the column. The bulging in VESC was smaller than that of in
Figure 1. Comparison between numerical analysis and experimental results for D = 100 mm.

(a) OSC   (b) VESC
Figure 2. Deformation of columns after test.

OSC. Bulging in reinforced stone columns was reduced due to the additional confinement arising from the reinforcement material.

The lateral deformations of the columns obtained from the experimental and numerical analysis are shown in Figure 3. The bulging in GEC was smaller than that of in OSC and it occurred at the depth of D to 2D from top of the column as with OSC. However, half-length geofoam columns (GEC-N2), fail from punching while full-length geofoam columns (GEC-N1) fail by bulging. Moreover, the bulging in VESC was the smallest.

3.3 Reinforcement ratio

Reinforcement ratio (RR) is defined as the load-carrying capacity of the reinforced stone column to unreinforced stone column. This parameter represents the impact of
Figure 3.   Lateral deformation of the columns (D = 100 mm).

reinforcement on the load-carrying capacity of stone columns. The ratio of the area replacement (RAR) is a crucial dimensionless parameter which provides the percentage of soft soil replaced by the crushed stone aggregate. It is defined as the area of the stone columns divided by the loaded area. Table 3 presents variations of RR with RAR for various diameters of the columns.

As seen, the variation of the RR is almost the same for GECs. Thus, although GECs enhance the load-carrying capacity of the kaolin clay bed, the performance of the GECs is similar to that of OSCs. It is found that the RR values for VESCs vary within the range of 1.18–1.59. Further, elevation of RAR leads to further increase in RR.

Table 3.   Variation of RR with RAR.

Diameter (mm)		50	60	70	80	90	100	110
RAR %								
Type of arrangement		6.25	9	12.25	16	20.25	25	30.25
RR	GEC-N[*]	1.04	1.05	1.03	1.04	1.03	1.03	1.03
	VESC	1.18	1.27	1.32	1.42	1.49	1.56	1.59

[*]Full-length

3.4   Load ratio

To extend the results of small-scale laboratory tests to large-scale and real conditions, it is necessary to examine the effects of scale in numerical models. Thus, the behaviors of the columns with diameters of 0.80 m and 1.0 m were studied by numerical analysis. Table 4 shows the various values of the load ratio (LR) for real diameters in the 50 mm settlement. As can be seen, the load ratio of numerical modeling has a good agreement with the LR values obtained from experimental tests. Thus, the results of small-scale experimental tests can be used to study the performance of GECs on a real scale.

Table 4. Various values of LR for real diameters.

Column	D (m)	
	0.8	1.0
OSC	1.3	1.54
GEC-N[*]	1.3	1.4
VESC	1.8	2.0

[*]Full-length

Although in the field practices well-established technique has been adopted in the installation of the OSC, but it has some problems. However, this study is an introduction to further studies on the use of geofoam columns. The technique of using geofoam columns is in the beginning and requires additional studies on a real scale condition to understand its behaviour.

4 CONCLUSION

The load-carrying capacity of GEC-N is almost equal to the load-carrying capacity of OSC. However, this amount is smaller than VESC.

The magnitude of the lateral deformation of GECs is between OSCs and VESCs. However, its region is less than both of them. In GECs, it was observed that encasing the stone column in the top of the column plays a fundamental role in the performance of the stone column. The reason is that the bulging failure usually occurs at the depth of D to 2D from the top of the stone columns. So, it might be obvious that half-length geofoam column is more economical than the other types of the group.

The load-carrying capacity of GEC-Ns with half-length and full-length is almost the same. So, using the half-length is recommended. The bulging of GECs is smaller than that of OSCs. The reason could be due to the lateral confinement provided by geofoam. However, in VESCs the bulging failure is very small because the strength of the encasement is high. So, the lateral confinement leads to increase in load-carrying capacity.

The load-carrying capacity of GECs with stone aggregates (GEC-H) and GECs with no stone aggregates (GEC-N) are the same. So, it is not recommended to use GEC-H.

The numerical studies help to predict the behavior of stone column in real condition.

Cyclic response of geosynthetics-reinforced soil with respect to scale effect

Gh. Tavakoli Mehrjardi*, R. Behrad* & M. Khazaei*
Department of Civil Engineering, Faculty of Engineering, Kharazmi University, Tehran, Iran

ABSTRACT: Existing studies confirmed that the response of geosynthetics-reinforced beds is directly affected by contributory factors, including soil's grains, reinforcement's characteristics, and surface loading geometries. In this paper, a series of plate load tests has been carried out for the further understanding of the behaviour of geocell and geogrid-reinforced soil. The considered variables were included with four different soil grains sizes, two different geocell's opening sizes, two different geogrid's aperture sizes and three different loading plate sizes. As it was expected, the geocell and geogrid-reinforced soil exhibited a few times higher bearing capacity than the unreinforced status, up to 524% and 635%, respectively. The results further focused on the important role of scale effect on the response of reinforced foundations. The optimum nominal aperture size of geocells and geogrids were obtained about 15 and 4 times of medium grain size of soil. Also, it was found that in order to obtain the highest reinforcement benefits, the footing's width should be in the range 13 to 27 (20 in average) times of medium grain size of the backfill. Finally, to provide more stable and reliable geocell-reinforced backfill, it is recommended that the aperture size of geocells and geogrids should be selected smaller than 0.67 and 0.2 times of footing width.

1 INTRODUCTION

Geosynthetics have been successfully utilized as reinforcements in geotechnical projects such as embankments over soft subgrades, road construction, slopes, retaining walls and railroads (Cardile *et al*. 2017; Moghaddas Tafreshi *et al*. 2011, 2015; Tavakoli Mehrjardi & Sardehaei 2017; Tavakoli Mehrjardi & Moghaddas Tafreshi 2020; Tavakoli Mehrjardi *et al*. 2012, 2013, 2015, 2016, 2019, 2020). Many experimental studies in the field of reinforced embankments have been carried out with small or large-scale physical modeling at which the scale effects are rarely fully considered. However, one of the most challengeable matters in this area is how the reduced scale model and prototype model tests can be bridged. Góngora & Palmeira (2016) investigated the performance of unreinforced and backfills reinforced with different types of geosynthetics under cyclic loading. They observed that for the ratio of equal aperture size of geogrids (a_{eq}) to maximum aggregates size (D_{max}) between 0.7 and 1.35, less breakage took place. Also, Brown *et al*. (2007) found out that, for the 50mm ballast that was used, the optimum aperture size was 60–80 mm. Moreover, Cuelho *et al*. (2014) conducted full-scale tests to compare the relative operational performance of geosynthetics used as subgrade stabilization. For the broad graded fill material (coefficient of uniformity, $C_u = 123$), the most efficient a_{eq}/D_{50} ratio was obtained about 3.9.

There is a serious lack of studies on the response of geocells in soil medium with regard to the geometrical variations. Therefore, development of practical and reliable design methods and specifications for particular applications are still required. Considering the scarcity of studies about the scale effect on the response of geocell and geogrid-reinforced soil, a series of plate load tests has been carried out to investigate the sensitivity of reduced-scale geosynthetic-reinforced soil to variation of prominent key factors, notably loading plate size, soil grain size, and the reinforcements opening size.

2 TEST MATERIALS

2.1 Soils

Four types of uniformly graded soils as backfill materials with the medium grain size (D_{50}) of 3, 6, 12 and 16 mm were considered. The grading of backfill materials which were classified as SP and GP in the Unified Soil Classification System (ASTM D2487-11) is graphically illustrated in Figure 1.
Figure 1.   Grain size distribution curves for backfill materials (Tavakoli Mehrjardi & Khazaei 2017).

2.2 Geocells

Geocells, namely "GC55" and "GC110" had the cell equivalent diameter/height of 55/50 and 110/50 mm, respectively. The provided aspect ratio (defined as the ratio of geocell's cells diameter (b) to the medium grains size (D_{50})) varies from 3.4 to 36.7. The engineering characteristics of the geocells are given in Table 1.

2.3 Geogrids

The geogrids, exploited in the backfill, were made of coated polyester with aperture sizes of 20×20 mm^2 and 25×25 mm^2. The provided aspect ratio (defined as the ratio of geogrid's aperture size (b) to the medium grains size (D_{50})) varies from 1.3 to 8.3. The mechanical characteristics of the geogrids used in this study are given in Table 1.

It should be mentioned that the efforts have been applied to each group of reinforcements that reinforcements provide the same tensile strength, besides having reasonable tensile strength in the considered physical modelling.

Table 1. Technical characteristics of geocells (obtained from the producer).

Reinforcement Type		Cells Size (mm × mm)	Elongation at Failure[*] (%)	Maximum Tensile Strength (kN/m)	Mass per Unit Area (g/m²)
Geocells	GC55	55 × 50	55	13	470
	GC110	110 × 50	55	21	350
Geogrids	R20	20 × 20	11.83	83.62	400
	R25	25 × 25	15.00	80.00	425

3 TEST SETUP, INSTRUMENTATION AND TEST PROCEDURES

Figure 2 shows the schematic representation of the test setup including test box, made of a steel frame, having inside dimensions of 1200 mm × 700 mm in plan (1200 mm in length, in X direction and 700 mm in width, in Z direction) and 700 mm in height (Y direction). Loading, unloading and reloading was chosen to replicate traffic or train loading. The repeated loadings were imposed by a hand-operated hydraulic jack on circular plates with diameters of 80, 120 and 150 mm which were situated at the centre of the soil surface. The loading was divided into four stages which are 200, 400, 600 and 800 kPa to simulate the light to heavy traffic loadings. In the absence of clear-cut failure, loading was stopped at a soil surface settlement of around 0.25 times of the related loading plate's diameter. The soil in dry condition was compacted to achieve 65% relative density of the soils.
Figure 2. Schematic representation of the test setup (a) Y-Z section, and (b) X-Y section (Not on scale) (Tavakoli Mehrjardi & Khazaei 2017).

According to Table 2, investigated variables were including soil's particle size (sand with D_{50} = 3mm and gravels with D_{50} = 6, 12 and 16mm, namely S3, G6, G12 and G16, respectively), the reinforcement statuses (reinforced (Re) and unreinforced (Ur) conditions) and loading plate size (B = 80, 120 and 150mm). It should be also mentioned that the burial depth of geocells and geogrids (u) was considered 0.1 and 0.2 times of loading plate's diameter (B), respectively. Also, according to Tavakoli Mehrjardi et al. (2013), the width of reinforcements (L) was selected four times of loading plate's diameter.

Table 2. Testing program.

Reinforcing Status	Plate Diameter (mm)	D_{50} (mm)
Unreinforced	80	3, 6, 12, and 16
	120	
	150	
Geocell Reinforcement "GC55" and "GC110"	80	3, 6, 12, and 16
	120	
	150	
Geogrid Reinforcement "R20" and "R25"	80	3, 6, 12, and 16
	120	
	150	

4 RESULTS AND DISCUSSIONS

Owing to reduced size model tests, the results presented in this paper are prone to scale effects. Therefore, further studies using full-scale tests are recommended to verify these observations. However, we can underpin our description of the problem by using dimensional analysis based on a certain amount of background knowledge, tending extrapolation towards the prototype case. The major physical parameters influencing the response of geogrid-reinforced soil systems can be summarized as: B, u, L, D_{50}, γ, E_{soil}, E_{geo}, b; where γ and E_{soil} are unit weight and secant elastic modulus of the backfill, respectively and E_{geo} is opening size of reinforcements. Other parameters have been defined previously. The function (f) that governs the geogrid reinforced backfill systems can be written as Eq. (1).

$$q_u = f(B, u, L, D_{50}, \gamma, E_{soil}, E_{geo}, b) \tag{1}$$

The equation comprises 8 parameters which two of them have fundamental dimensions (i.e. length and force). Therefore, Eq. (1) can be reduced to 6 independent parameters (π_1, π_2, π_3, ..., π_6) and substituted with Eq. (2). As can be seen the obtained non-dimensional parameters could predominantly affect the response of reinforced systems.

$$\frac{q_u}{\gamma B} = f\left(\frac{u}{B}, \frac{h}{B}, \frac{D_{50}}{B}, \frac{\gamma D_{50}}{E_{soil}}, \frac{E_{soil}}{E_{geo}}, \frac{b}{D_{50}}\right) \tag{2}$$

For a prototype footing (p) with diameter n times that of the model (m), Eq. (3) can be considered.

$$\frac{D_p}{D_m} = n \tag{3}$$

For similarity to be maintained, the π terms, both for model and prototype need to be equal. As an example, if a circular footing with diameter of 140 cm is studied. So, it means n = 10 and parameters u, L, D_{50} and b should be considered 10 times of the model parameters. Assuming that the soils used in the model and prototype do have same unit weight, then parameters E_{soil} and $E_{geo.}$ should be considered 10 times of model parameters, as well. In this situation, Eq. (4) can be satisfied to obtain the bearing capacity of prototype system.

$$\left(\frac{q_u}{\gamma B}\right)_m = \left(\frac{q_u}{\gamma B}\right)_p \xrightarrow{yields} (q_u)_p = n(q_u)_m \tag{4}$$

4.1 *The ratio of the aperture size to the medium grains size (b/D_{50})*

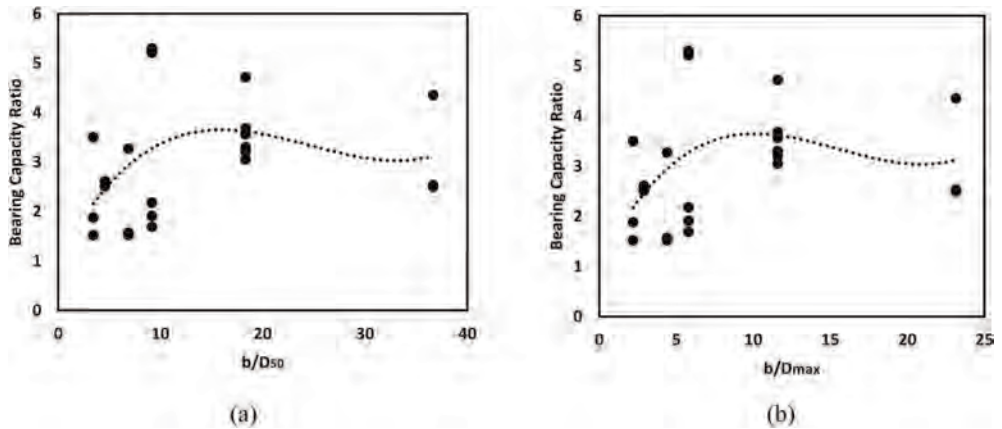
Figures 3 and 4 illustrate the effect of the ratio of the aperture size to the medium grains size (b/D_{50}) for both kinds of reinforcements. It is clearly seen that the highest values of BCR in geocell and geogrid-reinforced foundations, irrespective of the loading plate size, is attainable when the ratio b/D_{50} is in the range of 12–18 and 3.3–4.2, respectively. In other words, in the case of larger backfill's particles (left side of the mentioned range), reinforcements/backfill interactions get deteriorated, resulted in reduction in bearing capacity ratio. On the other side, for the smaller backfill's particles or larger aperture size, less stone-stone interactions are provided and therefore, lateral buckling of particles columns in the geocell's plane is encountered and eventually, bearing capacity ratio is reduced, dramatically. Tavakoli Mehrjardi *et al.* (2016), by conducting plate load tests on poor-graded fine and coarse sands and reinforced by geogrids, found out that the ratio of the geogrid apertures sizes to the medium soil grains sizes is a deciding factor in the interaction between soil's grains and geogrid. Moreover, According to Figures 3 and 4, there is an optimum range (b/D_{max}) of 7–11 and 2.1–2.6 for geocell and geogrid-reinforced foundations in which affords the maximum bearing capacity ratio.


Figure 3. Variation of bearing capacity ratio versus the ratio of the geocell's cells size (b) to (a) the medium grains size (D_{50}), (b) the maximum grains size (D_{max}) (Tavakoli Mehrjardi *et al.* 2019).
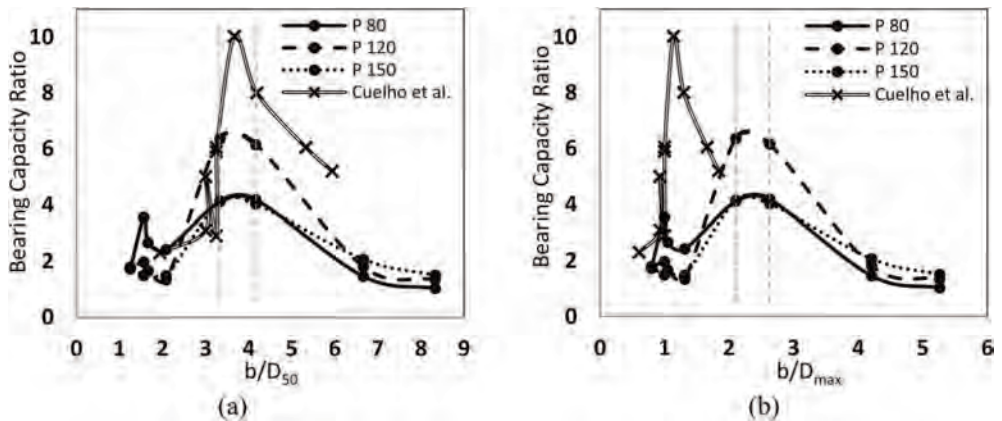

Figure 4. Variation of bearing capacity ratio versus the ratio of the geogrid apertures size (b) to (a) the medium grains size (D_{50}), (b) the maximum grains size (D_{max}) (Tavakoli Mehrjardi & Khazaei 2017).

4.2 The ratio of the loading plate size to the medium grains size (B/D_{50})

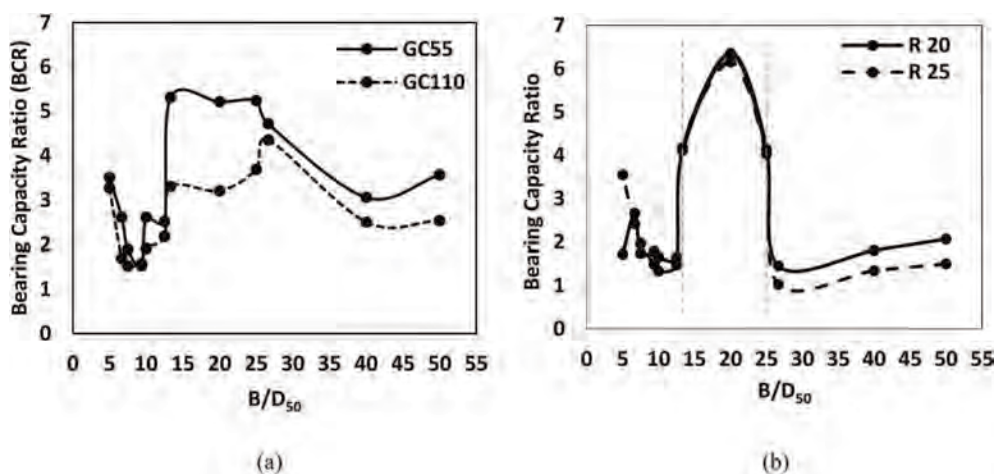
With this respect, Figure 5 presents the variation of bearing capacity ratio versus the ratio of the loading plate size to the medium grains size (B/D_{50}) for geocell and geogrid reinforcements. According to the observed variations, the best efficiency of geocell and geogrid reinforcements has been achieved for the optimal amount of B/D_{50} in the range of 13–27 (approximately 20; in average). In the outer of the mentioned optimum range, BCR decreased drastically. In the line with this conclusion, Tavakoli Mehrjardi & Khazaei (2017) observed that in order to obtain the highest benefits from geogrid reinforcement in geogrid-reinforced backfill, the footing's width should be in the range of 13–25 times of medium grain size. Moreover, Hsieh & Mao (2005) reported when the loading plate's diameter was larger than 15 times the D_{50} of the soil test, no marked influence of plate size on surface settlement would be expected.


Figure 5. Variation of bearing capacity ratio versus the ratio of the loading plate's diameter (B) to the medium grains size (D_{50}) for a) geocell and b) geogrid reinforcements (Tavakoli Mehrjardi & Khazaei 2017; Tavakoli Mehrjardi et al. 2019).

5 CONCLUSIONS

In this study, a series of repeated plate load tests was performed to investigate the sensitivity of reduced scale geosynthetics-reinforced soil to the contributory factors including loading plate size, soil grains size, and reinforcements apertures size. The detailed conclusions from the acquired results and presented in this paper are:

– Reinforcements are to hold much promise as a strong method to enhance the bearing capacity of foundations. In conditions with appropriate selection of effective parameters, reinforcements could strengthen the unreinforced backfill up to 6.35 times.
– It is recommended that the ratio of aperture size of geocells and geogrids to medium grain size of backfill materials should be selected 15 and 4, respectively.
– In order to obtain the highest benefits of reinforcements, the footing width should be in the range 13 to 27 (20 in average) times of medium grain size of backfill materials.

Effect of strip footing on the stress-strain behavior of soil-geogrid interaction: A new simple concept

Hussein Ahmad*
Faculty of Civil Engineering, Tishreen University, Latakia, Syria

Ahmad Mahboubi
Faculty of Civil, water and environmental Engineering, Shahid Beheshti University, Tehran, Iran

ABSTRACT: To determine the interface characterization of geogrid inclusion, soil-geogrid interaction is of particular importance. Tensile strength, tensile strain, and interfacial shear stress are all characteristics induced along with geogrid reinforcement. In this paper, a series of small-scale physical modeling has been carried out to investigate the stress-strain behavior and deformation of geogrid after final loading. Therefore, a simplified expression model has been developed to model the behavior of tensile stress-strain of geogrid inclusion. This simple model is similar to the Mohr-Coulomb model that is used in the nonreinforced soil. In general, the results have been confirmed by experimental testing and are consistent with the analytical results. In the main results, it is demonstrated that strains and deflections induced within two layers of geogrid inclusions are less than those induced within one layer. In addition, the tensile force induced in the first geogrid sheet is larger than that in the second geogrid layer.

Keywords: Strip footing, soil-geogrid interaction, stress-strain behavior, Tensile strength.

1 INTRODUCTION

Geogrid-reinforced soils are utilized in foundation building, embankment, railway, and road infrastructure in geotechnically challenging areas with the potential for the formation of failures in weak soils, differential settlement, or localized subsidence. Using the geogrid as a preventative measure, the weak soil and its above infrastructure are supported through the tensile strength created by the geogrid deflection. The deformations are transferred through the geogrid to the soil body with a critical effect on the footing behavior. Among the most obvious and popular methods of strengthening weak soil and reducing settlements under shallow foundations has been the use of geogrid-reinforced soils. The reinforced soil foundation (RSF) bearing capacity has also been investigated by some researchers and some theoretical solutions have been proposed (Binquet & Lee 1975; Chen 2007; Chen & Abu-Farsakh 2015; Huang & Tatsuoka 1990; Huang & Menq 1997; Shukla & Chandra 1994; Sharma *et al*. 2009; Wayne *et al*. 1998). The researchers applied the mode of failure to the reinforced soil and observed the impact of the tensile strain in the geosynthetic element on bearing capacity. Geosynthetics tensile strength is proportional to their tensile modulus. In this work, according to the experimental findings, a simple solution method is presented for a strip footing laid over reinforced fine sand. The analysis concluded that the tensile force

*Corresponding Author: Houssein.ah@gmail.com

produced by any of the reinforcement layers is contained in all of them; therefore, its analytical equation overestimates the usefulness of increased bearing capacity.

McCartney and Cox, 2013 investigated the deformation response of geosynthetic reinforced soil layers for evaluating the strain level needed for mobilizing reinforcement mechanisms over the surface loading. However, there is not much information regarding the magnitude of the strain needed for mobilizing the shear-resisting interface mechanisms. Hence, this work addresses investigating the performance of geogrid-reinforced soils beneath shallow footings to determine the advantages of the reinforcement in decreasing the magnitude and extent of soil deformations against settlement and suggests a proper novel technique. In a geotechnical 1-g model test, physical model tests were conducted to assess the performance of geogrid-reinforced fine sand beneath the strip footing, evaluate these mechanisms, and contribute to comprehending this performance.

2 MATERIALS USED

Sandy soil with fine grains (N.151) was used in the laboratory test. The soil sample was taken from the Firozkoh mountainous area, in northeastern Iran. The grain size was presented in Figure 1 by the soil classification ASTM D422 standard. Using the Unified Soil Classification System (USCS) and based on Figure 1 and Table 1, this soil is categorized as sand-poor-graded soil (SP). The mechanical features of the geogrid-sand interaction coefficient and fine sandy soil were determined by applying six direct shear tests based on ASTM D5321 at a relative density of 40%. The obtained basic properties values were included in Table 1.

Table 1. Soil properties.

Parameter	Value
Cohesion, C (kPa)	15
Specific gravity, G_s	2.68
Residual friction angle, $\phi_{residual}$ (°)	29.33
Peak friction angle, ϕ_{peak} (°)	36.50
Maximum dry density, γ_{dmax} (kN/m^3)	16.61
Minimum diy density, γ_{dmin} (kN/m^3)	14.09
Dry unit weight, γ_d (kN/m^3)	15.00
Relative density, D_r (%)	40
Mean particle size, d_{50} (mm)	0.34
Impact particle size, d_{10} (mm)	0.20
Maximum particle size, d_{max} (mm)	0.60
Minimum particle size, d_{min} (mm)	0.01
Coefficient of curvature, C_c	1.11
Coefficient of uniformity, C_u	1.90
Oedometric modulus, E_{oed} (kPa)	28000
Fine percentage	5
Figure 1. Particle size distribution analysis.

The geogrid CE161 manufactured by an Iranian company, (Ahmad *et al.* 2020) was used here. This material has a thickness of 3.3 mm, an aperture size of 10 mm × 10 mm, and a unit weight of 0.70 kg/m^2. The ultimate tensile strength was assessed to be approximately 6.1 kN/m. Here, one strip footing made of steel material was utilized to perform physical modeling of the footings. The thickness of foundations was considered to be 20 mm; thus, it is viewed as a solid element that is not subjected to scale impact. The footing width is 100 mm. The strip footing length (i.e., 450 mm) is in the same direction as the laboratory model box width but 10 mm less.

3 THE EXPERIMENTAL PROCESS AND TEST ARRANGEMENT

The experimental tests were performed in a rectangular box made of steel with width, length, and height of 500 mm, 1400 mm, and 800 mm, respectively. The horizontal plane of the box was chosen according to the conditions of the plane strain problem. To avoid interfering with the failure surfaces with the model side dimensions, the model length to the footing width ratio of 16 is adequate. Similarly, the height of the soil mass in the model was selected to be up to 800 mm. The box width was equal to the footing width. Additionally, to prevent contact footing with the sandbox wall, the footing length decreased by 5 mm from each side. A pneumatic cylinder equipped with an air compressor was considered as a loading system to provide an air pressure of approximately 10 bars. The system can secure a steady periodic load after applying the pressure circumstances to the soil specimen. The applied force was calculated utilizing a load cell, and the settlement of the footing was measured through two linear variable differential transformers (LVDTs). The test method was performed in compliance with ASTM D 1196 2016, in which the load measurements were implemented and continuously held for three minutes until the settling rate was lower than 0.03 mm/min. the strain distribution along the geogrid was measured by attaching strain gauges on the geogrid at various distances from the center of the footing (x/B = 0, 0.5, 1.5, and 2), as shown in Figure 8b. The increased vertical stresses were measured by placing ten pressure cells under the center of the footing and at these distances from the footing center (x/B = 0.5, 1, 1.5, and 2). The load cell, LVDTs, pressure cells, and strain gauges were all connected to a 20-channel Mutest data logger, which was connected to a desktop computer for monitoring the data readings. For the preparation of the sample, the regular placement of the soil was obtained in the sandbox proportional to the needed relative density using the method of rain sandy soil (Kolbsuzewski 1948). The proper soil unit weight was obtained using a tamper. Figure 2 presents a schematic illustration of this system.
Figure 2. Schematic view of the experimental model study.

4 DISCUSSION OF STRAIN ANALYSIS

Geogrid reinforced soil has numerous uses as a result of its engineering effectiveness and cost. Consequently, it is essential to assess the mechanical performance of reinforced soils. In this regard, plate load tests were carried out for comparison of the mechanical performances of fine sand soil in both reinforced with geogrid and unreinforced status, and the observed results are reported herein. According to Figure 3, the mobilized strain at the midpoint of the interface soil-geogrid interaction was larger than the strain along the geogrid length (the distance increases from the footing center). The mobilized interface strain was largest under the midpoint of the footing center and fell until the distance of 2B from the footing center,

which signifies that the geogrid reinforcement sheet was restricted in the soil mass more strongly than in the folded model, which ensued from the stronger interface parameters. As shown in Figure 3, the deformation of the geogrid sheet was placed after the edge of the foundation up to 150 mm from the middle. It can be reasoned that the mobilized axial load in the geogrid and the interface shear stress between the soil and geogrid are both also localized in the same position. The localized mobilization of the reinforcement forces depends on the failure mode of the soil (Ouria & Mahmoudi 2018; Patra & Shahu 2012). No mobilized interface shear stress occurs in the last 50 mm of the geogrid from either position. Thus, it can be reasoned that only (4B = 400 mm) of the geogrid length had fully interacted with the surrounding soil and participated in the improvement in the carrying capacity.
Figure 3.   The two-dimensional strain distributions from the footing center.

5   THE CHARACTERISTICS AND PERFORMANCE OF SOIL-GEOGRID INTERACTIONS

The following Figure 4 shows the linear association between the tensile strength mobilized in the geogrid and the highest deformation created in the geogrid rooted in the soil at different depths. This diagram is based on the findings of the plate loading test. It shows the linear behavior association between tensile strength and greater strain at a certain burial depth. By increasing the burial depth, the tensile strength values decrease, thus reducing the reinforcement deformations. The single geogrid-reinforced soil has a higher deformation value than the strain in the two geogrid layers system. According to these curves, the linear relationship of the tensile force-strain can be expressed as:

$$T_{tot} = J_{mobilized} \times \varepsilon_{\max} + T_{interaction} \qquad (1)$$

This relationship indicates the impact of the reinforcing element and the high performance of the soil-geogrid reaction. The first term shows the impact of the tensile strength resulting from the geogrid (the effect of the opening size and the resistance of the transverse and longitudinal ribs), while the second term represents the effect of the passive frictional force on the interface surface. This finding can be regarded as an original principle to express the modeling of the geogrid-soil system and to represent the performance of reinforced soil under strip foundations. This mechanical linear behavior relationship provides the true impact of the tensile strength assembled when burring the geogrid into the soil. Moreover, it proves the contribution of the resistance force of the interface friction caused by the soil-geogrid mutual reaction. This novel performance of the soil-geogrid contact surface indicates the smaller packed tensile stiffness modulus ($J_{mobilized}$) value of the buried geogrid compared to the geogrid stiffness modulus ($J_{nominal}$) caused by an in-isolation laboratory test. The reduction level in the reinforcement hardness coefficient is associated with the calculation of

deformations occurring in the joint, and the transverse and longitudinal ribs. The distribution of deformations across the length of the geogrid is realistically affected by this event; hence, more than two adjacent nodes are obtained (plastic strain effect) by the concentrated load on the contact surface. This results in the assumption of a new type of geogrid deformation in the soil similar to a trapezoid to some extent. This is not consistent with the hypothesis of (Abu-Farsakh *et al.* 2009; Chen *et al.* 2009), assuming that the triangular kind of strain distribution is under the center of the footing. Thus, in more than two nodes, the maximum value of the tensile strain is equivalent to the length of three aperture sizes of geogrid (on a width five times an open size), as represented in the last two figures. Given the interruption and rupture at the joints or the longitudinal ribs in the weak points exposed to the concentration of stresses, some geogrids reach the condition of occurrence and yield plastic deformation. Considering the triangular distribution of shear stresses on the contact surface in Equation 1, as represented by former researchers, the force-induced interaction at the interface soil-geogrid surface can be assumed to be in Equation 2:

$$T_{interaction} = \frac{1}{2} \quad \tau_{inter} \times L_{geogrid} \times d_{s-g} \qquad (2)$$

where the frictional stress, τ_{inter} (kN/m^2), is mobilized at the interface between the sandy soil and the geogrid reinforcement, $L_{geogrid}$ denotes the effective length of the geogrid reinforcement (m) and ds-g indicates the depth of the general shear zone induced under the strip footing when the geogrid is included in the soil mass (m).

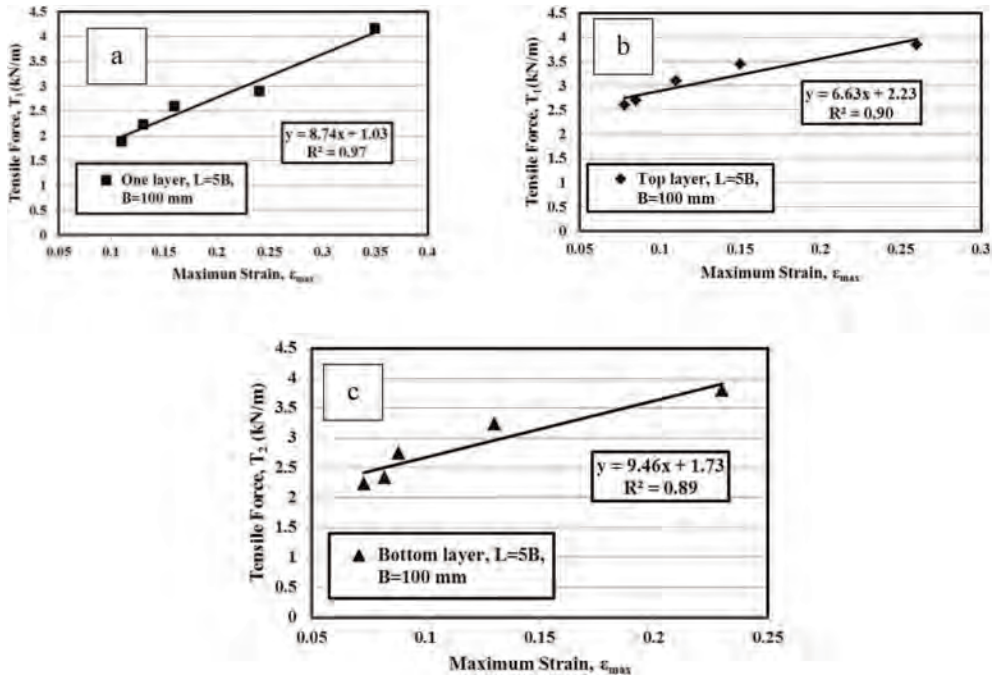
Figure 5 shows the results of the plate load tests. The trend line passing through the experimental points is termed the interaction strength (or failure) envelope, indicating the maximum tensile force of the soil-geogrid interaction at failure (T_{tot}), withstood by the soil without failure, which is mathematically explained in Equation 1. Since numerous


Figure 4.   The tensile force-maximum strain performance of (a) one geogrid layer, (b) upper geogrid layer and (c) lower geogrid layer.
Figure 5. Analysis of data from five plate load tests to obtain the tensile force-strain behavior of the soil-geogrid interaction.

laboratory and field results exist on the experiment of plate loading in reinforced soil in the literature, the following technique can be adopted for modeling the reinforcement in the Soil-Geogrid interface area: (1) The findings of at least five experiments with various depths of burial of the geogrid were confirmed. (2) Mining the total packed tensile force in the geogrid from these curves. (3) Determining the maximum deformation calculated under the center of the footing in the geogrid layer. The maximum deformation values were adopted since they express the highest effective contribution of the geogrid in mobilized tensile strength and transporting the stresses into the soil body. (4) Drawing the linear relationship, the total tensile strength is the geogrid strain, where the horizontal axis exhibits the axis of deformation and the vertical axis shows the tensile strength (kN/m). (5) The intersection point of the straight line with the axis of the total tensile strength is determined. The interfacial shearing force is obtained, representing the role of the interface friction resistance of the soil-geogrid. (6) The slope of the straight line shows the stiffness coefficient of the packed geogrid, representing the real role of the reinforcement in improving the soil resistance and the result of the deflections in the reinforcement. Three principles exist behind the main parameters of this criterion, including the highest deformation, the stiffness reinforcement modulus, and the shear strength interface in the contact zone. This model can be explained and defined in mathematical and numerical analysis by specifying these basic parameters. This could be adopted as a new criterion to represent the soil-geogrid interaction and use this linear association as an inelastic linear model in numerical analyses such as the finite element technique.

6 CONCLUSION

This paper presents an advanced mathematical formula for determining the increased bearing capacity of a strip footing over geogrid-reinforced soil, whether with horizontal or folded geogrid sheets, according to the literature theory of failure. This method helps calculate the reinforcing soil's exact bearing capacity at various depths and demonstrates the effectiveness of the strain-induced soil-geogrid interaction of the reinforcing element to provide the required tensile strength. It was found that the geogrid's effective strain is maximum at the midline of the geogrid layer on a width five times an open size and does not induce at (2–2.5) times the footing width, exceeding the value of the tensile strength will be negligible. Therefore, a new method is proposed to fold the ends of the reinforcing layer to ensure greater efficiency and to reduce settlement and deformations occurring in the soil and reinforcement, respectively. In this novel technique, reinforced soil behaves as a bounded material. A nonelastic linear decay in the geogrid tensile force distributions was found in

geogrid-fine sand for various burial depths as a function of peak normal strain. This reveals that to mobilize the tensile stresses in the geogrid reinforcement layers, larger plastic surface deflections and strains are required. A simple new model was proposed to define the real performance of geogrid-sand interactions in terms of the static plate load test.

On the practical use of geosynthetics for karts reinforcement

G. Valdeyron, F. Clément, C. Respaud & E. Vedie
Cerema, Bordeaux, Nouvelle-Aquitaine, France

ABSTRACT: The Aquitaine Basin is a sedimentary basin widely compounded by karstic limestones aged from Jurassic to Oligocene series. Throughout years and particularly in future, designers would have to consider resilient structures regarding climate changes that, for instance, emphases karst issues. A methodology based on hydraulic and geological criteria, is provided to assess karst collapse hazard. Applied to a roadway study-case (Departmental Road n°1215), the methodology carries on a set of disposals to ensure the robustness of the design and is about to be published in a Cerema/BRGM guidelines textbook (Cerema & BRGM 2023). Amongst them, a strengthening of the road by a geosynthetics is designed according to the French standards. The importance of the karst diameter and the limiting value of the accepted deformation of the roadway structure, on the required strength resistance of the geosynthetics is enlighten. That confirms the relevance of the methodology to assess a reasonable hazard.

1   DESCRIPTION OF THE DEVELOPMENT AND GEOLOGICAL AND GEOTECHNICAL CONTEXT

1.1   *Roadway infrastructure description*

The project consists in the building of the detour road (called Departmental Road n°1215) of the towns Saint-Aubin Medoc and Taillan-Medoc near Bordeaux (France). The aim of this roadway, expected since approximatively 30 years, is to improve access to the North Medoc area, secure the transit in the town centers and enhance the economical context. The development is 8 km long and composed by 13 structures (2 road bridges, 1 tunnel, and 11 ecological bridges or hydraulic structures). Earthworks consist on two cuttings and two embankments.

1.2   *Geotechnical and geotechnical context*

Two geotechnical units are identified in the vicinity of the project: from top to bottom, recent detrital alluvial deposits of the Garonne or slopes formations, respectively composed by Molasse sands and fine or coarse sands, are underlying the Oligocene marl and limestone which form the geotechnical bedrock of the roadway structures. The limestone of the Oligocene serie is recognized as a karstic complex. During earthworks, a karst collapse appeared on the vicinity of a new built bridge as visible on Figure 1, the groundwater level was measured 5 meters below the bottom of the collapse – it corresponds to the drinking water resource supply to the inhabitants. As it is shown, the landslide appeared in the temporary sanitation infrastructure of the roadway hugely alimented by rainfalls. Explanations of this karstic collapse are summarized in Figure 2. Lateron specific ground investigations were realized in order to identify weathered or fractured zone within the Oligocene limestone. They are first composed by geophysical surveys (electrical resistivity) and inspection

of geophysical irregularities by measurements while drilling (rotational and vertical speed of the drill bit, pressure on the bit, water flow volume, barehole image by camera). Investigation were not carried out on the overall path roadway (8 km) but were restricted to the most exposed area on regards of the karst collapse hazard assessed according to the methodology exposed afterwards. So 9 geophysical surveys of each 150 m long and 20 drillings of 12 m depth were achieved. A sample of the geotechnical model is reported on Figure 3, for instance two representative zones are illustrated: on the left, a clayey zone overlying the karstic limestone, and on the right, a molasse and sandy layer above karstic substratum (zone of the collapse described above).

Figure 1.   Geographical context and RD1215 (in red on left) and karst collapse (on right).
Figure 2.   Kinematics of the karst collapse (2021-02-09).
Figure 3.   Geotechnical model (samples) – absence of accessible voids is shown.

2 ASSESSMENT METHODOLOGY FOR KARST HAZARD

2.1 *Mechanisms involved in karstic collapse*

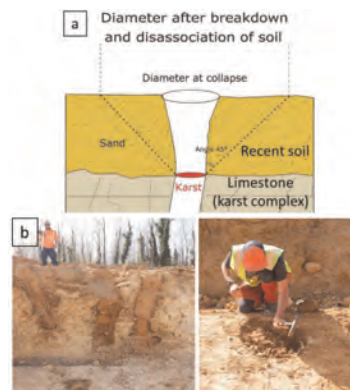
Karst collapses are developing by a cluster of inter-related processes, including suffusion, soil down-washing, soil collapse and rock collapse (Waltham *et al.* 2005), they are illustrated on Figure 4. Each mechanism is initiated by a serie of criteria, which are identified in the methodology. The soil collapse mechanism was clearly identified during the site inspection: eroded/fractured limestone and karstic well are visible on Figure 5b. On ground level the diameter of the hazard depends on the properties of the upper layer of ground: in case of bare karst without soil cover, the diameter is about the karstic well's one. The motion of the upper layer soil grains throughout the karstic substratum initiates the soil down-washing mechanism. Thus, it is highly dependent of the properties of the upper layer (cohesive or not) and the hydrodynamic conditions of the site: soil particles are driven by the hydraulic gradient between the surface and the groundwater level. In case of cohesionless ground surface, the diameter of the collapse depends on the importance of the "hourglass effect" (stability of the slopes of the upper layer). Moreover, the rock collapse corresponds to the rupture of the bedrock of a significant void, it happens when the rockmass is incompetent otherwise when the bedrock has insufficient thickness or when its strength is reduced by fractures.
Figure 4. Karstic mechanisms: a. soil down washing, b. soil collapse, c.rock collapse.


Figure 5. Hourglass effect (a), karstic wells (b).

2.2 *Governing criteria of karstic collapse*

As exposed previously, 3 criteria are supposed to explain and quantify the site predisposition to karstic collapse: strength and quality or level of karstification (voids, fractures, fault) of the rockmass, properties of the upper layer of ground cover and hydrodynamic conditions of the site. For each mechanism, the karstic hazard susceptibility is determined by a set of qualitative criteria matrix developed by the Cerema considering the comparable experience of many roadway infrastructure developments (National Road n°21, 141). For instance, regarding the soil down-washing mechanism (see Figures 6), each predisposition factor is assessed considering the geological knowledge of the site (study desk, comparable experience, geotechnical investigations). In fact, only samples are given here and other matrix, referenced in a handbook (Cerema/BRGM 2023), are needed to evaluate the predisposition. Then, the karstic collapse hazard is assessed by cross-referencing predisposition factors (see Figure 7). According to this methodology, karst hazard is evaluated, within the downfall zone, as "high".

Figure 6. Assessment of karst hazard – susceptibility factors.

Figure 7. Assessment of karst hazard – Soil down-washing (a) and rock collapse (b) within downfall zone.

2.3 Characteristic karst size collapse

Intensity of the landslide depends on the sort of void (fracture, karst well or chamber) but also on the ground cover layer behavior (see Figure 5a). The hourglass effect corresponds to the slope stability of the covering materials and is estimated considering the thickness and the properties (cohesion or not) of the upper layer of ground. In our case, considering the geotechnical model, intensity is assessed as "high". To conclude, the characteristic karst size collapse is combined with the disposition to quality hazard, in our example, it leads to "high" hazard (blue and white boxes on Figure 8), which corresponds to at least 3 meters diameter size hazard (without taking into account of the "hourglass effect" illustrated on Figure 5a).

Figure 8. Assessment of karst hazard – Intensity and collapse size.

3 DESIGN OF REINFORCEMENT

3.1 *Principles of the reinforcement*

The methodology described above was applied to the 8 km long development, depending on the geotechnical model, several homogenous areas (geotechnical units), of about 50 to 200 m long, particularly exposed to karstic mechanisms, could have been identified. Designing a geosynthetic parachute system for a 14 m collapse would not be technically and economically possible, thus the principles of the reinforcement design are based on the mitigation of the susceptibility factors. The reduction of the sensitivity of the bedrock by solid injection for instance was not possible for environmental reasons (risks of pollution of the drinking water resource). Nevertheless, the hydrological factor was enhanced by getting the roadway diches and hydraulic structures impervious. The main issue was to deal with the hourglass effect. The upper layer susceptibility was reduced by an optimization of earthworks: it was decided to reemploy cohesive excavated materials, as much as possible, below the parachute system (see Figure 9), that needed to ensure the chemical compatibility between the geosynthetic and molasses. This action also reduces the amplitude of the hourglass effect. In cuttings, this provision needed an over-excavation of 1 m and a substitution by molasses (cohesive materials). Finally, applying the methodology with principles previously defined, allowed to reduce, after treatment of aggravating factors, the karst hole diameter for initially 14 m to a 5 m residual collapse diameter (including hourglass effect).
Figure 9.   Predisposition factor reduction and geosynthetics reinforcement.

3.2 *Geosynthetics design*

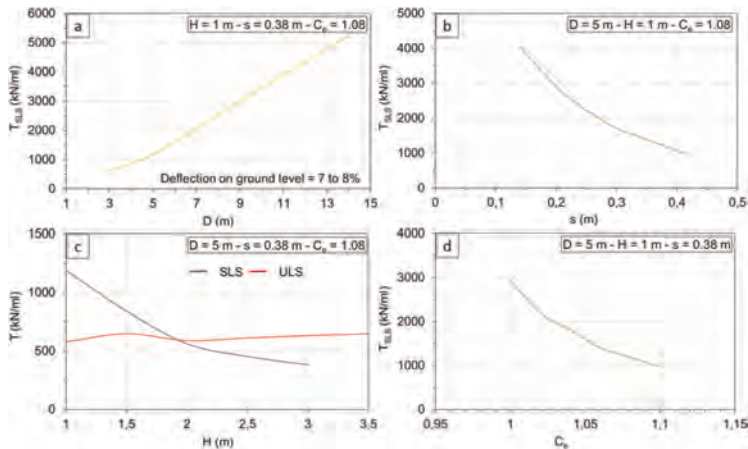
The design of a geosynthetic parachute system is a compromise between the acceptable settle-ment on surface, the reinforcement depth and the strength of the geosynthetic (Figure 10). Veri-fications are done under Ultimate Limit State (ULS – verification of the resistance) and Serviceability Limit State (SLS – verification of ground deformation and required resistance T_{SLS}). Safety factors are introduced to account for long-term creep, installation damage, effects of environmental conditions. They are defined in standards or calibrated by testing by the producer. A parametric study is carried out in order to identify the importance of the main parameters (H, D, C_e, s – Figure 10), results are plotted on Figure 11. Usually, the SLS resistance is the design case, because of acceptable deformation threshold
Figure 10.   Geosynthetics for reinforcement karts reinforcement – Rafael method.


Figure 11.   Geosynthetics design – parametric study.

(11.c). As seeable, expansion coefficient (C_e) of the granular layer has a huge influence on the design, $C_e = 1.08$ was choosen for the verifications (11.d). The assessment of the diameter of collapse (D) and the relevance of the methodology previously exposed is highlighted: it permits to design a reinforcement and reduce hazard from 14 to 5 meters after treatment (by impermeable ditches and sandy layers substitutions) of aggravating factors. For karst reinforcement, acceptable deformations on ground level is a major concern: in our case, the purpose was to prevent an accident by a parachute system, so high deformations were reached (7-8% of ground level deflection). This approach is consistent with the fact that high deformations are needed to mobilize the resistance of the geosynthetics (11.a) and for the ability to quickly detect landslide when occurred. Generally, in order to benefit of the arching effect in the granular layer, which conduce to the reduction of settlement, a layer of granular materials is layered above the geosynthetic with H/D > 0.375. In our case, it would have needed an over-excavation of about 2 meters that was not economically acceptable. Therefore, it was decided to design the reinforcement without taking into account arching effect. To conclude, the characteristic geosynthetic strength needed was about 1200 kN (11.a).

4   CONCLUSION

The proposed approach based on a new methodology to assess karst hazard provides relevant elements for the design reinforcements by evaluation and especially attenuation of the susceptibility factors. Effects of the different reinforcement designs on karst hazard can be easily tested. The method was applied to many roadways and railways infrastructures and permitted an enhanced comprehension of karst phenomena's and the optimization of the reinforcements. In the present study case, the design tensile strength of the geosynthetic is reduced from 5000 kN to 1200 kN by the combination of mitigation actions (on water flow, on the upper layer for example). Moreover, mix of solutions can be adapted on each identified geotechnical units.

2D behavior of a granular platform above a soft soil reinforced by rigid inclusions and geogrid subjected to a rolling load traffic

T. Dubreucq, L. Thorel, S. Lerat, A. Jagu & A. Neel
Geotechnical Centrifuge Laboratory, University Gustave Eiffel, Bouguenais, France

ABSTRACT: In a 2D geometry, the effect of rolling loads on a thin granular platform based on a soil reinforced by rigid inclusions, is studied on centrifuged model. Scaled at 1/10th, the physical model consists of a sand Fontainebleau NE34 layer, an analog polystyrene soft soil and spaced vertical metal plates. A strongbox with a transparent face allows image analysis. At a g-level of 10, fatigue tests on a few round-trip cycles were carried out to simulate linear traffic. Perturbations in arching effects in the platform are observed, even with a geogrid reinforcement.

1 INTRODUCTION

In the framework of the French National Research Programme ASIRI+, launched in 2019 (Briançon *et al.* 2020), new research topics have been investigated, including the case of the rolling load. One approach used is the centrifuge modelling. Here, the experimental work in macro-gravity concerns the 2D study of the behavior of thin load transfer platform (LTP) installed on a soft soil reinforced by RI subjected to rolling loads induced by traffic on the platform (Figure 1). The physical model consists of a pavement for rolling load case covering a sandy layer (the granular LTP), possibly reinforced by a geogrid layer, an analog soft soil (geofoam) and spaced vertical metal plates (to simulate RI) installed on a rigid substratum. The rolling load intensity is deduced from the load settlement curves obtained from strip footing loading (Dubreucq *et al.* 2022). Q_p is here the vertical force at top of a RI, and q_{LTP} the pressure beneath the LTP without arching effect as developed further.
Figure 1. 2D geometry of the physical model – roller in translation.

The 1/10th scale 2D model is placed in a strongbox with a transparent face, under an acceleration of N.g=10×9.81 m/s^2, to visualize the LTP deformations under vertical cyclic rolling load.

The height H_m of the LTP, the spacing s between RI, the width a of a RI and the geogrid elevation (in the middle of LTP) are constant (Figure 1). The 2D geometry is a first step in the understanding of load transfer mechanisms in service state (Lukiantchuki et al. 2018).

2 ROLLING LOAD DESIGN

The strongbox dimensions are L=80 cm long and l =25 cm wide (Figure 2). The 10×g acceleration is applied to the base of the roller. The LTP is a NE 34 Fontainebleau sand. Its thickness H_m is equal to 4 cm (40 cm in prototype scale). The sand (d_{50} = 0.21mm) is moderately dense (density Index: I_d = 0.75). It is implemented by air pluviation in the container to obtain a dry volumic mass of ρ=1648 kg/m^3. Its peak friction angle is 32 degrees with zero effective cohesion. Starting from the strip footing loads, an inverse elastic calculation leads to a modulus of about 10 MPa for the LTP alone.

The 2D RI located every s=10 cm (1 m in prototype scale) consists of flat rigid aluminum plates, laid on a thick rigid aluminum plate to simulate substratum. The RI thickness is a=1 cm (10 cm in prototype scale). The area of the RI over the area of the continuous mesh is thus α =10%. The compressible soil is simulated with a 15.5 kg/m^3 expanded polystyrene (Th.38, Knauf©). Two superimposed 2 cm thick layers (40 cm in prototype scale) are arranged above the substratum. From loading tests of shallow foundations on polystyrene alone, its measured equivalent modulus of 1 MPa is representative of a soft soil in undrained behavior at constant volume, and its measured plasticity stress is about 40 kPa. Compression is followed with mobile marker image analysis. With an zero Poisson's ratio, the polystyrene does not transmit horizontal pressure on the RI when it is compressed. So, there is very few lateral frictions on the RI during loading.
Figure 2. The roller in the transparent-faced strongbox.
Figure 3. Mobile rolling gantry.

The 2D rolling load consists of an outer steel tube[1] D^1 =6 cm in outside diameter in model scale (Figures 3 and 4), inside which can fit an intermediate tube[2] D^2=4 cm and a rod[3] D^3=2 cm. Their masses are 2.9; 1.8 and 0.6 kg respectively to simulate variable loads up to the critical load measured in static conditions. The roller translation speed is 25 cm/min in model scale. A flexible 0.5 mm thick plastic film is placed on the sand platform to prevent the roller from getting stuck in the sand. In a series of tests, a rectangular fiberglass geogrid (80 cm long and 25 cm wide), with a square mesh of 1.6×1.6 mm^2 and 0.4 mm thick (Windhager©) is placed horizontally in the middle of the LTP layer (Figure 1). Its tensile strength is 10 kN/m (100 kN/m in prototype scale) for a deformation of 1%. So its stiffness is high: J=1 MN/ml in model scale (10 MN/ml, in prototype scale).

The "TactArray" (PPS©) is a 1 mm thick flexible pressure sensor pad (16×32 cells of 1 cm^2), located between the analog soft soil and the LTP. The Figures 3 and 5 show the A-B central mesh of the RI^2 with its soft soil surface S_{soil} equal to $(s\text{-}a).w$, where w is the sensor pad width (w=16 cm), in order to calculate in §.3 the average pressure $q_{average}$ measured by all the pad cells which are inside S_{soil}, and to locate the maximum pressure q_{max} measured among these cells.
Figure 4.   Drawings of roller design.
Figure 5.   Central mesh of the RI^2.
Figure 6.   Details of 3 green flat-headed spikes.
Figure 7.   Location of vertical force sensors.

Figure 6 shows the spikes symmetrically hooked along the longitudinal edge of geogrid, on the side of the glass. An adherence to the glass is provided owing to a film of grease. On Figure 7, two vertical force sensors of 25 daN support the central rigid inclusion RI^2 and are embedded both in the ends of this RI and in the rigid base plate. The surface of the RI's heads is sandblasted to give them a normalized roughness $R_n = R_{max}/d_{50}$ = 0.46 which implies an rough interface friction.

3   RESULTS AND ANALYSIS

The Figure 8 shows the variation without geogrid of the vertical stresses measured by the sensor pad (which is placed on the RI and the polystyrene, Figure 3). During the movement of the roller, before rolling and after 5 round trips of the 2.9 kg roller which is a service load for this foundation.

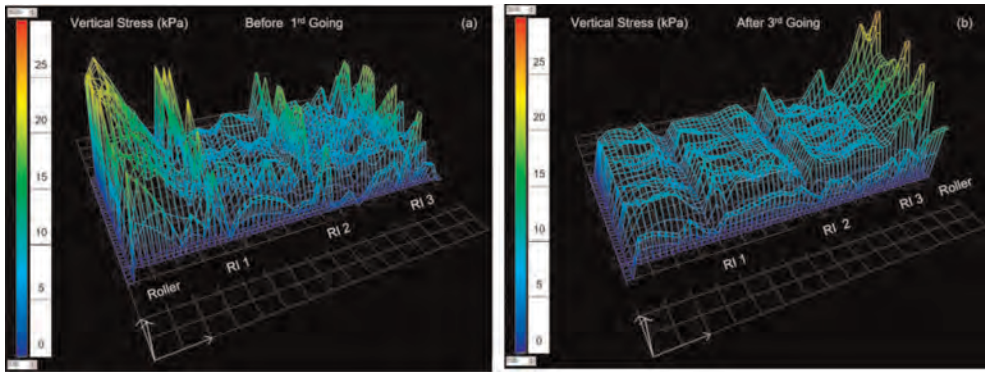
From scaling laws, model stress and prototype stress on the analog soft soil are equal. The evolution of the vertical stress measured during rolling shows that the localization change of the rolling load induces huge variations on the maximum recorded load, especially at the vertical of each RI. Before rolling, the vertical stress exerted by the roller on the polystyrene after diffusion in the sand is close to that on RI^1 (22 kPa on average). Those on RI^2 and RI^3 are lower (18 kPa on average). This stress distribution over RI before 1st going is due to arching effect in the sandy LTP between two adjacent RI, when the acceleration of the model grows from $1\times$g to $10\times$g, confirmed by a complementary image analysis (not shown here). After the 3rd going, the maximum


Figure 8.   Vertical stress above the analog soft soil and the 3 RIs: a) before 1st going; b) after 3rd going.

pressure on the analog soft soil can still reach 12 kPa, around an average pressure of 7 to 8 kPa. The stress distribution between RI and polystyrene is now reversed. Following the observed elastic return of the markers in a complementary analysis, the compression then the decompression of the analog soft soil with the rolling can create an "inverse arching effect" above the RIs.

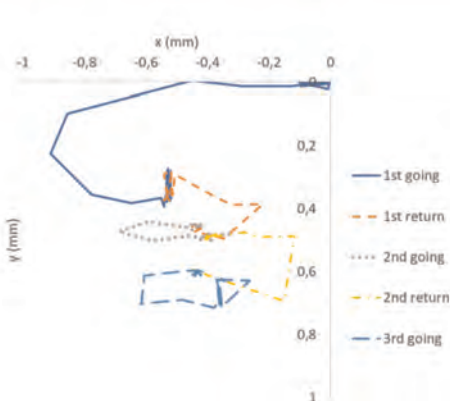
The Figures 9 and 10 show the trajectories over the 5 roller passages (3 going + 2 returns) of mobile marker located in the LTP, above the central IR^2, in cases without and with geogrid in the middle of the LTP. From the scaling laws, the prototype displacement is N=10 times greater.


Figure 9.   Trajectory of the central marker.   Figure 10.   Trajectory of the marker fixed to geogrid.

Without the geogrid (Figure 9), the marker moves horizontally in the direction of the translation of the roller when it comes towards the RI2, then in the opposite direction after the roller passes vertically. The horizontal amplitudes decrease over the 5 passages (from 1 to 0.3 mm in model size), as well as for the vertical displacement (from 0.4 to 0.1 mm). The movement of markers between RIs (not represented here) are similar.

With the geogrid (Figure 10), the horizontal displacements of the marker above the RI2 are more or less blocked after the 1st going. Its vertical displacement is half as much. Besides, the geogrid does not reduce the vertical displacements between RIs (not representated here).

The Figure 11 shows the evolution of the vertical load Qp at the top of RI^2, with and without geogrid. From the scaling laws, the load must be multiplied by $Ng^2=100$ for transposition to the prototype scale.
Figure 11. Evolutions of the vertical load at the top of the central RI during the round trips (model scale).

At the "initial" state (t=0s), once the required acceleration has been reached ($10 \times g$), arching effect is visible in both cases with a force concentration about 3.5 times than the calculated load without arching, from the unit weight and the thickness of the LTP, i.e. $\rho.N.g.H_m.l.a = 1.6$ daN here. The rolling load modifies the chain force between the sand grains resulting in variable load transfer.

Without geogrid, the rolling load alternates upwards or downwards in the load transfer with the passages. Thus, the peak load Q_p increases and decreases alternately with the passages, between 10 and 13 daN. This result is related to the alternating movement of the grains of sand located above the RI (Figure 9). The Q_p load is canceled on each return trip. After each going, Q_p approaches by lower value the calculated load without arching effect. This result is in accordance with the stress fall recorded above the RI between the passages (Figure 8). So, the load amplitude on the RI varies alternately on each passage between 9 and 12 daN (+33%).

With the geogrid, the rolling load modifies downwards the load transfer with the passages. The load peak Q_p thus decreases after the 1st going, dropping from 19 to 16 daN, in relation with the loss of initial arching effect (Figure 8). The Q_p load at the head of the RI is always higher than that without geogrid: 17 against 11 daN (+54%) on average at the peaks. The minimum loads between 2 passages also approach by lower value the calculated load of 1.6 daN without arching effect. After the 1st going, the load amplitude varies little over the round trips and remains around 14 daN.

The Figure 12 shows the evolution of the maximum pressure q_{max} and that of the average pressure $q_{average}$ on the analog soft soil inside the RI^2 mesh (Figure 5). From scaling rules, model stress and prototype stress are equal. With or without geogrid, q_{max} presents a double peak before and after the roller passage above the RI^2, for each round trip. The peaks are equal without geogrid (28 kPa) and alternated with geogrid (30/33 kPa).

Between two passages, q_{max} is similar with or without geogrid (12 kPa, see Figure 8). With geogrid, when the roller passes over the RI in return, q_{max} is lower of 3 kPa compared to the going, in connection with the maximum effort Q_p at top of RI (Figure 11).
Figure 12. Evolutions of pressure above the analog soft soil beside the central RI[2] during round trips.

Between each going and return, $q_{average}$ approaches by upper value the calculated pressure q_{LTP} beneath LTP without arching effect, i.e. $\rho.N.g.H_m$ = 6.5 kPa, in accordance with the average pressure recorded on the analog soft soil between the passages (Figure 8).

4 CONCLUSIONS

First physical modelling simulations of 2D traffic show an evolution of the load transfer with rolling load and a reversal effect on vertical remaining pressure above inclusions. An additional geogrid reduces the vertical displacement of LTP above the RI, and accentuates the diffusion of the rolling load at depth when crossing, both on the RI whose head is more loaded and somewhat the adjacent analog soft soil. Future tests should include a more rigid pavement to take advantage of this load transfert increase to RI.

Numerical analysis of low height piled embankments

S. Ahern

ABSTRACT: A parametric variation using Plaxis 2D showed that the ratio of embankment height to clear spacing between adjacent pile caps and geogrid stiffness were key parameters in the design of low height piled embankments. Increased geogrid stiffness was found to reduce both the geogrid and embankment surface deformations. Geogrid deformations were reciprocated at the embankment surface when the embankment height to clear spacing between pile caps was less than unity. Geogrid tension was not uniform and generally increased with distance from the embankment centre line to the crest of the embankment, before reducing to zero at the embankment toe. Geogrid tension increased with embankment height, with peaks in tension observed at the edge of pile caps; magnitudes 2 – 3 times the mean tension in the geogrid. The geogrid strain was dependent on the geogrid stiffness, with stiffness greater than 5000kN/m resulting in geogrid strain less than 0.5%.

1 INTRODUCTION

A piled embankment consists of piles, usually on a square grid, driven through the unsuitable foundation soil to a firm-bearing stratum. The piles directly reinforce the soft soil and distribute the embankment load onto the firm stratum. Geosynthetic reinforcement is installed over the pile caps at the base of the embankment to further assist in the transfer of load. Low height piled embankments arise where the height of the embankment is less than the clear spacing between adjacent pile caps. Full arching may no longer be mobilised in the embankment fill, with a danger that the embankment surface could imitate the ripple effect occurring at the pile level where the geosynthetic deflects downward between the pile caps.

BS 8006-1 (2016) places a restriction on the design strain in the geosynthetic reinforcement once the height of the embankment is less than 0.7 times the clear spacing between adjacent pile cap edges. In this case the design strain should be less than 3%, significantly less than the 6% design strain allowed for higher embankment heights.

This paper presents data from a plane strain analysis of piled embankments conducted using Plaxis 2D. The Plaxis models are discussed, together with validation of the models against previous studies. The aim of the study is to better understand the performance of low height piled embankments.

2 METHODOLOGY

Plane strain numerical modelling using Plaxis 2D, Version 20, (2021) was used to analyse piled embankments with height, H, ranging from 0.428m to 1.714m. All embankments investigated

had side slopes of one vertical to two horizontal. The model was symmetric about the embankment centre line, requiring only one side of the embankment to be analysed. The piles had a centre to centre spacing, s, of 1.156m with a pile cap diameter, a, of 0.3m, Figure 1. The depth of the foundation soil was 5m. The pile and pile cap geometry together with the depth of the foundation soil were held constant in all analysis. The boundary conditions were fixed along the lower horizontal boundary and horizontally fixed along the vertical left and right boundaries. A tolerated error of 5% was adopted in this study.

2.1 Model parameters

The numerical model for both the validation and parametric variation consisted of embankment fill, geogrid reinforcement, foundation soil and pile and pile caps. In this study the embankment fill was modelled using a Mohr-Coulomb model with the properties given in Table 1. The foundation soil was modelled using the soft soil model in Plaxis, Table 1. The weight density of the foundation soil was 0.39 kN/m^3 and corresponded to the actual value of the material that represented the soft soil in centrifuge modelling reported by Jennings (2012). The geogrid reinforcement was modelled using the geogrid element within Plaxis, which only required the axial stiffness, EA, of the geogrid, Table 1. The piles were modelled using Plaxis embedded beam row elements and were fixed at the lower boundary of the model. The pile caps which were fixed at the top of the piles were modelled as plate elements. The properties of the pile and pile caps are listed in Table 1.
Figure 1. Schematic of model developed in this study.

Table 1. Properties of embankment fill, foundation soil, pile and pile cap used in this study.

Parameter	Embankment fill	Foundation soil	Pile	Pile cap
Youngs modulus (MN/m^2)	20	–	1900	–
Poisson's ratio	0.2	–	–	–
Cohesion (kPa)	1.0	3.0	–	–
Angle of friction (deg)	30	25	–	–
Dilatancy angle (deg)	6.5	0	–	–
Weight density (kN/m^3)	15	0.39	25	–
Modified compression index	–	0.045	–	–
Modified swelling index	–	0.0045	–	–
Width (m)	–	–	0.12	0.3
Centre to centre spacing, out of the plane (m)	–	–	1.156	–
Axial stiffness (GN/m)	–	–	–	3.521
Flexural rigidity (GNm^2/m)	–	–	–	26.9

2.2 Model validation

The model was validated against plane strain physical modelling in the ATU Sligo geotechnical centrifuge and numerical modelling using Plaxis 2D reported by Jennings (2012). The

validation model developed in this study had the material properties listed in Table 1. The embankment height in the validation model was 1.714m, corresponding to a H/(s-a) ratio of 2.0. The geogrid stiffness, EA, was 282kN/m. Overall good agreement was observed between the predicted values and those reported from Plaxis analysis and centrifuge testing by Jennings (2012), Table 2. Based on this data the Plaxis 2D model developed in this study was validated.

Table 2. Comparison of predicted values from this study with data reported by Jennings (2012).

Measurement	This study	Jennings (2012)	
		Plaxis	Centrifuge
Outermost pile displacement (mm)	66	55	45
Vertical deformation of geogrid near embankment toe (mm)	192	160	180

2.3 *Parametric variation*

The parametric variation focused on examining the influence of embankment height and geogrid stiffness on the deformational response of piled embankments. The range of geogrid stiffnesses and embankment heights examined are summarised in Table 3.

Table 3. Embankment heights and geogrid stiffness examined in this study.

Parameter	Geogrid stiffness (kN/m)	Embankment height (m)	H/(s-a) ratio
Range	282 – 15000	0.428 – 1.714	0.5 – 2.0

3 RESULTS AND DISCUSSION

The predicted values from the Plaxis analysis are discussed in terms of the geogrid and embankment surface vertical deformations and the tension and strain in the geogrid.

The vertical settlement of the geogrid increased with higher H/(s-a) ratios, Figure 2(a) for a geogrid stiffness of 282kN/m and Figure 2(b) for a geogrid stiffness of 15000kN/m. In all cases a catenary deflected geogrid shape was observed between adjacent pile caps. The magnitude of vertical displacement increased proportional to the H/(s-a) ratio and inversely proportional to the geogrid stiffness. The deflection of the geogrid with a stiffness of 282kN/m, Figure 2(a), was approximately double that of the geogrid with a stiffness of 15000kN/m, Figure 2(b). The vertical displacement near the outer piles were also greater than that predicted closer to the centre line of the embankment. At higher embankment hights, rotation of the pile caps could be observed, particularly in the outer most piles. At lower H/(s-a) ratios the vertical displacement of the geogrid was relatively flat over a central portion, indicating that the strength/stiffness of the foundation soil was sufficient to restrict the displacement of the geogrid. At higher H/(s-a) ratios the deflected shape was fully curved, indicating that the support from the foundation soil was exceeded. The deflected shape under the side slope where no piles were included was the same for both geogrid stiffnesses.

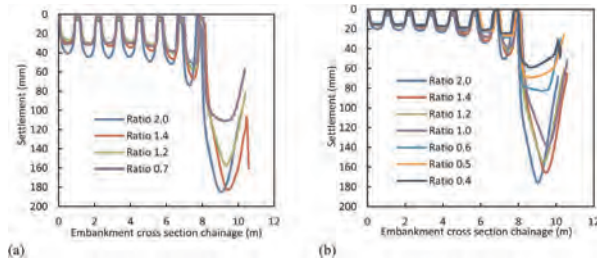
The predicted vertical deformation at the embankment surface is presented in Figure 3(a) for a geogrid stiffness of 282kN/m and Figure 3(b) for a geogrid stiffness of 15000kN/m. All cases experienced some vertical deformation, with the geogrid with the lower stiffness (282kN/m) experiencing about three times the vertical displacement of the stiffer geogrid (15000kN/m). The deformation of the embankment surface was nonuniform with more settlement occurring closer to the crest of the embankment at chainage 19m, Figure 3. However, for H/(s-a) ratios greater than 1.0, a more uniform deformational response was observed. For


Figure 2.   Settlement of the geogrid for various H/(s-a) ratios and a geogrid stiffness of (a) 282kN/m and (b) 15000kN/m.

lower H/(s-a) ratios, less than 1.0, the surface deformation was more irregular, indicating that at lower embankment heights, the surface deformation may follow that of the geogrid.

The plane of equal settlement is the height above the pile caps were differential settlement ceases in the embankment fill (Naughton 2007). Table 4 summarises the location of the plane of equal settlement, expressed in terms of H/(s-a), from the literature. The plane of equal settlement in BS8006-1 (2016) and Carsslon (1987) was derived from theoretical considerations, Horgan & Sarby (2000), Terzaghi (1936) and Britton & Naughton (2010) from experimental measurements and Lally & Naughton (2012) from numerical analysis. A significant variation in the height of the plane of equal settlement is observed, ranging from 1.16 – 2.45 H/(s-a). In all cases the height of the plane of equal settlement is higher than the value of H/(s-a) determined in this study. One possible explanation for this discrepancy is that this study defined the location of the plane of equal settlement using only embankments surface deformations.

	Marston	Hewlett & Ran-dolph						
H/(s-a)	1.4	1.4	1.87	1.545 – 1.92	2.5	1.16 – 1.47	1.95 – 2.45	1.0

The tension in the geogrid for H/(s-a) ratios between 0.7 – 2.0 are shown in Figure 4(a). Peak tensions were observed at the edge of pile caps. The ratio of peak to mean tension,

Figure 4(b), varied with both location; with larger peaks occurring in the crest of the embankment (chainage 19m), and geogrid stiffness, with the magnitude of peak tension proportional to the geogrid stiffness. Overall, the magnitude of peak tension was 2 – 3 times that of the mean tension. Currently this phenomenon is not considered in design.

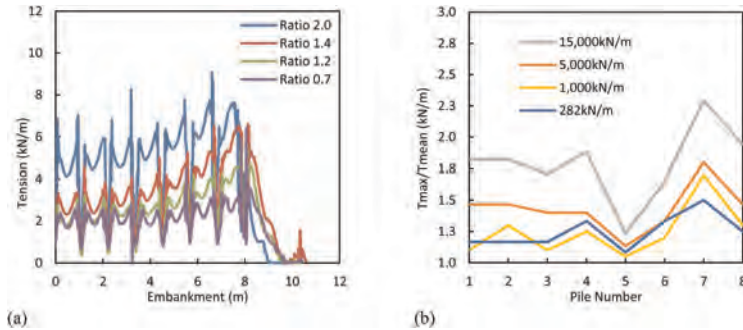
The mean tension in the reinforcement increased proportional to geogrid stiffness, Figure 5(a). However, the higher tensions developed at significantly lower reinforcement strains, Figure 5(b). The strain in the reinforcement was relatively uniform over the piled area. The reinforcement strain was inversely proportional to the geogrid stiffness, with the geogrids with stiffnesses of 5000kN/m and 15000kN/m predicting strains less than 0.5%. All predicted geogrid strains were less than the 3% suggested in BS 8006-1(2016). However, it should be noted that for H/(s-a) less than unity, some surface differential settlement may occur at the embankment surface.


Figure 4.   (a) Geogrid tension for various H/(s-a) ratio and a geogrid stiffness of 282kN/m and (b) ratio of maximum tension to mean tension for H/(s-a) ratio of 2.0 and geogrid stiffness between 282kN/m – 15000kN/m.
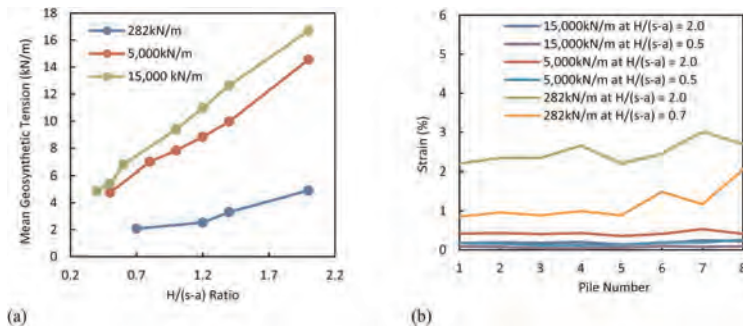

Figure 5.   (a) variation of mean geogrid tension with H/(s-a) and geogrid stiffness and (b) reinforcement strain with location in the embankment, geogrid stiffness and H/(s-a) ratio.

4   IMPLICATIONS FOR DESIGN

Low height embankments, where the height of the embankment to clear spacing between adjacent pile caps is less than 0.7 can be problematic to design. The overriding criteria is to limit differential settlement at the surface of the low height embankment. BS 8006-1 (2016) recommends that the design strain in the geogrid reinforcement should be a maximum of 3%.

The data presented in this paper indicates that both H/(s-a) ratio and geogrid reinforcement stiffness are important factors in the design of low height embankments. Under plane strain conditions limiting the H/(s-a) ratio to a minimum of 1.0 can significantly reduce differential settlement at the surface of the embankment. However, this H/(s-a) is lower than the height determined in other studies for the location of the plane of equal settlement.

Using stiffer geogrid reinforcement will reduce deformation of the geogrid between pile caps, resulting in a reduction in differential settlement at the surface of the embankment. Stiffer geogrid reinforcement will also significantly reduce the strain in the reinforcement to values significantly lower than the 3% maximum value recommended in BS 8006-1 (2016).

However, using higher stiffness geogrid reinforcement will increase the ratio of peak to mean tension in the geogrid at the pile cap. Consideration should be given to careful detailing of the pile cap edge to accommodate this peak tension without damage to the geogrid reinforcement.

5 CONCLUSIONS

Piled embankments are typically used to support road and rail embankments over soft foundation soils. The design of piled embankments is complex and is not yet fully understood. Low height piled embankments, where the height of the embankment is similar to the clear spacing between adjacent pile caps, are known to be difficult to design. The principal design criterion is the serviceability limit state and the requirement to eliminate the differential settlement at the embankment surface.

The impact of embankment height to clear spacing between pile caps and the stiffness of the geogrid reinforcement were investigated under plain strain conditions in Plaxis 2D. The Plaxis 2D numerical models were validated against previous physical and numerical modelling reported by Jennings (2012). A parametric variation showed that the ratio of embankment height to clear spacing between adjacent pile caps and geogrid stiffness were key parameters in the design of low height embankments. Increasing the geogrid stiffness was found to reduce both the vertical geogrid and vertical embankment surface deformations. Piled embankments with low H/(s-a) ratios appeared to receive support from the subsoil, however this diminished for higher H/(s-a) ratios.

Deformations at embankment surface level were reciprocated of the settlement behaviour that occurred at geogrid level for low H/(s-a) ratios, however, when the H/(s-a) ratio was >1.0, the surface deformations were largely uniform and independent of geogrid deformations. H/(s-a) equal to unity is lower than the height of the plane of equal settlement found in other studies.

The tension in the geogrid was not uniform and generally increased with distance from the embankment centre line to the crest of the embankment, before reducing to zero at the embankment toe. Tension in the geogrid increased with embankment height. Isolated peaks in tension were observed at the edge of pile caps, with magnitudes 2 – 3 times the mean tension in the geogrid.

The strain in the geogrid was also dependent on the geogrid stiffness, with geogrid stiffness greater than 5000kN/m resulting in geogrid strain less than 0.5%. Lower stiffness geogrids recorded strain up to approximately 3%.

ABSTRACT: Pile-supported earth platforms provide an economical and effective solution for embankments constructed on soft soils, particularly during their rapid construction or when strict control over their deformation is necessary. Based on a three-dimensional assumption of soil arching, an analytical approach is developed to explore the soil arching of the pile-supported earth platform with geosynthetics under the embankment load and uniform pressure. Further, the expression of stress concentration ratio in the pile-supported earth platform with geosynthetics is improved through the analysis of the two regions on top of the pile caps. The results from the in-situ and centrifuge tests are compared with those from the analytical method.

1 INTRODUCTION

Pile-supported embankments with geosynthetics have received considerable attention in soft areas because of their advantages such as rapid construction, easy control of settlements, and suitability for various geological conditions (Magnan 1994). Conventional pile-supported embankments typically have equal-length rigid piles (with caps) floating in the soft soil or embedded in firm soil. Geogrids or geosynthetics are used over the pile head for non-uniform differential settlements between the piles (caps) and the soil. These have been applied to resolve several geotechnical problems such as widening the existing road (Han 2007), bridge approach (Lin & Wong 1999; Reid & Buchanan 1984), subgrade improvement (Jones 1990), and improving the soft ground for constructions (Pinto & Ribeiro 2005).

The main difficulty in their design is assessing the degree of support offered by the pile caps. Terzaghi (1943) defined the "soil arching effect" to measure the degree of support offered by the pile caps. Since then, several researchers have focused on this new ground improvement method through theoretical methods, numerical methods, in-situ tests, physical model tests, etc. Hewlett and Randolph (1988) conducted model tests and developed a three-dimensional theoretical solution based on the dome assumption of soil arching. Low *et al.* (1994) performed four cap-beam model tests with and without geotextile and presented a two-dimensional theoretical analysis. Russell and Pierpoint (1997) and Naughton and Kempton (2005) summarized different analytical methods for modeling the soil arching effect and compared them with the results from three-dimensional numerical analysis. Lin and Wong (1999) performed field measurements of the pressures both on the pile caps and the soil surfaces between the caps, settlements, and

*Corresponding Authors: libo_auliso@126.com, lingweichan@163.com and wdeng@seu.edu.cn

pore-water pressures. Han and Gabr (2002) conducted a numerical study to investigate the pile-soil-geosynthetic interactions by considering the embankment fill height, tensile stiffness of the geosynthetics, and the elastic modulus of the pile material. Cao *et al.* (2007) assessed several existing design methods by comparing the results from the experiments and the numerical and design methods. Chen *et al.* (2004) improved the conventional Hewlett-Randolph three-dimensional soil arch analysis to calculate the efficiency when the soil arch is in the elastic or plastic state. Abusharar *et al.* (2009) calculated the efficiency of the pile support and the tension force of the geosynthetic under universal pressure based on the analysis of Low (1997).

In this paper, based on a three-dimensional assumption of global soil arching, an analytical approach is presented to explore the soil arching effect of the pile-supported embankments with geosynthetics under the embankment load and uniform pressure, as shown in Figure 1. A three-dimensional assumption of soil arching can better reflect real soil arching than using plane strain and axisymmetric geometries. Based on the study by Naughton and Kempton (2005), the geosynthetics is divided into primary and secondary reinforcements. Further, the efficiency expression of pile-supported earth platforms with geosynthetics is improved in the analysis of the two regions on the top of the pile caps. However, owing to the limitations of field testing, it is difficult to conduct in-situ tests to compare the load-sharing ratio of the conventional embankment with equal-length piles. Nevertheless, centrifuge modeling is an effective tool for exploring the mechanism underlying the foundation treatment, as it can simulate a full-scale prototype using a small-scale model by increasing the gravitational acceleration. It even has the advantages of easy management, repeatability, greater control over the test process, and remolded soil properties. Two centrifuge model tests on the pile-supported embankments with uniform piles were conducted to investigate the effect of length ratios on the load-sharing ratio and settlements of the pile-supported embankments. Finally, the proposed analysis method is verified via comparison with the in-situ and centrifuge tests.
Figure 1.   Pile-supported embankment with geosynthetics.

2   THREE-DIMENSIONAL SOIL ARCHING ANALYSIS

Similar to the three-dimensional analysis reported by Hewlett and Randolph (1988), soil arching is assumed to be a combination of the dome and plane soil arches. Based on the radial equilibrium equations and the boundary condition on the exterior of the soil arch, the equation for the soil arching effect is derived and uniform pressure is assumed. Two separate efficiencies of the soil arch can be calculated when the soil arch fails at either the crown or the pile caps. The lower of the two efficiencies calculated should be used for engineering design.

2.1   *Pile-supported embankment without geosynthetics*

2.1.1   *Crown of the arch*
The vertical stress σ_s acting on the subsoil between the pile caps is given by

$$\sigma_s = \left(q + \gamma H - \frac{\sqrt{2}\gamma s(K_p - 1)}{2K_p - 3} \right)(1 - \delta)^{2(K_p - 1)} + \frac{\gamma(s - b)(2K_p - 2)}{\sqrt{2}(2K_p - 3)} \tag{1}$$

where q is the uniform pressure on the top of the embankment; γ is the unit weight of the embankment fill; H is the embankment height; s is the spacing between the pile caps; b is the

pile cap width, $\delta = b/s$; Kp is the Rankine passive earth pressure coefficient, $Kp=(1+\sin\varphi s)/(1-\sin\varphi s)$; φs is the angle of shearing resistance of the embankment fill.

The following two related terms are used to assess the effect of soil arching:

$$E = 1 - \frac{(s^2 - b^2)}{s^2(\gamma H + q)}\sigma'_s \qquad (2)$$

$$n = \frac{\sigma_p}{\sigma'_s} \qquad (3)$$

where E is the efficiency of the pile-supported embankment; n is the stress concentration ratio. The two terms have different physical meanings. Efficiency indicates the support ratio of the pile caps. The concentration can only show the ratio of pressure acting on the pile caps to that on the soil surface because of the soil arch effect. σ'_s is the mean pressure on the surface of the soil, $\sigma'_s = \alpha\sigma_s$, and α is usually equal to 0.8–1.0 (Low *et al.* 1994). σ_p is the uniform pressure acting on the pile cap and can be obtained using the overall equilibrium equation, as follows:

$$\sigma_p = \frac{1}{b^2}[s^2(\gamma H + q) - (s^2 - b^2)\sigma'_s] \qquad (4)$$

2.1.2 *Pile cap*

One of the four parts of the primary geosynthetics is considered an example that can be simplified as a plane soil arching. As the direction of the radial stress is vertical to that of the fill weight, the arching is considered to be weightless for this simplified case. The pressure acting on the top of the pile cap can be obtained by integrating the tangential force across the cap, which is given by

$$P = 4\int_{(s-b)/2}^{s/2}\sigma_\theta \cdot 2\left(\frac{s}{2} - r\right)dr \qquad (5)$$

where σ_θ is the tangential stress, $\sigma_\theta = K_p\sigma_r$, and σ_r is the radial stress, which is the solution of the plane strain soil arching (Hewlett & Randolph 1988).

2.2 *Pile-supported embankment with geosynthetics*

Low *et al.* (1994) and Abusharar *et al.* (2009) considered soil arching of the pile-supported embankment with geosynthetics in the plane strain case, which could not precisely simulate the real three-dimensional soil arching. Based on the characteristics of its settlement over the elevation of the pile cap, the geosynthetics can be divided into two parts: the primary reinforcement, which is a high-strength reinforcement material that spans between adjacent pile caps; the secondary reinforcement, which covers the entire piled area, as shown in Figure 2 (Naughton & Kempton 2005). Region ② is supposed to be a part of the spherical surface with the equation $x^2+y^2+z^2=R^2$. Region ① can be simplified to be a plane strain case, for which the governing equation is $z = \sqrt{R^2 - \frac{(s-b)^2}{4} - x^2}$ or $z = \sqrt{R^2 - \frac{(s-b)^2}{4} - y^2}$
Figure 2.   Plan view of the base of the embankment.

First, region ② is considered the study object. The $y = y_0$ section is considered as an example, which is controlled by $z = \sqrt{R^2 - x^2 - y_0^2}$, as shown in Figure 3. The vertical tension of the geosynthetics at $x = (s - b)/2$ is given by:

$$T_{2z} = 2 \int_0^{\frac{s-b}{2}} K_G \varepsilon_G \sin \theta dy = 2 \int_0^{\frac{s-b}{2}} K_G \frac{l - (s - b)}{s - b} \sin \theta dy \tag{6}$$

where K_g is the tensile stiffness of geosynthetics (kN/m); θ is the angle subtended by the circular arch of the geosynthetics (°), $\theta = \arctan\left(-\frac{s-b}{2} \frac{1}{\sqrt{R^2 - y_0^2}}\right)$ at x=0; l is the deformed length of geosynthetics, $l = 2 \int_0^{\frac{s-b}{2}} \sqrt{1 + \left(\frac{\partial z}{\partial x}\right)^2} dx$.

The reaction of the soft soil below the geosynthetics can be determined by the relation $\sigma - \varepsilon$, which is simplified to exhibit an elastic relationship. Thus, we obtain:

$$F_{R2} = \int_{-\frac{s-b}{2}}^{\frac{s-b}{2}} \int_{-\frac{s-b}{2}}^{\frac{s-b}{2}} \sqrt{R^2 - x^2 - y^2} dx dy \frac{E_s}{D} \tag{7}$$

where D is the depth of soft soil, and E_s is the compression modulus. The vertical equilibrium of region ② requires that:

$$4T_{2z} + F_{R2} = \sigma_s'(s - b)^2 \tag{8}$$

Substituting equations (10) and (11) into equation (12), the value of R is obtained. Subsequently substituting R into equation (10) yields the value of T_{2z}.

Next, region ① of the geosynthetics is considered the study object. Similar to the analysis of region ②, the section parallel to the x-axis is selected, whose governing equation is $z = \sqrt{R^2 - \frac{(s-b)^2}{4} - x^2}$. The reaction of region ① below the geosynthetics is given by:

$$F_{R1} = \int_{-\frac{s-b}{2}}^{\frac{s-b}{2}} \sqrt{R^2 - x^2 - \frac{(s - b)^2}{4}} dx \frac{b}{2} \frac{E_s}{D} \tag{9}$$

The overall equilibrium of region ① requires that:

$$b^2 \sigma_{pG} + bT_{1z} + \frac{b}{2}\left(\frac{E_s}{D} - \lambda\right) \int_{-\frac{s-b}{2}}^{\frac{s-b}{2}} \sqrt{R^2 - x^2 - \frac{(s - b)^2}{4}} dx = \sigma_s'(s - b)\frac{b}{2} + Pb^2/2 + 2T_{2z} \tag{10}$$

The stress concentration ratio of the pile-supported embankment with geosynthetics is defined as the ratio of the average pressure applied on the pile caps to that on the regions ① and ②.
Figure 3.   Settlement analysis of the two regions.

3 VERIFICATION BY CENTRIFUGE TESTS

The load-sharing ratio of a non-uniform pile-supported embankment with geosynthetics was studied through centrifuge tests and three-dimensional numerical analysis (Huang *et al.* 2010). Table 1 demonstrates that four 1:80 scale centrifuge model tests were conducted on the pile-supported embankment with geosynthetics using a 3-m-balanced beam centrifuge at Tongji University.

Table 1. Details of the centrifuge tests.

Test No.	Material Parameters				
	Piles	Length	Total number	Total length (cm)	Saturated soil
1	Uniorm	l = 30 cm	90	2700	$\gamma = 19.5 \text{kN/m}^3$, $c = 1.2\text{kPa}$, $\varphi = 306°$, Water
2	Uniform	l = 23 cm	90	2070	Content = 35.5%, Permeability Coefficient = 5.45×10^{-6} cm/s

Triangular distribution of piles was adopted in the centrifuge tests. Six earth pressure transducers (EPTs) were installed on the top of the piles and the soil between the piles. Four strain gauges were attached to the flank of each of the two piles that were in the middle of the embankment. A rigid plate was located on the top of the sand that can be vertically loaded with the jack when the model box was in the 80-g-centrifugal field. The loading procedure follows four steps: the sand embankment gravity, the rigid plate gravity, and 5000 kN and 9000 kN vertical pressure of the applied loading in sequence.

Table 2 shows the comparison of the stress concentration ratio. There are two stress concentration ratios separately for the long piles and the short ones in Tests 3 and 4. The stress concentration ratio is an important parameter to assess the degree of soil arching and is defined as the pressure applied on the top of the pile to that on the soil. The hybrid method proposed in this study can be used in the analysis of composite embankments with long and short piles as well as for traditional embankments with equal-length piles. The comparison shows that the new method can better predict soil arching in the pile-supported embankment than the Hewlett method.

Table 2. Comparison of the stress concentration ratios.

Test No.	Centrifuge tests With geosynthetics	Finite Element Method With geosynthetics	Present study	
			Without geosynthetics	With geosynthetics
1	38	37	20	34
2	29	20		

4 CONCLUSION

In this study, the three-dimensional soil arching effect was analyzed to examine the incremental generation and progressive failure of arches. Stress concentration ratio of the pile was determined by solving a system of equations, including the equilibrium differential equation, boundary condition equation, and relational expression of the two different soil arching

effect coefficients. The reinforcement tension was calculated by assuming deformed curves considering the presence of geosynthetic reinforcement. Subsequently, a new equilibrium differential equation was established for the elevation of the pile caps. Several improvements were developed in the proposed hybrid analysis method. The deformation and tension of the geosynthetic reinforcements were evaluated in different regions. Furthermore, both the embankment load and uniform pressure were considered to reflect more complicated loading.

ABSTRACT: This paper presents a full-scale experiment of a geosynthetic-reinforced piled embankment over soft soil. Three tests were carried out in a bench of 8m x 8m x 1m where the type and the position of the geosynthetic were variables. A comprehensive monitoring program was set up in order to follow the stress distribution of the structural elements, the settlement of soil and the strain of the geosynthetics. This work is a part of the cooperative national research project ASIRI+ (2019 - 2024) which gathers about forty organizations and aims at proposing dimensioning rules in the field of soil reinforcement by rigid inclusions. From these experimental results, the understanding of complex mechanisms developed inside the load transfer platform were investigated such as the soil arching, the load efficacy and the differential settlement.

1 INTRODUCTION

Over the past few years, the increasing of urbanization and public works (portion of roads or railways, wind farm reinforcement of quays and dykes, etc.) had led to the construction of geotechnical infrastructure over weak soil with high compressibility. To remedy this problem, new techniques of soil reinforcement have been developed. The French national project ASIRI (2012) set out to define, conduct and interpret the experiments and numerical modelling necessary to understand the mechanisms by which the soil improvement by rigid inclusions works. This technique aims at inserting a network of concrete columns in a soft soil with low bearing capacity in order to transfer the majority of the load to the heads of the inclusions thanks to a granular platform by friction along the pile. The mechanisms developed within the load transfer platform (LTP) called "arching", as well as those due to friction along the inclusion are involved in the complex phenomenon of soil/structure interaction.

With the aim of improving the efficiency of this composite foundation, one or several layers of geosynthetics can be inserted within the granular mattress. The presence of horizontal reinforcement allows a better transfer of the load to the piles through membrane effect. Experimental or numerical investigations of a geosynthetic-reinforced pile-supported embankment have been carried out (Briançon & Simon 2012; Lian *et al.* 2014; Lee *et al.* 2021; Liu *et al.* 2007; Nguyen *et al.* 2022; Sloan 2011; Van Eekelen 2012). However, the number, the type, or the position of geosynthetic in the mattress remains an issue.

As the part of the French national project ASIRI+ (2019 – 2024), which is the extension of ASIRI project, three full-scale tests were carried out in an experimental bench containing 16 rigid inclusions. The soft soil is a three-layer made of sand, rubber granulates and honeycomb cardboard. The objective was to be able to model a two steps settlement, firstly with the compressibility of the rubber granulates and secondly with the biodegradation of the cardboard by water. The first test was conducted without geosynthetic, the second one with one layer of biaxial geotextile and the last one with two layers of crossed monoaxial geogrids.

2 FULL-SCALE TEST MODEL

2.1 *Test model*

As mentioned in the introduction paragraph, three tests were carried out in the experimental bench. The first one was set up without horizontal reinforcement, the second with a biaxial geotextile and the last one with two layers of crossed monoaxial geogrid.

The dimensions of the experimental bench are 8 m x 8 m x 1 m (depth) in which is inserted a square mesh of 16 rigid inclusions. The circular inclusions measure 300 mm diameter and 1 m high. The center-to-center distance between the piles is 2 m. Destructive tests were performed on three concrete samples of 11cm×22 cm after 100 days of pouring. The elastic modulus is 35 GPa. A slab was poured at the bottom of the bench on which were placed the inclusions.

The different layers of materials placed in the experimental bench, as shown in Figure 1, are the following (from the bottom to the top):

- 2.5 cm of duckboard, their role is to allow a water saturation of the Biocofra from below,
- 10 cm of honeycomb cardboard, called Biocofra,
- 50 cm of rubber granulates,
- 38 cm of sand,
- 50 cm of load transfer platform,
- 1.5 m of backfill.

Each layer is separated with a separation geotextile to facilitate dismantling. Those geotextiles have no reinforcing function.
Figure 1. Cross section of the test model.

2.2 *Materials*

As mentioned in the introduction, the soft soil is simulated by three layers made of 10 cm of Biocofra, which correspond of the height of a cardboard, 50 cm of rubbery aggregates from the recycling of used tires (Deltagom) and 38 cm of sand. Laboratory tests in GEOMAS

(INSA Lyon) were performed to characterize the mechanical parameters of each material, referred in Tables 1 and 2.

Table 1. Properties of the soft soil layers.

Parameters	Biocofra	Deltagom	Sand
Unit weight of soil γ (kN/m^3)	–	10	18
Young modulus E_Y (MPa)	–	0,341	35
Cohesion c' (kPa)	–	100	1
Internal friction angle φ' (°)	–	0	32
Compressive strength (kPa)	50	–	–

Table 2. Properties of the LTP and the backfill.

Parameters	Load transfer platform	Backfill
Grain size	0/31.5	0/63
Unit weight of soil γ (kN/m^3)	19	18
Cohesion c' (kPa)	2	8
Internal friction angle φ' (°)	40	33

2.3 Instrumentation

In the case of a full-scale test, the number of rigid inclusions must be sufficient so that the measurement is not affected by edge effects. In the case of a square mesh, 16 inclusions allow a measurement of the central mesh under good conditions (Briançon & Simon 2012). The instrumentation of those tests is therefore concentrated on the four central inclusions.

As shown on Figures 2a and 2b, a total of 8 earth pressure cells were installed. 4 of them were placed directly on the heads of the 4 central inclusions to measure the stress on the pile, their dimensions are equal to the diameter of the inclusion. Three were installed at the center of the mesh on the soil respectively at the top of the Deltagom layer, on the sand and on the LTP. The last earth pressure cell was placed at the right of one inclusion at the top of the

Figure 2. a. Rigid inclusions mesh and sensors positions on the sand; b. Positions of settlement plates, pressure cells and anchor load cells on a cross section.

platform. Twelve settlement plates were installed on the soil, at strategic positions, in order to follow the deformation of the soft soil, to measure the differential settlement and locate the plane of equal settlement in the backfill. Four load cells have been set up at the bottom of the 4 central inclusions to determine the force at the toe.

In the case of test 2 and 3, the geosynthetic layers have been instrumented by a Rayleigh scattering optical fiber which allows a millimetric resolution of the strain.

2.4 Test procedures

After the completion of the installation of the soft soil, the load transfer platform had been setting up alternating a layer of 20 cm of expended material and a compaction until reach 50 cm. The backfill was compacted every 50 cm. This static load was kept constant for one month in order to give way to the formation of arching. After each loading stage, the settlement of the soil, the stress on the pile caps and on the soft ground, and the deflection of the fiber optic were measured.

After a month, water has been injected at the bottom of the bench until it reached the lower part of the Biocofra. The water then migrated by capillarity inside the material allowing its biodegradation. This stage generates an imposed settlement of 7 cm. The evaluation of the stresses, settlements and geosynthetic strain was thus done during these three stages:

- During the installation of the LTP and the backfill,
- During a month of constant static load,
- During the biodegradation of the Biocofra.

3 RESULTS ANALYSIS

3.1 Test 1

The first test, carried out without horizontal reinforcement, was considered as the reference test for the dimensioning of the geosynthetics. Figure 3a shows the evolution of the stress and the settlement on the soft soil during Test 1. The load transfer platform has been set up in two compacted layers of 25 cm. On top of the sand, we measured a stress of 7 kPa after the first 25 cm and 12 kPa after the second layer generating a settlement of 15 mm and 45 mm respectively. This settlement is less at the top of the Deltagom (9 mm and 27 mm) highlighting the deformation of the sand layer. The placement of the backfill generates a stress of 47 kPa at the top of the soft soil, i.e. an increase of 25 kPa. After a month of constant static load, the stress has decreased (load transfer to the inclusion) from 47 kPa to 18 kPa.

Figure 3.   a. Stress and settlement evolution on the soft soil and during test 1; b. Stresses evolution on the pile head and at the toe during test 1.

As the 4 sensors installed on the 4 inclusions head and toe give approximately the same values, an average stress is taken (Figure 3b). As the opposite phenomenon of what happened on the soft soil, during the constant static load of 1 month, the stress on the inclusions is increasing. Moreover, with the generation of a second settlement the stress increases from 847 kPa to 1455 kPa towards the inclusions. The pile efficacy E is a parameter known to assess this technique of soil improvement. It is equal to the load on the pile cap divided by the total load imparted by the embankment over the tributary area of the pile. In the Test 1, E = 71%. The differential settlement on the top of the LTP is not represented in this article but for this test, it is equal to 3 cm.

3.2 *Geosynthetics used for test 2 and test 3*

After this first test, a call for tenders was made to the producers of geosynthetics in order to halve the final soft soil settlement. Two products were selected: 1 biaxial geotextile (formed with 2 monoaxiales geotextile crossed, placed one on top of the other) and 1 monoaxial geogrid. These products are subject to a confidentiality clause, so their exact properties won't be shared in this article. However, the stiffness J (at ε = 2%) is between [6000;7000] kN/m and [5000;6000] kN/m respectively for the geotextile and the geogrid. Table 4 presents the characteristics of the geosynthetics required from producers.

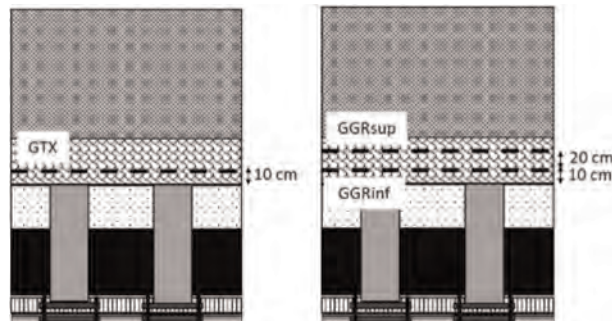
For the second test, 2 layers of superimposed crossed monoaxial geotextile were installed at 10 cm above the pile caps. Concerning the third test, two crossed monoaxial geogrids were installed in the LTP, the first one 10 cm above the pile cap and the second 20 cm above (Figure 4).


Figure 4.   Positions of the geosynthetics within the LTP for test 2 and test 3.

3.3 *Comparison of the 3 tests*

The load transfer mechanisms are different for all 3 tests. The insertion of horizontal layers in the LTP made it possible to reduce the increase in stress on the ground during the rise of the embankment as shown on Figure 5a. For all 3 tests, the arching is appearing during the month of constant static load as the stress on the soil decreased. Moreover, when comparing the stress variations during dissolution, we note that pad 3 with geogrids allows a better transfer of loads to the inclusions. Even if the stress on the soft soil is limited thanks to geosynthetics, the settlement has not been reduced (Figure 5b). However, we observe a stabilization of the settlement (Δs = 2mm) during the constant static load for Test 3 with geogrids.

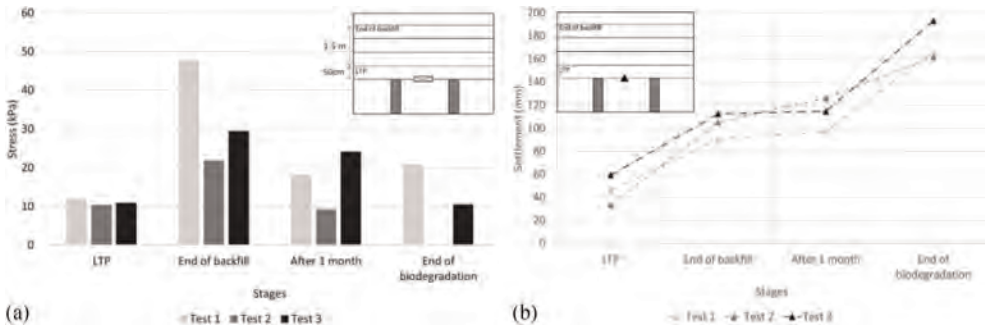
At the end of the embankment installation, the loads transferred to the inclusions are higher than in the test without reinforcement as shown on Figure 6a. However, the load transfer mechanisms do not occur at the same time. For the test with geotextiles, the transfer occurs mainly during the constant static load of 1 month, whereas for Test 3 with geogrids


Figure 5.   a. Stress evolution for all 3 tests on the soft soil; b. Settlement evolution on the soft soil.

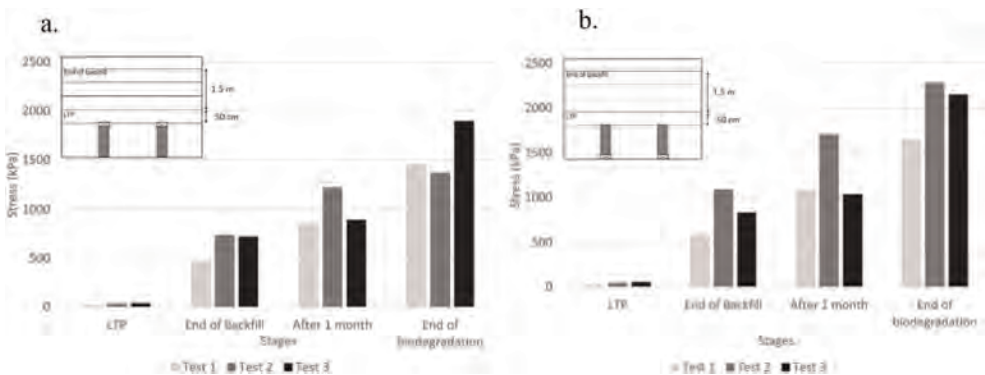
the transfer occurs mainly during the dissolution (1000 kPa increase towards the heads). By calculating the efficiency at the head of the IR at the end of the dissolution, we obtain respectively E = 67% and E = 93% for the test 2 and the test 3. However, the stress at the bottom of the inclusion is almost equal for plot 2 and 3 (Figure 6b), the load transfer along the inclusion does not occur in the same way for these two tests.


Figure 6.   a. Stress evolution for all 3 tests on the pile cap; b. Stress evolution at the bottom of the inclusion.

Figures 7a and 7b presents the fiber optic strain on an inclusion line; for Test 2, during the installation of the first 50 cm layer of the embankment and after a month; for Test 3, only after a month. Measurements (Figure 7a) indicate deformation on the order of 8000 µdef (0.8%) on the inclusions before dissolution. In test 2, the geotextile sheets were not sufficiently stressed, which did not reduce the settlement of the subsoil. Regarding Test 3 (Figure 7b), fiber optic measurements indicate that the lower geogrid was not stressed during fill placement, with an average deformation at the inclusions of 0 µdef after a month of constant static load. It is conceivable that the reinforcement layers followed the settlement of the soil without coming under tension.

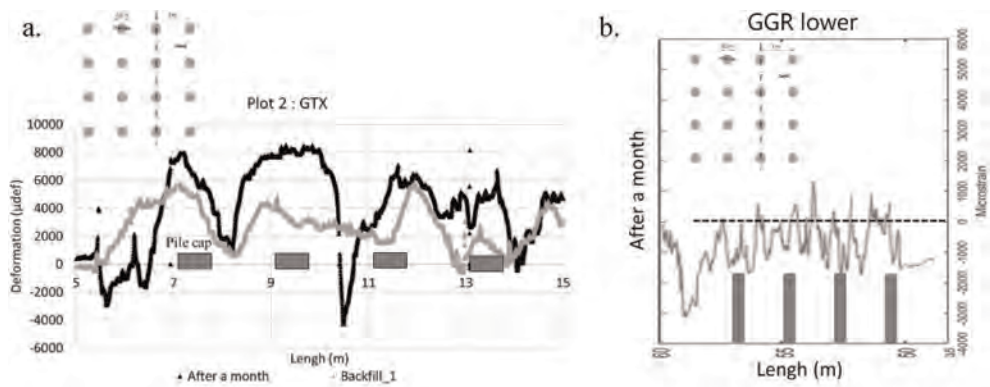
The comparison between the three tests shows that in this configuration the geosynthetics have not brought an upper efficiency than those obtained with the non-reinforced platform. Even this observation is unexpected, other authors have recently led to this conclusion from their experimental studies: Lee et al. (2021) showed approximatively the same efficiency with and without geosynthetic with the same level of settlement, Nguyen et al. (2022) showed a good efficiency of the reinforced granular platform without tension measured inside the geogrid.


Figure 7. a. Fiber optic deformation on geotextile; b. Fiber optic deformation on lower geogrid.

4 CONCLUSIONS

Three full-scale model tests on a geosynthetic-reinforced pile-supported embankment were conducted. For the three tests, the settlement and load transfer take place during the installation of the embankment. The reference test (Test 1) showed that with a 50 cm load transfer platform under a 1.5 m embankment, an efficiency of 70% is already achieved. Even if the insertion of geosynthetics in the mattress has slightly increased the arching load over the pile caps, the settlement of the subsoil has not been reduced. As the dimensioning of the geosynthetics, perhaps the settlement reductions requested from the producers were not the most realistic and a total reduction in differential settlement should have been requested from the LTP roof. Other tests will be performed in order to verify the measured values of stresses and strains by improving the instrumentation. As the platform is already very efficient without reinforcement, a test with a thinner LTP could be considered.

ABSTRACT: The geosynthetic reinforcement in a pile-supported (GRPS) embankment can be designed using the CUR226 (2016) design guideline. CUR226 has adopted the Concentric Arches (CA) model of Van Eekelen et al. (2013, 2015), which was validated using measurements in field and experiments. The validated use of CUR226 is only possible for conditions that match the conditions of these measurements. This means that the embankmentfill should be positioned above the ground water table, and that at least one layer of the geosynthetic reinforcement should be a geogrid.

This paper describes measurements in a partly submerged piled embankment, reinforced with geotextiles only. The seasonable effect in the measured geotextile strains strongly matches the seasonable temperature variation. However, no correlation with the varying groundwater table was found. The measurements match the calculations with the Concentric Arches model well and remain sufficiently on the safe side. Therefore, the CUR226:2016 design guideline may be used for this type of geotextile-reinforced pile-supported embankments.

1 INTRODUCTION

The design guideline CUR226 (2016) for geosynthetic-reinforced pile-supported (GRPS) embankments adopted the Concentric Arches (CA) model of van Eekelen (2015). This model was validated with more than 100 measurements taken in field and experiments (van Eekelen et al. 2015). These embankments were reinforced with at least one layer of geogrid. Furthermore, all the embankments were unsaturated, and installed above the groundwater table.

Limited research was done on the influence of water in a piled embankment. Briançon and Simon (2012), Sloan (2011), and Van Eekelen et al. (2020) showed that heavy rainfall affects measurements. Song et al. (2018) presented 2D trapdoor tests with sand and concluded that the arching mechanism can degrade. Wang et al. (2019), however, showed that the soil arching strengthened with an increasing water level in full-scale 3D model experiments.

The validated use of CUR226 is only possible for geometries, conditions and materials that match the situation where the measurements for the validation were taken. So, the entire embankment should be positioned above the ground water table, and that at least one layer

---

*Corresponding Author: suzanne.vaneekelen@deltares.nl

of the reinforcement should be a geogrid. If these requirements are not met, measurements should prove that the CA model gives good results for these conditions.

For this purpose, field measurements were done in a partly submerged piled embankment, reinforced with geotextiles only, without geogrids. This paper compares the measured strains with the varying groundwater table and air temperature, and with calculations with the CA model of CUR226.

2 A PARTLY SUBMERGED GEOTEXTILE-REINFORCED PILED EMBANKMENT

Van Eekelen et al. (2022) described the piled embankment that was constructed to connect an industrial area and the regional road N210 in the Netherlands. It was opened on 6 April 2019. Pile caps (0.75 m x 0.75 m), with smooth, rounded edges, were installed on end-bearing prefab concrete piles with an average centre-to-centre spacing of 2.28 m x 2.27 m (across x along the road axis). The basal reinforcement consists of two layers of woven geotextile (TenCate Geolon® PET 400/50). The bottom layer was installed across the road axis, the second layer was installed parallel to the road axis.

Figure 1 shows the monitoring program. Strain transducers E1 to E4 measure the geotextile strain. Pore pressure transducers ppt1 and ppt6 measure the varying groundwater table and ppt7 measures the water level in the adjacent ditch. Furthermore, the air temperature at the test location was measured hourly.
Figure 1.   Lay-out of the geotextile-reinforced piled embankment and the monitoring equipment.

3 MEASUREMENTS

3.1 *Pore pressures and ground water table*

Figure 2 shows the measured pore pressures, translated into groundwater table in m NAP, where NAP is a reference level in the Netherlands. As indicated in the figure, ppt 1 lies on top of a pile cap, and ppt6 lies approximately 0.65 m higher. Therefore, ppt1 lies in saturated soil, well below the groundwater table. However, the groundwater table sometimes drops below ppt6.

Pore pressure transducers are sensitive to air bubbles. Figure 2 nicely shows what can happen if a pore pressure transducer is installed in unsaturated soil. Until June 2020, ppt1 and pp6 match. However, around 1 June 2020, the groundwater table drops below ppt6. This causes an air bubble that disturbs the measurements of ppt6. At this moment, the values of

ppt6 remain well below those of ppt1. In September 2020, the groundwater level passes ppt6 again, the air bubble disappears, and ppt1 and ppt6 match again. In April 2021, the ground-water table passes ppt6 again, resulting in another air bubble that makes the measurements of ppt6 unreliable again. However, it seems plausible that ppt1 continuously gives reliable results; it shows a low water table during the very dry summer of 2022, followed by a rainy period in September 2022. The pore pressure transducer in the ditch was installed in February 2020 and gave reliable results until June 2021 and between November 2021 and March 2022.
Figure 2.   Measured pore pressures, translated into groundwater table (ppt1, ppt6) ditch water table (ppt7).

3.2   *Geotextile strains compared to groundwater table and average day air temperature*

Figure 3 compares the measured geotextile strains with the measured groundwater table. Strain gauges E1 and E2, that are located on the east-side, give higher values than the two other strain gauges, E3 and E4. The authors cannot explain this difference. All measured strains show a seasonable effect; during the summers, the strains are higher than in the winters. Furthermore, each summer gives slightly higher strains than the previous summer. This can be explained by the creeping behaviour of the geotextile.
Figure 3.   Comparison measured geotextile strains and to measured groundwater table (ppt1).

The measured strains do not correlate clearly with the groundwater table. Figure 4 zooms in on two four-week-long periods. Figure 4a shows a dry period, without rain resulting in a decreasing groundwater table. Figure 4b shows a wet period, with rainy periods and an increasing ground-water table. The measured strains show a clear daily cycle, which the authors cannot explain. Other papers present a similar daily effect, such as van Eekelen and Bezuijen (2007).

The daily cycle of traffic load, or soil temperature, may have an influence. However, the different strain gauges do not have a peak at the same time of the day. Figure 4b shows an immediate response on rain: the daily cycle is less clear. Possibly, this is caused by the relatively constant and low temperature caused by the rain, which flattens the daily cycle.

Figure 5 shows a clear correlation between the seasonable cycle of the geotextile strains and the average day temperature. The geotextile strain is higher in summer. The thermal expansion of the road surface may play a role in this mechanism.
Figure 4. Four-week details of Figure 3; measured geotextile strains and measured groundwater table (a) dry period (no rain) and (b) wet period (several rainy periods).
Figure 5. Comparison measured geotextile strains and the day-average of the air temperature which was measured hourly at the field monitoring location.

4 CALCULATIONS WITH THE CONCENTRIC ARCHES MODEL

The geotextile strains were calculated using the CA model (CUR226 2016; van Eekelen 2015). No partial factors were used. Table 1 gives the input parameters that were used. Some remarks:

- For design purposes, the characteristic value of the internal friction angle should be used. For comparison with measurements, the weighted average value of average values for the two soil layers within the soil arch should be used (van Eekelen & Han 2020). For the well-compacted sand layer, an average value of 35° is a good estimation. The 0.6 m aggregate layer below the sand layer consists of mixed concrete and masonry granulate, with a high masonry content. The shape of the grains was sub-angular, and the grain distribution was average to good. An average value for this layer is 36.5° to 38.5°. The weighted average of the friction angle for the two soil layers varies between 35.8° and 36.9°. In the calculations in this paper, the value for the average weighted friction angle was varied between 34° and 38°.
- As usual, we calculate without traffic load when we compare to field measurements. In addition to that, a calculation was conducted with 25% of the design load, to account for the permanent influence of the traffic load on the strains in the geotextile.
- CUR226 (2016) requests to reduce the soil arching for a piled embankment like this one, with a relatively thin embankment, and high traffic load. It is assumed that the soil arching reduces permanently due to the on-going traffic load. The soil arching reduction factor $\kappa = 1.58$ for this configuration and traffic load, as prescribed by Table 2.3 of CUR226.
- It is expected that the calculation with some traffic load and soil arching reduction matches the real situation best.

Table 1. Parameters used for the calculations with the Concentric Arches model[*].

Date	28 Feb '19	1 Mar '19	5 Mar '19	12 Mar '19	24 Apr '19	29 Feb '20	25 Aug '30
Height fill (m)	0.00	0.30	0.60	1.00	1.51	1.51	1.51
Tensile stiffness geotextile (kN/m)	3200	3200	3200	2961	2722	2544	2426

[*]And: centre-to-centre distance piles s_y = 2.28 m, square pile caps width a = 0.75 m, unit weight fill γ = 19 kN/m^3, fill friction angle φ = 34° and 38°, subgrade reaction k = 0 kN/m^3, traffic load p = 0 kPa and 11.5 kPa (25% of the design load), soil arching reduction coefficient κ is 1.0 (no soil arching reduction) and 1.58 (soil arching reduction).

5 COMPARISONS MEASUREMENTS AND CALCULATIONS

Figure 6 compares the measured and calculated geotextile strains. The calculated strains are maximum values at the edge of the pile caps. To safely design with CUR226, the calculated strains should be larger than, or equal to the measured values. The figure shows that the smallest calculated strains agree reasonably with the average values of E1 - E4. All other calculations give higher values than the measured values. This is a safe result.

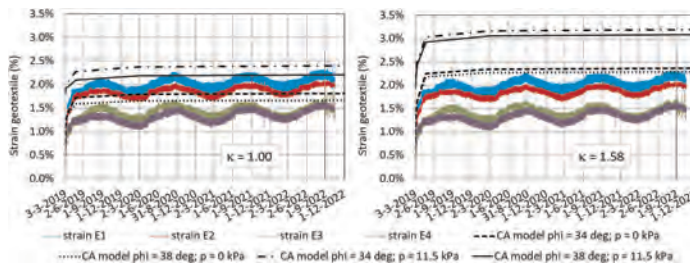
Figure 7 gives an extension of the validation conducted by van Eekelen et al. (2015). The figure shows that the measurements of E1 and E2 agree well with the calculations, and the measurements of E3 and E4 give lower values than calculated. This is on the safe side. From this we may conclude that the CA model, and therefore the CUR226:2016 design guideline,


Figure 6. Comparison measured geotextile strains and geotextile strains calculated with the CA model.
Figure 7. Extension of the validation of the CA model with the new data, with in the calculations: φ = 38°, traffic load = 0 kPa and κ = 1.58.

is applicable for this piled embankment of which the embankment was installed partly below the groundwater table. This conclusion is valid for woven geotextiles as applied in this monitoring project.

6 CONCLUSIONS

Geotextile strains, the varying groundwater table and the air temperature were measured in a geotextile-reinforced piled embankment that was partly submerged. The measured geotextile strains show no correlation with the groundwater level. However, the measured strains have a strong seasonable cycle that match the seasonable cycle in the average day air temperature quite well. This relationship between the air temperature and the geotextile strains may be caused by the thermal expansion of the road surface.

The CA model matches the measurements well. The CUR226:2016 design guideline adopted this CA model. Therefore, the CUR226:2016 is applicable for this type of geotextile-reinforced piled embankment, of which the embankment was installed partly below the groundwater table. This conclusion is valid for the woven geotextiles as applied in this monitoring project.

ABSTRACT: A DEM-FEM coupled numerical model was used to investigate the behaviour of a platform reinforced by geotextile (GTX) over soft soil subjected to cyclic loading. The ability of the numerical model to consider the settlement of the granular and the subgrade soil surface and the stress transmitted to the top of subgrade layer was established by comparisons with the experimental data for the first loading cycle. A parametric study was carried out using two GTX tensile stiffnesses, one with a medium tensile stiffness and the other with a low tensile stiffness. The comparison between the stress acting on the upper and the lower face of each GTX showed the effect of the tensile stiffness on the tensioned membrane mechanism and confirm the role of the GSY sheet in the numerical model.

1 INTRODUCTION

Poor subgrade is a widespread issue in unpaved roads construction. The geosynthetic (GSY) is considered one of the most innovative solutions since it was used in the late 1970's. Depending on the type of the GSY used, one or many functions among the separation, the reinforcement and the stabilisation can be ensured. Reinforcement takes place in the road structure system when the GSY, which is under tension with a curved shape, transfers the tensile force to the location where it is anchored through the tensioned membrane effect (Figure 1). While the stabilisation is provided to the base course materials when a soil-GSY composite material is formed by interlocking and/or friction and becomes less deformable than the soil.

A few design methods have been presented in the literature and quantifies either the tensioned membrane effect or the confinement mechanism by friction or interlocking between the GSY and the base course material. However, all of these methods have limitations because they have been calibrated on limited GSY and soil parameters and sometimes under static loading rather than cyclic loading. Each method is validated in a range of rut depth which is linked to the mechanism quantified. The most used method has been proposed by Giroud and Han (2004) and accounts for the confinement mechanism by friction or interlocking between the GSY and the base course material with neglection of the tensioned membrane effect. This method is validated when the rut depths ranges between 50 mm and 100 mm and is calibrated on a limited number of GSY.

To highlight the understanding of such mechanisms and to set bases to improve existing design methods, a full-scale experimentation has been recently carried out and investigated the reinforcement performance under cyclic vertical and traffic loadings using two types of

GTXs with different tensile stiffnesses and two base course thicknesses (Abou Chaz et al. 2022). In addition, a numerical model using a Spherical Discrete Elements Code (called SDEC) is used and calibrated based on the experiment results after applying the static load of the first cycle applied experimentally. The confrontation between the numerical model and the experiments carried out for the same purpose is presented below and will allow to give relevant conclusions about the influence of the GTX stiffness on the reinforcement performance.
Figure 1.   Tensioned membrane effect mechanism involved in reinforced platform by GSY.

2   THE LABORATORY EXPERIMENT

This section summaries the experiments presented by Abou Chaz et al. (2022), to which the numerical results are compared. The conducted laboratory experiments are developed to investigate the reinforcement performance under vertical loading using two GTXs with different tensile stiffnesses and two base course thicknesses (35 cm and 50 cm).

The experimental box of 2 m long, 1.8 m wide, and 1.1 m high is used to build a 60 cm of subgrade layer thickness, with a CBR around 1%, covered by a compacted granular layer with a thickness equal to 35 cm or 50 cm (Figure 2a). To reinforce the section, a woven GTXs sheet (made of an assembling of polypropylene filaments) is placed at the interface between the soft soil and the granular platform.

The applied cycles are shown in Figure 2b. The frequency of a cycle is 0.77 Hz. The maximum load applied on a circular plate of diameter D (D = 30 cm) is 45 kN, chosen to obtain a pressure equal to 560 kPa which is equivalent to the contact pressure of a wheel. The unpaved road is expected to support 10 000 ESAL passes, with a maximum rutting of 75 mm. Hence, 10 000 cycles are applied to each tested platform.

Each tested section is instrumented with Earth Pressure Cells (EPC), hydraulic settlement sensors (S) and laser displacement sensors (L). The EPCs are placed on the GTX, within and on the top of the subgrade to measure the stress distribution. Each settlement sensor is positioned on an EPC. Laser displacement sensors are fixed to a beam and placed above the circular plate to measure its penetration during the test with a great accuracy.
Figure 2.   a) Plate load test setup, b) Cycles applied.

3 THE NUMERICAL MODEL

3.1 *Basic principle of DEM-FEM model*

In this study, a FEM-DEM coupled numerical model (Villard et al. 2009) that considers the discrete nature of the granular material, the fibrous and continuous nature of the GTX and the frictional interaction at the interface (rolling sliding and friction) between the soil particles and the finite elements (used to restore the GTX behaviour) is adopted.

The GTX sheet is modelled by three node triangular finite elements. Each triangular element consists of a set of fibres with various orientations forming a plan. The behaviour of a fibre network is obtained by superposition of behaviours obtained in each fibre direction (no sliding between fibre). The mechanical behaviour of the fibres is non-linear elastic, and the compression elasticity modulus is very low compared to the tensile elasticity modulus (Villard & Giraud 1998). The non-linear force-displacement relation (1) is adopted for each three nodes triangular element used in the iterative process of calculation included in the coupling code.

$$\{F_e\} = \{K_e\} * \{u_e\} + \{R_e\} \tag{1}$$

$\{F_e\}$ are the forces acting on the nodes of an element, $\{u_e\}$ the nodal displacements of the element, $\{K_e\}$ is the elementary matrix of rigidity depending on the final position of the three nodes, and $\{R_e\}$ a corrective vector force resulting from the large displacement formulation.

Within the granular mattress, the discrete elements interact through contact points based on the molecular dynamic method developed by Cundall and Strack (1979). A classical linear elastic contact law and a perfect elastic plastic law are used for the normal interaction and the tangential interaction respectively. The normal component of the contact force F_n is related to the normal overlap u between the grains by the normal stiffness K_n and the incremental tangential component of the force F_t is related to the incremental relative tangential displacement v by the tangential stiffness K_t. The interaction between the particles follows the Coulomb friction law. Thus, the tangential force is limited to a maximum absolute value of $|F_t| \leq \mu F_n$, where μ is the intergranular friction coefficient. The normal contact stiffness (or tangential contact stiffness) between two spheres of radius R_i and R_j, expressed in N/m^2, is defined as follows (2) by a function of the normal rigidity K_{nij} (or tangential rigidity K_{sij}) of the two constitutive materials in contact.

$$K_n = \frac{K_{nij} \left(R_i * R_j \right)}{\left(R_i + R_j \right)} \tag{2}$$

An iterative procedure that alternates successively the resolution of Newton's second law of motion and the actualization of the interaction forces at each contact point is used to solve the problem. The motion equations are integrated using an explicit centred finite difference algorithm involving a time step Δt.

A contact law similar to that used in the DEM method between the grains is used to describe the interaction between the soil particles and the triangular finite elements.

3.2 *Geometry and parameters selected for application to reinforced platform over soft soil*

The used numerical model (Figure 3) is 1.8 m long, 1.8 m wide and 0.36 m deep and includes, from top to bottom:

1. an assembly of clumps (composed of two overlapped and unbreakable spheres of same diameter D with d is the distance between the center of two particles, see Figure 3) describing the behaviour of the granular mattress and interacting through contact points,
2. thin, finite, triangular elements describing the membrane and tension behavior of the GTX,
3. a layer of spheres regularly distributed in a square mesh at the base of the model and associated to springs to represent the supporting soft soil which displace only vertically (no rolling admitted).

Horizontal and vertical frictionless walls are used on the lateral sides to define the boundary conditions. A circular rigid plate (Diameter=0.3 m) made with small spheres is placed at the centre of granular mattress to apply static loading (or cyclic). The incremental load is low enough to avoid dynamic effects.

The granular elements are modelled by means of clusters of two overlapped spheres (Figure 3) in order to approach the mechanical macroscopic behaviour of the experimental soil with respect to a calibration process. A specific method (ERDF method) based on the iterative growth of the particles radii and intergranular friction reduction is used to control the density of the numerical sample. For the calibration process, the micro-mechanical parameters (K_n, K_t and μ) were set in order to obtain vertical displacement of the numerical assembly similar to those measured in the experiment. For this purpose, numerical triaxial tests were performed with a set of microscopic contact friction angle (δ), for several porosities (ranging between 0.3 and 0.41). In the present case a dense state of the numerical assembly is retained to fit the real macroscopic mechanical behaviour. The values of the microscopic contact parameters between the spheres of the granular mattress and the average macroscopic mechanical parameters of the selected numerical model are summarized in Table 1.

The interface friction parameters between the GTXs and the lower subgrade or the upper granular mattress are obtained by pull out tests using a test box $0.5 \times 0.5 \times 0.3$ m^3 while the tensile parameters of the GTX in x and y direction are deduced from traction tests performed by the GTX manufacturer. All these parameters are also presented in Table 1.

Table 1. Numerical parameters describing the different components of the model.

Granular platform parameters		
Normal contact stiffness (MN/m^3)	K_n	100
Tangential contact stiffness to normal contact stiffness	K_s/K_n	1
Micromechanical friction coefficient	$\mu = \tan \delta$	1.11
Peak friction macroscopic angle (°)	Φ_p	46
Young's modulus (MPa)	E	31
Porosity	n	0.34
GTX		
Tensile stiffness in the x direction (kN/m) [0 - 5% strain]	J_x	1200
Tensile stiffness in the y direction (kN/m) [0 - 5% strain]	J_y	1200
Soil-GTX interface friction parameters		
Angle between the clumps and the upper interface of the GTX (°)	$\Phi_{clumps-GTX}$	35
Angle between the subgrade and the lower interface of the GTX (°)	$\Phi_{sphere-GTX}$	25
Lower supporting soil		
Subgrade reaction modulus (MPa/m)	K	3
Figure 3. Geometry of the simulated sample and illustration of grain shapes used in simulation.

The subgrade soil rigidity and its evolution with cycles are estimated by experimental cyclic plate load test performed on the subgrade soil placed in a box ($2 \times 1.8 \times 0.6$ m^3). The subgrade reaction modulus retained for the loading phase of the first cycle (that allows to make coincide experimental and numerical vertical displacements of the loading plate) is presented in Table 1.

4   NUMERICAL RESULTS

4.1   *Comparison between the numerical model and the experimental results of the laboratory experiment*

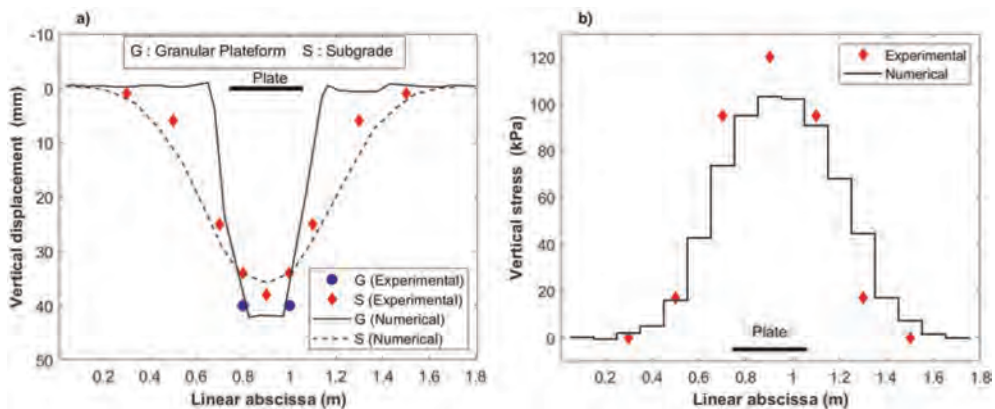
A static load of 40 kN (560 kPa) is applied on a rigid plate placed at the centre of the numerical model. The experimental results of the subgrade and the base course surface settlements obtained after application of the first loading cycle and the calibrated numerical results are plotted in Figure 4a. To evaluate the relevance of the numerical model, Figure 4 b compares the stress measured at the top of subgrade soil at the end of the loading phase of the first cycle to the numerical stress obtained under the GTX. As it can be seen, the relatively good agreement between the experimental and the numerical results of the stress attest to the ability of the numerical tool to well reproduce the experimental behaviour and the possibility to study the mechanism involved in the model.


Figure 4.   Comparison between experimental and numerical: a) subgrade and base course surface settlement, b) subgrade surface stress.

4.2   *Numerical analysis of the tensioned membrane effect*

As explained in Figure 1, the tensioned GSY with a curved shape (i.e. out of plane deformation) transfers the load to the location where it is safely anchored. Therefore, the maximum load transmitted to the subgrade is reduced since the loads transmitted to the subgrade are distributed by the geotextile over an area larger than that above the GSY. To clarify this mechanism, called the tensioned membrane effect, two numerical simulations with two different GTX stiffnesses are carried out. The stiffness of the GTX 1 is 1200 kN/m in both directions (Simulation 1), whereas the stiffness of the GTX 2 is 1 kN/m in both directions (Simulation 2). This low value of stiffness is chosen in order to have a non-reinforced model because of the reinforcement GSY should have at least a tensile stiffness equal to 8 kN/m (Hufenus et al. 2006).

The granular mattress parameters are the same as that described in the section 3.2. In the simulation 2, the lower geotextile interface friction angle ($\Phi_{\text{sphere-GTX}}$) is increased to reach 60°, rather than 25° used in the simulation 1, to avoid the geotextile sliding due to its low

stiffness. A subgrade reaction modulus equal to 2 MPa/m is chosen in order to induce a deformation in the GTX more significant than that obtained in the simulation presented in section 4. The same static load of 40 kN (560 kPa) is applied on a rigid plate placed at the center of the numerical model. The maximum subgrade surface settlement obtained with the GTX 1 is 62 mm lower than that obtained with the GTX 2 which is 120 mm. Figure 5a shows that the vertical stress acting on the lower face of the GTX 1 (J=1200 kN/m) is lower than that acting on the upper face in the zone located under the plate, whereas the vertical stress acting on the lower face of the GTX 1 becomes higher than that acting on the upper face in the zone located around the plate. Thus, a part from the stress acting on the upper face of geotextile and located below the circular plate is not transmitted vertically to the top of subgrade, but transmitted by the geotextile to the zone around the plate. However, the stresses acting on the upper and the lower face of the GTX 2 with a low stiffness (J=1 kN/m) are rather similar (Figure 5b). Moreover, it is important to note that the stresses transmitted to the supporting soil are much greater for GTX2 than for GTX1. This shows that the GTX with an enough stiffness has a key role in the load transfer to the top of the subgrade.

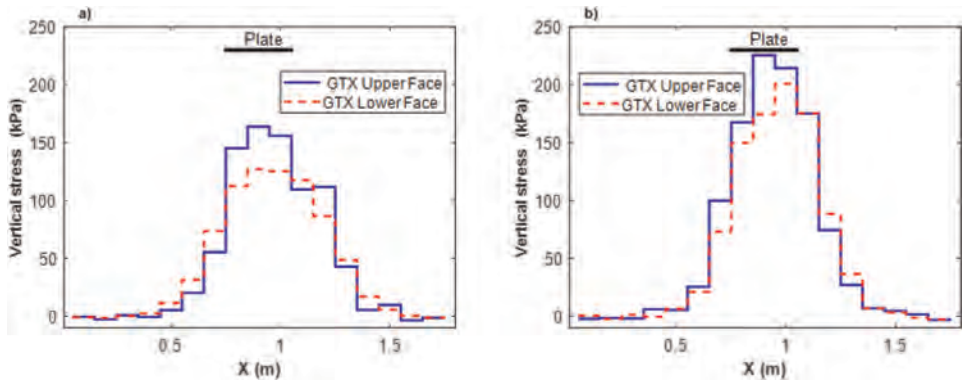
The resultant of the vertical stress acting on the lower face of the GTX subtracted from the vertical stress acting on the upper face of the GTX is expressed by $\Delta\sigma_{zz}$ (in kPa) and showed in Figure 6. $\Delta\sigma_{zz}$ is positive in a circular zone with a centre equal to the loading plate centre and a diameter D1 = 1,5D (D is the diameter of the loading plate equal to 0.3 m) and


Figure 5.   Vertical stress acting on the upper face and on the lower face of the: a) GSY 1, b) GSY 2.
Figure 6.   The resultant of the vertical stress acting on the lower face of the GTX subtracted from the vertical stress acting on the upper face of the GTX: a) case of GTX 1, b) case of GTX 2.

negative in the zone located between the circle with D1=1,5D m and the circle with a diameter D2=3D (Figure 6.a). This means that a part of the stress acting on the upper face of the GTX is transmitted directly to the subgrade and the other part is transmitted by the GTX (tensioned membrane effect) to the adjacent area (1.5D<diameter<3D). Figure 6b shows that the $\Delta\sigma_{zz}$ values, whether positive or negative, obtained with GTX 2 are more important than those obtained with the GTX 1, and concentrated over separate areas so that their sum is less than the entire area referred to with the GTX1. Hence, the GTX 2 with a low stiffness does not show a clear load transmission by membrane effect.

5 CONCLUSION

A numerical tool based on the coupling between DEM and FEM is used to study the behaviour of a granular platform reinforced by GTX over soft soil. It has shown by comparison with the experimental results that the numerical model provides relevant information on the surface settlement, the stress transmitted to top of the subgrade soil for the first loading cycle. The GTX tensile stiffness effect on the load transfer to the top of the subgrade has been demonstrated by a comparison between the stresses acting on the upper and the lower faces of GTX. This comparison points out the tensioned membrane effect mechanism that takes place in this application.

The calibration of this model with further number of cycles is in progress with a calibration of the behaviour law for the soft subgrade soil under cyclic loading. This numerical work will provide access to additional information difficult to be quantified during the experimentation.

Numerical study of shear behavior of a geosynthetic encased stone column under direct shear loading

M. Ji, J. Wang & Y. Zheng*
Wuhan University, Wuhan, China

ABSTRACT: Geosynthetic encased stone column (GESC) has higher strength than conventional stone column due to the radial confinement of geosynthetic encasement. This technology has been used for ground improvement in soft soils. In this study, the shear strength behavior of GESC under direct shear loading was investigated using the three-dimensional finite difference program FLAC3D. The stone column and surrounding soil were modeled using the linearly elastic-plastic Mohr-Coulomb model, and the geosynthetic encasement was characterized using linearly elastic elements with isotropic behavior. The model also considered the interaction between geosynthetic encasement and adjacent soils (i.e., stone column and surrounding soil). The shear stress-strain response and the development of longitudinal and circumferential strains of GESC during the shear process were presented and discussed. Simulation results indicated that the geosynthetic encasement can increase the shear resistance of stone column, and the longitudinal strains of GESC are greater than the circumferential strains under direct shear loading.

1 INTRODUCTION

Geosynthetic encased stone column (GESC) technology has been widely used for ground improvement in soft soil foundation and provides many advantages over traditional stone column (SC), including higher bearing capacity and better stability (Castro & Sagaseta 2011; Gniel & Bouazza 2010; Lo *et al.* 2010). In addition, GESC has also been used in the construction of infrastructure, such as embankments and dams (Almeida *et al.* 2015; Alexiew & Raithel 2015). The GESC under the center of the embankment is primarily subjected to vertical loading. Many investigations have studied the bearing characteristics of GESC under vertical loading, which indicate that the geosynthetic encasement significantly improves the bearing capacity and reduces the settlement of stone column (Kadhim *et al.* 2018; Khabbazian *et al.* 2010; Murugesan & Rajagopal 2010; Yoo 2010). The GESC under the toe of the embankment is primarily subjected to lateral loading (Almeida *et al.* 2015; Chen *et al.* 2015). However, research on the GESC under lateral shear loading is limited, and further investigations are needed.

Several experimental and numerical studies have been conducted for the shear behavior of GESC and generally indicate that the geosynthetic encasement increases the shear resistance of stone column under direct shear loading (Cengiz *et al.* 2019; Mohapatra *et al.* 2016). Mohapatra *et al.* (2017) conducted a 3D slope stability analysis through the strength reduction method and found that the geosynthetic encasement improves the factor of safety of embankment slope in soft soil ground improved using stone column. These findings indicate that GESC has better performance over stone column under shear loading conditions. However, the mobilization of shear resistances from the geosynthetic encasement, stone column, and surrounding soil during the shear process has not been studied. Therefore, further investigations are needed to understand the shear reinforcement mechanism of GESC.

This paper presents a numerical study of the shear strength behavior of GESC model under direct shear loading. The evolution of the shear strength contributions of geosynthetic encasement, stone column, and surrounding soil during the shear process are presented and discussed. Results of this study provide insights on the shear reinforcement mechanism of GESC.

2 NUMERICAL MODEL

In this study, a unit cell model of GESC improved foundation is used to simulate the shear stress-strain response of GESC under direct shear loading using the finite difference program FLAC3D (Itasca Consulting Group 2019).

2.1 Model geometry

Figure 1 shows the geometry and finite difference mesh for the unit cell model of the GESC improved foundation. The GESC has a height of 1.2 m and a diameter of 0.8 m. The geosynthetic encasement wraps around the stone column for the entire length. The unit cell model has a diameter of 2.06 m, which represents a GESC improved ground with a typical area replacement ratio of 15%. This model represents a typical configuration for field conditions. The horizontal shear plane is located at the mid-elevation of the model. The diameter of the lower part below the shear plane was large enough so that the area of the shear plane remains constant during the shear process.
Figure 1. Model configuration for the GESC unit cell model.

2.2 Material models and properties

The column infill material and surrounding soil were modeled using a linearly elastic-plastic material with the Mohr-Coulomb failure criterion. The elastic moduli of the stone column and surrounding soil were selected as 40 MPa and 10 MPa, respectively. The friction angles of the stone column and surrounding soil are 42° and 32°, respectively. The soil parameters used in the simulations are listed in Table 1, corresponding to typical values in field engineering. The geosynthetic encasement was modeled using linearly elastic embedded liner element with isotropic behavior. The liner element was modeled by using the three-node plane-stress Constant Strain Triangle (CST) element. The geosynthetic encasement has tensile stiffness of 4000 kN/m and Poisson's ratio of 0.1.

2.3 Interfaces

The embedded liner element was adopted to simulate the geosynthetic encasement. It provides two links at each node on both sides, which can consider the interaction of geosynthetic encasement with different soils on both sides. The interaction between the geosynthetic encasement

Table 1. Soil parameters.

Property	Column infill	Surrounding soil
Elastic modulus, E (MPa)	40	10
Poisson's ratio, v	0.3	0.3
Friction angle, f (°)	42	32
Apparent cohesion, c (kPa)	1	1

and soils on both sides was simulated through two interfaces, including the surrounding soil-geotextile interface and the column infill-geotextile interface. The horizontal shear plane at the mid-elevation of the unit cell model was modeled using two interfaces for the surrounding soil and the column infill, respectively. These interfaces were predefined in the GESC model to ensure that sliding occurs along the horizontal shear plane. The shear strength parameters of the two interfaces were set as the same strength parameters with the surrounding soil and column infill, respectively. The normal stiffness and shear stiffness of the two interfaces were determined according to the approach suggested by the FLAC manual (Itasca Consulting Group 2019). The normal stiffness and shear stiffness for surrounding soil interface are 0.45 GPa/m, and the normal stiffness and shear stiffness for column infill interface are 1.79 GPa/m.

2.4 Modeling procedures

The direct shear process was simulated in stages. Firstly, the construction of the GESC model under gravitational loading was performed and the horizontal shear plane was set. Then, the embankment loading was modeled by applying a vertical stress of 50 kPa on the top surface of the unit cell model and solved for equilibrium. Figure 2 shows the monitoring points of the GESC, which were arranged on the geosynthetic encasement at an interval of 0.2 m to monitor the development of longitudinal and circumferential strains during the shear process. A shear loading rate of 1×10^{-3} mm/step was applied to the circumferential boundary grid above the shear plane, while the bottom and circumferential boundaries of the lower part below the shear plane were fixed. When the shear strain reaches 20%, the shear loading was stopped.

The unbalanced force at each step were added up first, which is equivalent to the total shear force. The total shear force was then divided by the total area of shear plane, which was taken as the equivalent shear stress on the shear plane (Mohapatra et al. 2017). The shear resistance provided by the geosynthetic encasement was obtained by subtracting the corresponding shear forces generated by the two soil interfaces on the horizontal shear plane (i.e., the surrounding soil interface and the column infill interface) from the total shear force. The shear stresses of surrounding soil, stone column, and geosynthetic encasement are obtained by dividing the
Figure 2. Monitoring point of the GESC unit cell model.

corresponding shear forces by the areas of surrounding soil, stone column, and stone column, respectively. The calculated shear stress for the geosynthetic encasement is contributed by the shear resistance due to the tensile force developed in geosynthetic encasement.

3 RESULTS AND DISCUSSION

Figure 3 shows the development of shear stress and shear strength contribution for the unit cell model. In Figure 3(a), the shear stress of surrounding soil develops very fast in the initial stage, and then reaches stable gradually. When the shear strain reaches 20%, the shear stress of stone column is greater than that of the surrounding soil. The shear resistance contributed by the geosynthetic encasement is much smaller than the surrounding soil and stone column in the initial stage. This is because the shear resistance comes from the mobilized tensile force in geosynthetic encasement in the shear direction, which significantly depends on the development of longitudinal strains. However, the shear resistance provided by the geosynthetic encasement at 20% shear strain is the largest, which indicates that the geosynthetic encasement could provide strong shear resistance for the GESC.

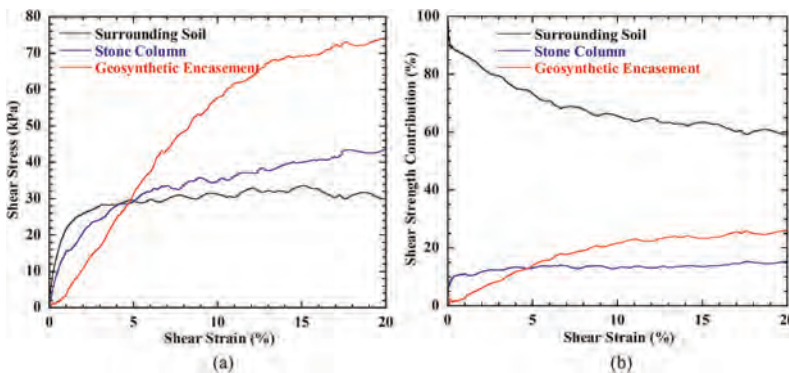
Figure 3(b) shows that with the increase of shear strain, the shear strength contribution of surrounding soil decreases, but those of the stone column and geosynthetic encasement increase. The shear strength mainly comes from the surrounding soil in the initial stage because the shear loading starts from the edge of surrounding soil. The shear strength of the stone column gradually develops with increasing strain, as the shear movement of the surrounding soil drives the stone column to move in the shear direction. Meanwhile, the geosynthetic encasement was deformed by the movement of stone column and surrounding soil, which results in mobilization of longitudinal tensile strains. At 20% shear strain, the shear strength contributions are 59%, 15%, and 26% for the surrounding soil, stone column, and geosynthetic encasement, respectively. The shear strength contribution of surrounding soil is the largest due to the large area (i.e., 85% area of the unit cell), though the shear strength of the surrounding soil is lower than that of the stone column.


Figure 3. Development of shear stress: (a) shear stress; and (b) shear strength contribution.

The development of longitudinal and circumferential strains of geosynthetic encasement at different elevations are shown in Figure 4. Figure 4(a) shows the development of longitudinal strains with the increase of shear strain. The maximum longitudinal strain of geosynthetic encasement occurs at the shear plane and decreases with the increasing vertical distance from the shear plane. The longitudinal strains of the geosynthetic encasement above the shear plane are larger than those below the shear plane for the same vertical distance from the shear plane, as the upper part is the driving part during shear process. Figure 4(b) shows the development of circumferential strain with increasing shear strain. In general, the

circumferential strains of geosynthetic encasement above the shear plane were affected first in the initial shear stage. As the shear loading continued, the circumferential strain right below the shear plane gradually developed. In general, the circumferential strains near the shear plane increase significantly, especially above the shear plane.
Figure 4.   Development of geosynthetic encasement strain: (a) longitudinal strain; and (b) circumferential strain.

Figure 5 shows the longitudinal and circumferential strains of the geosynthetic encasement with elevation. It can be seen from the figure that within the vertical distance of 0.2 m from the shear plane, the longitudinal strains are greater than the circumferential strains. Moreover, the maximum value of longitudinal strains is approximately twice than that of the circumferential strain, which indicate that the longitudinal tensile rupture is more critical than the circumferential rupture for GESC under shear loading. At the vertical distance further away from the shear plane, the longitudinal strains are slightly smaller than the circumferential strains, as the tensile forces due to shear loading is not obvious at these elevations.
Figure 5.   Geosynthetic encasement strain profiles.

4   CONCLUSIONS

This paper presents a numerical study of the shear strength behavior of GESC under direct shear loading. The backfill soil was characterized using a linear elastic-plastic model and the Mohr-Coulomb failure criterion. Geosynthetic encasement was characterized using linearly elastic elements with isotropic behavior. Two interfaces were included to simulate the horizontal shear planes of the stone column and the surrounding soil. The shear stress-strain

response and the development of longitudinal and circumferential strains of GESC during the shear process were presented and discussed. Simulation results indicate that the geosynthetic encasement can provide shear resistance for stone column from the mobilized tensile force on geosynthetic encasement in the shear direction, which significantly depends on the development of longitudinal strains of geosynthetic encasement. The longitudinal strains are generally much larger than the circumferential strains, which indicates that the longitudinal tensile rupture is more critical than the circumferential rupture for GESC under shear loading.

ABSTRACT: The Hong Kong International Airport has expanded its existing two-runway system to a three-runway system based on a reclamation project over a seabed of soft marine clay. In the reclamation area, a layer of load transfer platform (LTP) was designed with geosynthetic reinforcement to bridge the overlaid surcharge loadings of reclamation fills and underlaid marine clay improved by deep cement mixing method. In this study, firstly, a small-scale physical model test of geotextile-reinforced sand layer over soft marine clay improved by cement-treated soil columns was performed to investigate the load transfer mechanism among columns, soils, and geotextile under different surcharge loadings. The results from the scaled model test were then adopted to verify the parameters used in a finite element model established using PLAXIS. Furthermore, the finite element model was used to reveal the development of soil arching.

1 INTRODUCTION

The third runway reclamation project of the Hong Kong International Airport has been constructed over a seabed of soft marine clay improved by deep cement mixing (DCM) method. A layer of geosynthetic-reinforced load transfer platform (LTP) was designed in between the reclamation fills and the DCM-treated marine clay seabed (Lee 2016). The consideration of the load transfer mechanism and the design of geosynthetic reinforcements in LTP are similar to geosynthetic-reinforced column-supported (GRCS) embankments. The load transfer in a GRCS embankment is normally related to soil arching effect which develops with the settlement of subsoils or the deflection of geosynthetic reinforcements (Iglesia *et al*. 2014; King *et al*. 2017; Zhang *et al*. 2022). Various theories and models for soil arching in column-supported embankments were proposed based on empirical methods or analytical approaches, among which the semi-spherical arches model proposed by Hewlett and Randolph (1988), multi-shell arches model proposed by Zaesek (2001), and concentric arches (CA) model proposed by van Eekelen *et al*. (2013) have been adopted in British, German, and Dutch design guidelines.

In this study, a small-scale physical model test was conducted on a geotextile-reinforced sand layer over a soft subsoil improved using cement-treated soil columns to investigate the load transfer mechanism and tensile strains of the geotextile reinforcement. In addition, a numerical simulation was performed using PLAXIS software to reveal the development of the soil arching in the geotextile-reinforced sand layer at different stages.

2 EXPERIMENT

2.1 Test setup

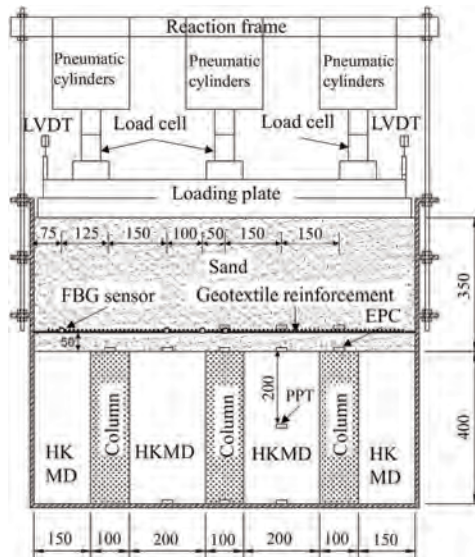
The physical model test was conducted in a steel tank with the dimension of 1000 mm (length) × 600 mm (width) × 800 mm (depth). Six prefabricated cement-treated soil columns with a cement content of 20% (in terms of dry mass of soil) were installed in the subsoil of Hong Kong marine deposits (HKMD) overlaid by a geotextile-reinforced sand layer. The subsoil was prepared by consolidating the reconstituted HKMD with the initial water content of 100 % under a uniform load of 5.35 kPa. The columns were subsequently installed using the replacement method adopted by Ho *et al.* (2020). A sand layer (thickness of 350 mm) over the HKMD was filled in seven times with a 50 mm thick sublayer formed each time after compaction. The total weight and volume of sand were controlled to ensure a relative density of 80%. A piece of woven geotextile (secant tensile modulus of 680 and 150 kN/m in longitudinal and transversal directions) was installed 50 mm above the subsoil, as shown in Figure 1. A rigid porous plate was placed on the top of the sand layer to serve as a platform for setting the LVDTs (manufactured by SHOWA) and as a loading plate. Earth pressure cells (EPCs) and porewater pressure transducers (PPTs), manufactured by DMKY, were used to measure the vertical stress and excess porewater pressure at different locations. Fiber Bragg grating (FBG) sensors (manufactured by T&S) were adopted to measure the tensile strain of the geotextile reinforcement. NI PXIE 4331 datalogger was used to record electronic signals from all conventional transducers. FBG-based transducers were connected to Micron Optics SM130 interrogator.


Figure 1.   Schematic diagram of the physical model test (unit in mm).

2.2 Test results

The surcharge loading was applied by pneumatic cylinders following a loading sequence of 10, 20, 40, and 80 kPa. Each loading stage lasted until there was no further change in excess porewater pressure. Figure 2a shows the average surface settlement measured by LVDTs and the actual loading applied to the top of the sand layer measured by load cells. The responses of excess porewater pressure measured by PPTs at the middle and bottom levels of the subsoil are presented in Figure 2b. Rapid dissipation of excess porewater pressure at both

locations can be observed at the very beginning of each loading stage. The accelerated consolidation was mainly because of the mechanical contribution of the columns on loading transfer (Wijerathna *et al*. 2017; Wu *et al*. 2020).

Different terminologies and definitions were proposed to assess the soil arching effect and interpret load transfer mechanisms. In this study, pile (or column) efficacy, proposed by Hewlett and Randolph (1988), is adopted:

$$E = \frac{A + B}{(\gamma H + p)s^2} \tag{1}$$

where A and B represent load parts A and B defined by van Eekelen *et al*. (2013); p is the surcharge loading; s is the center-to-center spacing of columns; γ and H are the unit weight and height of the sand layer. Load parts A and B are calculated as follows:

$$A = \sigma_c^a A_c \tag{2}$$

$$B = \left(\sigma_c^b - \sigma_c^a\right)A_c \tag{3}$$

where σ_c^a and σ_c^b are the average vertical stresses measured by EPCs above and beneath the geotextile reinforcement in column zones; A_c is the area of column zones. Figure 2c presents the values of efficacy with different surcharge loadings. It is found that the efficacy decreases during the process of increasing the surcharge loading. This is because of the partially undrained condition of the subsoil delays the loading transfer. With the consolidation of the subsoil under the given surcharge loading, differential settlements between columns and the surrounding soils increase inducing an increase in the deflection of the geotextile reinforcement, and thus leading to an increase in efficacy. The efficacy of columns after the consolidation slightly increases with the increase of the surcharge loading. This finding agrees with the simulation results from van der Peet and van Eekelen (2014).

Figure 2d presents the maximum tensile strains in both longitudinal (x) and transversal (y) directions of the geotextile reinforcement. The maximum tensile strains under different surcharge loadings can be also calculated according to Dutch design guidelines (van Eekelen & Brugman 2016) and German design guidelines (EBGEO 2010). It is found that the Dutch method gives better predictions in terms of the maximum tensile strains of geotextile reinforcement when the surcharge loading was less than 40 kPa, while German EBGEO method provides closer results to the measured strains under 80 kPa.

3   NUMERICAL SIMULATIONS

3.1   *FE models*

A 3D finite element (FE) model of four quarter columns and HKMD subsoil is built using PLAXIS 3D, as shown in Figure 3. HKMD subsoil is simulated by Soft Soil Creep (SSC) model, cement-treated soil columns are simulated by Mohr-Coulomb (MC) model, the sand layer is simulated by Hardening Soil (HS) model, the geotextile reinforcement is simulated by geogrid elements with elastic properties. Table 1 lists the input parameters for the simulation. Standard boundary conditions with the bottom boundary fixed in all directions, side boundaries normally fixed, and top boundary free are applied to the FE model. Horizontal interfaces are assigned on both sides of the geotextile reinforcement facing to overlaid and underlaid sand layers. A reduction factor of 0.8 is selected to consider the interfacial friction angle between the sand and geotextile reinforcement (Yapage & Liyanapathirana 2018). Vertical interfaces are assigned between DCM columns and HKMD. Similar to the FE models of van der Peet *et al*. (2014), the vertical interfaces are extended 0.1 m into the overlying sand layer. The properties of the extended interface are identical to the

surrounding sand. The FE model is meshed into 55446 10-noded soil (tetrahedrons) elements. In order to consider large deformation and the membrane effect of the geotextile reinforcement, the function of updated generated mesh should be utilized.

3.2 Simulation results

Selected observation points for checking the simulation results are marked in Figure 3. Figure 2a presents the simulated settlement at observation point a, representing the surface settlement. Good agreement can be seen from the simulated settlement and measured settlement. The simulated excess porewater pressures at observation points d and e represent the excess porewater pressures measured by PPTs at the middle and bottom levels, as shown in Figure 2b. Similar to Section 2.2, efficacy can be calculated based on the simulated vertical stresses. It can be seen from Figure 2c that the simulation results agree well with the test results.

The simulated tensile strains of the geotextile reinforcement are calculated as:

$$\varepsilon_{x,y} = \frac{T_{x,y}}{J_{x,y}} \tag{4}$$

where $\varepsilon_{x,y}$, $T_{x,y}$, and $J_{x,y}$ are the tensile strain, force, and stiffness in x and y directions, respectively. Figure 2d shows the comparison between the simulated and measured maximum tensile strains of the geotextile reinforcement under different surcharge loadings. It is found that the FE simulation underestimated the maximum tensile strain. This difference between the simulation and test results might be mainly attributed to that the geotextile reinforcement was treated as a linear elastic material in the FE model.

Table 1. Parameters for different materials.

Material	Model	Parameter
HKMD*	SSC	γ_{sat} = 16.5 kN/m^3; λ^* = 0.107; κ^* = 0.027; μ^* = 0.002037; ν = 0.15; c' = 0.5 kPa; φ' = 24°; $k_{x,y}$ = 7.0×10^{-4} m/day; k_z = 3.5×10^{-4} m/day; POP = 5 kPa
Columns	MC	γ_{sat} = 16.5 kN/m^3; E'_{50} = 40 MPa; ν = 0.25; c' = 80 kPa, φ' = 42°;
Sand**	HS	γ_{sat} = 17.5 kN/m^3; E'_{50} = 30 MPa; E'_{oed} = 20 MPa; E'_{ur} = 90 MPa; m = 0.5; ν = 0.2; c' = 0.1 kPa, φ' = 34.6°; ψ' = 4.6°; POP = 10 kPa; p_{ref} = 100 kPa
Geotextile	Elastic	$J_{x,y}$ = 680,150 kN/m

*The parameters used in SSC model were determined from oedometer and triaxial tests on reconstituted HKMD.
**The parameters used in HS model were determined from CD triaxial tests on sand.

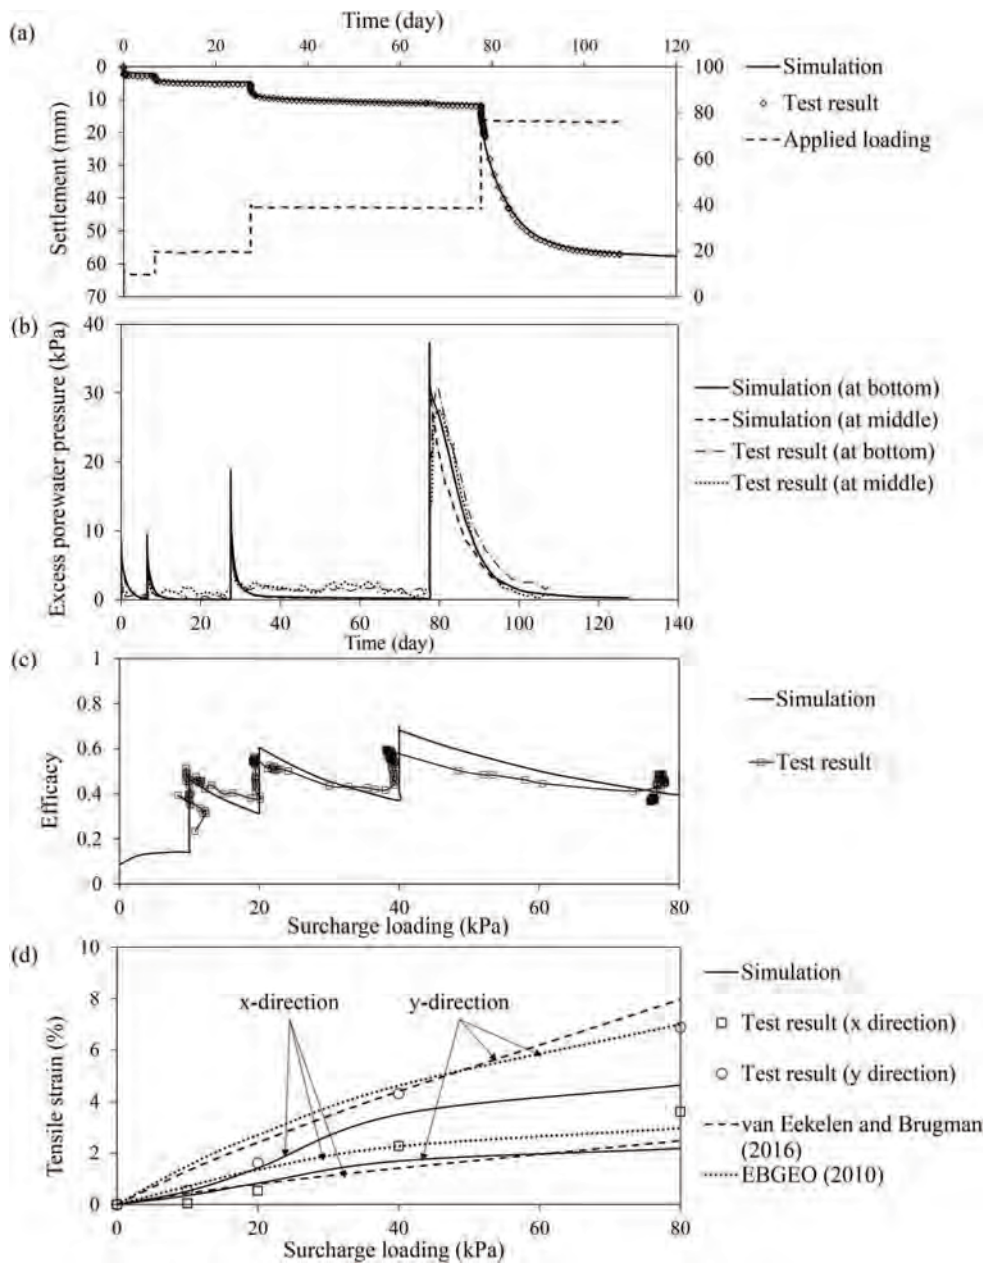
The shape and size of soil arches are usually assumed in different arching models and design guidelines of GRCS embankments (Lee *et al.* 2021). The calculation of load part A highly depends on the shape and size of soil arches. van der Peet *et al.* (2014) considered that the principal stress is parallel to the arches and verified CA model by presenting the directions of principal stress. To investigate soil arching in the physical model test of this study, principal stress directions between two adjacent columns and those between two diagonal columns at different stages are presented in Figure 4. The case with a surcharge loading of 40 kPa is taken as an example to show the difference between the simulation results and CA model in terms of the shape of arches. The arches determined from this study are denoted by dotted curves while the outmost arches determined according to CA model are represented


Figure 2. Experimental and numerical results of (a) surface settlement, (b) excess porewater pressures, (c) column efficacy, (d) tensile strains.

by dashed curves. It can be seen from Figures 4a and b that the shape of arches between adjacent columns and between diagonal columns are quite different from those determined by CA model at the loading stage. Triangular arches similar to those shown in Figure 4a were also found by Rui *et al*. (2016) and van Der Peet and van Eekelen (2014) using 2D trapdoor tests and numerical simulation, respectively. After the consolidation of the HKMD
Figure 3. Illustration of the FE model and locations of observation points.
Figure 4. The shape of soil arches: (a) between two adjacent columns at loading stage, (b) between two diagonal columns at loading stage, (c) between two adjacent columns after consolidation, and (d) between two diagonal columns after consolidation.

subsoils, the inner triangular arches between two adjacent columns tended to become concentric semi-circular arches, which agrees with the assumption of CA model about the shape of arches. More clear concentric arches can be also observed between two diagonal columns. Although the outermost arches determined from the simulation results are triangular between two adjacent columns and bell-shaped between two diagonal columns, their sizes are similar to those determined by CA model.

4 CONCLUSIONS

A physical model test on geotextile-reinforced sand fill over soft marine clay improved by DCM columns has been successfully conducted with the measurement of earth pressures and the tensile strains of the geotextile reinforcement. The tensile strains calculated according to Dutch design guidelines agree with the measured data. Soil arching developed during loading stages and after the consolidation of the subsoil was revealed using the verified finite

element method and compared with CA model. Unlike the ideal concentric semi-spherical arches assumed in CA model, the shape of the arches observed in the simulation is more complicated.

System efficacy and diffused arching in embankments supported by piles

K. Brzeziński
Warsaw University of Technology, Poland

R.L. Michalowski
University of Michigan, USA

ABSTRACT: A pile support system is a common solution for embankments constructed over soft, normally consolidated fine-grained, or organic soils. Piles are installed to reach the stronger layers of the foundation soil, while the transfer of the embankment load to the piles relies on the development of the stress distribution often referred to as arching. In addition, geosynthetic reinforcement is used in a load transfer platform to enhance the transfer of the load to the piles. A series of numerical simulations (FEM) were carried out to study the formation of arching in embankment fill placed over a square-grid pile support system. The development of the load transfer process was also studied, quantified by the system efficacy. The efficacy of the support system without geosynthetic can easily exceed 80%, but it can be larger than 90% if a geosynthetic-reinforced load transfer platform is used. Numerical simulations provided some insight into the development of the load transfer mechanism, but distinct arching as assumed in many design methods was not detected.

1 INTRODUCTION

Construction of embankments supported by piles is a successful technology used for the development of transportation infrastructure through regions with soft fine-grained or organic soils. Design of such embankment is predicated on inducing soil arching within the lower portion of the embankment, which aids in load transfer from the embankment to the piles. Early efforts to account for soil arch formation are due to Terzaghi (1943), and applications to pile-supported embankments were considered by Hewlett & Randolph (1988). The Distinct Element Method is a good technique to demonstrate development of strong force chains forming a soil arch (Nadukuru & Michalowski 2012), and the literature abounds with papers indicating how to construct a soil arch within a soil mass as part of design procedures. Many of these attempts are variations on the original arch/dome considerations of Hewlett & Randolph (1988).

The practical purpose of studying the process of load transfer is the development of design methods for the pile support systems, so that the required efficacy of the system can be met and the load transferred to the soft soil is minimized. Studies in the area of pile-supported embankments have two foci: improving methods of design (Filz *et al*. 2012; Van Eekelen *et al*. 2013), and gaining better understanding of the load transfer process in granular soils (Brzeziński & Michalowski 2021; King *et al*. 2019). This study will focus on the latter, with special attention paid to the formation of soil arching.

The practical outcome of this study is evaluation of efficacy of the support system, and the factors affecting the efficacy. It is expected that observations of shear strains and stresses in constructed embankments yield some information about the development of the load transfer process, and, in addition, become useful in drawing conclusions regarding the critical embankment height.

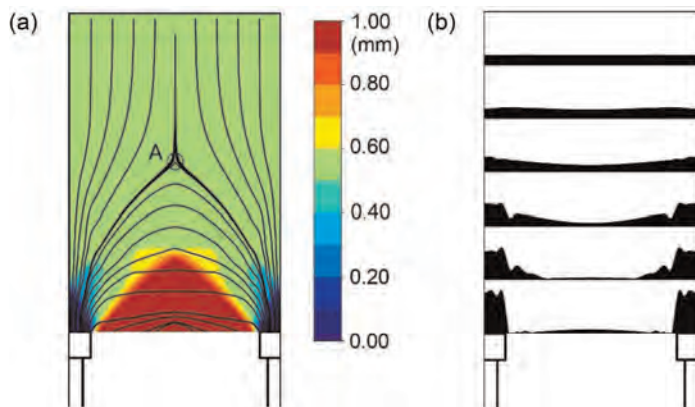
Earlier plane strain FEM simulations of a column system with cap beams yielded a reasonable efficacy of the system. They also were found useful in demonstrating the non-compliant columns "attracting" the bulk of the load (Brzeziński & Michalowski 2021).


Figure 1. (a) Vertical displacements of the fill associated with 1-mm settlement of the soft soil and trajectories of major principal stresses, and (b) normalized distribution of vertical stress (2D simulation after Brzeziński & Michalowski 2021).

This is demonstrated in Figure 1(b) where the vertical load on horizontal planes is being gradually attracted to the columns as the depth increases. Figure 1(a) indicates the largest vertical displacements immediately above the soft soil, no vertical displacement immediately above the non-compliant columns, and uniform displacements in the upper portion of the embankment. The major principal stress trajectories are shaped in an arch-like structure, but this does not necessarily indicate the formation of a soil arch. Inspection of the stress field did not reveal the existence of a distinct band with increased stresses indicating arch formation, yet a clear divergence of the vertical stress occurs with greatly reduced stress on the soft soil. This phenomenon is now studied through analyses of stress distribution in a three-dimensional support system with piles distributed in a square-grid pattern.

2 SQUARE-GRID PILE SUPPORT MODEL

A periodic cell of the pile support system considered in this study is illustrated in Figure 2(a). Piles are distributed in an $s \times s$ grid (s being the pile spacing).

The cell has four planes of symmetry and its coverage ratio (ratio of pile cap area to the cell area) is

$$\mu = \pi \left(\frac{R}{s} \right)^2 \tag{1}$$

where R is the radius of the pile cap. The geometry of the model cross-section A-A is shown in Figure 2(b). The left and right vertical boundaries are traces of symmetry planes; hence, they coincide with principal directions and will be modeled as shear-free boundaries. The origin of the coordinate system is at the center of the pile at the elevation of the working platform.

The model of the embankment fill is elastic-plastic, with Hook's law describing the deformation prior to reaching the limit state. The plastic state is described by the Mohr-Coulomb criterion

$$f = R_{mc}q - p \tan \phi - c = 0 \tag{2}$$

where $q = \sqrt{3J_2}$ and $p = -I_1/3$, with I_1 being the first invariant of the stress tensor and J_2 being the second invariant of the deviatoric stress tensor, and

$$R_{mc} = \frac{1}{\sqrt{3}\cos\phi}\sin\left(\theta + \frac{\pi}{3}\right) + \frac{1}{3}\cos\left(\theta + \frac{\pi}{3}\right)\tan\phi \qquad (3)$$

with Lode angle θ defined by (J_3 is the third invariant of the deviatoric stress tensor)

$$\cos(3\theta) = \frac{3\sqrt{3}}{2}\frac{J_3}{J_2^{3/2}} \qquad (4)$$

The plastic flow is assumed to be non-associative

$$\dot{\varepsilon}_{ij} = \dot{\lambda}\frac{\partial g(\sigma_{ij})}{\partial\sigma_{ij}} \qquad (5)$$

with plastic potential $g(\sigma_{ij})$ defined by Menetrey & Willam (1995).
Figure 2. (a) Periodic cell of the pile-support system with pile spacing of $s = 2.0$ m, and (b) section A-A of the symmetric half of the cell.

Material properties of the fill (density ρ, Young's modulus E, Poisson's ratio ν, internal friction angle ϕ, and dilatancy angle ψ) are included in Table 1.

Table 1. Material properties of the embankment fill model.

ρ (kg/m^3)	E (MPa)	ν –	ϕ (°)	ψ (°)
1900	60	0.3	40	10.0

The working platform was modeled as elastic, with a density of 1900 kN/m^3, $E = 60$ MPa, and $\nu = 0.3$. The soft consolidating layer of saturated fine-grain/organic soil was modeled as elastic with density $\rho = 1137$ kN/m^3, $E = 3$ MPa, $\nu = 0.3$, initial void ratio $e = 1.30$, and hydraulic conductivity of $3.5 \cdot 10^{-8}$ m/s. Properties of piles and pile caps are: $\rho = 2400$ kN/m^3, $E = 27$ GPa, and $\nu = 0.16$. The low-stiffness granular fill immediately beneath the geogrid reinforcement was modeled as elastic with $\rho = 1460$ kN/m^3, $E = 3$ MPa, $\nu = 0.3$.

Geogrid reinforcement was assumed to have a strength of 200 kN/m and stiffness of 2000 kN/m. In field conditions, a separation layer (non-woven geotextile) would be placed between the soft consolidating soil and the working platform. This layer, however, is not modeled as it has a negligible influence on the mechanical response of the support system.

3 SIMULATIONS

Simulations were carried out using commercial FEM system ABAQUS. Finite elements used in the model are listed in Table 2.

With the exception of the last column in Table 2, all elements are of the variety of a 20-node brick element. The geogrid is modelled with an 8-node membrane element (M3D8R).

Table 2. ABAQUS elements used in model construction.

	Piles Pile caps	Embankment fill	Working platform	Granular fill layer	Soft subsoil	Geogrid
Model	Elastic	Elastic-plastic	Elastic	Elastic	Elastic consolidating	Elastic tension only
Abaqus Element	C3D20R	C3D20	C3D20R	C3D20RP	C3D20	M3D8R

3.1 Construction process

The embankment construction process is modeled with step-wise increases of the embankment fill in 50-cm lifts, as illustrated in Figure 3. These lifts are added in 7-day intervals.

The results for a given interval are recorded 7 days after application of the load, i.e., just before the next lift is constructed. For example, the results for an instant when the embankment has reached a height of 3 m are collected at 42 days after the start of construction. If 3 m is the final height, then the final results would be collected after an additional 365 days. Construction of the 6-m tall embankment is illustrated in Figure 3. The construction process is considered to end in 84 days (7 days after the construction of the last lift), and the final data is collected in 449 days from the beginning of construction (84 + 365 = 449 days).
Figure 3. Embankment construction process of a 6-m tall embankment.

3.2 *Development of shear strains and attainment of critical height*

Of particular interest is the development of the load transfer mechanism in the embankment fill and observation of strain localization (*shear banding*), indicative of the embankment fill reaching the limit state.

Graphs in Figure 4(a) show maximum shear strain increments, in a 3-m tall embankment, after 21, 28, 35, 42, and 407 days from the start of construction. The maximum shear strains are shown in cross-section A-A, and Figure 4(b) shows the same in the diagonal cross-section B-B (see Figure 2(a) for sections A-A and B-B). The graphs show the results within the embankment fill above the elevation of the pile cap and the geosynthetic reinforcement. The lower horizontal boundary is supported by the pile cap on the left-hand side and by the geogrid and the layers beneath on the right, as illustrated in Figure 2. Increments of maximum shear strains in the last 7 days are presented in the graphs, except for the last graph in each of the two rows, where the increment includes the strains in the previous 365 days.

Let us concentrate on the results collected from cross-section A-A. The color scale indicates the magnitude of the maximum shear strain increment (or increment of deviatoric strain) at each point in the graphs. The red shows zero shear strain, and it indicates the regions moving approximately as rigid bodies. The color blue shows the maximum shear strain increment of 0.30%, and the regions with a white background are off the scale (larger than 0.30%).

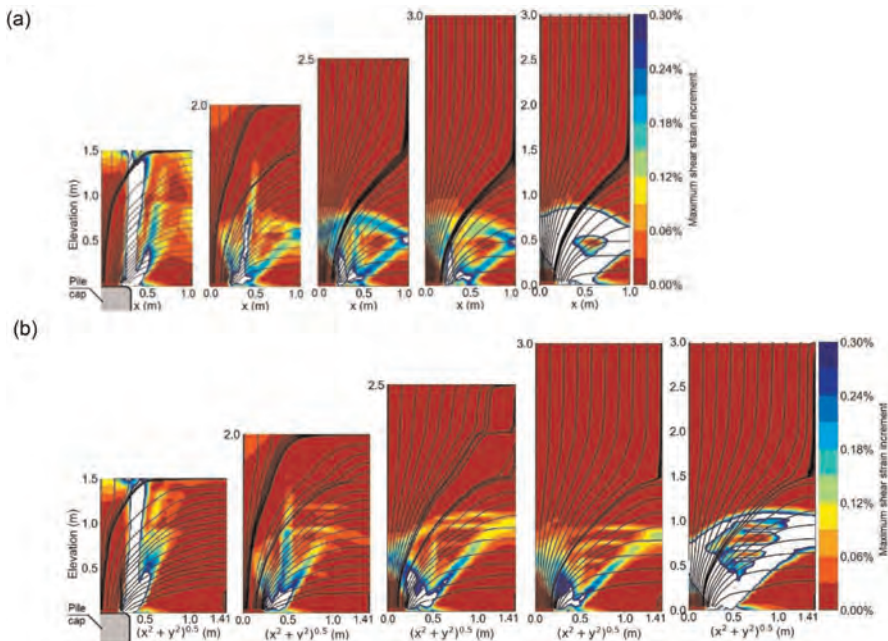
A characteristic feature of the shear strain incremental field is the development of the shear bands indicating a formation of a mechanism. The color scale in Figure 4 indicates the maximum shear strain increments. However, the total maximum shear strains within the shear bands increased from about 4% after the placement of the first 0.5-m layer, to about 12% after embankment reached the height of 3.0 m (maximum shear strain is an invariant quantity for a given strain state). It is clear that once the construction reached the height of


Figure 4. Maximum shear strain increments and trajectories of major principal stresses during construction of a 3-m tall embankment: (a) section A-A at construction times: 21, 28, 35 and 42 days, and the final result after 407 days, and (b) maximum shear strains in section B-B. Pile spacing 2.0 m.

1.50 m, a vertical shear band formed, reaching the embankment top boundary; this shear band separates the almost stationary fill above the pile on the left from the portion resting on the reinforcement and moving downward due to the settlement of the soft soil. The embankment did not reach its critical height yet, and this mechanism is considered a failure mechanism in the fill (loss of integrity of the top surface). Once the construction reaches a 2-m height, the vertical shear band no longer intersects the top boundary, indicating that the embankment has reached its critical height. At the height of 2.5 m a mechanism has formed in the lower portion of the embankment, and it persists through the end of the construction process of the 3-m tall embankment. While this mechanism allows plastic deformation in the lower portion, it does not lead to embankment collapse. A similar process takes place in diagonal section B-B illustrated in Figure 4(b).

The plastic mechanism can be accommodated by the embankment in its lower portion when the embankment height exceeds its critical value, presumably because of a redistribution of stresses in the field above the mechanism, referred to often as *soil arching*. Arching is an elusive concept that is not revealed by the strain field; rather, some specific features in the stress field might indicate whether or not arching has occurred. This will be attempted in Section 3.5.

3.3 Force in the reinforcement

The computational model used in this study makes it possible to monitor the development of the force induced in the geosynthetic reinforcement as the embankment is being constructed.

Figure 5 illustrates the maximum force in the geogrid in embankments with heights: 1.5, 3.0, and 6.0 m, and for a pile spacing of 1.5 and 2.0 m. In all cases, the maximum force was found to be at the edge of pile cap, about 30 cm from its center (pile caps had rounded edges and a radius of 32 cm).

Not surprisingly, the force in the reinforcement was mobilized the least in the low-height embankments, and for the lesser pile spacing. Besides the embankment height and the pile spacing, the magnitude of the maximum force is also sensitive to the reinforcement stiffness and compliance of the layers beneath the reinforcement.

There is a distinct jump (discontinuity) in the maximum force associated with each lift of the fill, and a steady increase in the force during 7-day intervals before the subsequent lift is placed. The increase in the force appears to be linear in the first few weeks following the completion of construction, but the force reaches a plateau sometime within the first year
Figure 5.   Maximum force in reinforcement.

after construction. This conclusion, however, may be dependent on the properties of the soft soil, reinforcement stiffness, etc.

One would expect the reinforcement to be more effective if the larger force is mobilized. This conjecture, however, has to be interpreted carefully, because the efficacy of the support system is affected predominantly by the vertical component of the force in reinforcement. Consequently, it is the deflection of the geosynthetic reinforcement that is a key factor in its effectiveness.

The largest force in the reinforcement was mobilized in the tallest, 6-m embankment, with a pile spacing of 2 m. For the properties of the soil and reinforcement used in the simulations, this force was over 35 kN/m at the end of construction (84 days), and it increased to over 40 kN/m in the following year. With the same parameters, but spacing reduced to 1.5 m, the maximum force in reinforcement did not exceed 15 kN/m.

In general, the larger the embankment height and the pile spacing, the larger the force mobilized in the reinforcement.

3.4 *Efficacy of the pile support system*

The effectiveness of the pile support system can be quantified by the ratio of the load carried by the piles to the total load transferred to the subgrade. The latter can be taken as the weight of the embankment fill in a single cell of the support system, and the former is the load transferred to a single pile. This ratio will be referred to as efficacy E_f. Consider polar coordinate system r, θ with the origin at the center of a single pile cap, and R being the radius of the cap. Efficacy E_f can be calculated as

$$E_f = \frac{4 \int_0^{\frac{\pi}{2}} \int_0^R \sigma_{zz} \, dr d\theta}{\rho g s^2 H} \tag{6}$$

where σ_{zz} is the vertical stress on the pile cap, ρ is the mass density of the embankment fill, g is the gravity acceleration, and H is the embankment height.

If the stress caused by the embankment load is transferred uniformly on piles and the soft soil, the efficacy would be equal to coverage area ratio μ in Eq. (1). However, the elastic response of the system, even after the placement of the first lift, causes an instantaneous redistribution of the stress in that layer, producing an increase in efficacy at time $t = 0$.

General observations of the simulation outcomes indicate that efficacy increases with an increase in construction time, and for a fully constructed embankment, the higher the embankment the larger the efficacy. Not surprisingly, the efficacy decreases with the increase in pile spacing, even though the force in the reinforcement increases with the increase in pile spacing.

The development of efficacy is a periodic process defined by the cyclic placement of the lifts of the embankment fill. In the initial stages of construction, placement of a single lift causes a substantial increase in efficacy, but the rate of increase drops after the load is placed. The increments in efficacy associated with consecutive lifts become smaller with increasing embankment height. This is understandable, because the efficacy is defined in terms of the total loads, and the consecutive layers/lifts produce relatively smaller load increments when compared to the total load.

An interesting feature in the increase in efficacy in later cycles (for the 6-m embankment) is a small drop in efficacy at the time of placing the subsequent lift, before it starts increasing again. For example, in the construction process of the 6-m embankment on a 1.5×1.5 m grid of piles, the first drop in efficacy occurred at 21 days, and the placement of all subsequent layers was associated with some initial drop in efficacy. This is because the increase in efficacy develops in time with the settlement of the soft soil, but the placement of the layer (lift) of soil is instantaneous and the load distribution it initially produces is less favorable when compared to the already developed efficacy. This does not happen in the first cycles, where the developed efficacy is still relatively low.

It may be interesting to examine some of the efficacy numbers in Figure 6. The highest final efficacy of all cases shown is achieved by the 6-m embankment with pile spacing of 1.5×1.5 m; the value calculated is $E_f = 0.921$, and the second highest, 0.891 is for the 3-m embankment and 1.5 m pile spacing. It is interesting to notice that the 3-m embankment with 2.0 m pile spacing and the 1.5-m embankment with 1.5 m pile spacing developed almost the same efficacy: 0.819 and 0.823, respectively. Not surprisingly, the lowest efficacy of 0.702 was developed by the 1.5-m embankment and pile spacing of 2.0 m. This is the case where the height of the embankment has not reached the critical value yet, and the plastic mechanism propagates all the way to the top surface, as illustrated in Figure 4.
Figure 6. The development of system efficacy.

3.5 *Load transfer and diffused arching*

The current state of knowledge assigns the development of high efficacy of pile support systems to the presence of soil arching, often illustrated as the formation of arches or domes within the embankment fill, spanning the space between the supporting piles. These arches and domes are to carry the elevated amount of load, transferring the bulk of the embankment gravity load to the piles. Successful design methods were developed based on the assumption of soil arching. The reinforcement placed over the system of piles, sometimes referred to as the *load transfer platform*, is to aid in transferring the load to the piles, improving the efficacy of the support system.

Earlier simulations of plane-strain support systems (with cap beams) did not yield evidence for formation of distinct soil arching, but it did reveal an effective stress distribution that produced high efficacy of the system (Brzeziński & Michalowski 2021). We now inspect the distribution of the major principal stresses in the embankment constructed over the square-grid system of piles in an effort to identify features that might indicate the formation of dome-like regions with elevated stresses associated, in many studies, with arching.

Figure 7 illustrates the distribution of the major principal stresses (color scale) and their trajectories (continuous lines in Figures 7(a) and 7(b)). These graphs correspond to the graphs in Figure 4 for a construction time of 42 days. The principal stresses in Figure 7 are normalized with the stress value of $\rho g d$, where d is the depth measured from the top surface of the embankment (ρ - mass density, g - gravity acceleration).

The green-light green indicates the normalized major principal stress value of 1, as it would be in the state of rest, and the stress in the upper 1 m of the fill is consistent with such a distribution. Beneath, however, on the left side (above the pile) the major principal stress
Figure 7. Major principal stresses (normalized) and their trajectories in a 3-m tall embankment: (a) section A-A, (b) section B-B, and (c) plot of the major principal stress magnitudes in section B-B (black bands). Pile spacing 2.0 × 2.0 m.

quickly increases. The areas with the white background are off-the-scale. This time, if the white region borders with dark red, the normalized stress is above 1.5, whereas if the while area borders dark blue, the normalized major principal stress is less than 0.50.

While the stress above the pile increases quickly below the elevation of 2.0 m, the stress on the right side, above the reinforcement and the soft soil beneath, drops. This is more distinct in diagonal section B-B (Figure 7(b)) than section A-A. The pile cap is loaded with much larger traction than the region underlain by the soft soil.

It is demonstrated in both cross-section A-A and B-B that the major principal stress above the pile cap is vertical, but above the soft soil it is horizontal. Hence the preferential load transfer is to the piles, presumably owed to soil arching, and one would expect that arching would approximately follow the major principal stress trajectories.

Figure 7(c) is an edited Figure 7(b), where the lower contours of the black bands coincide with the trajectories of minor principal stresses, and the thickness of the bands indicates the magnitude of the normalized major principal stresses. In the presence of soil arching, one would expect a distinct band in the fill, approximately following the major principal stress trajectories, with elevated stresses that could be identified as a soil arch. Such formation in the stress field, however, was not detected. Understandably, the normalized major principal stresses are uniform in the upper portion of the fill, but they increase significantly in the lower portion, as they approach the left boundary of the model. However, the thickness of the bands increases monotonically, without formation of a distinct "arch" in the stress field.

The efficacy of the system with the geometry in Figure 7 had the final (calculated) efficacy of 0.82, which is a quite respectable value considering that the coverage ratio (Eq. (1)) was only 0.08; i.e., 82% of the gravity load produced by the embankment weight was transferred to 8% of the horizontal area (pile cap area) of the computational cell. That is an effect one would expect to be associated with arching, but a distinct arch was not detected, as was the case in the two-dimensional analysis (Brzeziński & Michalowski 2021). For a lack of a better term, we refer to the effect illustrated in Figure 7(c) as *diffused arching*.

4 CONCLUSIONS

Construction of embankments on the pile support systems has two distinct phases: prior to reaching the critical height, and after the critical height has been reached. The former is characterized by formation of the plastic mechanism with kinematic discontinuity reaching the embankment surface and causing a system failure. The latter is associated with the formation of the plastic mechanism confined to the lower portion of the embankment, which does not cause the collapse of the structure as this mechanism is supported by the piles and the lower layers of the system.

Efficacy of the pile support system is developed in a cyclic process as the sequential layers of embankment fill are being placed. The cyclic increases in efficacy became smaller with the time of construction. The final efficacy of the support system increases with an increase in the embankment height and a decrease in pile spacing. The force in the reinforcement and its effectiveness increases with pile spacing, and is also dependent on reinforcement deflection. The outcomes of simulations with parameters used indicated a maximum efficacy in excess of 0.90.

Arches or domes in the stress field within the embankment fill, commonly referred to as soil arching, were not detected in the simulations. However, the effect of load transfer to stiffer elements of the system was very much present in the simulations, leading to high efficacy of the support systems. The term *diffused arching* was used to describe this type of load transfer.

ABSTRACT: This paper conducts a 1g model test on soil foundations reinforced by geosynthetic encased granular columns (GECs) across a reverse fault. The aim is to evaluate the effectiveness and reinforcing mechanism of GEC foundations in mitigating the ground surface deformation associated with reverse faulting. For comparison, 1g model tests were also performed on unreinforced and GRS foundations. The test results indicate that GEC foundations can effectively mitigate the ground surface deformation induced by reverse fault movement; compared with the unreinforced foundation, the GEC foundations can reduce the maximum angular distortion at the ground surface by 23.3%–55.6%. A percentage reduction for maximum angular distortion of 23.3% was achieved as the fault offset reached 30% of the foundation height, which mitigates the risk of the surface fault hazards associated with large reverse fault movement.

1 INTRODUCTION

Geosynthetics have been applied in engineering practice to mitigate surface faulting hazards. In central Taiwan, a highway embankment was constructed across the Chelungpu Fault. In the 1999 Chi-Chi earthquake (M_L = 7.3), the vertical surface movement of the Chelungpu Fault reached 2–4 m on average (Chen *et al*. 2001), which resulted in the severe failure of the overlying buildings and infrastructure. The failure of rigid gravity retaining walls was also observed because of the considerable surface rupturing induced by the fault movement. To reduce the risk of a similar event, the Chelungpu Fault was crossed by constructing a ductile highway embankment comprising a geosynthetic-reinforced soil (GRS) wall overlying a GRS foundation.

Yang *et al*. (2020) conducted a series of 1g model tests for investigating the performance of GRS foundations subjected to normal fault movement. The test results revealed that GRS foundations can reduce the fault-induced angular distortion at the ground surface by up to 60% in comparison with unreinforced foundations; this reduction is attributed to the development of the reinforcement tensioned membrane and shear rupture interception effects. Chiang *et al*. (2022) conducted numerical studies to develop design methods for GRS foundations against reinforcement breakage and significant pullout when subjected to normal fault movement. Although studies have validated the benefits of using GRS foundations to mitigate normal fault hazards, the performance of GRS foundations subjected to reverse fault movement has not been understood. Furthermore, GRS foundations might have poor

effectiveness for reducing reverse fault-induced ground deformation because tensile force is not expected to develop in the reinforcement as the hanging wall moves upward. Another type of reinforced foundation, soil foundation reinforced by geosynthetic encased granular columns (GECs), might overcome the deficiencies. In the present study, the performance of GEC foundations in mitigating reverse faulting hazards was evaluated.

In this study, 1g model tests were conducted to investigate the performance of GEC foundations in mitigating the surface hazards associated with reverse faulting. For comparison, 1g model tests were also performed on unreinforced and GRS foundations. A 3-m thick foundation in prototype subjected to a reverse fault displacement up to 90 cm was modeled in the 1g model tests. The effectiveness of GEC foundations and the reinforcing mechanism of geotextile encasement in mitigating ground surface deformation was investigated. The key findings of this study provide valuable information that can be used by engineers to optimize the design of GEC foundations for mitigating reverse faulting hazards.

2   MODEL TESTS

2.1   *Test setup*

The 1g model tests on unreinforced, GRS, and GEC foundations were conducted using a sandbox in the geotechnical research laboratory at National Taiwan University. Figure 1 presents an illustration and overview image of the sandbox and test setup of the 1g model tests. The dimensions of the sandbox were 100 cm × 20 cm × 60 cm (length × width × height). Transparent plexiglass walls were installed on the front and back sides of the sandbox for visual observations during the tests. Thin plastic sheets with lubricant were applied to each plexiglass wall to minimize soil–wall interface friction. The bottom of the sandbox comprised a movable hanging wall and fixed footwall. Reverse fault displacement was generated by moving the hanging wall upward by using a driving motor installed under the sandbox. The initial location of the reverse fault tip was 58 cm from the left boundary, and the fault dip angle was set to 60° in this study.
Figure 1.   The sandbox and test setup: (a) illustration; (b) panorama.

2.2   *Material properties*

The soil and reinforcement materials used in the 1g model tests were carefully selected in accordance with the similitude requirements to ensure that the test models and the prototypes have comparable behavior. The material properties adopted in the 1g model tests were scaled down by using scaling factors derived in accordance with Buckingham's theorem

(Buckingham 1914). Table 1 summarizes all the scaling factors and the corresponding values in prototype for the model geometry and material properties. The soil material used in the 1g model tests was uniform quartz sand, which is classified as poorly graded sand (SP) according to the Unified Soil Classification System (USCS). The mean particle size of the test sand was $D_{50} = 0.98$ mm, and the target dry unit weight was $\gamma_d = 15.3$ kN/m^3 at a relative density $D_r = 70\%$. The effective cohesion and peak friction angle of the test sand were $c' = 0$ kN/m2 and $\phi' = 39.2°$, respectively, with confining pressures σ_3 ranged from 50 to 200 kPa; these values were obtained from triaxial consolidated–drained (CD) compression tests (ASTM D7181).

The reinforcement material used in the 1g model tests was nonwoven polypropylene geotextile. The ultimate tensile strength and failure strain of the nonwoven geotextile in the machine direction were $T_{ult} = 0.7$ kN/m and $\varepsilon_f = 32.4\%$, respectively. The tensile stiffness of the nonwoven geotextile in the machine direction at the stress level of 50% of the ultimate tensile strength was $J_{50} = 5.47$ kN/m. For the geotextile encasement used in the GEC foundation test, the nonwoven geotextile in the designated machine direction was oriented along the circumferential direction of the geotextile encasement to develop hoop stress. The sand–geotextile interface friction angle was $\delta' = 27.4°$, and the efficiency factor was calculated to be $E_\phi = \tan \delta'/\tan \phi' = 0.63$.

Table 1. Scaling factors and values based on the similitude requirements.

Parameters	*Scaling factor	Model	Prototype
Geometry			
Foundation height, H (m)	$1/\lambda$	0.2	3.0

Reinforcement parameter			
Ultimate tensile strength, T_{ult} (kN/m)	$1/\lambda^2$	0.70	157.5
Stiffness, J_{50} (kN/m)	$1/\lambda^2$	5.47	1231
Interface parameter			
Soil-geosynthetic friction angle, δ'	1	27.4	27.4

[*]Target scaling ratio $\lambda = 15$.

2.3 *Test models and digital image analyses*

The soil layer was constructed with a target relative density $D_r = 70\%$ by using the volume control method. In the GRS foundation test, a layer of planar geotextile was placed on a soil layer, and the process was repeated until the foundation reached $H = 20$ cm. Three layers of planar geotextile were placed in the foundation with a vertical spacing of $S_v = 6.67$ cm. In the GEC foundation tests, low-friction stainless steel tubes with lubricant were penetrated into a full-height soil layer (i.e., $H = 20$ cm) at the desired locations. The location of the outermost GEC installed in the footwall was determined by considering the influential zone of the free-field fault rupture. Each steel tube had a thin-walled tip to minimize its disturbance to the soil layer. The sand inside the steel tubes was extracted using a customized vacuum machine. The geotextile encasement was fabricated in advance and placed into the steel tubes, and the soil material was filled into the encasement and compacted to the target relative density. After the installation was completed, the steel tubes were carefully removed from the soil layer. A 1.5-cm thick soil layer was then constructed on the top of the GEC foundations to

provide overburden pressure. Figure 2 displays an illustration of the GEC foundation test. The diameter of the GECs was $d_c = 3$ cm, corresponding to a diameter of 0.45 m in prototype, and the length-to-diameter ratio of the GECs was $l_c/d_c = 0.67$. Fault displacement was generated after the test models were constructed, and the maximum fault displacement was set to $S = 6$ cm due to the limited displacement capacity of the sandbox. The ratio of fault displacement to foundation height was $S/H = 30\%$.
Figure 2. An illustration of the GEC foundation test (not in scale).

During the 1g model tests, charge-coupled device cameras, aimed at the front and top of the sandbox, were used for continuously monitoring the deformation of the test models. The recorded photographic data were analyzed using various digital image analysis (DIA) techniques to obtain the surface displacement profile, maximum angular distortion, and shear rupture propagation for the unreinforced, GRS, and GEC foundations at various fault offset magnitudes. Because the ground surface deformation induced by fault movement critically affects superstructure damage, the maximum angular distortion at the ground surface (β_{max}) was used as a key indicator in this study to evaluate the performance of the unreinforced, GRS, and GEC foundations. Details of the DIA techniques used in this study are provided in the paper of Yang *et al.* (2020).

3 RESULTS AND DISCUSSIONS

3.1 *Unreinforced foundation*

Figure 3a presents a series of test images of the unreinforced foundation subjected to reverse fault movement at fault offsets $S = 1.5$, 3, 4.5, and 6 cm. The test results indicate that the ground surface deformation became pronounced as the reverse fault displacement increased (Figure 3b). The β_{max} at the ground surface were 0.25, 0.76, 0.84, and 0.84 at $S = 1.5$, 3, 4.5, and 6 cm, respectively (Figure 3c). As expected, the β_{max} at the ground surface increased as the fault displacement increased and approached the slope of the peak friction angle of the sand ($\approx \tan \phi = 0.81$) at large fault offsets. The fault influence length was $L_I = 27.7$ cm at $S = 6$ cm.

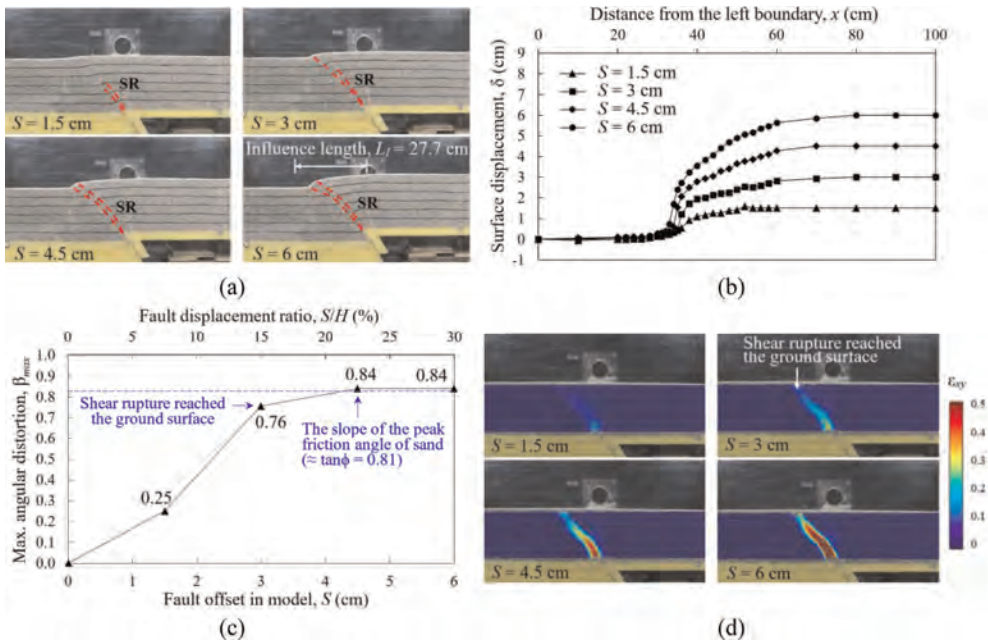
Figure 3d presents the shear strain contours of the unreinforced foundation subjected to reverse fault movement. The shear rupture propagated upward from the fault tip to the ground surface, and decreased in dip as it approached the ground surface. At $S = 3$ cm ($S/H = 15\%$), the shear rupture broke through the foundation soil, and a surface fault rupture occurred at the ground surface. At this moment, the β_{max} at the ground surface considerably increased from 0.25 to 0.76 (Figure 6a), which indicated a high surface fault hazard risk.


Figure 3. Results of the unreinforced foundation test (Test U) at various fault offsets: (a) test images; (b) surface displacement profiles; (c) maximum angular distortion; (d) shear strain contours.

3.2 GRS foundation

Figure 4a presents a series of test images of the GRS foundation subjected to reverse fault movement at fault offsets S = 1.5, 3, 4.5, and 6 cm. When reverse fault displacement occurred, the ground surface deformed in a similar manner to that of the unreinforced foundation (Figures 3b, 4b). The fault influence length was L_I = 22.1 cm at S = 6 cm, which is similar to the fault influence length for the unreinforced foundation (i.e., L_I = 27.7 cm). The β_{max} values were 0.18, 0.52, 0.74, and 0.84 at S = 1.5, 3, 4.5, and 6 cm, respectively (Figure 4c). The percentage reduction for β_{max} at S = 1.5, 3, 4.5, and 6 cm were R_d = 30.2%, 31.5%, 11.7%, and 0%, respectively, compared with the unreinforced foundation.

The test results revealed that the GRS foundation was effective in reducing β_{max} at relatively small fault offsets S = 1.5 and 3 cm (i.e., a fault displacement ratio $S/H < 15\%$). However, the effectiveness in reducing β_{max} decreased considerably after the shear rupture reached the ground surface (i.e., at S = 3 cm, as shown in Figure 4d). Similar shear strain contours were obtained for the unreinforced and GRS foundations (Figures 3d, 4d) because the mobilization of the reinforcement tensile strain was not developed when the hanging wall was moving upward (i.e., the GRS foundation was compressed).

3.3 GEC foundation

Figure 5a presents a series of test images of the GEC foundation subjected to reverse fault movement at various fault offsets. Stepped surface displacement profiles were observed as the reverse fault displacement increased (Figure 5b). The values of β_{max} were 0.17, 0.34, 0.59, and 0.64 at S = 1.5, 3, 4.5, and 6 cm, respectively (Figure 5c). Compared with the unreinforced foundation, the β_{max} at the ground surface significantly decreased. The percentage reductions for β_{max} at S = 1.5, 3, 4.5, and 6 cm were R_d = 33.3%, 55.6%, 30%, and 23.3%, respectively.

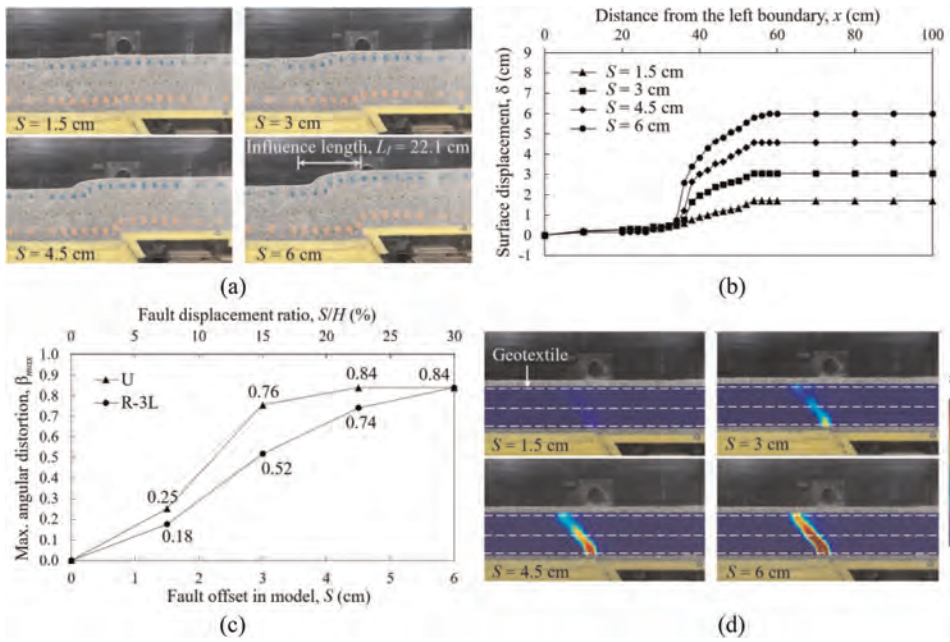
Figure 5d shows the shear strain contour for the GEC foundation subjected to reverse fault movement. Two reinforcing mechanisms, the shear rupture diffusion and diversion


Figure 4. Results of the GRS foundation test (Test R-3L) at various fault offsets: (a) test images; (b) surface displacement profiles; (c) maximum angular distortion; (d) shear strain contours.
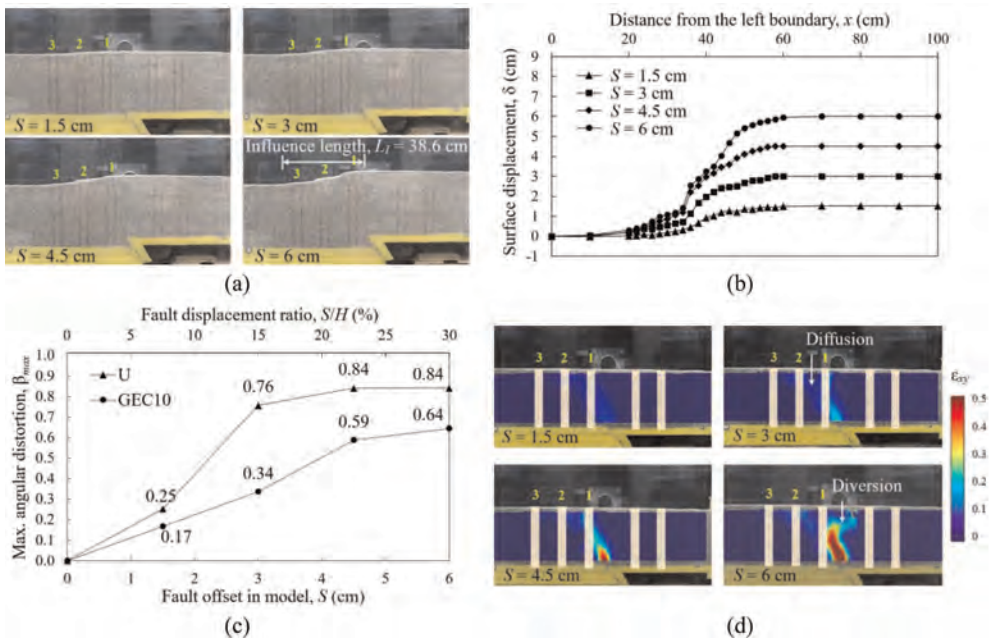

Figure 5. Results of the GEC foundation test (Test GEC10) at various fault offsets: (a) test images; (b) surface displacement profiles; (c) maximum angular distortion; (d) shear strain contours.

effects, were identified. When reverse fault displacement occurred, the fault-induced shear rupture propagated toward the first row of GECs placed in the footwall (indicated by 1 in Figure 5d). The fault-induced shear rupture diffused to the second and third rows of GECs (indicated by 2 and 3 in Figure 5d) during its propagation. The fault influence length was L_I = 38.6 cm at S = 6 cm, which is greater than the fault influence length for the unreinforced foundation (L_I = 27.7 cm). This result indicates that the mobilized tensile strain developed in the geotextile encasement, and the friction developed in the soil–geosynthetic interface effectively spread out the fault-induced shear rupture to a wider influential zone and further decreased the β_{max} at the ground surface. As the fault offset reached S = 6 cm (S/H = 30%), the fault-induced shear rupture was diverted toward the hanging wall, resulting in a considerable decrease in β_{max}. This diversion of the shear rupture was attributed to the increase in the lateral earth pressure acting on the GECs, enhancing the shear strength and bending stiffness of the GECs placed in the footwall. The increases in the shear strength and bending resistance of the GECs eventually diverted the fault-induced shear rupture.

4 CONCLUSIONS

The key findings of this study are as follows:

- For the unreinforced foundation, the β_{max} at the ground surface increased as the fault displacement increased and approached the slope of the peak friction angle of the sand at large fault offsets. At S = 3 cm (S/H = 15%), the shear rupture broke through the foundation soil, and a surface fault rupture occurred at the ground surface. At this moment, the β_{max} at the ground surface increased considerably, which indicated a high surface fault hazard risk.
- The GRS foundation was effective in reducing β_{max} at relatively small fault offsets. However, the GRS foundation was ineffective in reducing β_{max} after the fault-induced shear rupture reached the ground surface, with the R_d value decreasing to 0% at S = 6 cm (S/H = 30%).
- For the GEC foundation, stepped surface displacement profiles were observed as the reverse fault displacement increased. The β_{max} at the ground surface significantly decreased, with the percentage reduction for β_{max} ranging from R_d = 23.3%–55.6%. An R_d value of 23.3% was achieved as the fault offset reached 30% of the foundation height, which mitigates the risk of the surface fault hazards associated with large reverse fault movement. Two reinforcing mechanisms, the shear rupture diffusion and diversion effects, were identified.

Revisiting the reinforced fill over a void problem considering geosynthetic reinforcement stiffness

F.M. Naftchali
GeoEngineering Centre at Queen's-RMC, Queen's University, Kingston, Canada

R.J. Bathurst
GeoEngineering Centre at Queen's-RMC, Royal Military College of Canada, Kingston, Canada

ABSTRACT: The reinforced void problem is reexamined with special focus on the load-strain-time-dependent behaviour of the geosynthetic reinforcement. In current analytical model approaches, a single-value (constant) estimate of reinforcement stiffness is used for the design of reinforced fills over voids. Hence, the choice of an equivalent (elastic) stiffness value requires careful consideration. A simple hyperbolic stiffness model proposed by the writers is shown to be a useful approximation to the constant-load isochronous creep-strain behaviour of these materials, at least at low load levels, which are applicable to operational (serviceability) conditions of geosynthetic-reinforced soil structures. The paper uses the UK method for the solution of the reinforced fill over a void problem to compute tensile load and strain for a prescribed surface deformation (or maximum reinforcement settlement). An empirical approximation is introduced that links the isochronous stiffness of the reinforcement to its ultimate strength when product-specific creep test results are not available.

1 INTRODUCTION

The problem of a thin reinforced fill spanning a void has been the subject of investigation for many decades including the early seminal work of Giroud *et al.* (1990). The general problem is presented in Figure 1. The void may develop as a result of subsurface pipe failure, collapse
Figure 1. Reinforced thin fill over a long-void shape (width b). Draw angle assumed as $\theta_d = \phi$ using the method of BS 8006-1 (2010).

of mine workings, karstic terrain, openings below landfill liners and thawing in permafrost. The geosynthetic reinforcement prevents collapse of the fill layer into the void. In order to provide sufficient support the reinforcement must not strain excessively, exceed an allowable tensile load and it must have adequate tensile stiffness. Current design methods assume that the stiffness of the reinforcement is linear elastic. In fact, geosynthetic reinforcement products are rate-dependent to different degrees depending on the product type. This means that the stiffness of the reinforcement varies with load, strain, time and temperature. The impact of this so-called "creep" on the design of thin reinforced fills over a void has only been recently addressed by the authors in the journal literature (Naftchali & Bathurst 2023). This paper reviews these developments with special emphasis on the isochronous load-strain stiffness of these materials using a two-component hyperbolic model developed by Bathurst & Naftchali (2021). The analytical framework follows the method found in BS 8006-1 (2010) but without partial factors. To simplify the discussion, a long-void shape with plane strain geometry is assumed and temperature effects are ignored.

2   PRELIMINARIES

The design limit states for the long-void problem of width b are vertical deformation at the elevation of the reinforcement or at the surface (d or d_s), maximum strain in the reinforcement (ε_{max}), maximum tensile load (T_{max}) and mobilized geosynthetic stiffness (J_{mob}). The calculation of maximum strain for a long void is (BS 8006-1 2010):

$$\varepsilon_{max} = \frac{8 \times \left(\dfrac{d_s}{D_s}\right)^2 \left(b + \dfrac{2H}{\tan \theta_d}\right)^4}{3b^4} \tag{1}$$

Here, D_s is the width of the void at the fill surface, d_s is the fill surface deflection, H is the fill height, and γ and ϕ are the bulk unit weight and peak friction angle of the cohesionless granular fill, respectively. Assuming $d = d_s \times D_s/b$ leads to (BS 8006-1 2010):

$$\varepsilon_{max} = \frac{8}{3} \left(\frac{d}{b}\right)^2 \tag{2}$$

Assuming that there is no surcharge at the surface of the fill leads to the maximum tensile load computed as (BS 8006-1 2010):

$$T_{max} = 0.5(\gamma H)b\sqrt{1 + \frac{1}{6\varepsilon_{max}}} \tag{3}$$

The mobilized tensile stiffness now becomes:

$$J_{mob} = T_{max}/\varepsilon_{max} \tag{4}$$

3   ANALYSIS AND DESIGN STEPS

An example flow chart with problem parameters shown in the caption appears in Figure 2. The focus here is on the solid lines. The dashed lines refer to specific products that appear in Table 1 and the example design calculations demonstrated at the end of the paper.

1117

The design starts with a prescribed maximum vertical deflection (d) at the reinforcement elevation or a maximum permissible tensile strain in the reinforcement (Figure 2a). The strain ε computed using Equation 1 must not exceed a maximum allowable strain, (e.g., $\varepsilon_{max} \leq 5\%$). The solid lines in Figure 2b show solutions for T_{max} for different heights of fill (H) using Equation 3.

The maximum tensile load (T_{max}) must not exceed the maximum allowable tensile strength of the reinforcement (T_{al}) which is the ultimate strength of the reinforcement reduced by factors that account for strength loss due to creep, installation damage and chemical durability mechanisms. Next, Figure 2c shows the mobilized stiffness (J_{mob}) computed using Equation 4. The mobilized stiffness (solid lines in the plot) must not exceed the available isochronous stiffness (J_{avail}) at a strain level equal to ε_{max}.

4 STIFFNESS LIMIT STATE AND CALCULATION OF AVAILABLE REINFORCEMENT STIFFNESS

Figure 3a shows isochronous load-strain curves deduced from constant load (creep) tests carried out on product-specific test specimens using conventional creep test protocols. The curves can be approximated as:

$$T(\varepsilon, t) = J(\varepsilon, t) \times \varepsilon \tag{5}$$

where, $J(\varepsilon,t)$ is the non-linear isochronous secant stiffness. The matching isochronous creep stiffness curves are shown in Figure 3b. Each curve corresponds to a different isochronous time (t).

Bathurst & Naftchali (2021) developed a two-component hyperbolic model to approximate isochronous curves of the type shown in Figure 3. The general form of the equation is:

$$J(\varepsilon, t) = \frac{1}{\frac{1}{J_o(t)} + \frac{1}{\chi(t)}\varepsilon} \tag{6}$$

Parameter $J_o(t)$ is the initial stiffness at zero strain for isochronous time t, and $\chi(t)$ is a parameter that captures the curvature of the isochronous curves in Figure 3. These parameters are determined by non-linear regression fitting to the curves in Figure 3b. The values of $\chi(t)$ are the same for all curves for this particular material based on fitting but this is not the typical situation for all products and isochronous times in the database compiled by Bathurst & Naftchali (2021).

Figure 4 shows the range of $J_o(t)$ and $1/\chi(t)$ (and $\chi(t)$) parameters collected from fitting to creep test results for sheet reinforcement products and an isochronous time of t = 1000 h.

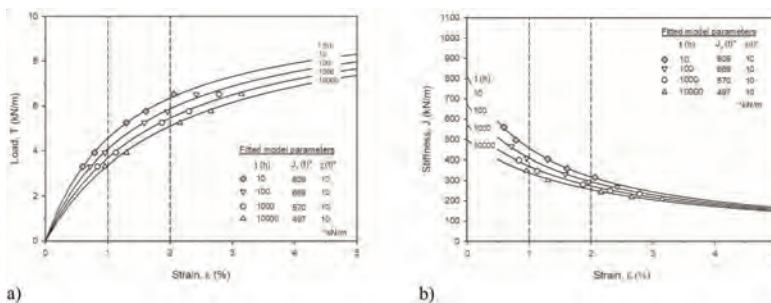
If product-specific data are not available, then the stiffness can be estimated from correlations developed by the authors that describe the isochronous stiffness as a linear function


Figure 3. Isochronous: a) load-strain curves, and; b) stiffness curves from constant load (creep) testing of a HDPE punched and drawn uniaxial geogrid. Data from Bathurst & Naftchali (2021).
Figure 4. Range of $J_o(t)$ and $\chi(t)$ parameters for geosynthetic sheet reinforcement types at $t = 1000$ h. Data from Bathurst & Naftchali (2021). Data for $\chi(t) > 0$ only.
Figure 5. 1000-h isochronous creep stiffness at $\varepsilon = 5\%$ versus ultimate tensile strength for geosynthetic sheet reinforcement types. Data from Bathurst & Naftchali (2021).

of the ultimate strength of the reinforcement (T_{ult}). Examples of such data for a strain of 5% and an isochronous time of 1000 h are shown in Figure 5. Similar plots of the form:

$$J(\varepsilon, t) = R \times T_{ult} \qquad (7)$$

at different strain values are available in the paper by Bathurst & Naftchali (2021) where R is a dimensionless constant. The fit to all (pooled) data with R = 4.5 is also shown in Figure 5 and is useful for preliminary design purposes. However, it is clear that the accuracy of the linear approximation using group data and pooled data is less than the calculation of stiffness J using Equation 6 with product-specific parameters from creep testing.

5 EXAMPLE DESIGN

Candidate products for the design conditions identified in Figure 2 are shown in Table 1. The allowable strengths are computed as $T_{al} = RF \times T_{ult}$ where RF = 3 for PET products and RF = 5 for the HDPE materials. In this example, we assume that there will be a single layer of reinforcement and the maximum allowable tensile strain is 5% in order to keep the reinforcement below a strain level that could lead to creep-to-rupture over the project design

life. The red dashed lines in Figure 2b are T_{al} values for the candidate reinforcement materials. From this figure, it can be seen that all products are satisfactory if the fill height is H = 0.5 m. If the fill height is H = 3 m, then only the three strongest reinforcement materials are adequate. For the stiffness limit state using Figure 2c, and a fill height of H = 0.5 m, four out of five of the reinforcement materials have adequate stiffness. However, for the case with H = 3 m, only the strongest materials in Table 1 will suffice. A strategy to widen the number of design solutions is to use a double layer of reinforcement; doing this will lift the dashed lines in each figure by a factor of two.

An important observation from Figures 2b and 2c is that as the maximum allowable tensile strain becomes less, the demand side for each limit state increases sharply which in turn requires reinforcement products with increasing strength and stiffness. In fact, for very low strains at (say) 2% or less, there may not be practical solutions available unless multiple layers of high-strength and stiffness reinforcement sheet materials are used.

6 CONCLUSIONS

This paper highlights the importance of reinforcement stiffness in the analysis and design for the stiffness limit state for the reinforced fill over a void problem. Two different methods are described to compute the isochronous stiffness of the reinforcement. The first is based on a two-parameter isochronous hyperbolic model with parameters fitted to product-specific creep test results. The second approach uses isochronous stiffness correlations with readily available ultimate strength values for reinforcement products falling into different product categories or, simply using all available (pooled) data. The second approach is useful for preliminary analysis and design and when reinforcement product-specific creep test results are not available.

This paper uses the BS 8006-1 (2010) method as the general approach. However, the three limit states identified in the paper also apply to other similar analytical design methods. The hyperbolic model and correlations discussed above are equally applicable for the resistance side in the load and stiffness limit states discussed in the paper.

ABSTRACT: There are few studies on shallow foundations placed close to the crest of slopes. Many of those studies are based on small scale physical models and include recommendations for the reinforcement layout (usually normalised to the width of the footing, *B*). Such studies have limitations, particularly regarding the unrealistically low stress levels applied. To address such limitations, this paper presents a numerical analysis of a full-scale footing close to the crest of a sandy slope reinforced with geosynthetics, using the finite element method. The parametric analysis focuses on the effect of the depth of the upper reinforcement layer (u) and number of reinforcement layers (n). The response of numerical models reinforced with one layer of geosynthetic was compared to that of the unreinforced model analysed under the same conditions. The installation of a reinforcement at 0.3B allowed a significant increase in the bearing capacity of the shallow foundation. For the same prescribed displacement, the failure mechanism of the reinforced model involved a smaller mass of soil and exhibited more localised shear strains than the unreinforced model. In contrast to what has been reported in the literature for reduced scale models, the optimal depth for one layer of reinforcement was 0.3B (and not 0.5B). This value agrees with recent studies performed in centrifuge and full-scale models. For the optimal depth of reinforcement, adding a second reinforcement layer (equally spaced from the first), led to the maximum bearing capacity improvement: 70% more of the unreinforced model and 38% more of the model with one layer of reinforcement.

1 INTRODUCTION

Geosynthetics have been used to increase the bearing capacity of poor foundation soils and/ or to reduce excessive settlements. In the literature, particular attention has been given to the case of shallow foundations on reinforced soil with a horizontal surface. Few studies have been carried out for the case of shallow foundations on reinforced soil slopes (resting on a horizontal surface above the slope or on the slope itself), mainly considering drained conditions and small scale physical models (1g). Such studies have significant limitations, particularly regarding the unrealistically low stress levels applied. Alternatively, geotechnical centrifuges (Ng) can be used, as they allow inducing realistic stress levels. Such studies have shown that optimum reinforcement layouts obtained from small scale tests (1g) may differ from those obtained using realistic stress fields. For example, for an horizontal soil surface, recent studies [Guo *et al*. 2020; Kyparissis & Pinho-Lopes 2018] showed that the optimal depth of the reinforcement layer (u) is smaller than the value obtained from small scale tests (i.e., 0.3B instead of 0.5B).

Table 1 summarises the optimal reinforcement layout found in the literature and obtained from small scale physical models (1g) for the case of a footing on a reinforced soil slope. To analyse the validity of the optimal layout resulting from 1g models for real-scale structures, herein numerical simulations of a full-scale reinforced soil slope were conducted. The influence of the depth of the upper reinforcement layer and of the number of reinforcement layers was studied.

Table 1. Summary of optimal reinforcement layout from the literature using 1g models.

2 PROBLEM ANALYSED

2.1 *Footing close to the crest of a slope*

The problem analysed is a foundation near the crest of a slope in plane strain conditions (Figure 1), set up to encompass an optimal layout identified from the literature. A footing of 1 m width (B) was considered, placed at $\lambda B = 0.2B$ from the crest of the slope. In a parametric analysis, the depth of the first reinforcement layer was set to 0.3B, 0.5B or 0.7B. In addition, a slope with two reinforcement layers was considered: depth of the first layer u =0.3B; spacing between the first and the second layer $h = 0.3B$, which results in a depth of the second reinforcement layer of 0.6B.

The objectives of this work are the following: assessing if the optimal depth of a single reinforcement layer is that obtained from small-scale (1g) tests; analysing the influence of a second layer of reinforcement.
Figure 1. Geometry and dimensions of the problem analysed.

2.2 *Numerical models*

The finite element method was used and the numerical models were prepared using a commercial software (*Plaxis 2D v22*). Five numerical simulations were carried out in plane strain conditions (Table 2).

Table 2. Numerical simulations conducted.

Model	UR	R-03B	R-05B	R-07B	R-03B-06B
N° reinforcement layers	0	1	1	1	2
u/B (h/B)	–	0.3	0.5	0.7	0.3 (0.3)

Figure 2 shows the main characteristics of the numerical model: i) the lowest contour is considered fully fixed; ii) the left and the right vertical boundaries are assumed normally fixed; iii) the footing is modelled as a rigid foundation by applying prescribed incremental displacements by means of a series of plastic phases. The mesh is the same for all the simulations, consisting of a series of 15-node triangular elements, whose dimension is adequate for the assumed geometry and the prescribed boundary conditions. A quality ratio indicator, defined in the software considering the shape of an element reactively to the ideal element, was used to check the initial quality of the mesh, which can be considered good as the lowest value of this ratio is 0.49 (Figure 2). The mesh comprises 10,054 elements and 8441 nodes.
Figure 2. Model boundary conditions and mesh quality ratio.

The soil is considered homogenous, it is modelled using a Mohr-Coulomb constitutive law with properties that can be attributed to a dry sand, as presented in Table 3, wherein: γ_{dry} is the dry soil unit weight; e is the void ratio; $E_{elastic}$ is the elastic stiffness; ν the Poisson's ratio, c' is the effective cohesion (mathematical intercept); ϕ' is the peak angle of friction of the soil. The geosynthetic is modelled using a linear elastic constitutive law represented by its axial stiffness for 2% extension ($EA_{2\%}$). The soil-geosynthetic contact is modelled using

Table 3. Summary table of the material properties.

Material	Constitutive model	Property (unit)	Value
Sand	Mohr-Coulomb	γ_{dry} (kN/m^2)	19.32
		e (-)	0.80
		$E_{elastic}$ (kN/m^2)	7800
		υ (-)	0.3
		c' (kPa)	5.0
		ϕ' (°)	33
Reinforcement	Linear elastic	$EA_{2\%}$ (kN/m)	258
		R_{int} (–)	1.0

interface elements, above and below the geosynthetic, which allow for relative movement of the two materials (soil and geosynthetic). The interface strength is set by means of its ratio to the soil shear strength (R_{int}). Herein, for simplicity, and because no particular reinforcement was modelled, the interface strength corresponded to the soil shear strength. The reinforcement layers extend from near the slope face to 0.50 m from the right boundary of the model.

The initial stress field is applied by gravity loading. The calculation is carried out in phases, by applying successive displacements at the footing considering steps of 0.1% B until a displacement of 1.0% B and then considering steps of 1.0% B up to a cumulative prescribed displacement of 16% B. This led to 25 different plastic calculations phases per simulation.

3 RESULTS AND DISCUSSION

3.1 Summary

The prescribed settlements at the footing are ranging, as mentioned above, from zero to 16% B. The numerical model outputs include the force mobilised at the footing for a given prescribed displacement (Figure 3). In the first four simulations, the maximum prescribed displacement allows to reach a final almost-constant value of this reaction force, which is an indication of a bearing capacity global failure. For the interpretation if the results, despite
Figure 3. Prescribed displacement vs. total reaction force (Fy) in the five simulations: [UR], [R-03B], [R-05B]; [R-07B] and [R-03B-06B].

the fact that for simulation [R- 03B-06B] the reaction force is still clearly increasing, the bearing capacity of the footing was assumed always equal to the maximum force mobilised and a bearing capacity ratio, BCR (Equation 1), was used to quantify the increase in bearing capacity with the different reinforcement layouts (Binquet & Lee 1975).

$$BCR = \frac{q_{(R)}}{q_{(UR)}} \tag{1}$$

where: $q_{u(R)}$ and $q_{u(UR)}$ are the bearing capacity of the reinforced and unreinforced soil models, respectively.

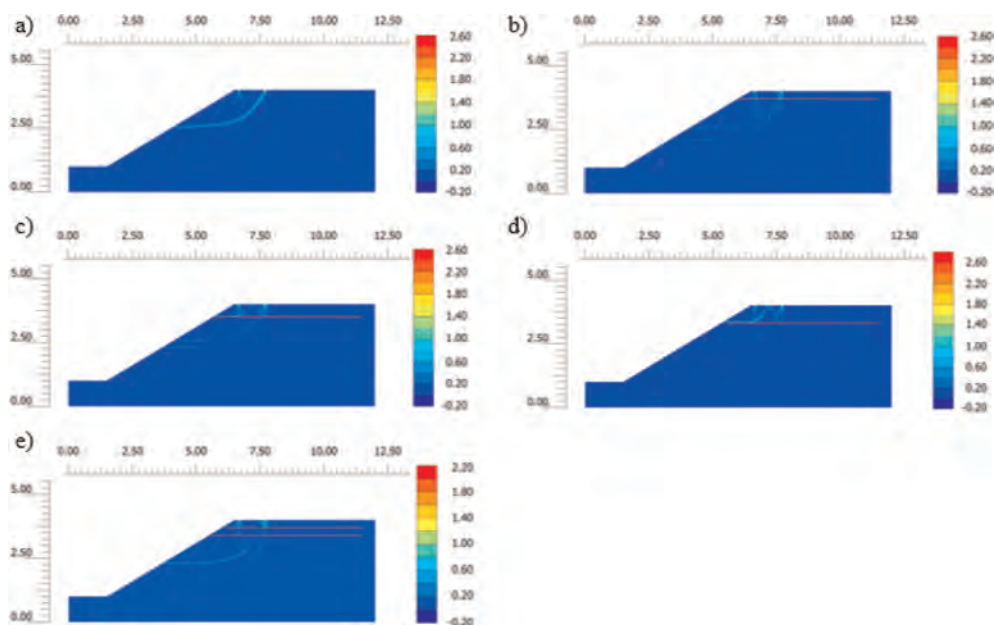
The numerical models exhibited two different failure mechanisms: FM1, total slope failure mechanism (relatively shallow); FM2, failure surface above the reinforcement layer. Such mechanisms are illustrated in Figure 4, by showing the deviatoric strains of the simulations for a prescribed displacement of 16% B. Table 4 summarises the main results obtained from the numerical models: failure load (maximum force mobilised at the footing); bearing capacity ratio (BCR), and failure mechanism (FM1 or FM2).


Figure 4. Deviatoric strain for a prescribed displacement of 16% B: a) [UR]; b) [R-03B]; c) [R-05B]; d) [R- 07B]; e) [R-03B-06B].

Table 4. Summary of the main results obtained from the numerical simulations.

Model	UR	R-03B	R-05B	R-07B	R-03B-06B
Failure load (kN/m)	110.1	152.7	150.9	144.7	187.5
BCR (-)	1.00	1.39	1.37	1.31	1.70
Failure mechanism	FM1	FM1	FM1 / FM2	FM2	FM1

The unreinforced model reached the bearing capacity for a prescribed displacement of 8.0% B, which corresponds to a reaction force at the footing of around 110 kN. Considering that the foundation is 1.0 m wide, the bearing capacity reached by the numerical model for the unreinforced condition is equal to 110 kPa.

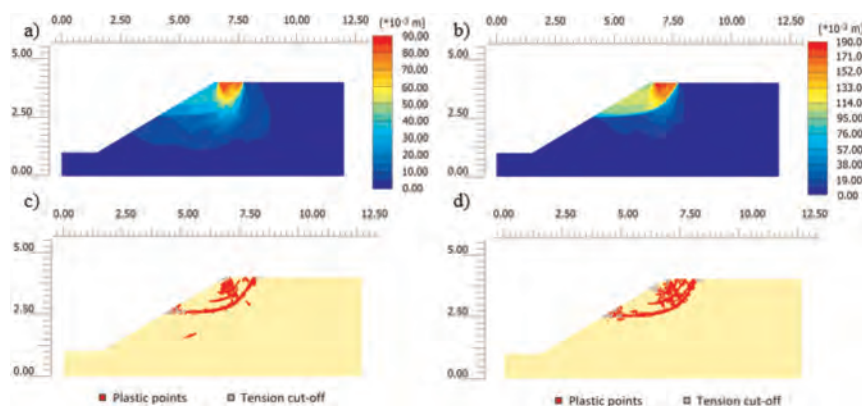
Figure 5 illustrates the total displacements of the soil slope for different values of the prescribed displacement. Initially, the displacements are mostly in the vicinity of the footing and, as the prescribed displacement increases, a larger mass of soil is affected. For a prescribed displacement of 16% B, a relatively shallow global failure mechanism is formed (FM1). The plastic points (Figure 5) for 8% B and 16% B confirm the failure mechanism already identified.


Figure 5. [UR] Total displacement |u|: a) |u| = 8.0%B; d) |u| = 16%B [Note: each subfigure has a different scale for the total displacements]; Plastic points. c) 0.8%B d) 16%B.

3.1.1 Influence of the depth of the reinforcement

One layer of reinforcement resulted in an increased bearing capacity (Table 4): the highest BCR (1.39) was obtained for $u/B = 0.3$ [R-03B]; the lowest BCR (1.31) refers to $u/B = 0.7$ [R-07B]. If the reinforcement layer is placed at a depth of 0.3B or 0.5B there is an increase in the bearing capacity associated with a failure mechanism FM1. For a reinforcement at 0.7B, a different failure mechanism (FM2) is observed, above the reinforcement layer. This means that the reinforcement is too deep to be mobilised, as reported by Chen & Abu-Farsakh (2015).

Nevertheless, for large settlements, [R-03B] exhibited a slightly stiffer behaviour than [R-05B], for this reason a deeper failure surface is observed for [R-03B]. The deviatoric strains for [R-05B] (Figure 4) indicate that several failure surfaces are forming (FM1 / FM2). Relative to the unreinforced model [UR], when a layer of reinforcement is placed at $u = 0.3B$ and $u = 0.5B$, the failure surfaces FM1 have similar dimensions. Thus, contrary to what was observed in small scale models [Altalhe et al. 2015; Baah-Frempong & Shukla 2020; Lee & Manjunath 2011] and for the conditions analysed herein, the optimum depth of the first reinforcement layer is 0.3B.

3.1.2 Influence of the number of reinforcement layers

The installation of a second layer of reinforcement [R-03B-06B] with spacing between layers equal to the depth of the first layer ($h = u = 0.3B$) increased the bearing capacity of the foundation, relatively to the unreinforced model (BCR = 1.70) and when compared to the model reinforced with only one layer [R-03B]. The second reinforcement layer is installed at a depth greater than 0.7B, which has previously been shown to be inefficient. However, as

this is a doubly reinforced model, the deeper layer allows the *deep footing effect* to be optimised (Huang *et al*. 1994). The failure mechanism formed for [R-03B-06B] is qualitatively similar to that of [R-03B], but with a larger volume of soil mobilised, thus presenting higher resistance.

4 CONCLUSIONS

In this paper, the bearing capacity of a strip footing on a reinforced soil slope was analysed. The response of numerical simulations wherein the slope is reinforced with one or two layers of geosynthetic were compared to the numerical simulation of an unreinforced model analysed under the same conditions. The installation of a reinforcement at 0.3B allowed a significant increase in the bearing capacity of a shallow foundation. For the same prescribed displacement, the failure mechanism of the reinforced model involved a smaller mass of soil and exhibited more localised shear strains than the unreinforced model. In contrast to what has been reported in the literature for reduced scale models, the optimal depth for one layer of reinforcement was 0.3B (and not 0.5B). This value agrees with recent studies performed in centrifuge and full-scale models. For the optimal depth of reinforcement, adding a second reinforcement layer (equally spaced form the first), led to the maximum bearing capacity improvement: 70% more of the unreinforced model and 38% more of the model with one layer of reinforcement.

Seismic design with geosynthetics

Effectiveness of Geofoam cushion on seismic performance of retaining structures: Numerical study

A. Edinçliler & Y.S. Toksoy
Boğaziçi University, Istanbul, Turkey

E. Danyıldız
Movea Construction Company, Istanbul, Turkey

ABSTRACT: In the last years, EPS Geofoam, which has extremely low density and high compressibility properties, is used to construct earthquake resistant infrastructure in seismic regions. In earthquake prone areas, retaining walls should be designed to resist the excessive dynamic lateral earth pressures. In this study, the effects of EPS geofoam cushion with different densities on seismic performance of retaining wall under two different earthquake motions were determined. Numerical analyses were performed by a finite element analysis program, Plaxis software. Results of parametric analysis were used to evaluate the effectiveness of cushion compared to the model without cushion. Numerical simulations with selected earthquake motions and EPS Geofoam with the different densities are compared. The comparative study showed that the Geofoam cushion can improve the seismic behavior of the retaining wall and the effectiveness of EPS Geofoam is highly dependent on the density of the material and the characteristics of earthquake motions.

1 INTRODUCTION

Earthquakes significantly threaten geotechnical engineering structures such as quay and retaining walls. These structures are likely to suffer excessive deformation or damage from increased earth pressure during the earthquake. However, these structures are the key elements of ports and harbors, transportation system lifelines, and other infrastructural facilities. Therefore, it is necessary to implement a cost effective technique to retrofit such structures, hence enhancing their seismic performance. Inclusion of vertical compressible layers called as cushion can be a solution to increase the stability of the retaining structures in seismic regions. One function of the tire chips cushion is to reduce the load of the retaining structure during earthquake due to the compressibility and energy absorption capacity of the cushion material. Another function is to restrict the permanent displacement of the structure by exploiting the compressibility, the ductility and the energy absorbing capacity of tire chips (Hazarika *et al.* 2008).

Historically, the first use of vertical compressible layers placed against rigid soil retaining wall structures with the aim of reducing the lateral static earth pressures has been reported in the literature by Partos & Kazaniwsky 1987; Horvath 1997; Karpurapu & Bathurst 1992. Expanded polystyrene (EPS) which is also called as Geofoam and tire wastes (tire chips and tire shreds) as cushion materials were studied to attenuate earthquake-induced dynamic earth pressures against rigid walls.

Performed shaking table tests in the literature prove that earthquake induced lateral loads can successfully be diminished by up to 40% on the retaining wall models with compressible

inclusions compared to that of the models with no compressible inclusions (Bathurst *et al.* 2007; Hazarika *et al.* 2003; Zarnani *et al.* 2005; Zarnani & Bathurst 2007;2008).

There are a number of numerical studies in the literature using the finite element model (FEM) code to model rigid wall structures with compressible inclusions. In the studies of Edinçliler and Toksoy (2014, 2017), it is revealed that the existence of a tire waste cushion layer can successfully and efficiently increase the seismic performance of retaining walls. From experiences and knowledge from previous studies, it is known that the dimensions of the seismic cushion affect the dynamic performance of geotechnical structures. In the numerical study performed by Dabiri and Notash (2020), the effects of the geofoam layer behind the cantilever wall on static and dynamic earth pressures have been investigated while considering various parameters such as wall height, wall type (yielding and non-yielding), and geofoam characteristics. According to the tests, as the thickness of inclusion increased, the relative stiffness decreased. The reduction in stiffness resulted in an increase in compressibility of geofoam, which decreased lateral forces against the wall and increased lateral displacement of soil. The geofoam inclusion showed a significant impact on lateral forces under static and dynamic loadings.

The aim of this study is to assess how the EPS geofoam density and earthquake characteristics affect the seismic performance of retaining walls. Three different cushion densities and two different earthquake records were considered throughout the study. Performance criteria have been selected as total displacements, rotations, axial and shear stresses, bending moments, and transmitted accelerations. The results of numerical simulations are compared to an identical retaining wall without a cushion layer. The protective cushion layer provides flexibility, and thereby stability to the structures during earthquakes by absorbing the energy. More importantly, this study is a direct attempt to develop an environmentally friendly, sustainable and earthquake resistant cushion technique that has a reasonably good balance of cost and performance for improving the seismic performance of retaining structures.

2 NUMERICAL STUDY

The aim of this numerical study is to assess the effectiveness of using EPS geofoam behind cantilever type retaining walls for dynamic conditions. Three different geofoam density and two different real earthquake records have been used.

Numerical study has been performed using the PLAXIS 2D Connect Edition. It is known that the thickness (t)/Height (H) ratio of geofoam cushion plays an important role for the stability. Previous studies indicate that the selection of t/H=0.3 increases the dynamic performance of retaining walls (Edinçliler & Toksoy 2018). Thus, the selection of t/H=0.3 has been implemented in the numerical study, where H=5m and t=1.5m. The mesh element distribution was generated as "Fine" for the accuracy of results. The numerical model and the generated mesh are given in Figure 1.
Figure 1.   a) FE model used in this study, b) Generated mesh.

As the cohesionless backfill material, "Silivri Sand" has been used behind the retaining wall. According to the USCS system, the sand material is classified as poorly graded sand (SP) with C_u = 2.29 and C_c = 1.1. The material has been modeled using the Hardening-Soil model with γ = 16.5kN/m^3, $\emptyset$ = 33° and E = 20000kN/m^2.

In order to determine the effect of the density of the EPS geofoam cushion on the dynamic behavior of the retaining wall model, three different cushion densities were selected with respect to the NCHRP (2004) guidelines. Namely, EPS 20, EPS 24 and EPS 32 were used during the study and modeled using the linear elastic soil model.

The retaining wall itself was modelled as a concrete plate element with model parameters of EA=7.5E^6 and EI=1E^6. Model boundaries were selected as compliant base boundary at the bottom of the mesh and free-field boundaries at the left and right end of the mesh due to the nature of the problem. Geofoam properties are given Table 1.

Table 1. Material properties of EPS geofoams.

	EPS 20	EPS 24	EPS 32
γ_{unsat}	0.20 kN/m^3	0.24 kN/m^3	0.32 kN/m^3
E	5000 kN/m^2	7000 kN/m^2	10000 kN/m^2
v'	0.01 kN/m^2	0.01 kN/m^2	0.01 kN/m^2

In order to determine the effect of earthquake characteristics on the seismic response of retaining wall models, two different real earthquake records were used. Records of 1940 El Centro Earthquake and 1995 Kobe Earthquake, which were obtained from KOERI database, are given in Figure 2. Peak ground accelerations and pre-dominant frequencies are 0.36g and 4Hz for the 1940 El Centro Earthquake and 0.68g and 2.1Hz for the Kobe Earthquake motions.
Figure 2. Acceleration time history of the 1940 El Centro and the 1995 Kobe Earthquake motions.

3 RESULTS

Numerical results are presented by means of total displacement of the backfill and the retaining wall model, rotations of the wall due to the combination of the static and dynamic forces, axial and shear forces, bending moments and peak transmitted accelerations. These results were evaluated in detail to obtain the influence of the cushion density in addition to the earthquake characteristics on the dynamic performance of cantilever type retaining walls. Numerical results are given in Tables 2 and 3 for El Centro and Kobe Earthquake motions, respectively.

Compressible vertical cushions behind rigid walls can successfully absorb the additional dynamic forces. Meanwhile, displacements may increase a bit due to the compressible nature of the geomaterial.

Table 2. Numerical results from the El Centro Earthquake motion.

	No Cushion	EPS 20	EPS 24	EPS 32
Total Backfill Displacements (cm)	3.4	5.2	5.2	5.0
Total Wall Displacements (cm)	2.3	3.4	3.4	3.3

Peak Transmitted Acceleration (g)	1.58	0.47	0.44	0.27

The cantilever-type retaining wall model under El Centro Earthquake motions experiences peak values of total backfill and wall displacements due to the dynamic excitations of 3.4cm and 2.3cm in case of no cushion behind the wall. However, when EPS 20 and EPS 24 type cushions are placed behind the wall, total backfill and wall displacements slightly increase to 5.2cm and 3.4cm, respectively (Table 2). It is seen that the increase in EPS geofoam density leads to a minor reduction in displacement values. The retaining wall model with EPS 32 experiences 5.0cm of total backfill and 3.3cm of total wall displacements. Similar seismic behavior was observed when the retaining wall models were subjected to Kobe Earthquake excitations. Total backfill displacement of 30.8cm for no-cushion model increases to 46.1cm in EPS 20 and EPS 24 model and slightly reduces to 45.8cm in EPS 32 model as shown in Figure 3.
Figure 3. Total displacement distributions under Kobe Earthquake, a) No-cushion case, b) EPS 20 case, c) EPS 24 case and d) EPS 32 case.

Rotations of the wall from normal are directly related to the displacement of the wall and thus they follow the same pattern. Under El Centro Earthquake motions, the wall model with no-cushion rotates 0.17° where the wall model with EPS 20 and EPS 24 cushion rotates 3.4° and the model with EPS 32 cushion rotates 3.3°. Similarly, the 1.40° rotation value in no-cushion case under the Kobe Earthquake motions increases to 1.90° and 1.89° in the retaining wall models with EPS 20, EPS24 and EPS 32 cushions, respectively.

Peak axial forces acting to the retaining wall model under El Centro Earthquake show minor increase with the inclusion of the geofoam layers. The influence of the geofoam density is negligible under the given dynamic motion. Observed peak axial force for no-cushion case is 74.4kN/m where as it is 74.8kN/m for EPS 32 case. Under the Kobe Earthquake motions, peak axial forces in no-cushion case are obtained as 71.8kN/m. However, with the inclusion of the EPS 20, it increases to 79.8kN/m. With the increased cushion density, axial forces slightly decrease under current ground motion. Thus, the obtained axial forces in EPS24 and EPS32 cases are 75.2kN/m and 67.4kN/m, respectively.

Observed peak shear forces acting to the retaining wall models noticeably decrease with the inclusion of the compressible vertical cushions. Shear forces decrease from 103.9kN/m in no-cushion case to 70.9kN/m in EPS 20 case under El Centro Earthquake. Increased cushion density leads to a slight increase in shear forces under current dynamic motion as the obtained shear forces are 71.4kN/m and 72.0kN/m in EPS 24 and EPS 32, respectively. On the contrary of the El Centro Earthquake, increased cushion density leads to a reduction in shear forces under Kobe Earthquake. Obtained results are 111.8kN/m, 91.1kN/m, 84.2kN/m and 83.3kN/m for no-cushion, EPS 20, EPS 24 and EPS 32 cases, respectively.

Obtained results by means of bending moment acting to the wall model are clearly more influenced by the earthquake characteristics than the Geofoam inclusion itself. Under the El Centro Earthquake motions, the inclusion of cushion material decreases the observed bending moments and these values are directly proportional to the increased cushion density as seen in Table 2. The observed peak bending moment value is 58.8kNm/m in the no-cushion case, 52.6kNm/m in EPS 20 case and 54.5 kNm/m in EPS 32 case. Under the Kobe Earthquake excitations, 60.1kNm/m of bending moment value in the no-cushion case increases to 72.9kNm/m in EPS 20 case. However, it is obtained as 62.2kNm/m in EPS 24 case and 68.3kNm/m in EPS 32 case.

Peak transmitted accelerations along the retaining wall model can successfully be decreased by implementing compressible vertical cushions. Under the El Centro Earthquake motions, the peak acceleration value in the no-cushion case is 0.34g. Due to the cushion effect, peak acceleration values successfully decrease to 0.23g in EPS 20 case and to 0.22g in EPS 24 and EPS 32 cases (Table 2). Similarly, when the retaining wall model was subjected to the destructive motions of Kobe Earthquake, observed peak transmitted accelerations in the no-cushion case is 1.58g. Due to the material properties of the EPS geofoam cushion, transmitted accelerations significantly decrease to 0.47g in EPS 20 case, 0.44g in EPS 24 case and to 0.27g in EPS 32 case.

In addition, deviatoric strains, which reflect the deformations which cause a shape change without a volume change, increase from 0.29 in no-cushion case to 0.88 in EPS 20 case, 0.87 in EPS 24 case and 0.83 in EPS 32 case.

4 CONCLUSIONS

Performed numerical analyses with the aim of determining the effectiveness of EPS geofoam cushion reveal that the inclusion of a geofoam layer has a great impact on many aspects of the dynamic performance of the retaining wall.

The inclusion of such ultra-light cushion layers behind rigid walls slightly increases displacements and rotations, absorbs seismic forces and transmits less acceleration to the retaining structure concerned. Peak transmitted accelerations are magnificently reduced by up to 35% and 83% under El Centro and Kobe Earthquakes, respectively. In addition, shear

forces and bending moments acting on the retaining wall model are successfully diminished by up to 32% and 21%, respectively.

EPS geofoam density also has a reasonable impact on the numerical results. Additional total displacements and rotations tend to decrease with the increased geofoam density. Also, peak transmitted accelerations attenuate directly proportional to the cushion density. Axial and shear forces and bending moments are not found to be influenced by the geofoam density directly. The influence of earthquake characteristics on the seismic performance of the retaining wall model is clear. It is seen that the developed model is sensitive to the relatively high peak accelerations and relatively low frequency content of the record that lead to increased displacements therefore higher efficiency of the geofoam cushion layer.

This study is a direct attempt to develop an environmentally friendly, sustainable and earthquake resistant cushion technique that has a reasonably good balance of cost and performance for improving the seismic performance of retaining structures. Obtained numerical results have the potential to encourage researchers and engineers for further applications. It should be noted that presented results and outcomes of this study are only valid for the current model parameters and variables. Authors suggest further studies on this subject.

Geosynthetic-reinforced soil wall failure encountered in reduced scale shaking table testing

E. Guler
Professor, Bogazici University, Istanbul, Turkey

O. Selek
Former Ph.D. Student, Bogazici University, Istanbul, Turkey

ABSTRACT: An extreme case of model geosynthetic-reinforced soil wall failure encountered during shaking table testing is described in this paper. A ¼ scale, 2 m high model wall with concrete block facing and geotextile reinforcement length of 85 cm was brought to collapse under dynamic loading in which the maximum shaking table acceleration reached 2g. Failure started with the upper facing blocks falling and continued with overturning of the wall face. The test was terminated before the wall fully collapsed. In this paper, the failure mechanism is investigated and the performance of the model is compared to that predicted by design recommendations. The stiffness of geotextile layers and the silt content of the fill are suggested as the reason for the good performance up to such large dynamic loads.

1 INTRODUCTION

To get an insight to the performance of geosynthetic-reinforced soil walls (GRS walls) under seismic loads, a series of reduced-scale shaking table tests were conducted using the shaking table facility at Kandilli Observatory and Earthquake Research Institute (KOERI) of Bogazici University, Istanbul, Turkey. All model GRS walls were constructed on rigid foundation using sand as fill material, a woven geotextile for reinforcement, and concrete facing blocks that have no shear connections but rely only on the interface friction with the geosynthetic. Eight different model setups were tested under El Centro earthquake loading applied at different amplitude scales. The effects of change in peak ground acceleration, reinforcement length, reinforcement spacing, model scale, and treatment of top two facing block layers were evaluated by Guler and Selek (2014). This study concluded that the geotextile reinforced GRS walls with concrete block facing with only frictional connection between facing blocks showed negligibly small permanent displacements. There are many shaking table tests cited in the literature as well investigating geosynthetic reinforced walls (Bathurst *et al.* 2002; El-Emam & Bathurst 2004; Guler & Enunlu 2009; Watanabe *et al.* 2003). However a case with a catastrophic failure is very rare. Therefore to check for the validity of the model and this observation a test has been conducted by applying an extreme acceleration of 2g to a model wall with relatively short reinforcement length. The acceleration of 2g caused failure of the GRS model wall tested. In this paper, this particular incident is reported and the failure mechanism is investigated.

2 LITERATURE REVIEW

Ling *et al.* (2005) performed shaking table tests on 2.8 m high, full-scale model GRS segmental walls with fine-grained sand backfill. The wall face had a 12% batter. For Wall 1,

reinforcement length, was 205 cm and reinforcement spacing was 60 cm. The reinforcement spacing was decreased to 40 cm in Wall 2. In wall 3, reinforcement spacing was 40 cm, and the reinforcement spacing was decreased to 168 cm, but the top reinforcement layer was extended to 252 cm and the vertical component of the Kobe earthquake accelerogram was added to the horizontal component that was applied to the first two walls. After the application of a scaled peak horizontal acceleration of 0.4g, only a hair crack was seen behind the reinforced zone at the surface. After testing with a scaled peak horizontal acceleration of 0.86g, maximum deformation measured was less than 100 mm; large cracks formed behind the reinforced zone at the top, but the cracks were shallow and no distinct failure surface was observed in the backfill during demolition.

Ling *et al.* (2012) performed similar tests using an SM-SC sand with 43.3% fines content. Wall 1 in this study was constructed using the same dimensions of Wall 3 of the previous study; reinforcement spacing was 40 cm, reinforcement length was 168 cm, the top reinforcement layer was extended to 252 cm. In walls 2 and 3, reinforcement spacing was increased to 80 cm and the top reinforcement layer was not extended. In Wall 3, the lips on the blocks were removed to eliminate interlocking between facing blocks. Both the horizontal and vertical components of the Kobe earthquake accelerogram was applied. After shaking with a scaled peak horizontal acceleration of 0.4g (and a vertical acceleration scaled using the same ratio), 3 shakings with a scaled peak horizontal acceleration of 0.8g were applied consecutively. Inclusion of silt, which is generally present in the granular backfill soil used at the site improved performance. There was no visible deformation after the application of 0.4g peak acceleration. After 0.8g peak acceleration, there was only local failure behind the facing blocks at the top. There was no damage to the geogrid reinforcement in any wall configuration.

Parametric studies generally involve models that are validated using shaking table test results. These models are then applied to predict performance under conditions other than those physically tested. In a numerical parametric study of a 6-m high GRS wall with a full-height rigid facing and six reinforcement layers, Bathurst and Hatami (1998) showed that increasing the reinforcement stiffness or the reinforcement length decreased the seismic displacements. Therefore at shaking table tests it is expected that lower deformations are obtained, because considering the height of the model, the stiffness of the reinforcement typically remains above what is common in practice.

3 TEST SETUP

Model scale for the investigated wall was 1/4. Wall height was 2 m and the total reinforcement length including the portion placed between the facing blocks, was 85 cm meaning that the reinforcement length to wall height ratio (L/H) is 0.4. Considering the scale factor, this means that the prototype wall height was 8 m and the prototype reinforcement length was 3.40 m. The geosynthetic reinforcement used was a woven polyester geotextile with tensile strength T_{ult} = 40 kN/m and ultimate strain at failure ε_{ult} = 11 per cent. 10 cm long x5 cm wide x 5 cm high concrete blocks were used to constitute the facing in the model, and the reinforcement was placed with two rows of block layers in between, i.e. the vertical reinforcement spacing, s_v, was 10 cm corresponding to a vertical spacing of 40 cm in the prototype. A general schematic of the model is given in Figure 1). The soil used as backfill was a well-graded sand with silt (SW-SM) with coefficient of uniformity, C_u=9.13 and coefficient of curvature, C_c=1.17. The percentage of fines (mainly silt-size particles) was 6%. The soil was used at its natural water content which was 4.6%.

The model wall was constructed in a steel container with 215 cm height, 278 cm depth, and 53 cm width, which was fixed to the shaking table. The back five centimeters was filled with granular rubber during construction to minimize the reflection of earthquake waves from the back of the steel container. The inner sides of the steel container were greased and
Figure 1.   Schematic of geosynthetic reinforced soil retaining wall model.

lined with floating insulation sheets to minimize the friction at the sides of the wall. Forward movement of the lowest layer of facing blocks was prevented by a steel bar fixed to the base in order to avoid external base sliding due to the low friction between the soil and the steel base because this mode of failure was not considered relevant. Before laying the reinforcement over each layer, the fill was compacted to reach the desired amount of compaction. The dry unit weight of the fill determined from the measurements during demolition was 17.7 kN/m^3. In practice the top two blocks are always tied to each other to prevent the failure of the uppermost block. In the remainder of the experiments reported by Guler and Selek (2014) the top two blocks were always tied to each other. However, for this model to make the model even more vulnerable, only the reinforcing geotextile was placed in between the blocks and no other measure was taken to fix the top two block layers.

The uniaxial shaking table ANCO R-148 at KOERI of Bogazici University was used for testing. Displacement of the shaking table was measured using a long stroke displacement transducer. Optical laser distance sensors were utilized to measure wall face displacements. Two layers of geotextile reinforcement (at 40 cm and 160 cm heights from the base of the model) were instrumented to measure the displacements on the reinforcement and calculate the strains in these reinforcement layers. Accelerometers were placed on the shaking table, on the wall face and in the top soil to measure accelerations at these locations. Further information on the test setup, shaking table used, instruments utilized for measurements can be found in Guler and Selek (2014).

The original North-South component of El Centro Earthquake record was scaled by dividing the time values by 2 for 1:4 scale tests, in accordance with the similitude rules proposed by Iai (1989), which are widely used for shaking table tests conducted in a 1-g gravitational field.

4   RESULTS

Measurements made were explained in detail by Guler and Selek (2014). For the model explained in this paper the measured accelerations increased from bottom to top on the wall face. Accelerations measured by the uppermost accelerometer on face were the highest. Very high amplifications were measured by the uppermost accelerometer on face, indicating high frequency vibrations of the top blocks that were not fixed to the more stable lower blocks.

The lower instrumented geotextile underwent higher strains at a distance of 10-20 cm from the block facing and the strain tended to increase with increasing maximum table acceleration, implying that a potential failure plane passes through this region. There is no such observation for the upper geotextile layer, indicating that the potential failure surface does not pass through the instrumented regions. Considering the actual failure location observed on the top surface of the model, the potential failure surface shown in Figure 2 was deduced, which coincides with the Rankine failure plane.

Figure 2.   Estimated failure plane based on reinforcement strains and top topography.

The shaking table system applied the earthquake record shown in Figure 3 on the model wall. As can be seen there were at least one peak in each direction which was approximately 2g. It can be further seen from the same graph, that the acceleration had several peaks as high as 1.25g. So as a summary it can be stated, that extraordinary accelerations acted on the wall which was constructed to be very weak in terms of reinforcement length. This resulted in failure of the GRS wall and the test was terminated.
Figure 3.   Acceleration applied to the model wall.
Figure 4.   Facing displacement relative to the shaking table at various elevations.

Figure 4 shows that the face displacements relative to the shaking table, measured at several elevations by the laser displacement sensors. The displacements suddenly reach very high values that are beyond the measuring range when the table acceleration is 1.25g, indicating that at that point facing blocks begin to fall and the GRS wall starts to fail.

Facing blocks from the top four layers fell down before the wall came to a stop. There was sliding between the facing block layers over the 15th layer of reinforcement as can be seen in Figure 5. There was no relative movement between the geotextile reinforcements and the facing blocks in the lower layers. Therefore, the face displacements were determined by measuring the geotextile length protruding from the reference steel box after removal of the facing blocks. The residual face displacements are illustrated on the photograph of the GRS wall face in Figure 5. The relative sliding over geotextile layer 15 is apparent in the photograph. The failure mode seems to be a combination of internal sliding for the upper layers, and external overturning which was actually initiated after the internal sliding started in the upper layers.

The view of the top of the GRS wall after failure is illustrated and dimensioned in Figure 6. The major failure location marked in the figure coincides with the intersection of Rankine plane with the top of GRS wall.

To be able to compare the observed behavior with the behavior to be predicted using state-of-the-art design recommendations, the pseudo-static limit equilibrium design method

Figure 5.   Displaced wall facing after application of extreme acceleration.
Figure 6.   Topography of model top surface after application of extreme acceleration.

described in FHWA recommendations (Berg *et al.* 2009; Elias *et al.* 2001) was used to calculate the factors of safety against external sliding and overturning failures for different peak ground accelerations. Internal tensile and pullout failures were also investigated for each reinforcement layer according to FHWA recommendations. The dynamic thrust exerted by the retained backfill and the horizontal inertia force on the reinforced mass are added as pseudo-static forces after the static limit equilibrium analysis for external stability is completed. These calculations indicate that an overturning should have occurred when the table acceleration is 0.4g. However, actual deformation leading to failure started only when the table acceleration reached 1.25g. As a result it was concluded that the design guidelines appear to be highly conservative in terms of external stability. Total loads in reinforcement layers were much lower than the allowable tensile load according to the analysis. So it can be said that the predicted and actual results are in agreement when internal stability is considered.

5   CONCLUSIONS

In the study by Guler and Selek (2014), the good performance of the tested configurations with higher L/H ratios encouraged the testing of models with L/H = 0.4 even though FHWA design guidelines recommend a minimum L/H ratio of 0.7 to be maintained. As a result, the extreme case of wall failure described in this paper could be witnessed.

The model GRS wall was tested consecutively under dynamic loading with the maximum table acceleration increasing each time. Maximum accelerations on the GRS wall during testing

increased from bottom to top, compliant with the literature. There were no residual deformations after each dynamic load application until the loading that resulted in failure. The GRS wall started to collapse when the shaking table acceleration reached 1.25g, which is much higher than the maximum acceleration predicted to be accommodated using design guidelines.

The actual failure started with internal sliding between the upper layers and continued with external overturning. Examination of the top of backfill indicated that the major failure location coincides with the Rankine plane. According to the design guidelines, failure by external overturning was to be expected much sooner, namely at 0.4g. Considering the expected and the encountered failure modes, the actual failure mechanism is not easy to predict. As indicated by Ling *et al.* (2005b), increasing the length of the top reinforcement probably would have resulted in a better performance; the local sliding failure at the top layers could be prevented.

The good performance of this model GRS wall with such short reinforcements up to 2g may partly be attributed to the high stiffness of the geotextile layers, which decreased the seismic displacements and partly to the small silt content that is shown to increase performance (Kilic *et al.* 2021). The apparent cohesion resulting from the silt content has more pronounced effects in the low height model walls, so its favorable effect in the prototype cannot be easily established. Although the typical backfill soils used in GRS wall construction are very similar to the backfill used in this study, incorporating the apparent cohesion into design is not recommended.

Finite difference parametric study of seismic behavior of a GRS bridge abutment

K. Fakharian, M. Kashkooli & S. Nasrolahzadeh
Department of Civil & Environmental Engineering, Amirkabir University of Technology, Tehran, Iran

ABSTRACT: The main objective of this study is to evaluate the influences of different engineering parameters on the seismic response of reinforced bridge abutments. The Founders/Meadows reinforced bridge abutment in Denver Colorado was considered as a case study. In former studies conducted on the same bridge, base isolator was not considered in the model between deck and the deck footing. However, the new finite difference numerical model is comprised of two abutments, one pier in mid-span, concrete deck, and base isolators connecting deck to deck footing. Parameters used in parametric study are related to base isolator, foundation soil, reinforced soil, and input ground motion. Horizontal displacement of facing as well as rotation of deck footing are selected as the main seismic excitation outputs. The overall results show that the response of the two-abutment model with the base isolator is significantly dependent on the base isolator damping, strength of foundation as well as reinforced soils, and frequency of input acceleration wave. The overall response of the GRS bridge abutment subjected to seismic excitations is evaluated and discussed.

1 INTRODUCTION

Reinforced earth walls have been widely used as geotechnical structures in different projects. Reinforced bridge abutments are similar to earth walls except that they carry a surcharge load near the top edge (from the bridge deck) in addition to the soil horizontal pressure behind the reinforced earth zone. Due to significance of bridges as infrastructures, they are expected to remain in service after earthquakes and the destructive effects have to be reduced. Seismic base isolators are used in bridges to notably improve the performance under the seismic excitations. Using base isolators leads to an economical and practical solution mitigating the magnitude of the seismic force by providing both lateral flexibility and energy dissipation through the insertion of the isolation device (Hall *et al.* 1995; Rao & Jangid 2001; Shen *et al.* 2004).

Several numerical and physical modeling studies have been conducted on the response of GRS bridge abutments for static and dynamic loading conditions (For instance: Askari *et al.* 2021; Hatami & Bathurst 2001, 2005, 2006; Fakharian & Kashkooli 2018; Zheng *et al.* 2018). Founders/Meadow segmental bridge abutment was extensively studied for its well-documented field instrumentation data. For instance, Fakharian & Attar (2005, 2007) used FLAC2D v4.0 to simulate the dynamic response of the Founders/Meadows reinforced bridge abutments to seismic excitations. They applied a point load on the top of bridge deck footing to consider the weight of bridge deck. Therefore, the interaction of bridge deck and bridge deck footing were not considered in the analysis. The results showed that the horizontal displacements of the facing increase with number of cycles and reach values at the end of seismic excitations considerably greater than static displacement magnitudes. The

vertical displacement and rotation of the bridge deck footing, however, were not significant. Fakharian & Aghania (2014) continued the study on Founders/Meadows reinforced bridge abutment, incorporating the deck inertia and its interaction with the footing and abutment. The results showed that the horizontal displacement of the top and bottom points of facing were decreased by considering the role of deck. However, one of the instabilities observed in their model was the excessive rotation of the bridge deck footing caused by cyclic horizontal loads, understood to be exerted from bridge deck to the bridge deck footing. The other instability observed was the backward rotation of upper facing segmental blocks of the abutment facing.

Fakharian & Nasrolahzadeh (2017) investigated the influence of base isolators between bridge deck and bridge deck footing in Founders/Meadows reinforced bridge abutments subjected to seismic excitations. They realized that the base isolator significantly contributes to reducing the excessive rotation of the bridge deck footing and the instabilities of upper blocks of footing as reported by Fakharian & Aghania (2014) when no base isolators were installed.

This paper further investigates the behavior of Founders/Meadows reinforced bridge system under seismic excitations considering base isolators between the bridge deck and deck footing. The 70 m long M/F segmental bridge abutment in Denver with one pier in the mid span and base isolators is simulated using FLAC2D v7.0. Post-cyclic facing horizontal deformations and abutment footing deformations are compared with the results of the two-abutment model without considering base isolators (Fakharian & Aghania 2014) and also with single-abutment system (Fakharian & Attar 2005, 2007). Parametric studies of two-abutment model with base isolator are also presented and discussed.

2 FOUNDER/ MEADOWS BRIDGE ABUTMENT

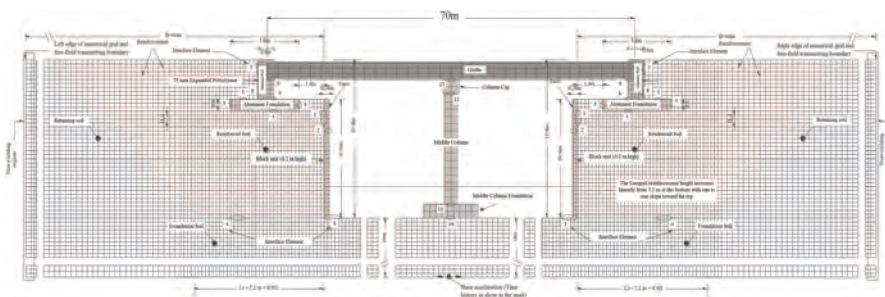
The Founders/Meadows (F/M) bridge abutment constructed and fully instrumented in Denver, Colorado is used for seismic numerical modeling in this study. The Founders/Meadows segmental bridge abutment was completed in 1999 near Denver, by the Colorado Department of Transportation. The plan view and section of the reinforced abutment can be viewed in Abu-Hejleh *et al.* (2000, 2001) and Fakharian & Attar (2007). The bridge deck/ girder load is carried by a strip footing on top of the segmental reinforced abutment. The facing was constructed using solid masonry concrete blocks (toe-to-heel dimension equals to 280 mm and height of 200 mm). Plastic connectors prevent relative slip between the segmental concrete units, and are used to attach the reinforcing geogrids to the facing. The reinforcing geogrids were placed with uniform spacing but varying length. The model geometry and details are generated in FLAC2D v7.0 as shown in Figure 1 with slight differences


Figure 1. Grid, interface elements and boundary conditions for numerical modeling (FLAC2D v7.0) of the Founders/Meadow segmental bridge abutment.

compared to the prototype, such as changing the facing height (h) from 5.9 m to 6.0 m, geogrid element lengths from 8 to 7.2 m at the base (equivalent to 0.9H, where H is the total height of abutment) and removing the soil beside the facing wall.

3 NUMERICAL MODEL

3.1 Modeling of abutment

The initial condition for the seismic analysis is static stability (end-of-construction) of the system including the initial stresses while resetting all the deformations. The grid geometry is the same throughout the static and seismic analyses, but the boundary conditions and stress-strain relations are different. The soil model is nonlinear elastic (hyperbolic model) with M-C (Mohr-Coulomb) failure criterion under static condition while the softening effects after the peak failure are considered. In the dynamic analysis, a hysteretic nonlinear behavior applying Masing rule in unload/reload process is used (Cai & Bathurst 1995). The reinforcing elements are modeled by elasto-perfectly plastic cable elements with no compressive strength, available in FLAC. The injection layer option around cable elements was used as the interface to simulate the frictional behavior of soil-geogrid. The thickness of this layer was assumed zero and friction angle and cohesion were considered 0.75φ and zero, respectively. The interface element of FLAC was used to model the friction between difference contact surfaces of soil-soil, soil-concrete and concrete-concrete. The interface element is described by shear and normal stiffness, friction, cohesion, sliding and separation. At soil/soil and soil/concrete contact surfaces, the magnitude of the interface friction angle controls the onset of slip. The shear and normal stiffness values for the interface elements were based on the properties of the adjacent materials, as recommended in the FLAC manual. A variable-amplitude sinusoidal harmonic motion was used as an input at the bottom nodes for seismic excitations. More details of the numerical model can be found in Fakharian & Attar (2007).

3.2 Modeling of base isolator

Seismic base isolators (B.I) are material elements used to diffuse the energy induced at the time of the earthquake before being transferred to the structure. In this project, the base isolator type NRB (Natural Rubber Bearing) which is an elastomeric support with low damping was modeled. Cyclic behavior of base isolator can be modeled using nonlinear cyclic relations by applying hysteretic damping in FLAC v7.0. Elastic element with hysteretic behavior is used in order to model the base isolator. The factor used for defining hysteretic behavior in FLAC is Hardin factor (Hardin & Drnevich 1972). Investigation of primary analysis on reinforced abutment system with base isolators carried out by Fakharian & Nasrolahzadeh (2017) showed that damping characteristic of Hardin factor 0.00001 was compatible with laboratory test results, thus Hardin factor of 0.00001 was used in this research.

4 ANALYSIS RESULTS AND DISCUSSION

4.1 Effects of base isolator on seismic behavior

To investigate the performance of the abutment system with base isolator (B.I), comparisons are made with the results of abutment systems without base isolator modeled by Fakharian & Attar (2007) and Fakharian & Aghania (2014). Normalized vertical displacements of the bridge deck footing (rotation of it) and horizontal displacements of the facing are compared in Figures 2a and 2b, respectively. In Figure 2, comparisons are made among three models of
Figure 2. Incremental displacement profiles before and after applying seismic excitations in 1-abutment model and 2-abutment models with and without base isolator: (a) vertical displacement and rotation of bridge deck footing; (b) horizontal displacement of facing.

abutment system to understand the similarities and differences. As shown in Figure 2a, the displacement and rotation of bridge deck footing in both one-abutment and two-abutment models with B.I systems are similar to each other, but the deformations are much lower than the two-abutment model without B.I. Through embedding the base isolator, the performance of bridge deck is isolated from the reinforced abutment. Therefore, the footing is not experiencing excessive rotation due to the impact of bridge deck.

One of the instabilities of the model without the base isolator, as reported by Fakharian & Aghania (2014), was the backward rotation of upper facing blocks of the abutment (Figure 2b). Figure 2b shows that the horizontal displacement of the wall facing in the one-abutment model is almost double of the two-abutment model with B.I. This is attributed to the fact that the other abutment and bridge deck inertia are influencing the wall response to some extent, even with the presence of the base isolator. However, as the performance of the reinforced system is isolated from the bridge deck through embedding the base isolator between bridge deck and footing, the shape and trend of horizontal displacement of facing in the two-abutment model with B.I. is similar to the results of one-abutment model. In fact, with the presence of the base isolator in the system, the interactive effects between bridge deck and foundation wall are reduced.

All the mentioned differences are the result of existence of the base isolator under the bridge deck. In the 2-abutment system without B.I., the deck is directly put on the concrete footing underneath and their horizontal interaction is through the frictional resistance between deck and footing, that is concrete-to-concrete interface. The high frictional resistance between deck and footing has resulted in preventing the footing to experience a significant horizontal movement. In the system with B.I. on the other hand, the frictional interaction of these two elements is isolated and the footing experiences horizontal displacements the same as the underneath reinforced soil. Although the connection effects are ignored in the one-abutment model, the trend of deformations are similar to the two-abutment model with B.I.

4.2 Parametric study

Parametric studies have been carried out in order to investigate the effects of different characteristics on the performance of bridge abutment. Three different parameters were selected among all parameters of different components of abutments, including: damping

factor of base isolator, friction angle of reinforced soil, and input acceleration frequency. Parametric study results in terms of incremental displacement profiles of deck footing as well as facing due to applying seismic excitations in 2-abutment models are shown in Figure 3.

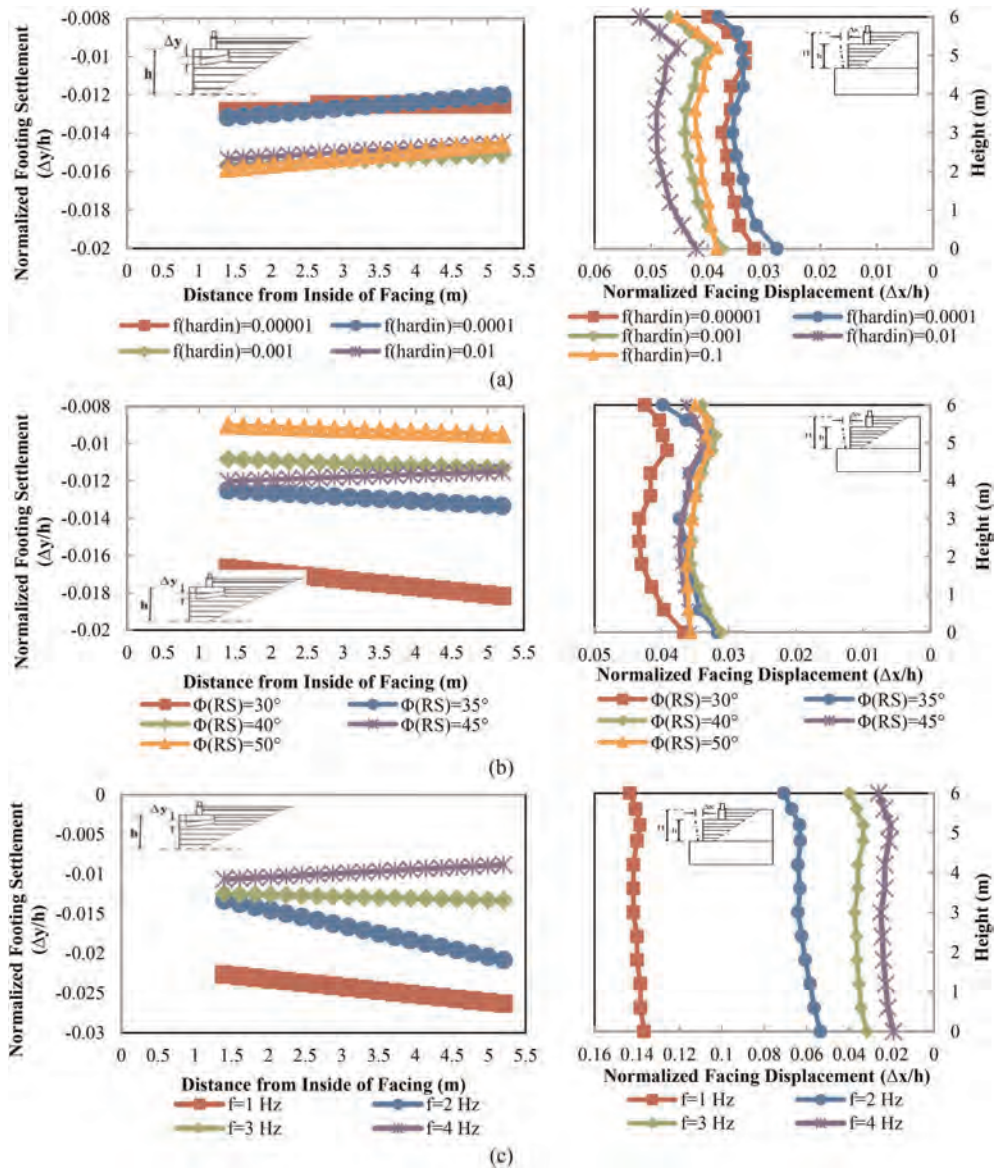
Fakharian & Nasrolahzadeh (2017) showed that damping characteristic of Hardin factor 0.00001 was more compatible with laboratory test results than Hardin factor 0.001. To investigate the effects of this factor, damping of base isolator has decreased with the increase of Hardin coefficient from 0.00001 to 0.1. As shown in Figure 3a, with the increase of


Figure 3. Incremental displacement profiles of deck footing and facing after applying seismic excitations in 2-abutment models with different parameters of: (a) base isolator damping Hardin factor; (b) friction angle of reinforced soil; (c) frequency of input ground motion.

Hardin coefficient of base isolator and consequently a decrease of damping, the horizontal deformation of the facing has increased. As the existence of a base isolator generally separates the performance of the substructure from the bridge deck, it is not expected to have a significant effect on the results and performance of the substructure. According to Figure 3a, the settlement of deck footing has also increased with the increase of Hardin coefficient and the reduction of damping.

The seismic response of the reinforced soil abutment is evaluated by changing the internal friction angle of reinforced soil (φ_{RS}) from 30° (assuming a relatively loose sand) to 50° (assuming very dense sandy gravel). By increasing φ_{RS} of reinforced soil, the resistance of the soil mass increases and the horizontal displacement of the facing decreases (Figure 3b). With increasing φ_{RS} of the reinforced soil, in addition to less movement across the facing height, the facing has undergone less deformations in general and hence has better preserved its straight shape.

The response of the reinforced soil abutment was evaluated by changing the frequency (f) of input wave from 0.5 to 4 Hz (0.5, 1, 2, 3 and 4 Hz). Due to the plastic deformations that occurred under input excitation with the frequency of 0.5 Hz, the entire system has undergone large displacements and it made the results of this analysis unreliable. Therefore, the results of the model with frequency of 0.5 Hz have not been taken into account. In the case that the input wave frequency was equal to 1 Hz, the bridge deck system and the middle column remained stable, but the foundation soil mass was severely deformed. In this case, after applying the harmonic wave for 4 seconds, the analysis became unstable due to large deformations that occurred in the soil mass and the analysis was stopped. This problem can be attributed to resonance occurrence. The natural frequency of the system and resonance is discussed in the following section. As shown in Figure 3c, the greatest change in the horizontal displacement of facing as well as settlement of the deck footing are related to the model with frequency of 1 Hz.

5 CONCLUSIONS

The most important findings of the study are summarized below:

- Embedding a base isolator between bridge deck and footing, the performance of bridge deck and deck footing supported on reinforced wall is isolated. This isolation contributes significantly to improving the stability of the footing as well as the upper blocks of the facing wall.
- If damping of base isolator decreases, the horizontal deformation of the facing increases. Lower damping of the base isolator means that the characteristic of separating the superstructure from substructure is lower and hence the bridge deck will have a greater impact on the substructure.
- The comparison between the 3 analysis types show that the model with base isolator generates the most reliable results, while the model with 2-abutment but without base isolator is the least accurate. The results of the model without considering the interaction of deck (1-abtment) is more close to the 2-abutment model with base isolator. Therefore, it could be used for quick checks and preliminary analysis considering its simplicity.

Segmental retaining wall system as approach slab's retaining wall reinforcement on active fault line at the Kretek II Flyover's, Yogyakarta, Indonesia

F. Widhiastuti, N.A. Anindita, D.A. Nurjannah & D.S. Harninto
P.T. Geoforce Indonesia, Central Jakarta, Indonesia

ABSTRACT: The Kretek II Flyover is in Yogyakarta. The location of this flyover is in an earthquake potential area and is on an active fault line that crosses the embankment wall of the flyover. GSRW (Geoforce Segmental Retaining Wall) is an MSEW system that will be used for the construction of the approach slab's retaining wall located on the fault line. In the case of this project, GSRW is installed into 3 segments which were separated by dilated concrete. The purpose of the segment's division is to reduce the damage that will occur to the approach slab if there is movement due to faults. Although the displacement distance and the magnitude of the plane caused by the fault cannot be predicted, the GSRW construction is expected to reduce the damage that will occur, because this system can move independently so that the concrete panels are more flexible against shocks. The global stability was then analyzed using PLAXIS 3D software and yield safety factor 1.792 for static analysis and 1.136 for pseudo-static analysis.

1 INTRODUCTION

The Kretek 2 Flyover located in Bantul, Yogyakarta Special Region (DIY) is part of the Java Southern Cross Road (JJLS) project that connects Samas-Kretek and Kretek-Parangtritis. The location of this flyover is in an earthquake potential area and is on an active fault line that crosses one side of the Kretek Flyover approach slab. The approach slab spans up to 125.5 meters with the height as high as 7 meters. GSRW (Geoforce Segmental Retaining Wall) is the system that will be used for the retaning wall construction of the flyover located on the fault line. GSRW is a Mechanically Stabilized Earth Wall that has a concrete facing and reinforced with Polyester Strip anchored from the facing to the body embankment according to the design calculations.

2 IMPLEMENTATION METHOD OF GEOFORCE SEGMENTAL RETAINING WALL ON ACTIVE FAULT LINE AT THE KRETEK II FLYOVER'S

2.1 *Geoforce Segmental Retaining Wall*

Geoforce Segmental Retaining Wall (GSRW) is an earth retaining wall system that consists of layers of compacted backfill material and facing elements made from high-quality precast concrete, also reinforced with a belt or known as GI Strip. The distinction between GSRW and other products lies in the robustness of the structure which has been tested, the competitiveness of the price compared to a similar segmental product, the fast and easy

Figure 1.   Kretek II Flyover's, Yogyakarta, Indonesia.

installation of the structure that affects the time efficiency of the project, and also the aesthetic side which capable of adding the enticing aspect of the constructed segmental system.

The Geoforce Segmental Retaining system is reinforced with the friction belt made out of high tenacity polyester yarn namely GI-Strip. The strip has been specially designed to generate reinforced belt with high tensile strength and friction coefficient. This component is what makes the structure robust. The selection of the tensile strength type is adjusted with the design calculation from the GSRW construction which will be built. Another advantage from GI-Strip is the high durability of the material, resistance from organic bacteria and acidity from the backfill material. The GSRW system is shown in Figure 2.
Figure 2.   Typical of geoforce segmental retaining wall system.

2.2   *Geological conditions*

Based on the Geological Map, the Tirtohargo area is a deposit area of the Young Merapi Volcano (Qmi), namely tuff, ash, breccia, agglomerates, and inseparable lava flows. This area is also an area that is on the fault line. Faults are faults in rock that are formed due to forces originating from within the earth such as tectonic and volcanic forces. Faults are areas of discontinuity (discontinuity) in rock, where there has been significant displacement as a result of rock mass movement due to forces from within the earth. The Opak fault is a fault located around the Opak river, in the Special Region of Yogyakarta. According to the research of several experts, based on the direction of movement of the Opak fault, it is included in the Normal Faults fault, which is a fault that occurs due to the maximum compressive force in the vertical direction, causing one of the rock planes to move downward following the fault plane.

Figure 3.   Geological map at Bantul.

2.3   *Implementation method*

The fault line is expected to cross the Geoforce Segmental Retaining Wall structure. However, the distance of the fault shift that will occur cannot be predicted. The fault shift can occur only a few millimeters to tens of kilometers, while the fault planes can also occur ranging in size from a few centimeters to tens of kilometers.
Figure 4.   Faults line in geoforce segmental retaining wall construction.
Figure 5.   Segment division.

In the case of GSRW Kretek construction, there are some special things that distinguish it from the implementation of GSRW in general.

GSRW Kretek is divided into 3 segments which are separated by dilated concrete. The purpose of this 3-segment division is to reduce the damage that will occur to the approach slab walls if there is movement due to faults. Segment 2 or the middle segment is the area crossed by the fault line and spaced up to a dozen meters from the line.
Figure 6.   Dilated column detail.

One of the advantages of using this system, in this case is that the Geoforce Segmental Retaining Wall (GSRW) system can move independently (behaving like a puzzle) so that the panels are flexible against earthquakes or shocks. What can be done when a fault occurs is to repair or replace only the damaged part.

3   DESIGN METHODOLOGY

3.1   *Soil investigation*

Based on the SPT results, it can be concluded that the area is dominated with loose sand material at the surface until the depth of 3 meters. Therefore, a replacement of up to 1.5 until 3 meters was carried out using gravel sand to increase the bearing capacity.
Figure 7.   Soil data profile.

3.2   *Global stability analysis*

Global Stability Analysis is carried out to determine the safety factor of the segmental wall system to be made. To carry out this analysis, the following parameters are used based on interpretation and assumptions of the soil data because the available data are incomplete.

The analysis was carried out using the finite element method with the Plaxis 3D program with soil modeling as follows. The soil parameters are based on assumptions and the closest

available soil data BH 08. The whole system was then assessed with the activation of the 15 kPa traffic load. The soil parameter is as shown in Table 1, as for the geometry model is as shown in Figure 8 and the analysis yield results as shown below in Figures 9 and 10.

Table 1. Soil data parameter with hardening soil model.

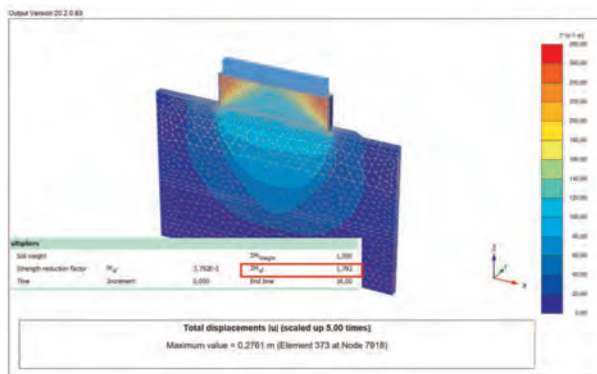
Soil type	Υ_{unsat} [kN/m^3]	Υ_{sat} [kN/m^3]	c' [kPa]	φ' degrees	E_{50}^{ref} [kN/m^2]	E_{oed}^{ref} [kN/m^2]	E_{ur}^{ref} [kN/m^2]	Ψ degrees
Sand, loose	16	18	–	27	20000	14000	60000	0
Sand, very dense	19	20	–	37	90000	63000	270000	7
Sand, dense	17	19	–	33	32000	22400	96000	3
Sand, very dense	19	20	–	37	70000	49000	210000	7
Sand, dense	17	20	–	33	32000	22400	96000	3
Sand, very dense	19	20	–	38	54000	37800	162000	8
Fill	17	19	5	35	30000	21000	90000	5
Figure 8. PLAXI 3D model of GSRW of Kretek II.


Figure 9. Estimation of static failure mode and safety factor of GSRW of Kretek II.
Figure 10. Estimation of pseudo-static failure mode and safety factor of GSRW of Kretek II.

According to Figure 9, the static safety factor for **GSRW** of Kretek II Approach Slab is 1.792. This safety factor fulfills the criteria in Indonesian National Standard for Geotechnical Design Requirements which is above 1.50. After that, the analysis combines with the pseudo-static load which was adopted from design response spectrum in Map of Indonesia Earthquake Sources and Hazards in 2017. The Peak Ground Acceleration value is 0.6 g and multiplied by the amplification factor of 1.0 and 0.5, which results in horizontal acceleration 0.3g. The pseudo-static load analysis yields safety factor 1.136. This safety factor also fulfills the criteria in Indonesian National Standard for Geotechnical Design Requirements for embankment with seismic load which is above 1.10.

4   CONCLUSIONS

GSRW (Geoforce Segmental Retaining Wall) is an MSEW system that will be used for the construction of the flyover wall located on the fault line at the Kretek II flyover. In this case, a replacement of up to 1.5 until 3 meters was carried out using gravel sand to increase the bearing capacity. In the case of this project, GSRW is installed into 3 segments which were separated by dilated concrete. The purpose of the segment's division is to reduce the damage that will occur to the approach slab if there is movement due to faults. Although the displacement distance and the magnitude of the plane caused by the fault cannot be predicted, the GSRW construction is expected to reduce the damage that will occur, because this system can move independently so that the concrete panels are more flexible against shocks. The global stability was then analyzed using PLAXIS 3D software and yield safety factor 1.792 for static analysis and 1.136 for pseudo-static analysis.

ABSTRACT: Roads are permitted to go through some deformation caused by a severe seismic event (so-called Level 2 such as 1996 Kobe and 2011 Tohoku) as long as they could be recovered quickly and easily. The authors have conducted to verify the effect of the countermeasure using geosynthetics sandwiched with gravel layers after a Level 2 seismic event through experiments and dynamic analyses. This countermeasure was found to be effective for maintaining the overall original shape of the embankment by suppressing the stretching of the toe of the embankment. It is legitimate for approach embankments near bridges and box culverts to be designed for a Level 2 seismic event. But because roads are extensive in the longitudinal direction, applying the Level 2 design for the rest of the embankment seems costly, thus Level 1 design approach seems feasible for these locations. Authors have verified the amount of settlement after a Level 1 seismic event (180 gal) by numerical simulations. The authors were able to summarize the settlement levels under various conditions that can be used as reference guidelines for designing embankments.

1 INTRODUCTION

Japan Road Association assigns the required performance for road structures, which are summarized in Table 1. Performance 2 design allows limited deformation that can be easily restored. The Level 1 seismic event is expected to occur once or twice during the service time of the structure (once in 100 years) while the Level 2 seismic event has a very low probability of being experienced by the structure (once in 1000 years).

Importance 1: Highway, national and prefectural roads, roads without alternative routes at the
event of disaster
Importance 2: Not as important as roads classified as Importance 1
Performance 1: Keeps sound condition
Performance 2: Allows limited deformation, easy to restore
Performance 3: Does not totally collapse

The authors conducted research on shallow ground reinforcement structures using geosynthetics. The purpose of this study is to confirm the deformation reduction effect of the embankment over the liquefied ground by the countermeasure. As a result, the effect of

Table 1. Performance of earthwork structure.

Case	Importance 1	Importance 2
Static loading + traffic	Performance 1	Performance 1
Static loading + rainfall	Performance 1	Performance 1
Level 1 Seismic loading	Performance 1	Performance 2
Level 2 Seismic loading	Performance 2	Performance 3

suppressing settlement of the embankment crest by the countermeasure in this study was not sufficient as expected. However, the effect of suppressing the embankment shoulder and slope toe stretching by the countermeasure was demonstrated, and the effect of retaining the shape of the embankment was confirmed by experiment and reproduction, and predictive analysis.

The guideline of Japan Road Association assigns that important roads must sustain the same performance after a seismic event for structures such as bridges, embankments, box culverts, cut slopes and etc., in order to keep the roadability. Because roads are extensive in the longitudinal direction, applying Level 2 countermeasure for their entire span seems too expensive. Although approach embankments near bridges and other structures should consider severe seismic events, Level 1 design approach seems feasible for the remaining embankments. The authors conducted static numerical simulations of a Level 1 seismic event (180 gal) in order to verify the effectiveness of the countermeasure under various ground conditions.

2 DYNAMIC CENTRIFUGAL MODEL EXPERIMENT

2.1 *Experimental outlines*

A 50G dynamic centrifugal model experiment was conducted using a large-scale dynamic centrifugal load test apparatus at the Public Works Research Institute. The outline of the model of countermeasure is shown in Figure 1.
Figure 1. Outline of model ground.

2.2 *Material and seismic wave*

The liquefied layer was prepared by air-drop method using a sand hopper. The target relative density of the liquefied layer was Dr = 50%. A pore water pressure gauge and an accelerometer were set in the middle of the ground. The materials used in the experiment and their properties are shown in Figure 1. The Level 2 seismic wave (1995 Kobe, Japan) was used. The excitation time was 50 sec and the maximum acceleration was 557 gal.

2.3 *Results of dynamic centrifugal model experiment*

2.3.1 *Deformation of embankment*

The settlement of the embankment crest against time for each experiment is shown in Figure 2. The amounts of settlement at the center of the embankment crest and the embankment shoulder at 50 sec are 95 cm and 106 cm in Case 1 and 83 cm and 76 cm in Case 2, respectively. The settlement ratio of with/without the countermeasure is 87% at the center of the embankment crest and 72% at the embankment shoulder. The effect of suppressing settlement of the embankment crest by this method was lower compared to the previous study (Hla Aung 2021). The relation of excess pore water pressure ratio against time is shown in Figure 3. The negative excess pore water pressure ratio which is the same as positive dilatancy occurred during the first 5 sec to 15 sec for the case without the counter-measure, beneath the center of the embankment. This is because the shear deformation occurred at this location which is not compressive deformation by the liquefaction.
Figure 2.   Relation of embankment crest settlement with times.
Figure 3.   Relation of excess pore water pressure ratio against times.

2.3.2 *Factor analysis of embankment deformation*

The stretching amount of the embankment shoulders and toes was defined as the amount of widening in the horizontal direction. The lateral displacement of the liquefaction layer was defined as the maximum lateral displacement of the area directly under the embankment. The deformation of the embankment and liquefied ground after a seismic event are shown in
Photo 1.   Deformation after seismic motion.

Photo 1. The stretching amounts of embankment shoulder without and with the counter-measure are -42 cm (21 cm, -63 cm) and 0 cm (14 cm, -14 cm), respectively. The stretching amount of the embankment toe without and with the countermeasure is 90 cm (89 cm, 1 cm) and 28 cm (9 cm, 19 cm), respectively. The embankment shoulder and toe stretching are greatly suppressed. It can be noted that the reduction of the liquefaction-induced deformation of the embankment by the countermeasure.

3 TWO-DIMENSIONAL DYNAMIC EFFECTIVE STRESS ANALYSIS

The 2D dynamic effective stress analysis program, LIQCA2D21, was used to reproduce the experimental results and predictive analyses under multiple conditions.

3.1 *Reproduction analysis*

LIQCA2D21 can reproduce the liquefaction of the ground and evaluate the excess pore water pressure, the deformation of the ground, and the embankment. A preliminary analysis was carried out for the purpose of reproducing the model experiment.

3.1.1 *Analysis conditions*
Analyses cases are Case 1 and Case 2 for without and with the countermeasures. The analysis mesh for Case 2 is shown in Figure 4. A drainage boundary was fixed at a depth of 1 m from the ground surface and the other surfaces are non-drainage boundaries. A 1m non-liquefaction layer was set around the crushed stones because the drainage effect of the crushed stone causes a smaller increase of excessive pore water pressure around the crushed stones and this was verified in the previous study (Hla Aung 2021). By setting the non-liquefaction layer, the analysis well replicated the experimental results.
Figure 4.   FEM model.

3.2 *Analysis results*

3.2.1 *Embankment crest settlement*
Figure 5 shows the settlement of the embankment crest against time. The final settlement at the center of the embankment crest shows a larger value than the experiment in Case 1. The
Figure 5.   Relation of embankment settlement against times(Experiment · Simulation).

final settlement amount of the analysis of Case 1 is about 30% larger than the experimental value. Although the embankment settlement value obtained by the analysis is larger than the experimental value, the effect of settlement retention by the countermeasure can be expressed.

Figure 6 shows the relation of excess pore water pressure ratio against time. The excess pore water pressure ratio of the experiment and simulation of Case 1 is close to each other at the initial stage. After 5 sec, the analysis value of excess pore water pressure is about 7 times larger compared to the experiment. These results caused the settlement of analysis to enlarge compared to that of the experiment without the countermeasure shown in Figure 5.
Figure 6.   Relation of excess pore water pressure ratio against times(Experiment · Simulation).

3.2.2 *Deformation retention effect*
Figure 7 shows the deformation of the liquefied ground and embankment at the end of the vibration. The amount of stretching of the toe in Case 1 and Case 2 are 96 cm (57 cm, 39 cm) and 15 cm (10 cm, 5 cm) respectively. According to the above reproduced analysis results, it is possible to analytically confirm the effect of the countermeasures on the deformation reduction of the embankment.
Figure 7.   Deformation after seismic motion.

3.3 *Predictive analyses*

The predictive analyses were performed to verify the effects of the countermeasure under various conditions.

3.3.1 *Analysis conditions*
Analysis conditions are as follows: embankment heights of 2 m, 6 m, and 10 m, and liquefaction thicknesses of 5 m and 10 m. The embankment width and slope are 12 m and 1.5 m, respectively. The relative density of 50% and 70% of the liquefied ground and the Level 2 seismic motion are used in the predictive analysis.

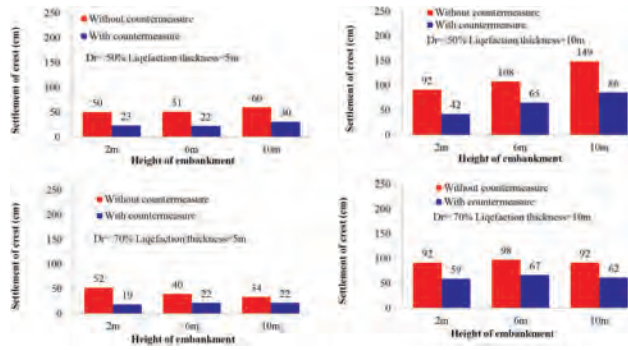
3.3.2 *Analysis results*
The embankment crest settlements are shown in Figure 8. All the results are arranged at the excitation time of 50 sec.


Figure 8.   Settlement of embankment crest.

In the case of the relative density of 50%, the settlement of the embankment crest increases as the embankment height increases. On the other hand, in the case of the relative density of 70%, the amount of settlement does not necessarily increase with the height of the embankment. A height of more than 6 m reveals the phenomena of less settlement occurrence due to the effective stress influences.

Although the effect differs from case to case, the embankment crest settlement ratio (with/ without the countermeasure) is 35% to 68%.

4   THE EFFECTIVENESS OF COUNTERMEASURE KEEPING EMBANKMENT SHAPE

The experiments and dynamic analysis show that the countermeasure refrains the embankment from spreading. It is similar to the deformation pattern IV in Figure 9, which appears in the guideline of road disaster countermeasure handbook published by Japan Road Association. The pattern illustrates the settlement without indifferential settlement and deformation while keeping the overall shape of the embankment. In this case, settlement below 50 cm is enough for a vehicle to pass. But it should be noted that the settlement of approach embankments, similar to Pattern V in Figure 9, must be below 20cm.

Figure 9.   Classification damage patterns.

5   LEVEL 1 SEISMIC EVENT'S STATIC FINITE ELEMENT ANALYSIS

5.1   *Analysis condition and summarized simulation results*

The static finite element analysis program, ALID (Analysis for Liquefaction-Induced Deformation), is used to predict embankment settlement in Level 1 seismic. Analyses are

conducted under various conditions of embankment heights (2 m, 6 m, 10 m), groundwater levels (GL-0 m, 1 m, 2 m), and liquefied ground thickness (3 m, 9 m,15 m).

5.2 *An example of estimation of settlement at the embankment crest*

An example of the estimation of settlements of the 5 m height embankment, under the condition of 1 m no liquefaction layer (groundwater level -1 m) and various liquefaction layers and $RL_{0.2}$, $RL_{0.25}$, are shown in Figure 10.

The settlement of the embankment at the crest of any thickness of liquefaction layers and RL values could be estimated using the two approximate equations shown in Figure 10.

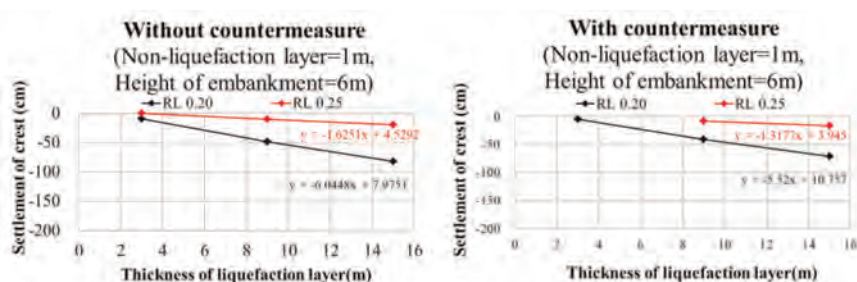
The static finite element analyses results under Level 1 seismic condition (180 gal) simulate the amounts of the settlements. These results will be used as a reference guideline so that the road administrators could obtain the settlement of the embankment with a countermeasure without conducting a static finite element analysis.


Figure 10.   Settlement prediction for level 1 seismic.

6 CONCLUSIONS

In case of a severe seismic event, Level 2, and for a road that requires Performance 2, geosynthetics sandwiched with gravel layers have been proved as a potential countermeasure that tolerates some deformation that can be restored easily.

Experiments and dynamic finite element analysis show that the countermeasure prevents the stretching of the toe of the embankment.

The static finite element analyses results under Level 1 seismic event (180 gal) simulate the amounts of the settlements. These results will be used as a reference guideline so that the road administrators could obtain the settlement of the embankment with a countermeasure without conducting a static finite element analysis.

Seismic performance assessment of approach embankment MSE wall near Valley Fault System

R.A. Luna, R. Quebral, A. Paulino, J.V. Razon, P.A. Selda & J.M. Tanap
AMH Philippines Inc., Quezon City, Philippines

ABSTRACT: This paper presents the assessment of the adequacy of a Mechanically-Stabilized Earth (MSE) wall, reinforced with steel geostraps, for a bridge approach within Metro Manila, located few kilometers away from the active West Valley Fault (WVF). Performance of the MSE Wall under static and seismic conditions were assessed using two approaches: (1) Limit Equilibrium Method (LEM) by GLE/Morgenstern-Price Method; and (2) Deformation Analysis by Finite Element Method (FEM). The study demonstrates that while inadequate factors of safety under seismic loading may be obtained using LEM, earthquake-induced deformation values are found to be within tolerable limits for lower-hazard design levels. It was also established that designing the geostrap reinforcement to fully withstand higher-hazard ground motions may be uneconomical for the available wall material. Nevertheless, cost-effectiveness of the design may also be achieved by allowing some deformation to the structure in case of higher-level earthquakes, while maintaining serviceability in keeping with current seismic design philosophy.

1 INTRODUCTION

Traffic congestion in Metro Manila, Philippines ranks among the highest in the world, necessitating construction of new roads and bridges to interconnect the various cities within the National Capital Region. Considering the dense urban population, efficient utilization of land is imperative. Thus, the use of vertical Mechanically Stabilized Earth (MSE) Wall for the approach embankment of a bridge is preferred over sloped embankments. Assessment of the seismic response of these walls is also imperative given the susceptibility of Metro Manila to seismic hazards such as ground motion and liquefaction.

This paper presents the slope stability analysis of a 400-meter long bridge with Mechanically Stabilized Earth (MSE) wall, reinforced with steel geostraps, at the approach embankment. Based on the 2021 Fault Map published by Philippine Institute of Volcanology and Seismology (PHIVOLCS), the proposed bridge is located approximately 330 meters from the West Valley Fault (WVF) which can produce a 7.2 magnitude earthquake. The structure was analyzed under both static and pseudo-static (level 1 and 2 earthquakes) conditions. Factors of safety for different soil saturation scenarios were assessed using the Limit Equilibrium Method (LEM). Meanwhile, Deformation Analysis by Finite Element Method (FEM) was used to determine the resulting deformations where the Factors of Safety were found to be inadequate.

2 GEOTECHNICAL EVALUATION AND SEISMIC DESIGN CONSIDERATIONS

2.1 *Idealized subsurface conditions and geotechnical parameters*

The idealized subsurface at the abutments, which were obtained from borehole data, and the corresponding geotechnical parameters for each layer are shown in Table 1.

Table 1. Idealized subsurface conditions.

Depth, m	USCS Classification	SPT N-value	Relative Condition / Consistency	Soil Type	Geotechnical Parameters		
					γ, kN/m^3	S_u, kPa	ϕ, deg
Abutment 1							
0.0 – 3.0	MH / CL	12 – 27	Stiff to Very Stiff	Clay	18	96	0
3.0 – 7.0	CH / MH [SM]	37 – 'refusal'	Hard	Clay	20	196	0
7.0 – 25.0	Rock	'coring'	9% – 55% Recovery RDQ = 0%	Sand	20	0	36
Abutment 2							
0.0 – 4.0	SM / SC-SM / SC	14 – 18	Medium Dense	Sand	18	0	30
4.0 – 9.0	SC / SW / SM	32 – 'refusal'	Dense to Very Dense	Sand	19	0	34
9.0 – 25.0	Rock	'coring'	13% – 67% Recovery RDQ = 0% – 20%	Sand	20	0	36

2.2 *Site class and design accelerations*

Based on the National Structural Code of the Philippines (NSCP) 2015 Table 208–2 and Department of Public Works and Highways (DPWH) – Bridge Seismic Design Standards (BSDS) 2013 Table C3.5–1, the subsurface underlying the bridge site can then be described as stiff soil (site class S_D) or Type II ground. The code-prescribed site class was further verified through a geophysical test data, wherein the average or representative shear wave velocity of the subsurface underlying the area is approximately 259.82 m/s.

Since the bridge location is in close proximity to the West Valley Fault, seismic loading and the consideration of near-source effects are crucial in the design. For bridge structures, DPWH-BSDS 2013 adopts a Performance-Based Design (PBD) approach, wherein two (2) earthquake levels are utilized in the evaluation of displacements and forces/stresses—Level 1 (100-year return period or 53% probability of exceedance in 75 years) and Level 2 (1000-year return period or 7% probability of exceedance in 75 years).

Following the seismic provisions of DPWH-BSDS 2013 Table 3.5.3–1 to Table 3.5.3–3, the recommended seismic parameters for Ground Type II are shown in Table 2.

Table 2. Seismic design parameters considering ground type II.

Earthquake Ground Motion	PGA*	A_S**	S_{DS}***	S_{DI}****
Level 1	0.12	0.19	0.47	0.28
Level 2	0.60	0.53	1.10	0.70

Notes
*PGA: Peak Ground Acceleration Coefficient
**AS: Effective Peak Ground Acceleration Coefficient

****$SD1$: Design Earthquake Response Spectral Acceleration Coefficient at 1.0-s period

3 SLOPE STABILITY ANALYSIS

The slope stability analysis (SSA) is done by LEM using the GLE/Morgenstern-Price Method for both circular and non-circular analyses of the embankment/s.

3.1 *Mathematical model*

Figure 1 presents the models of the sections that were analyzed. The sections selected for the analysis are located at the highest elevations within the embankment of each of the bridge
Figure 1. Abutment 1 (left figure) and abutment 2 (right figure) section LEM model.

abutments. These sections are extracted from the conceptual drawings and simplified for the analyses.

The subsurface idealization shown in the LEM models are based on the idealization previously presented in Table 1. Meanwhile, the geotechnical properties for the engineered materials used in the analysis are shown in Table 3. Moreover, the material properties of the geostraps used in the analysis are shown in Table 4.

Table 3. Engineering materials for LEM analysis.

Layer no.	Soil ID	γ, kN/m3	c, kPa	ϕ, deg
Level 1	Select Backfill	18	5	30
Level 2	Foundation Fill	20	5	35

Table 4. Geostrap properties (specified in conceptual drawings).

Length, m	Vertical Spacing, m	Tensile Strength, kN/m
6.13	0.75	29.0 to 55.3

To simulate the traffic load on the approach road upon operation of the bridge, a uniform load of 15.0 kPa is applied on the surface of the model. This live load induces additional surcharge loading to the embankment in the form of lateral earth pressure based on Boussinesq's theory. This may drive the slope to instability or may cause excessive deformation.

Aside from the static lateral earth pressure due to the surrounding structures, earthquakes can induce considerable destabilizing inertial force and permanently degrade the effective shear strength of the soil mass due to the stress and fatigue resulting from the prolonged exposure to cyclic loading. The pseudo-static method is the simplest and most common method in evaluating the stability slopes during earthquakes. Constant seismic coefficients are taken as fractions of the PGA in the idealization. The pseudo-static seismic load induces a horizontal inertial force—$k_h W$, and a vertical inertial force—$k_v W$—where the parameters k_h is the horizontal seismic coefficient, W is the weight of the potential sliding mass, and k_v is the vertical seismic coefficient. Note that the vertical seismic coefficient shall be applied for both upward and downward directions.

In the Philippines, it is common practice to adopt a k_h value taken as half of the surface PGA in accordance with the works of Hynes-Griffin & Franklin in 1994 and Kavazanjian *et al.* in 1997. On the other hand, k_v usually falls within one-fourth (25%) to two-thirds

(66.67%) of its horizontal counterpart. For simplicity, the k_v value was taken as one-half (50%) of k_h.

Based on the seismic provisions of DPWH BSDS 2013, the expected surface PGA is estimated to be 0.53g for the bridge site. The corresponding horizontal and vertical seismic coefficients for both ground motions are summarized in Table 5 for each analysis scenarios.

Table 5. Global slope stability analysis scenarios.

Case	r_u	k_h	k_v	Minimum Allowable FS
1 Long-term static (dry conditions)	0.0	0.0	0.0	1.5
2 Static with moderate porewater pressure	0.2	0.0	0.0	1.3
3 Dry condition with Level 1 earthquake	0.0	0.095g	±0.0475g	1.1
4 Dry condition with Level 2 earthquake	0.0	0.265g	±0.1325g	1.1

3.2 Analysis scenarios

High-intensity rainfall is expected to happen several times a year considering the climate of the Philippines. Conditions wherein pore water pressure build up becoming quite excessive is therefore plausible. The pore water pressure ratio, r_u, is defined as the fraction of pore water pressure to the total vertical pressure exerted by soil. This ratio represents the saturation level of the soil mass in case of a rainfall event. It assumed that adequate drainage is in place at the site which prevents saturation of the soil. As such, only moderate saturation was considered in the analysis. An r_u value of 0.2 would simulate a soil condition of moderately saturated soil. On the other hand, a water surface would be defined for the soils completely below the water table.

An acceptable factor of safety (FS) is based on various considerations such as the recurrent period of rainfall, seismic activity, as well as the assessment of risk or hazard brought about by the slope failure. With these factors considered, recommended factors of safety for static conditions range from 1.3 to 1.5 and a value greater than unity (>1) for earthquake conditions. The minimum allowable FS values for the different analysis scenarios are shown in Table 5.

3.3 Slope stability analysis results

Rocscience Slide 6.0® , a slope stability computer software, was utilized to facilitate calculations for determining the global stability of the embankments. The abutment sections analyzed generally yielded inadequate FS values. FS values for the abutment 1 section under static conditions range from 1.113 to 2.527. Pseudo-static conditions produced FS in the range of 1.239 to 2.263 for Level 1 ground motion and 1.098 to 1.783 for Level 2 earthquake. Abutment 2 section generally produced inadequate FS in all cases considered in the analysis. Table 6 shows the results.

The results of the analysis indicate that the abutment sections have inadequate Factors of Safety under static and Level 2 pseudo-static loading conditions. As such, further analysis is warranted to determine the magnitude of deformations which will be discussed in the following section.

4 DEFORMATION ANALYSIS

The failure surfaces determined from slope stability analysis are not deep-seated in nature. This suggests that localized, shallow failure is more critical than global instability. It should also be noted that the failure planes are typically located along the MSE composite walls.

The primary criterion for designing slope protection systems is the serviceability performance in terms of both vertical deformation (e.g. settlement, heaving) and lateral deflection.

Table 6. Summary of LEM results for approach road embankment of the proposed bridge.

Section	Analysis Type	r_u	Required FS	FS Right Side		FS Left Side	
				Circular	Non-circular	Circular	Non-circular
Abutment 1	Long-term static	0.0	1.5	2.531	1.230	2.527	1.246
	Static with rainfall	0.2	1.3	2.281	1.117	2.283	1.113
	Pseudo-static (Level 1)	0.0	1.1	2.248	1.239	2.263	1.241
	Pseudo-static (Level 2)	0.0	1.1	1.783	1.100	1.720	1.098
Abutment 2	Long-term static	0.0	1.5	1.300	1.019	1.312	0.892
	Static with rainfall	0.2	1.3	1.019	0.772	1.105	0.775
	Pseudo-static (Level 1)	0.0	1.1	1.218	1.042	1.203	0.904
	Pseudo-static (Level 2)	0.0	1.1	0.967	0.787	0.961	0.794

As such, deformation analysis will be performed using FEM to establish both the static and seismic performance of the MSE composite wall. The critical section from LEM was selected for the analysis.

Section 11.10.4 of AASHTO LRFD 2012 details the maximum deformation criteria for MSE walls. For MSE walls with full height precast concrete facing panels, total settlement should be limited to 2.0 in (50 mm) for the seismic conditions. However, given the width of the approach road, it is more crucial to apply this criterion on the road instead of the MSE walls for overall stability. Since lower settlements are expected in normal condition, an allowable settlement of 1.0 in (25 mm) is set for static conditions. The limiting differential settlement should be 1/500.

The maximum allowable lateral displacement of MSE wall, as prescribed by BS 8006 Code of Practice for Strengthened/Reinforced Soils and Other Fills, may be taken as 0.5% of the height of the supported embankment for the static condition. For the pseudo-static case, twice the allowable deflection for the static case or 1% of the height of the supported embankment may be set.

4.1 Soil constitutive model

The primary constitutive model adopted is the Hardening Soil Small-strain (HSS) model (Benz 2007; Schanz et al. 1999). The HSS model is a constitutive model that can vary stiffness depending on the stress state of the soil elements for both small and high strain levels. This is an ideal constitutive model for excavation projects because certain regions of the soil mass may possibly experience different stress state and conditions than those adjacent to them. It should be noted that the HSS model utilizes the Mohr-Coulomb (MC) yield criterion and the model's corresponding shear strength parameters. Due to the lack of advanced lab testing, the HSS parameters were correlated from reported/published values of soil samples with similar relative conditions and/or consistencies to the soil samples obtained from the study area.

PLAXIS, a geotechnical finite element analysis software, was used to obtain the expected deformations. In PLAXIS, the HSS model can generate the Modulus Reduction and Damping Curves by modifying the stiffness model developed by Hardin & Drnevich (1972). The modification revolves around a characteristic shear strain value at 70% stiffness ($\gamma_{0.7}$).

4.2 Deformation analysis results

Table 7 summarizes the deformations obtained from FEM of the critical section at normal (static) conditions. It could be observed that the resulting displacements are well within the tolerable limits.

Table 7. Summary of deformations for approach road embankment (static).

Scenario	Exposed Wall Height, m	Allowable Deformation, mm	Estimated Deformation, mm	Remarks
Left Wall Deflection	6.3	31.5	2.69	Satisfactory
Right Wall Deflection	6.3	31.5	2.67	Satisfactory
Road Settlement	-	25.0	8.57	Satisfactory

Table 8 presents the displacements under pseudo-static loading. Level 1 seismic event would yield tolerable deformations whereas a Level 2 earthquake would produce significant deflection of the embankment walls. A 475-yr earthquake, which has an approximate PGA value of 0.45g, was incorporated in the analysis for comparison, as this seismic design level/loading is adopted on other structures as prescribed by NSCP 2015. Likewise, excessive deformations were also obtained under the 475-year earthquake. As for the road settlement, acceptable values were calculated for all the pseudo-static cases.

The design of the MSE wall of the approach was iterated to come up with a scheme which would decrease the magnitude of the expected deflections. For the geostraps, the vertical spacing installation can be adjusted to 0.60 meters, and their lengths increased to 10 meters. The precast MSE panel was thickness was also adjusted to 200 mm with a compressive strength of 28 MPa.

Table 8. Summary of deformations for approach road embankment (pseudo-static).

Scenario	Exposed Wall Height, m	Allowable Deformation, mm	Estimated Deformation, mm		
			Level 1	Level 2	475-year
Left Wall Deflection	6.3	63.0	55.30	213.90	166.10
Right Wall Deflection	6.3	63.0	60.02	228.70	181.10
Road Settlement	–	50.0	11.95	32.51	27.02

Table 9 presents the resulting deformations from the proposed scheme. Deformations for Static and Level 1 cases are still within the tolerable limit. However, considerable deflections are still expected for the Level 2 and 475-yr earthquake events, albeit at a lesser degree compared to the original scheme (approximately 10 to 30 mm difference). With that, immediate repairs are still warranted if a Level 2 or 475-yr earthquake occur.

Table 9. Resulting deformations from iteration.

Scenario	Estimated Deformation, mm			
	Static	Level 1	Level 2	475–year
Left Wall Deflection	2.24	52.80	195.40	155.70
Right Wall Deflection	2.05	52.77	195.30	155.80
Road Settlement	7.31	6.86	16.56	12.33

5 CONCLUSIONS AND RECOMMENDATIONS

Designing the approach roads for a Level 2 earthquake may be impractical given that excessive deformations are expected. As such, it is proposed to design the approach embankment considering a 475-yr earthquake which minimizes the expected settlement to 25 mm while implementing minimal changes to the original scheme. To achieve this, it is recommended to use 7.0-meter length geostraps, which will be installed at the original vertical spacing of 0.75 m and use a precast MSE wall panel with at least 175 mm thickness. It is important that the internal stability of the geostraps is assessed. It should also be noted that any changes in the original design would require additional costs. As such, evaluation of the cost-effectiveness of the scheme is recommended.

Aside from the proposed scheme, the following are recommended to improve the stability and minimize the possible deformations of the approach embankment: (1) ensure that adequate drainage is implemented during construction to guarantee the relief of porewater pressure and (2) ensure that surface drainage atop the road embankment, as well as at the toe/base, are installed post-construction. Moreover, the construction methodology (staged construction, compaction, quality control and assurance) of the embankment must guarantee stability during various stages of the construction and mitigate slope failures.

Gravel-rubber mixtures as geotechnical seismic isolation systems underneath structures: Large-scale tests vs FEM modelling

G. Abate, A. Fiamingo & M.R. Massimino
Department of Civil Engineering and Architecture, University of Catania, Italy

D. Pitilakis, A. Anastasiadis, A. Vratsikidis & A. Kapouniaris
Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT: According to the sustainable growth, the need for low-cost seismic isolation systems has led to proposals of new projects. The use of granular soils mixed with granulated rubber derived from scrap tires as a layer underlying the foundations of structures represents a solution for the mitigation of seismic risk and the management of waste tires.

Only a few small-scale experimental studies on this subject are available in the literature. The first experimental campaign on a full-scale prototype structure founded on gravel-rubber mixtures (GRMs) with different rubber content per weight was recently carried out in Thessaloniki (Greece). Ambient noise, free- and forced-vibration tests were performed.

This paper shows a comparison between the results achieved during the forced-vibration tests and the results obtained by a non-linear 3D FEM modelling of these tests. This comparison allowed us to investigate the isolation capacity of GRMs and the effects of the rubber content per weight.

1 INTRODUCTION

Over the last decades, seismic isolation has been widely used as an effective strategy in the earthquake-resistant design of structures. The traditional systems, such as elastomeric bearings, sliding elements, and friction-pendulum systems, are quite expensive economically and technically for conventional buildings. In addition, traditional systems produce large volumes of waste both in production and at end-of-life disposal. So, according to the circular economy and sustainable growth, the need for low-cost seismic isolation systems has led to proposals for new projects.

In this context, Geotechnical Seismic Isolation (GSI) is a potential technique to mitigate the effects of seismic motion on superstructures. The main idea is to improve the mechanical properties of the foundation soil and dissipate the seismic motion before reaching the structure (Tsang 2022). Among several materials, soil-rubber mixtures (SRMs) represent an eco-friendly and low-cost solution. The use of end-of-life tires (ELT) for the rubber particles in the mixtures can provide a modern recycling system to reduce the considerable stockpile of scrap tires worldwide. On the other hand, SRMs are considered an affordable alternative for the seismic isolation of conventional structures, especially in developing countries having limited financial resources. SRMs have been investigated in the last years (Anastasiadis *et al*. 2012; Pistolas *et al*. 2018), demonstrating that their use is advantageous due to their good static and dynamic properties. Few small-scale experimental studies are available in the literature. Just one experimental campaign on a full-scale prototype structure founded on three different gravel-rubber mixtures (GRMs) was recently performed in Thessaloniki

(Greece) in the framework of the European Research Program SOFIA-SERA (Abate *et al.* 2022; Pitilakis *et al.* 2021). The three GRMs had variable rubber content per weight, equal to 0%, 10%, 30%, labelled as GRM 100/0, GRM 90/10, and GRM 70/30, respectively. Ambient noise tests and free- and forced-vibration tests were carried out.

This paper shows the main results achieved during the forced-vibration tests and by a 3D FEM modelling of these tests. The performed forced-vibration experiments were carried out in a frequency range of 1-10 Hz to include the fixed- and flexible-base natural frequencies of all three GRM-structure systems. This paper deals with the results concerning the structure founded on the GRM 100/0 and 70/30 layers, subjected to the input frequency equal to 4 Hz and 2.5 Hz, close to the fundamental natural frequency of the systems, using GRM 100/0 and 70/30, respectively.

The foundation soil and the GRMs were modelled by advanced visco-elasto-plastic constitutive model. The structure was modelled by a linear visco-elastic constitutive model.

The numerical results were successfully compared to the experimental ones. Moreover, the numerical simulation allowed to study more in-depth the dynamic behaviour of the GRMs, also considering the shear strains vs the shear stresses in the middle of the GRM layer and represent a valuable tool for future analyses.

2 THE LARGE-SCALE EXPERIMENTAL CAMPAIGN

EuroProteas prototype is the first full-scale model structure in Europe (at the Euroseistest facility, 30km NE of Thessaloniki in Greece), designed to study dynamic soil-structure interaction (DSSI) (Figure 1). It is a perfectly symmetric steel frame, on a reinforced concrete (RC) slab supporting two RC slabs, having the same size as the foundation slab (3.00x3.00x0.40 m). Steel X-braces (section L100×100×10 mm) connect the four steel columns (section QHS150×150×10 mm) in both directions.

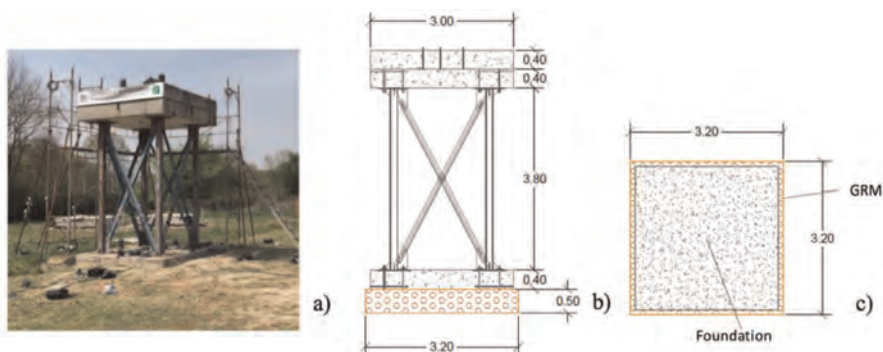
The foundation soil was investigated using extensive geotechnical and geophysical surveys, including static and dynamic in-situ and laboratory tests (Pitilakis *et al.* 2018). The subsoil consists of a 7 m thick upper layer of silty clayey sand, which overlies a layer of clayey to silty sand with gravels between 7 and 22 m and, after that, a layer of marly silt to silty sand until the depth of 30 m. More precisely, the soil profile can be subdivided into eight layers, called A, B, C, D1, D2, E1, E2, and F, whose main properties are shown in Table 1. More details are reported in Abate *et al.* (2017). The uppermost 0.50 m of the foundation soil was replaced with three different GRM backfills (Figure 1). The rubber content per mixture weight (p.w.) was fixed equal to 0%, 10%, and 30% for the three foundation mixtures, so labelled as GRM 100/0, GRM 90/10, and GRM 70/30, respectively. The gravel was characterized by $D_{50,G} = 20.76$ mm and $G_{s,G} = 2.67$. The granulated rubber was characterized by


Figure 1. (a) Photo, (b) section and (c) plan view of EuroProteas with the adopted GRM underneath the foundation (lengths in meters).

Table 1. Main properties for EuroProteas subsoil.

Layer	z(m)	V_s (m/s)	G_0 (kPa)	D_0 (%)	γ_d (kN/m^3)
A	0.5–3	100	21407	2.5	21.0
B	3–5	125	32652	3.0	20.5
C	5–8	170	58919	3.0	20.0
D1	8–13	210	89908	2.5	20.0
D2	13–17	210	89908	2.5	20.0
E1	17–20	260	137819	2.5	20.0
E2	20–24	260	137819	2.5	20.0
F	24–30	300	183486	1.7	20.0

$D_{50,R}$ = 3.27 mm and $G_{s,R}$ = 1.10. The ratio $D_{50,R}/D_{50,S}$ is less than unity. As for the mixtures, the main physical properties are reported in Table 2. The V_s values for the GRM's layer were obtained from G_0. The $G/G_0(\gamma)$ and $D(\gamma)$ curves for the mixtures GRM 100/0 and GRM 70/30 were achieved according to Menq equations (2003) and Pistolas ones (2015), respectively. Just the effects of these two mixtures are discussed in the present paper, because the experimental results did not show valuable differences in the behaviour of the analysed system using GRM100/0 and GRM90/10 (Pitilakis *et al*. 2021).

Table 2. Main properties of GRM100/0 and GRM 70/30.

GRM ID	$D_{50,R}/D_{50,R}$	G_s	D_r (%)	γ_d (kN/m^3)	G_0 (kPa)	D_0 (%)	V_s (m/s)
GRM100/0	–	2.67	98	16.2	60044	1.0	192
GRM70/30	0.16	2.19	59–71	11.8	2600	2.7	45

Ambient noise tests, free- and forced-vibration tests were performed at different excitation levels, with and without rubberized soil underneath the foundation. This paper deals with the forced-vibration tests. The input force was applied at the geometrical centre of the structure's roof by an eccentric mass shaker. The produced harmonic force was applied along the structure's principal axis at approximately 30° angle with the magnetic N-S direction. The output force amplitude is adjusted by the eccentricity and the operating frequency according to the equation $F_{sh} = E \cdot (2\pi f)^2$, where F_{sh} is the shaker force (in N), E is the eccentricity of the shaker (in kg-m), and f is the rotational velocity of the shaker (in Hz). The frequency range is 1-10 Hz to include the fixed-base natural frequency (equal to 9.13 Hz) and the flexible-base ones of all three GSI-structure systems (equal to 4.0 Hz and 2.5 Hz, for the systems resting on GRM 100/0 and GRM 70/30, respectively), evaluated by means of the ambient noise tests (Pitilakis *et al*. 2021). The tests characterized by the eccentricity equal to 6.93 kg-m and carried out at 4 Hz and 2.5 Hz, respectively, for the GRM 100-0 and 70-30, are here analysed and numerically simulated being characterized by frequencies next to the first resonant frequencies of the investigated systems. A dense instrumentation scheme was designed to evaluate the response of the structure, the foundation, the GRM layer, and the adjacent soil in the vertical "Z" and horizontal "N" and "E" directions.

3 THE 3D SOIL-GRM-STRUCTURE FEM MODELLING

The above-discussed forced-vibration tests were simulated by a 3D finite element model using the MIDAS FEA-NX (2022) code. Figure 2a shows the mesh of the whole soil-GRM-structure system. The soil layers subdivision was performed according to Table 1, but just the layers from A to E1 were modelled (Figure 2b) to minimize the computational efforts. Free
Figure 2. (a) 3D FEM model of the fully coupled soil-GRM-Europroteas structure; (b) details of the mesh.

field edges were defined along the lateral boundaries of the 3D model, to simulate the infinitely far conditions and to prevent the reflection of waves from the model boundaries. Viscous dampers connected the lateral boundaries of the model to the free-field edges. The viscous damper coefficients, according to P and S waves, were calculated automatically by the MIDAS FEA-NX code. The 3D model was fixed at the base. The columns and X-braces were modelled by beam elements. Solid elements were used to model the soil layers and the three slabs. The sizes of the mesh elements were fixed to reproduce all the waveforms of the whole frequency range under study. Contact surfaces were used between the foundation and the GRM to model uplifting and/or sliding phenomena. The Rayleigh damping was considered, evaluating the coefficients α_R and β_R according to the double frequency approach (Fiamingo et al. 2022; Massimino et al. 2019). The natural circular frequencies of the first two modes of the system response (ω_1 and ω_2) were adopted. As for the structure, a damping ratio equal to 3% was assumed for the steel elements and a value of 5% was considered for the concrete slabs. As for the soil, the values of the damping ratio reported in Table 1 were used. A harmonic displacement input was applied at the structure's roof in the x-direction according to the shaker force F_{sh} used during the tests (F_{sh} = 4.38 kN and F_{sh} =1.71 kN for the configuration with GRM100/0 and GRM70/30, respectively). The structure was modelled considering a linear visco-elastic behaviour, assuming E = 31500 MPa, $\nu = 0.2; \gamma =$ 25 kN/m^3 for the concrete slab and E = 210000 MPa, $\nu = 0.3; \gamma$ = 75 kN/m^3 for the steel elements. The GRM layers and the soil layers from A to C were modelled by the visco-elasto-plastic HSsmall constitutive model, whose parameters are reported in Table 3. The HSsmall constitutive model is an isotropic hardening elastoplastic hysteretic model based on

Table 3. Parameters adopted for modelling the GRMs and the soil layers A-C by the HSsmall model.

Parameters	GRM100/00-0.5 m	GRM70/300-0.5 m	Layer A0.5-3.0 m	Layer B3.0-5.0 m	Layer C5.0-8.0 m

the combination of the Hardening Soil (HS) model (Schanz *et al.* 1999) with the small-strain overlay model proposed by Benz (2006) and Benz *et al.* (2009). The calibration of the HSsmall constitutive model parameters was performed according to the procedure proposed by Amorosi *et al.* (2016). The soil layers from D1 to E1 were modelled using the Mohr-Coulomb model, adopting the parameters shown in Table 4. This last choice is due to the distance of the soil layers D1-E1 from the structure, where the input is applied, so a sophisticated constitutive model such as the HSsmall one is not necessary.

Table 4. Parameters adopted for modelling the soil layers D1-E1 by the Mohr-Coulomb model.

4 COMPARISON BETWEEN THE EXPERIMENTAL AND NUMERICAL RESULTS

To compare the experimental and numerical results two components of the dynamic motion were investigated: the horizontal response parallel to the direction of shaking (named as "N" direction), and the vertical response (named as "Z" direction). Due to the lack of space only some comparisons are reported in this paper.

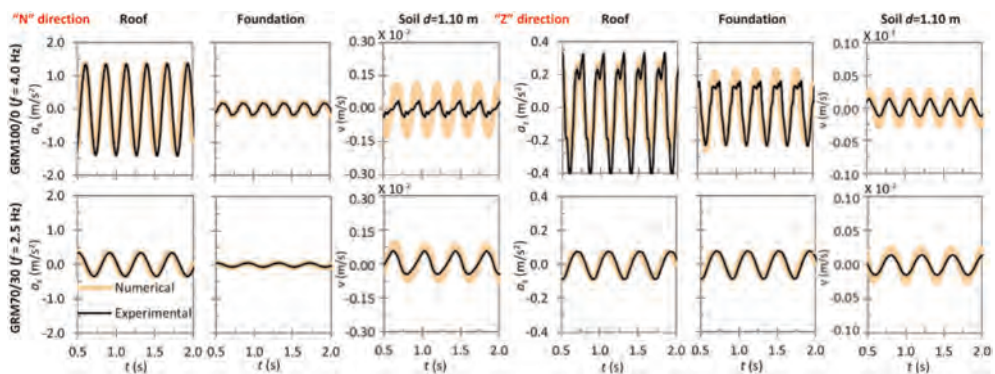
Figure 3 shows the numerical and the experimental results at the structure's roof and foundation in terms of acceleration time histories, as well as at the soil surface in terms of velocity time histories. The results deal with the instruments placed along the direction of shaking. Considering the complexity of the analyses, the various uncertainties and not controllable/unexpected factors accompanying in-field testing, the numerical simulations capture very well the experimental response of the structure and the velocities recorded on the soil surface for both the configuration with GRM100/0 and GRM70/30.


Figure 3. Experimental versus numerical results at the roof and at the foundation in terms of acceleration time histories and on the soil (at 1.10 m from the foundation) in terms of velocity time histories.

5 OTHER NUMERICAL RESULTS

Once the FEM model was validated, the dynamic behaviour of the soil-GRM-structure system was numerically investigated in terms of shear strains (γ_{xz}) versus the shear stresses (τ_{xz}) evaluated in a representative node of the GRMs in front of the foundation, at a depth z = 0.25 m and at the distance of the geometric centre of the foundation equal to x = 1.60 m. Figure 4 shows that γ_{xz} considering the configuration with GRM 100/0 is lower than that with GRM70/30 (0.30% versus 0.50%), due to its low compressibility. On the other hand, the maximum amplitude of τ_{xz} is very amplified for the configuration with GRM100/0 compared to that for the configuration with GRM70/30 (12.5 kN/m^2 versus 5 kN/m^2), due to the higher amplitude of the force applied at the roof. The slope of the loop, for the configuration with GRM70/30, tends to flatten out due to a decrease of the shear modulus compared to that for the configuration with GRM100/0.
Figure 4. Shear strains versus shear stresses in the middle of the GRMs.

6 CONCLUSIONS

In this paper, advanced nonlinear 3D numerical analyses were carried out to reproduce the forced-vibration tests performed on the prototype structure of EuroProteas in Thessaloniki, Greece, using Gravel-Rubber Mixtures (GRMs) as a means of Geotechnical Seismic Isolation. Two GRM layers with different rubber content per mixture weight (0% and 30%, respectively) were analysed. The experimental response on the structure is well-reproduced by the FEM model. The FEM modelling lightly overestimates the recorded velocities in the soil. As regards the shear strains-stresses curves in the GRMs, investigated only by the FEM model, GRM70/30 provides for a clearly higher maximum level of strains and stresses compared to GRM100/0. The maximum strain level is under the allowable value. The GRM 70/30 clearly act in mitigating the seismic motion before reaching the structure.

Influence of geosynthetic interface within a liner system in dynamic analyses of a landfill

D. Gioffrè & C.G. Lai
Department of Civil Engineering and Architecture, University of Pavia, Italy

ABSTRACT: Geosynthetic composites are extensively used in liner systems which are placed beneath the landfill to isolate waste material from the surrounding environment. However, geosynthetics can also be the weak interface, so analyses of seismic response and permanent deformation of landfill should be performed considering the influence of liner interface. This paper investigates the contributing role of the base liner on the seismic behavior of landfills. Based on the results of the site investigation, dynamic analyses of a landfill in Northern Italy were carried out with the finite difference computational platform FLAC-2D. The displacement of the geosynthetics resulting from the seismic loading was estimated along with the potentially induced seismic slip surface taking place at the interfaces. Results indicate that the geosynthetic liner system affects the dynamic response of landfill and that the seismic displacements on the geosynthetics should not be neglected. This paper also discusses results and implications on seismic design of landfills to ensure the integrity of the liner systems as well as the stability of the waste landfill.

1 INTRODUCTION

According to international codes and recommendations, the analysis of the seismic stability conditions of a waste landfill could be conducted using one of the following types of analysis:

a) pseudo-static methods;
b) simplified dynamic methods (displacement-based);
c) advanced dynamic analysis methods.

Methods a) evaluate a global safety coefficient for the slope (landslide section) along a predefined sliding surface and considering a statically applied seismic action in the center of gravity in the unstable rigid body. The magnitude of the pseudo-static inertial force depends on the peak acceleration value expected at the free surface at the study site and on the limit-state considered (return period). Pseudo-static methods do not allow an evaluation of the "performance" of the slope subjected to seismic shaking, a performance defined for example by permanent displacement.

In methods b) and c) the seismic stability is evaluated by comparing the permanent displacement with the admissible displacement defined by codes and recommendations. Therefore, methods b) and c) are based on a performance approach to seismic design. However, while method b) is based on an analysis in which the phases needed to define the seismic input and calculate the permanent displacement are uncoupled (decoupled approach), in method c) these phases are carried out jointly in the same numerical model (coupled approach). Furthermore, in method b) the numerical model used for the evaluation of the permanent displacements is typically carried out by means of a simplified approach that idealizes an unstable rigid body moving on a predefined sliding surface (like in pseudo-static methods).

In method c) the slope is idealized as a deformable body in which the sliding surface is not defined a-priori but it emerges as a narrow zone of intense shearing strain (shear band) during the analysis.

The simplified dynamic method (method b) is approximate and does not allow an accurate evaluation of permanent displacements in the presence of complex geometric configurations such as the presence of berm or embankment along the slope, reinforcement structures, and different types of materials separated by appropriate interfaces.

Furthermore, in systems with significant stiffness and strength differences, the evaluation of permanent displacements requires a coupled approach to account for the dynamic interaction between resistance, deformability, interface and seismic action (Lai *et al*. 2009; Rampello & Callisto 2008).

A liner system generally consists of one or more types of soil and/or geosynthetic materials such as geomembranes, geosynthetic clay liners, geonets and geotextiles. The shear strength of the liner system and the interface friction between the layers determine how susceptible the slope is to lateral movements along a geosynthetic interface in response to forces generated by the waste weight. In fact, sliding along a geosynthetic interface can harm the liner system's containment function. If sliding occurs below the geomembrane at a compacted clay liner/geomembrane interface, the geomembrane will stretch and possibly tear. For these reasons, it is important to assess the performance of the geosynthetic liner system of landfill.

The paper illustrates the seismic stability analysis conducted during the design of the extension to an existing landfill located in the Province of Parma (Northern Italy). The seismic stability analysis of the landfill allowed to evaluate the permanent displacement along the liner system and to reproduce in a satisfactory way the complex interactions that occur between the seismic action and the different elements of the landfill.

2 LANDFILL AND GEOTECHNICAL CHARACTERIZATION

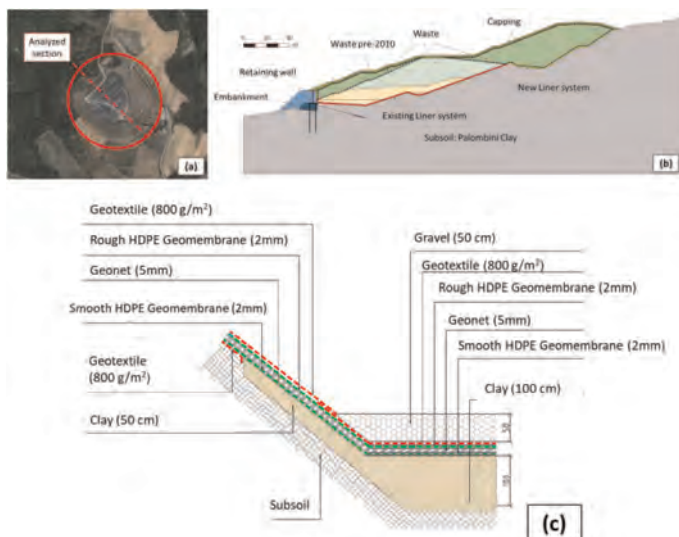
The landfill under study is located in the high hill sector of the Parma Apennines (Italy), in the geological context of the northern Apennine chain. (Figure 1)


Figure 1. Landfill: (a) Chorography of the site (source "Google Earth"). In the red circle the site of the landfill; (b) Analyzed section; (c) Liner system details.

Starting from an extensive survey campaign, it was possible to accurately define the seismic-stratigraphic model of the landfill and obtain an adequate geotechnical characterization of soil, waste and geosynthetic liner system.

The waterproofing package positioned at the bottom of the landfill is a geocomposite formed by a rough HDPE geomembrane, a draining plastic geonet and a smooth HDPE geomembrane.

The interface shear strength between the several layers of landfill liner has been evaluated using standard direct shear testing of each soil/geosynthetic, soil/waste and geosynthetic/geosynthetic interface.

Table 1 reports the characteristic parameters used in the seismic stability checks of the landfill. Their definition, obtained from a careful analysis of the on-site tests and laboratory tests carried out during the investigation campaigns, is not discussed in detail in this paper (Gioffrè *et al.* 2022).

The existing and the new liner system have been characterized performing several direct shear tests on different interfaces: geotextile - rough HDPE geomembrane; rough HDPE geomembrane -geonet; geonet - smooth HDPE geomembrane; smooth HDPE geomembrane - geotextile. In the numerical model liner systems have been modelled with an interface element which geotechnical parameters (Table 1) are referred to the most critical resistance parameters obtained with direct shear tests on smooth HDPE geomembrane - geotextile interface.

Table 1. Geotechnical parameters using in landfill seismic stability analysis.

Zone[#]	Material	γ[kN/m^3]	Cohesion c'[kPa]	Shear strength angle ϕ' [°]
1	Subsoil (Palombini clay)	20	27	21
2	Embankment	20	50	21
3	Waste pre-2010 with leachate	10	0	24
4	Waste pre-2010	14	0	24
5	Waste	14	8	32
6	Capping	20	15	30
	Interface 1 (Existing liner system)	–	0	10
	Interface 2 (New liner system)	–	0	14

The seismic-stratigraphic model of the landfill was defined with reference to the results of the seismic refraction prospecting (o prospection) for the most superficial part of the landfill (depth $\leq$ 15 m). At greater depths, the values of V_S measured in the MASW tests were used as far as available; in addition, experimental data were extrapolated using a linear interpolation approach.

Figure 2 shows the G/G_{max} decay curves obtained from experimental laboratory tests for soil and waste; G/G_{max} curves for embankment and capping were taken from the literature (Darendeli 2001).

3 NUMERICAL MODEL AND SEISMIC INPUT

Non-linear dynamic analyses were carried out using a 2D numerical model of the landfill implemented in a finite difference computational code (FLAC-2D v8) that is able to consider both large displacements and relative displacement at liner system interfaces.

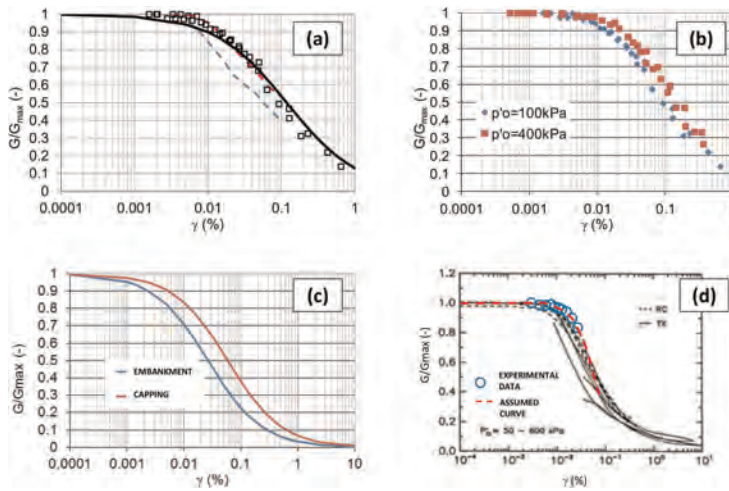
The model of the cross section of landfill (maximum reservoir section) is made up of 21,160 elements; the elements of the model have dimensions in height between 0.3 and 3.0 m (Figure 3). The dimensions of the elements have been chosen to respect the accuracy


Figure 2. Shear modulus G/G_{max} reduction curves: (a) Experimental curves for waste at the same confining pressure; (b) Experimental curves for waste at different confining pressures; (c) Assumed curves for embankment and capping from Darendeli (2001); (d) Experimental curve for subsoil (Palombini clay).
Figure 3. FLAC-2D model.

conditions of Kuhlemeyer and Lysmer (1973), i.e. they are equal to 1/10 of the minimum wavelength, which is a function of the maximum frequency of interest (assumed to be 30 Hz) and of the shear modulus at small deformations of the materials considered.

The constitutive model used for waste is elasto-plastic where the Mohr-Coulomb resistance criterion governs the triggering mechanism(s) of the permanent deformation. The non-linearity of the mechanical behavior is also taken into account by the reduction of the shear modulus G with the level of deformation (hysteretic behavior).

Dynamic analyses have been carried out imposing the following boundary conditions: absorbent conditions at the base and at the lateral edges ("quite boundaries") and free-field conditions along the lateral edges ("free-field boundaries").

Figure 4 shows the elastic acceleration response spectrum of the seven natural spectrum-compatible accelerograms selected for the analyses and the acceleration response spectrum calculated as the average of the selected signals.
Figure 4. Elastic acceleration response spectrum of the selected signals (thin blue lines) and spectrum-compatible acceleration response spectrum calculated as the average of the selected signals (thick black line).

4 RESULTS OF NUMERICAL ANALYSES

Displacement information is more beneficial than the seismic safety factor when geosynthetics are used because geosynthetics cannot withstand large displacements. Therefore, the design can be modified to ensure that little permanent displacement occurs with geosynthetics. The permanent displacement calculated from the analysis can be used to predict whether the latter will exceed the landfill components' ability to withstand earthquake-induced deformation.

Figure 5 shows the absolute permanent displacement at the end of the dynamic analysis for accelerogram 3 which can be considered representative of the dynamic response of the landfill. It is possible to observe that the interface (liner system) marks a clear separation of the movements between the waste body and the substrate. This result is due to the extremely low shear strength parameters that characterize the contact between the geosynthetics in the waterproofing package.

From Figure 5 it is also possible to observe that the maximum permanent displacements are concentrated in a surface area of the landfill near the embankment.

Considering that the most critical conditions for the stability of the landfill occur along the liner system, the permanent displacements along the interface were also evaluated.
Figure 5. Accelerogram 3: permanent displacement at the end of the analysis (displacements in m).

Table 2. Maximum permanent displacement and maximum permanent displacement along liner system.

Accelerogram	1	2	3	4	5	6	7
Maximum permanent displacement (cm)	15.0	18.0	65.0	27.5	130.0	22.5	8.0
Maximum permanent displacementalong liner system (cm)	12.2	14.5	47.2	21.4	95.2	16.2	4.3

Table 2 reports the horizontal component of the maximum permanent displacement and the maximum permanent displacements along the liner system obtained in the coupled non-linear numerical analyses using the two-dimensional landfill model implemented in FLAC-2D.

Results in Table 2 shows that the accelerogram 5 represents the most severe signal as it is the one associated with the greatest displacements in relation to its duration and its frequency content. The permanent displacements are so significantly greater than those obtained with all the other accelerometric signals, that this accelerogram has been considered an "outlier" signal.

Displacements along the liner system make it possible to carry out the conformity checks that will arise from the comparison between these displacements and the admissible displacement of the geosynthetics present in the waterproofing package.

Figure 6 shows the maximum permanent displacement along the liner system at the end of the dynamic analyses for the different accelerograms used. From Figure 6 it possible to observe that the accelerograms 3 and 5 are those that lead to the greatest permanent displacements along the interface. For all accelerograms, a maximum permanent displacement along the reduced interface is observed at the second tooth located in the upstream part of the landfill.
Figure 6. Maximum permanent displacements along the liner system at the end of the two-dimensional dynamic analyses (displacements in m).

5 CONCLUSIONS

The numerical results of the present study lead to the following conclusions: (1) The geotechnical investigation campaigns carried out over the years have made it possible to obtain an excellent geotechnical characterization of waste body, base clay, and liner system; (2) The seismic stability checks of the landfill were carried out by means of non-linear dynamic

analyses which allow to directly calculate the permanent displacement and to reproduce in a satisfactory way the complex interactions that occur between the seismic action and the different elements of the landfill through the mobilization of their strength and deformability. The constitutive model assumed for the waste is of the non-linear hysteretic elastoplastic type with reduction of the shear modulus with the level of deformation and Mohr-Coulomb failure criterion; (3) Permanent displacement data can be used to evaluate the performance of the geosynthetic liner system.

ABSTRACT: Compared with rigid retaining systems, Mechanically Stabilized Earth (MSE) walls offer various advantages, such as their cost competitiveness and a higher tolerance for deformations under earthquake loads. Accordingly, MSE walls have become widely popular in the last decades and a thorough understanding of their static and seismic behavior is required for advances in design. In this study, the effect of reinforcement stiffness on the static and seismic response of an MSE wall was investigated by performing two-dimensional finite element analyses. The MSE wall models were excited with a harmonic loading with a frequency content of 4 Hz. In the analysis, geogrids were modeled with two axial reinforcement stiffness values: 600 kN/m and 1200 kN/m. Relative horizontal displacements along the wall height, displacement along the reinforcements, and tensile loads in the geogrids were investigated. The results indicated that the effect of reinforcement stiffness on the MSE wall displacements was less pronounced in the static condition compared with the seismic condition. MSE wall displacements were more visible at about mid-height of the wall in the static case. In the seismic case, the increase in reinforcement stiffness caused a horizontal displacement reduction along the wall height. Doubling the axial reinforcement stiffness increase caused a visible increase in the reinforcement axial forces, in the mid to lower reinforcement levels in the seismic case.

1 INTRODUCTION

In the last decades, the use of Mechanical Stabilized Earth (MSE) wall systems has increased worldwide dramatically due to their economical and aesthetical advantages over conventional retaining walls (AASHTO 2014). MSE walls have especially been preferred in earthquake-prone regions (Koseki *et al.* 2006) as their flexibility help minimize the damage to nearby structures under earthquake load. Researchers have been conducting finite element analyses to evaluate the complex load transfer mechanism and seismic response of reinforced earth wall systems (Fan *et al.* 2020; Kamalzadeh & Pender 2023; Ling *et al.* 2005, 2010; Liu *et al.* 2014; Xu *et al.* 2023). Few researchers studied the effects of axial stiffness (*EA*) of reinforcement on the seismic behavior of MSE walls using numerical analysis and keeping all the other variables constant. Bathurst and Hatami (1998) parametrically varied *EA* values between 500 kN/m and 69,000 kN/m to compute its influence on the reinforced

earth wall displacements under dynamic loading conditions. The authors reported that the higher the reinforcement stiffness values, the lower the wall displacements were, and this effect was more pronounced when EA values were less than 2,000 kN/m. The current study evaluates the effect of stiffness on the MSE wall behavior, focusing on this lower, more critical range of reinforcement stiffness values (i.e., less than 1500 kPa). Accordingly, two types of geogrids with axial stiffness values EA = 600 kN/m and EA = 1200 kN/m were considered for this study. The performance of 8 m high MSE walls was investigated using numerical analyses. The models were excited with a harmonic motion with 0.2g amplitude and a frequency of 4 Hz. Horizontal wall displacements and reinforcement axial forces were evaluated in this study, considering both static (end-of-construction) and seismic conditions.

2 NUMERICAL MODEL

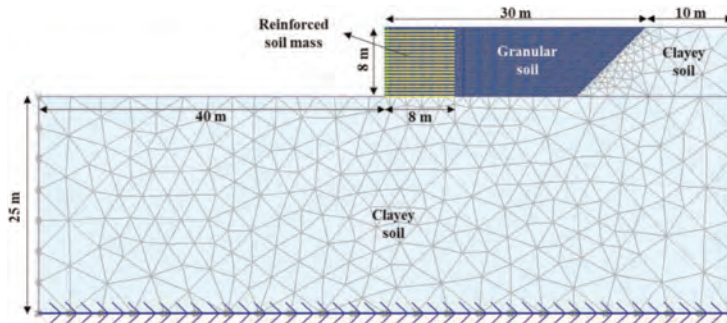
An 8 m high MSE wall model was prepared using the two-dimensional finite element (FE) software PLAXIS 2D (Brinkgreve *et al.* 2010) under plane-strain conditions. Figure 1 shows the general geometry of the analyzed MSE model (Turkel 2019). The wall in Figure 1 has a reinforcement length-to-wall height ratio (L/H) of 1.0 and a reinforcement vertical spacing (S_v) of 0.4 m. The total length of reinforcement is 8.0 m, starting from the front of the facing.


Figure 1.   MSE wall model.

Two different soils: (i) granular soil and (ii) clayey soil were defined in the model. Granular soil was used both in the retained zone and the reinforced soil mass. The material used for the foundation was the same as the natural soil behind the retained zone. The set of material parameters utilized were presented in Table 1. Hardening soil model was used for both the granular and the clayey soil in the model. The groundwater table was assumed to be deep.

Wall facing units were modeled as concrete modular blocks using linear elastic soil elements having a width of 0.5 m and a height of 0.2 m. The modular blocks had a defined elastic modulus of 4,400,000 kPa, Poisson's ratio of 0.17, and a unit weight of 21.8 kN/m³. Reinforcement elements were placed between the concrete modular blocks with vertical reinforcement spacing (S_v) of 0.4 m. Two typical extruded uniaxial geogrids were selected to investigate the effect of reinforcement stiffness on the behavior of the MSE wall. The axial stiffness of the geogrid, which is denoted by EA and defined as the product of the modulus of elasticity and the reinforcement thickness, is used to define the elastic behavior of the geogrids in the models. Axial stiffnesses of these geogrids were calculated as 600 kN/m and 1200 kN/m (International Organization for Standardization 2015). In the FE models, interfaces were incorporated to ensure that the soil-structure interaction in the MSE wall was represented accurately. The strength at all interfaces (i.e., between modular blocks, between the modular blocks and the soils, and between the geogrid and soils) was reduced to 70%.

Table 1. Material parameters used in the model.

Parameter[*]	Description	Granular soil	Clayey soil	Unit
γ_{dry}	Unit Weight (dry)	18	17	kN/m^3
c_{ref}	Cohesion	1	100	kN/m^2
ϕ	Friction angle	34	20	°
E_{50}^{ref}	Secant stiffness	60,000	30,000	kN/m^2
E_{oed}^{ref}	Tangent stiffness	60,000	30,000	kN/m^2
E_{ur}^{ref}	Unloading/ Reloading stiffness	180,000	90,000	kN/m^2

[*]Soil parameters were adopted from Turkel et al. (2020).

The reinforced zone of the MSE wall was modeled using 0.2 m-thick lifts of backfill soil as part of a staged construction approach and a uniform load of 15 kN/m^2 was applied on each lift. In the static condition, a surcharge load of 12 kPa was applied at the end of the staged construction. The average natural frequency of an 8 m high MSE wall was empirically estimated as 4.6 Hz by Turkel et al. (2020). The accelerogram proposed by Bathurst and Hatami (1998) was adapted in this study for harmonic loading. The seismic analyses were performed by applying a harmonic loading at the bottom boundary of the model with a frequency content of 4 Hz (i.e., near the empirically determined natural frequency of the MSE wall). The input duration was set to 5 seconds and the peak ground acceleration (PGA) was 0.2g. The reflection of the seismic waves was avoided by defining absorbent boundaries for the left and right vertical boundaries.

3 NUMERICAL RESULTS

The effect of reinforcement stiffness (i.e., EA = 600 kN/m and 1200 kN/m) on the static and seismic behavior of the 8 m high MSE wall are evaluated and discussed in this section. Figure 2 presents the effect of EA on wall behavior in static condition.

The horizontal face displacements of the MSE wall along its height, which are provided relative to the MSE toe, are shown in Figure 2(a). Horizontal displacements along the wall
Figure 2. The effect of EA on the wall behavior in the static condition a: (a) relative horizontal displacements and (b) maximum reinforcement axial forces along the wall height.

were reduced by a maximum of 26 mm (from 64 mm to 38 mm) at about the mid-section of the MSE wall when the axial stiffness of the reinforcement was doubled in the static case. Figure 2(b) presents the computed maximum axial force in reinforcements, those obtained from the distribution of the force envelopes. These forces are given with a positive sign indicating tensile loads. The impact of the change in EA was most notable in the lower layers of reinforcements in terms of maximum axial forces. Axial force at the bottom reinforcement increased by approximately 1.6 kN/m (from 4.1 to 5.7 kN/m) when EA was doubled.

Figure 3 presents the effect of EA on MSE wall reinforcement response at selected elevations in the seismic condition. The residual displacements presented in Figure 3(a) are given along the reinforcements (i.e., with distance away from the facing). Note that these displacements are residual or permanent/final deformations that occurred due to seismic loading only (i.e., they are residual) since displacements were reset after the static conditions. On the other hand, displacements provided in Figure 3 are absolute values and not relative to the toe of the wall. Observe how the horizontal displacements increased with wall elevation and the effect of EA became visible at the top of the wall. Figure 3(b) presents the axial forces on the corresponding reinforcements that were obtained from the force envelope distributions. Note that the maximum reinforcement axial force generated along the reinforcement during a seismic loading is the most critical value for the design.
Figure 3. The effect of EA on the response of MSE wall reinforcements at selected elevations in the seismic condition: (a) residual horizontal displacements and (b) axial forces along the reinforcements.

Figure 4 presents the effect of EA on the seismic wall behavior. The computed horizontal displacements along the MSE wall height presented in Figure 4(a) are permanent deformations at the end of the seismic loading with respect to the toe of the MSE wall, and hence they are relative and residual. The increase in EA caused a maximum relative displacement reduction of approximately 12 mm (from 42 to 30 mm) at the top of the wall. The effect of EA on the maximum reinforcement axial forces became significant in the mid to lower reinforcement levels as seen in Figure 4(b). These reinforcement axial forces are the
Figure 4. The effect of *EA* on the seismic wall behavior: (a) relative (residual) horizontal displacements and (b) maximum reinforcement axial forces along the wall height.

maximum ones obtained from the envelope. At the bottom of the MSE wall, the maximum axial force of the reinforcement wall was reduced by about 2.2 kN/m (from 8.3 to 6.1 kN/m) when the axial stiffness of the reinforcement was doubled.

4 CONCLUSIONS

A numerical parametric study was undertaken to evaluate the effect of reinforcement axial stiffness (*EA*) on the static and seismic response of an MSE wall. As the effect of *EA* is expected to be more pronounced for lower values of axial stiffness, values of 600 kN/m and 1200 kN/m were assigned for the reinforcements in the FE models. Initially, relative horizontal wall displacements and reinforcement axial forces were investigated in the static condition. Then a harmonic seismic load with a PGA of 0.2g and a frequency content of 4 Hz was applied at the bottom of the models. The results obtained from the seismic analysis were compared and discussed together with the static condition. The following main conclusions were drawn from this study:

- The effect of doubling *EA* was mostly visible at about the mid-section of the wall in the static case when the relative displacements are considered. A maximum relative horizontal displacement reduction of 26 mm was computed at about mid-height of the MSE wall when the *EA* was doubled in the static case.
- Maximum reinforcement axial forces in the lower layers of reinforcements experienced the effect of the change in EA in the static case. Axial forces in the reinforcements at these lower levels experienced a maximum increase of about 1.6 kN/m when *EA* was doubled.
- The effect of *EA* is more pronounced in seismic loading conditions compared with the static condition.
- The increase in *EA* caused a relative displacement reduction along the wall in the seismic case, which was anticipated. The effect was the most prominent with approximately

12 mm of maximum relative displacement reduction at the top of the wall when *EA* was doubled.
- Similar to the observations for the static case, the effect of *EA* on the maximum reinforcement axial forces became significant in the mid to lower reinforcement levels in the seismic case. The maximum axial force of the MSE wall was reduced by about 2.2 kN/m at the bottom of the MSE wall when the axial stiffness of the reinforcement was increased from 600 to 1200 kN/m.

ABSTRACT: Shallow foundations are sometimes built on geosynthetic mechanically stabilized earth (MSE) structures. Such structures are extensively used to support bridge loads and to form approach roads. In recent years many studies provided chart-based solutions to calculate the ultimate bearing capacity of the foundations of MSE structures. Such solutions are provided for different combinations of geotechnical and geometric input parameters. However, such design charts cannot be implemented as part of automated workflows as they contain curves that need to be used on a case-by-case basis. This paper presents a novel method to calculate the seismic bearing capacity of a shallow foundation positioned on the crest of a geosynthetic reinforced soil structure. Such approach is based on a predictive mathematical expression that can be readily used and implemented as part of performance-based design approaches. It relies upon a database of solutions obtained using the upper-bound limit analysis. The proposed expression is valid for static and seismic conditions. Examples are presented illustrating the implementation of this method as part of design procedures of selected foundation systems.

1 INTRODUCTION

Shallow foundations are sometimes built on mechanically stabilized earth (MSE) structures, such as retaining walls and artificial slopes and embankments. Such structures are used quite extensively to support bridge abutments, electrical transmission towers, railways, and road transportation networks. Such reinforcements produce a substantial improvement to the capacity to carry loading by these systems under static and seismic loadings. As a result, the bearing capacity of shallow foundations on sloped fill structures is considerably improved by incorporating geosynthetic reinforcements down to an appropriate depth. Over the past few decades, researchers have studied reinforced soil structures' stability-related applications by means of experimental models, analytical solutions, and numerical approaches. Experimental studies are typically based on the following model types: (1) full-scale structure models (Bathurst *et al*. 2003; Thamm *et al*. 1990; Yoo & Kim 2008), centrifuge model tests (Sommers & Viswanadham 2009), and reduced-scale models (Alamshahi & Hataf 2009; Choudhary *et al*. 2010; El Sawwaf 2007; Hoseini *et al*. 2021; Lee & Manjunath 2000; Mehrjardi *et al*. 2016; Patil *et al*. 2022; Selvadurai & Gnanendran 1989; Turker *et al*. 2014; Xiao *et al*. 2016; Yoo 2001). Such studies focus on the influence of various model input parameter (e.g., footing location and width, geometry of the reinforced soil structure, backfill properties, and reinforcement geometric and spacing characteristics) on the ultimate bearing capacity of such systems.

Several studies present analytical methods to evaluate the bearing capacity and settlement of footings placed on the top of reinforced soil structures. Some of these studies consider a uniformly distributed load (Ausilio 2012; Basha & Basudhar 2010; Jahanandish & Keshavarz 2005; Zhao 1996). Analytical studies on the bearing capacity behavior of a strip footing with loading width placed close to the crest of a reinforced soil structure are limited. The studies of Blatz and Bathurst (2003) and of Haza *et al.* (2000) considered such conditions under static loadings. More recently, Ausilio (2014) used upper-bound limit analyses to develop the seismic bearing capacity of strip footings placed close to the crest of geosynthetic-reinforced MSE structures using a log-spiral mechanism. Furthermore, by using the lower bound finite-element limit analysis technique proposed by Chakraborty & Kuma (2014), Halder & Chakraborty (2019, 2020) presented a series of design charts to compute the bearing capacity of a strip footing placed on the top of a cohesionless soil slope reinforced with layers of reinforcement, also considering the influence of inclined and eccentric loading and the effect of soil dilatancy. Xie *et al.* (2019) proposed a limit equilibrium approach to estimating the bearing capacity of strip footings placed on geosynthetic reinforced soil structures considering five different failure mechanisms. The results of these analyses are presented in a series of normalized design charts accounting for the following input model parameters: footing location and width, geometry of the reinforced soil structure, backfill properties, and reinforcement geometric and spacing characteristics. More recently, Xu *et al.* (2022) used a finite element limit analysis method based on a non-associated flow rule to investigate the load-bearing performance of reinforced slopes.

This body of literature clearly shows that the ultimate bearing capacity of the foundations of MSE structures are influenced by a finite number of geotechnical and geometric input parameters. As a result, many studies focused on providing design charts that can be used by practitioners. However, such design charts cannot be implemented as part of automated workflows as they contain curves that need to be used on a case-by-case basis. In this study we provide a novel mathematical expression to predict the bearing capacity of a shallow foundation positioned on the crest of a geosynthetic reinforced soil structures. It was developed using the nonlinear least squares (NLS) method. The database used to develop this novel expression comprises results from the upper-bound limit analysis used by Ausilio (2014) for a wide variety of input parameter ranges. The proposed mathematical expression can be used in both static and seismic conditions.

2 METHODOLOGY

Ausilio (2014) used the kinematic theorem of the plasticity theory to evaluate the seismic bearing capacity of a strip footing of width B on a geosynthetic reinforced soil slope with angle β at a distance D from the edge (Figure 1). Seismic actions are considered by means of the pseudo-static approach as equivalent horizontal and vertical forces acting on both the foundation and the soil below it. The kinematically admissible mechanism considered in this approach is characterized by a log-spiral failure surface (Ausilio *et al.* 2000), which is assumed to pass through the right edge of the strip footing on the surface of the reinforced slope with r_o which is the radius at initial angle θ_o, while θ_h is the final log-spiral angle (Figure 1). This approach uses three parameters to characterized the soil portion of the MSE system: γ (unit weight), c (soil cohesion) and φ (friction angle).

In this study, a uniformly-placed geosynthetic reinforcement is considered and referenced as an average tensile strength per unit cross-section as:

$$k_T = \frac{T}{d} \tag{1}$$

Figure 1. Geometry of the reinforced soil structure with the log-spiral failure surface (adapted from Ausilio 2014).

where T is the tensile strength of a single the reinforcement layer per unit width, and d is the vertical distance between the layers of the reinforcement layers (Figure 1). By equating the rate of external work to the rate of energy of dissipation, Ausilio (2014) obtained:

$$q = \frac{\frac{1}{2}k_t r_0 \left[\sin^2\theta_h e^{2(\theta_h - \theta_0)tg\varphi} - \sin^2\theta_0 \right] + \frac{cr_0}{2\tan\varphi}\left[e^{2(\theta_h - \theta_0)tg\varphi} - 1 \right] - (1-k_v)\gamma r_0^2 (f_1 - f_2 - f_3) - k_h\gamma r_0^2 (f_4 - f_5 - f_6)}{B\left[(1-k_v)\left(\cos\theta_0 - \frac{B}{2r_0} \right) + k_h\sin\theta_0 \right]}$$

(2)

Where functions $f_1 - f_6$ are dependent on the slope angle (β), the angles defining the position of the failure surface, (θ_o, θ_h) and the soil's friction angle (φ) (Chang *et al.* 1984; Saada *et al.* 2011). Equation 2 provides an upper-bound solution for the ultimate bearing capacity of a footing placed at the crest of a reinforced slope considering a log-spiral failure mechanism. In order to find the best estimation of q, Equation 2 needs to be minimized with respect to angles θ_o and θ_h. Once these angles are found, the limit load is calculated substituting these values into Equation 2. This approach was verified and validated by Ausilio (2014) through comparisons against numerical results and experimental data, respectively.

3 PROPOSED PREDICTION MODEL

In order to obtain a prediction model that can be incorporated as a mathematical expression to predict the ultimate bearing capacity of a strip foundation positioned on the crest of a geosynthetic soil structure, five input parameters are used: (1) the slope angle β; (2) the distance D from the edge; (3) the soil's friction angle φ; (4) the average tensile strength per unit cross-section k_T, and (5) the seismic intensity coefficient k_h. These parameters were identified as the most consequential for this phenomenon by Ausilio (2014) as they influence the slope instability and therefore affect the bearing capacity of a strip foundation. It is convenient to present the results in non-dimensional form and therefore the results are analyzed in term of normalized ultimate bearing capacity ($q/\gamma B$), edge distance (D/B) and non-dimensional geosinthetic factor ($\gamma B/k_t$).

Table 1. Coefficients of the proposed prediction model.

Coefficient	Value	Coefficient	Value	Coefficient	Value
c_1	−0.0043841	c_9	2.1148131	c_{17}	0.0086504
c_2	3.6873746	c_{10}	−0.0092696	c_{18}	1.7032957
c_3	−0.0030405	c_{11}	−0.6479434	c_{19}	1.3902525
c_4	0.0451191	c_{12}	2.6280113	c_{20}	0.026551
c_5	−0.7871863	c_{13}	−1.390382	c_{21}	2.1267126
c_6	0.838201	c_{14}	1.0066753	c_{22}	0.0337078
c_7	0.002757	c_{15}	0.0123847		
c_8	0.0294035	c_{16}	0.8098281		

In this study, data obtained applying the chart-based solution by Ausilio (2014) is fitted using a NLS regression model, in which the sum of the squares of the vertical distances of different points from the regression curve is minimized using the Gauss-Newton algorithm. Appropriate values of all input factors are defined in a way that they uniformly fill the experimental space determined by the following range of input parameters: $D/B = 0.25$–4, $\beta = 30°$–75°, $\phi = 20°$–45°, $\gamma B/k_T = 0.4$–2.75, and $k_h = 0.0$–0.6. The resulting NLS model provides the normalized ultimate bearing capacity ($q/\gamma B$) as (Table 1 provides model coefficient values):

$$\log\left(\frac{q}{\gamma B}\right) = c_1 * \left(\frac{D}{B}\right)^{c_2} + c_3 * \beta + c_4 * \varphi + c_5 * (k_h)^{c_6} + c_7 \frac{D}{B} * \beta + c_8 * \left(\frac{D}{B}\right)^{c_9} * \frac{\gamma B}{K_t} + c_{10}$$

$$* \beta * \frac{\gamma B}{K_t} + c_{11} * \frac{D}{B} * (k_h)^{c_{12}} + c_{13} * \frac{\gamma B}{K_t} * (k_h)^{c_{14}} + c_{15} * \frac{\gamma B}{K_t} * (k_h)^{c_{16}} * \beta$$

$$+ c_{17} * \left(\frac{\gamma B}{K_t}\right)^{c_{18}} * (k_h)^{c_{19}} * \varphi + c_{20} * \left(\frac{\gamma B}{K_t}\right)^{c_{21}} + c_{22}$$

(3)

4 VERIFICATION OF THE PROPOSED PREDICTION MODEL

To verify the reliability of the proposed model (Equation 3), its predictive power is tested against results obtained using the Ausilio et al. (2014) solution (design charts therein and solving Equation 2 for various input parameter permutations). Such verification offers an in-depth evaluation of the reliability of the proposed model and provides similar information, but in a different format, of the residuals analysis performed in the previous section. Representative plots of this verification effort are shown in Figures 2 for a variety of input parameter ranges including the following: $q/\gamma B$ versus $\gamma B/k_T$ for $\beta = 60°$ and $k_h = 0$–0.6 (Figure 2a), and ϕ versus $q/\gamma B$ for $\beta = 60°$ and $k_h = 0$–0.2 (Figure 2b). The comparisons presented in Figure 2 visually confirms that the proposed model is consistent with the solution by Ausilio (2014). Thus, Equation 3 can be reliably used to evaluate the seismic bearing capacity of strip footings placed close to the crest of geosynthetic-reinforced soil structure.

5 APPLICATION OF THE PROPOSED PREDICTION MODEL

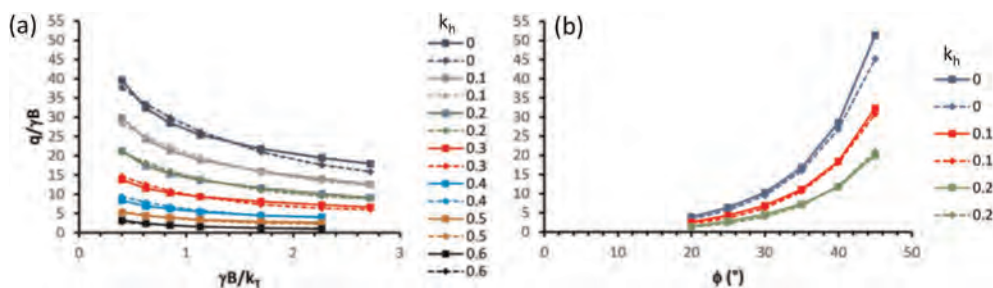
In this section, two example applications are proposed to illustrate the use of Equation 3 to evaluate the ultimate bearing capacity of a strip footing resting on reinforced earth structure. Example 1 assumes a 2m-wide strip foundation placed at a distance of 6 m from the edge of a


Figure 2. Comparison between the proposed model (dashed lines) and the Ausilio (2014) model (solid lines) for: (a) $\gamma B/k_T$ versus $q/\gamma B$ and (b) ϕ versus $q/\gamma B$. Both comparisons refer to $\beta = 60°$.

slope with an angle of $\beta = 45°$ and soil fill characterized by $\phi = 35°$ and $\gamma = 17$ kN/m^3. The reinforcement used is a strip reinforcement with a tensile limit force of T = 17 kN/m (per strip) and vertical distance of 0.5 m. The static ultimate bearing capacity (i.e., $k_h = 0$) can be calculated as follows: $k_T = T/d = 34$ kPa and $\gamma B/k_T = 1$, then from Equation 3 we obtain: $q/\gamma B = 32.06$ and q = 1,090 kPa. Example 2 Assume the same conditions as in Example 1 but with a seismic excitation summarized by $k_h = 0$. From Equation 3 we obtain $q/\gamma B = 15.20$ and q = 516.80 kPa.

6 DISPLACEMENT-BASED ANALYSIS

The results obtained with the pseudo-static analysis obtained in the previous section, indicate that the reinforcement force required to ensure an adequate bearing capacity could be impracticable for high seismic coefficients. In such circumstances, it is reasonable to accept that the structure is affected by tolerable permanent displacement. The conventional rigid-block analysis procedure originally proposed by Newmark (1965) is usually used to calculate such permanent displacements. In this procedure the earthquake-induced displacement can be obtained by double integration of the equation of motion, which in the case of a rotational failure-mechanism can be expressed in terms of the angular rotation of the failure mass relative to the stable soil. To evaluate the seismic induced permanent displacement, this method requires a scenario ground motion time series and a seismic yield coefficient (k_y) that can be calculated using Equation 3. As an alternative to this formal double integration procedure, empirical relationships can be used to predict the seismic induced permanent displacement of earth structures using the Newmark rigid-block theory. The relationship by Jibson (2007) is widely used in design practice:

$$\log\delta = -2.71 + \log\left[\left(1 - \frac{k_y}{k_{max}}\right)^{2.335} \cdot \left(\frac{k_y}{k_{max}}\right)^{-1.478}\right] + 0.424 \cdot M_w + S\sigma_{\log\delta} \qquad (4)$$

where, k_y is in g (gravity acceleration), k_{max} is the peak acceleration of the rock outcrop motion (in g), δ is the permanent displacement (in cm), $\sigma_{\log\delta}$ is the standard deviation of the logarithm (base 10) of displacement prediction and it is equal to 0.454, M_w is the earthquake moment magnitude, and S is the standardized normal variate. A simplified approach is to consider the displacement evaluated by Equation 4 as that of the unstable soil mass. This value of the seismic displacement is based on the application of the Newmark approach and it is not validated against observed displacements. As a result, it must be viewed as an index of the seismic performance. However, the predicted displacement can still be used effectively for preliminary design purposes. The subsequent step when designing MSE structures is to

decide whether the calculated displacement is acceptable. Such tolerable displacement depends on the characteristics of the geo-reinforced soil structure and what it supports and accordingly, allowable displacement levels must be established using engineering judgment.

Equations 3 and 4 can be used for practical applications in the seismic design where the performance expectations are established in terms of acceptable amount of displacement. Given a set scenario earthquake characterized by M_w and k_{max}, and knowing the width (B) of the footing and its position with respect to edge slope (D), soil (ϕ, γ) and reinforcement (T and d) parameters and the ultimate bearing capacity, k_y can be obtained by trial and error from Equation 3. The permanent displacements can then be calculated using Equation 4. If the displacements are judged to be too high then the process has to be repeated considering a different reinforcement configuration. To show how this procedure works, we propose an example application that assumes a 4m-wide strip foundation, placed at 12 m from the edge of the slope. Additional input parameter are: $\beta = 60°$, $\phi = 35°$, and $\gamma = 17$ kN/m^3. Strip reinforcements with T = 15 kN/m (per strip) are used and installed with a vertical spacing of 0.5 m. The design event is characterized by $M_w = 6.7$ and $k_{max} = 0.57$g. If the target bearing capacity of the footing is 950 kPa, then q/γB = 14 and γB/k_T = 2.26. For these values, a critical acceleration factor $k_y = 0.1$ is obtained from Equation 3. Then Equation 4 provides permanent displacements of 11 and 62 cm for confidence levels of 50% and 95 %, respectively. If these displacements values are not allowable then the process has to be repeated changing T and/or d, to have a greater value of k_T. This procedure, given a scenario event (M_w, and k_{max}), can be applied by calculating k_y as a function of the allowable displacement from Equation 4 and using Equation 3 to derive the value of the bearing capacity.

7 CONCLUSIONS

Geosynthetic reinforced soil structures are popular systems to be employed in modern seismic and static design. Various methods are present in the literature to design these geotechnical systems. However, most of them are based on design charts that are impractical to be applied in automated design workflows. In this paper we present a novel prediction model for the seismic bearing capacity of a shallow foundation positioned on the crest of a geosynthetic reinforced soil structure based on a simple mathematical expression. This model relies upon the upper-bound limit analysis method by Ausilio (2014). After providing a formal verification of this newly-proposed model, we show simple design applications and displacement-based design principles adopting simplified Newmark solutions. Such approaches are particularly useful when implemented as part of performance-based design protocols.

On the seismic performance of geosynthetic-reinforced soil retaining walls

G. Di Filippo & G. Biondi
University of Messina, Messina, Italy

N. Moraci
University of Reggio Calabria, Reggio Calabria, Italy

ABSTRACT: Large earthquakes occurring worldwide regularly renew the interest in the analysis of the post-seismic serviceability of Geosynthetic Reinforced Soil Walls (GRSWs). Several post-earthquake reports show that, differently from other types of retaining walls, GRSWs have generally exhibited a satisfactory performance characterized by a ductile behavior against seismic-induced deformations. Similarly, experimental data concerning shaking table and centrifuge tests emphasize the satisfactory seismic performance of GRSWs. In this vein, a simplified displacement-based predictive model, aimed to the evaluation of the seismic performance of GRSWs in terms of magnitude of seismic-induced permanent displacements, was proposed and, using the results of a parametric analyses, the main peculiarities of the seismic performance of GRSWs are discussed in the paper focusing on the possible coupling between the frequency content of the input motion and the vibration frequencies of GRSWs and on the influence of the mechanical properties of reinforcements

1 INTRODUCTION

The use of the earth-reinforced retaining structures has grown progressively in recent decades due to the excellent seismic performance that these geotechnical systems showed even in complex environmental contexts. During most of recent large earthquakes, earth retaining structures reinforced with geosynthetics suffered minor damages with respect to the conventional concrete retaining walls (e.g. Koerner 2000; Tatsuoka 2008) requiring cheaper re-construction costs and ensuring a lower environmental impact. Accordingly, geosynthetic-reinforced soil walls (GRSWs) are nowadays considered a suitable alternative to conventional retaining structures, especially in high seismicity areas (e.g. Moraci 2011; Tatsuoka *et al.* 1997a).

Among the procedures and methods aimed to analyze the seismic performance of GRSWs, simplified dynamic analysis, derived from the pioneer Newmark (1965) sliding block approach, are nowadays widely used also in current practice. The solutions and methods available in the literature were mainly derived modifying the original sliding block approach to account for the main features of the seismic response of GRSWs which is crucially influenced by the soil-geosynthetics interaction under the cyclic and dynamic loading conditions imposed by the ground motion. Available solutions and methos generally belong to two different categories which neglect (e.g. Ausilio *et al.* 2000; Cai & Bathurst 1996; Gaudio *et al.* 2018; Ling *et al.* 1997; Michalowski & You 2000) or account for (e.g. Di Filippo *et al.* 2014, 2019; Paulsen & Kramer 2004) the compliance of the reinforced soil mass and for the deformability of the geosynthetic reinforcements. Available studies also differ in

the assessment of the yield acceleration which has a crucial effect on the evaluation of the earthquake-induced permanent displacements and, thus, on the reliability of the prediction of the post-seismic serviceability condition of GRSWs.

With reference to the case of walls with inclined facing assembled using the wrap-around technique, this paper summarizes the main features of a recently proposed numerical model (Di Filippo *et al.* 2014, 2019) developed to predict the seismic performance of GRSWs in terms of earthquake-induced permanent displacements. Using a set of properly selected input ground motions, a set of numerical analyses have been carried out and the obtained results are presented and discussed in the paper focusing on the influence of the deformability of the reinforced soil mass and of the characteristics of the acceleration records adopted as input in the analyses.

2 PROPOSED NUMERICAL MODEL

The model by Di Filippo *et al.* (2014, 2019) refers to a GRSW of height H, with a face inclination θ and N layers of equally-spaced (s) geosynthetic reinforcement of length L (Figure 1a): γ, φ' and v_s are the unit weight, the angle of shear strength and an average value of the shear wave velocity of the backfill soil (whose profile is described in Figure 1b), respectively; J and, T_u represent the '*in air*' wide-width stiffness and the tensile strength of the reinforcements (Figure 1c, d); δ_i is the friction angle schematizing the shear strength available along the ith soil-geosynthetic interface. The input motion consists of a horizontal acceleration time-history $a(t)$, representing the motion at the base of the GRSW, having peak value $a_{max} = k_{max} \cdot g$.

As in the study by Paulsen & Kramer (2004) the actual GRSW was condensed into a simple rheological model consisting in the 2-degree of freedom (2DOF) system shown in Figure 1e: two masses, m_1 and m_2, define a compliant two-block system schematizing the portion of the actual GRSW involved in the failure mechanism, which has distributed total mass $m = m_1 + m_2$, distributed elasticity and infinite number of degrees of freedom.

Three discrete elements, the compliant two-block system, an elasto-plastic spring and a Coulomb slider, allow reproducing the primary mechanism that characterize the dynamic seismic response of GRSW: *i*) possible amplification of ground motion due to coupling between system and input frequencies; *ii*) possible occurrence of permanent deformations due to soil shearing, to stretching and potential yielding of reinforcements and *iii*), finally, to the possibly occurring pull-out of reinforcements.

Differently from the model by Paulsen & Kramer (2004), the effect of the reinforcement ductility $\chi = \varepsilon_u / \varepsilon_{uy}$ (Figure 1b) can be accounted for in the displacement analysis and proper values of the '*in air*' wide-width stiffness is used herein according to the experimental results
Figure 1.   a-d) reference scheme e) rheological model.

by Cardile *et al.* (2016, 2017). Also, the influence of the static effective stress state and of the soil-geosynthetic interaction under cyclic loading conditions (Moraci *et al.* 2017) are considered for a proper estimate of the interface apparent friction coefficient μ (Figure 1c). Specifically, suitable values of δ_i can be adopted for each layer of geosynthetic reinforcements and the special case $\delta_i = \delta = \varphi$ lead to the assumptions by Paulsen & Kramer (2004). Finally, a proper evaluation of the soil mass involved in the seismic failure mechanism and of the shape function that approximates the fundamental vibration mode of the actual GRSW, are also introduced. Further details on the numerical model can be found in the papers by Biondi & Moraci (2014) and Di Filippo *et al.* (2014).

3 PARAMETRIC ANALYSIS

A first group of parametric analyses were carried out considering two different input motions and several GRSWs schemes. Specifically, two acceleration time-histories (denoted hereafter as records #1 and #2) recorded during the Umbro-Marchigiana 1997 earthquake sequence were considered to define the input motions.

Figure 2 shows the two selected accelerograms (*a*) and the related Fourier Amplitude Spectra (*FAS*), together with some relevant seismic parameters: peak values of the time histories (*PGA*), strong-motion duration (D_{5-95}) and Arias's intensity (I_a). In the numerical analyses presented herein, the accelerograms have been scaled up to 0.8 g and the corresponding values of the relevant seismic parameters are given in brackets in Figure 2b, d.

The two accelerograms are characterized by a different frequency content: a narrow bandwidth (Figure 2a) is apparent for record #1 with a prevalent frequency content concentrated around a predominant frequency $f_p = 6.54$ Hz close to the mean frequency $f_m = 1/T_m = 6.05$ Hz computed starting from the values of the mean period evaluated according to Rathje *et al.* (1998). Conversely, record #2 is characterized by a wide bandwidth (Figure 2c) with a prevalent frequency content concentrated between 2 and 7 Hz; in this case the mean frequency $f_m = 4.98$ Hz is, on average, representative of the significant frequency range. The different frequency content of the two waveforms is also apparent through the acceleration time histories plots (Figure 2b, d).

Different schemes of *GRSWs* have been considered in the analyses. The wall height H range between 6 and 9 m; different values of the soil shear wave velocity ($V_s = 120, 240$ m/s) and of axial stiffness ($J = 550, 850$ kN/m) and tensile strength of the geosynthetic
Figure 2. Acceleration records adopted in the numerical analysis as input motions: a,c) Fourier amplitude spectra; b,d) time-histories.

reinforcements (T_u = 18.5, 24.6 kN/m) were also considered in the parametric analyses. In all cases it was assumed s_v = 60 cm, L/H = 0.7, φ' = 35°, γ = 20 kN/m³. Table 1 summarizes the different combinations of the geometrical and mechanical parameters considered in the parametric analyses.

The results of the dynamic analyses carried out using the proposed numerical model, are described herein using a time domain representation. Specifically, the obtained results are presented and discussed in the attempt of highlighting the influence of the wall height H, soil shear stiffness, axial stiffness of the reinforcements and characteristics of the input motions.

Table 1. Parameters of the GRSWs considered in the numerical analyses.

analysis	record	H (m)	V_S (m/s)	J (kN/m3)	T_u (kN/m)
1A	#1	6	120	550	18.5
1B	#1	9	180	550	18.5
2A	#1	6	160	550	18.5
2B	#1	9	240	550	18.5
3A	#1	9	240	850	24.6
3B	#1	9	240	850	18.5
4A	#2	6	160	550	18.5
4B	#2	9	180	550	18.5
4C	#2	9	240	550	18.5
5A	#2	9	240	850	24.6
5B	#2	9	240	850	18.5

3.1 Influence of V_s and H

The results of the analyses relative to the combination of the model parameters denoted as *1B* and *2B* in Table 1 are shown in Figures 3a–d in terms of time histories of displacements (d_1, d_2) of the two masses which characterize the numerical model (Figure 3b, d) and time history of the yield acceleration (Figure 3a, c) superimposed on the input accelerogram (#1). The comparison refers to a wall of height H = 9 m characterized by two different values of the shear waves velocity of the soil and therefore by two different values of the fundamental frequency equal to 5 Hz *1B* (analysis *1B*, V_s = 180 m/s – Figure 3a, b) or 6.67 Hz (analysis *2B*, V_s = 240 m/s – Figure 3c, d). The dynamic response is characterized by final values of the permanent displacements equal to d_2 = 4 cm in the case V_s = 180 m/s (Figure 3b) and d_2 = 8 cm if V_s = 240 m/s (Figure 3d).

The different seismic response is related to the difference coupling effects occurring in the two cases. In the case of analysis *2B* the value of V_s was specifically selected with the aim of providing a fundamental frequency of the system equal to f_s = 6.67 Hz which is almost coinciding with the predominant frequency of the considered input motion (f_p = 6.54 Hz – Figure 2a). For the case V_s = 180 m/s (analysis *1B*, f_s = 5 Hz) the fundamental frequency of the system falls within an interval for which the selected accelerogram is characterized by lower amplitudes (Figure 2a). In both cases (analysis *1B* and *2B*) the response computed for the upper and lower mass of the numerical model leads to a temporal variation of the yield acceleration (a_c in Figure 3a, c); this result cannot be found in conventional (rigid-block) displacement approaches where the deformability of the system and the effects of its dynamic response are not taken into account.

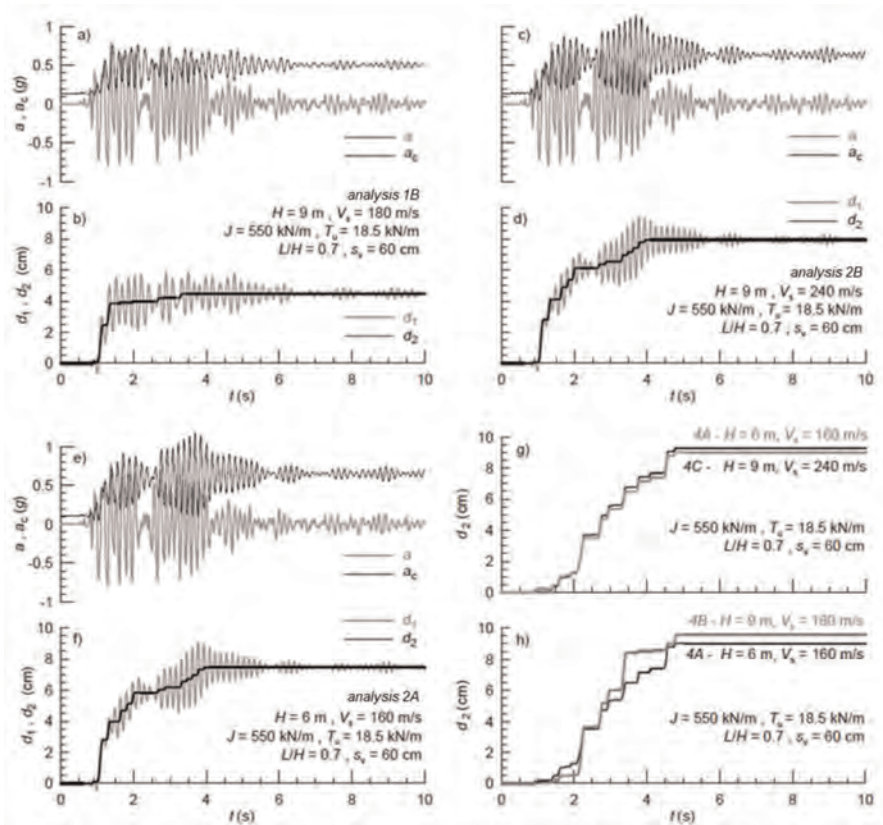
The stabilizing contribution offered by the geosynthetic reinforcements is highlighted by the average increasing trend of the yield acceleration during the seismic motion. The accumulation of permanent displacements involves an increase in the axial forces mobilized in the geosynthetic reinforcements, producing a stabilizing effect which progressively involves the limitation of the cumulative permanent displacements and the increase of the yield acceleration of the system.


Figure 3. Influence of the *GRSW* compliance on the displacement response.

The dynamic response computed in the analyses *4A* and *4C* is comparable since, in both cases, the systems are characterized by the same fundamental frequency (f_s = 6.67 Hz). Conversely, in more rigid systems (analysis *4A* and *4C*), the occurrence of permanent displacements of the same magnitude as those observed in more deformable systems (analysis *4B*) is mainly attributable to the broadband distribution of the frequency content of accelerogram #2 (Figure 3h).

Similar outcomes can be observed with reference to the comparison of the results relative to the analysis *2B* (Figure 3c, d) and *2A* (Figure 3e, f); the latter (*2A*) differs in the values of the wall height and soil stiffness (Table 1) which, however, were properly selected in order to obtain the same values of the fundamental vibration frequency of the model which is unchanged in comparison with the analysis *2B* (f_s = 6.67 Hz). Figures 3g-h show the results of the analyses carried out for the same systems but using accelerogram #2 (analysis *4A*, *4B* and *4C*). In this case the frequency content of the input motion (Figure 2e) and the values of the model parameters (H, V_s) lead to permanent displacements of about 9 cm for all the systems (Figure 3g).

3.2 *Influence of the reinforcement stiffness*

For the case H = 9 m, V_s = 240 m/s and T_u = 18.5 kN/m Figure 4 shows the influence of the reinforcement stiffness J on the magnitude of seismic-induced permanent displacements.
Figure 4. Effect of the stiffness of the reinforcements on permanent displacements.

Specifically, for the accelerograms #1 (Figure 4a) and #2 (Figure 4b) and for two different values of the reinforcement stiffness (J = 550 and 850 kN/m) the computed dynamic responses are shown in terms of displacements d_1 of the upper mass of the numerical model. In the proposed approach, the final value of the displacement time-history represents the permanent displacement of the actual *GRSW*. If the effects of reinforcement deformability are neglected, the two systems (J = 550, 850 kN/m) would be characterized by the same value (constant with time) of the yield acceleration a_c and, thus, the predictions of the permanent displacements would lead to the same result. Conversely, even the same initial value of the yield acceleration (T_u = 18.5 kN/m in both cases), the model characterized by stiffer reinforcements (J = 850 kN/m) exhibits smaller permanent displacements with a reduction of about 15–20% in comparison to the case J = 550 kN/m.

4 CONCLUSIONS

A simplified numerical model was used with the aim of modeling the main mechanisms influencing the seismic response of the geosynthetic-reinforced soil retaining walls (GRSWs) with inclined facing assembled using the wrap-around technique. The seismic performance is evaluated in terms of seismic-induced permanent displacements due to the onset of various plastic mechanisms, also concomitant, caused by the temporary exceeding of the resistances in the soil, in the reinforcements and at the soil-reinforcement interfaces. A set of numerical analyses, carried out in the time domain using actual seismic records as input motions, were presented and discussed in the paper. The analyses show that, due to the possible coupling effects, the amplitude and frequency content of the selected input motion may significantly affect the computed response in terms of permanent displacements. The analysis results also show that, regardless the axial strength, GRSWs equipped with stiffer reinforcements exhibit limited permanent displacements. In the proposed model the better seismic performances are due to the substantial contribution of the reinforcements which modify the fundamental frequencies of the system and limit the amplitudes of the permanent displacements as a consequence of the increase with time of the system yield acceleration.

Review of the German geotextile robustness classes (GRK) for separation layers with nonwoven geotextiles using large-scale field tests

H. Zanzinger
SKZ - German Plastics Center, Würzburg, Germany

J. Retzlaff
GEOscope GmbH, Weimar, Germany

R. Kroh
SKZ - German Plastics Center, Würzburg, Germany

ABSTRACT: As part of large-scale field tests, a range of twelve mechanically bonded nonwoven geotextiles from three manufacturers made of polypropylene staple fibres were tested about their robustness against installation loading in their function as separation layers between soft subsoil and coarse-grained base course material ranging from round-grained, sandy gravel to sharp-edged, stony gravel were used for this purpose. Four different installation situations were simulated. The impact by site traffic was controlled based on the ruts resulting from truck crossings. A suction excavator was used to gently reveal the geotextiles.

All samples were visually assessed for damage and then classified. The energy absorption and the derived damaging work were used to evaluate the mechanical changes based on both, wide-width tensile tests and static puncture tests. Half of the exposed samples remained with more than 80% of their original performance. Almost all materials didn't exceed 50% of performance loss after the tests. A classification system should quantify the complexity of the soil-geosynthetic-system for separators. The tests have shown that strength alone is not enough to assess them and to avoid damage. The evasion principle should be followed instead. For this purpose, it is necessary to consider the deformability. The energy absorption together with the minimum elongation ability provides a good basis for this. Against this background, a proposal for an update of the current classification system was made.

1   INTRODUCTION

Empirical classification systems are used for the function of separating soils of different grain sizes with geotextiles. In the current German classification system of the "Merkblatt über die Anwendung von Geokunststoffen im Erdbau des Straßenbaues - M Geok E" (FGSV 2016), a distinction is made between five application cases that consider the influence of the fill material. These are in turn combined with five stress cases resulting from the installation of the geosynthetic and the associated construction operation. This results in 25 possible application combinations, which are nowadays concentrated on three Geotextile Robustness Classes (GRK 3 to GRK 5) and thus describe the loading of the separation layer. The most common are mechanically bonded nonwoven geotextiles (GTX-NW) with staple fibres made of polypropylene. (Bräu *et al*. 2004; Bräu & Laier 1984; Watn & Zeniti 1997) It is important that there must be no holes or damage that would locally disable the filter and separation functions.

2 INVESTIGATIONS

For the investigations of the project, GTX-NWs with and without single-sided thermal treatment were selected. The characteristic as-delivered state (ADS) values for mass per unit area acc. to EN ISO 9864, thickness acc. to EN ISO 9863-1, wide-width tensile strength acc. to EN ISO 10319, static puncture force F_{CBR} acc. to EN ISO 12236, resp. the energy absorption (EA) as integral of the force-strain-line were determined for both tensile tests and CBR tests.

"Energy absorption, uniaxial" $W_{Tensile}$ is based on uniaxial strain whereas "energy absorption, multiaxial" W_{CBR} is based on multiaxial strain ε_{CBR} in a CBR-test (Eq. 1), calculated as the ratio of the increase of the surface area A, here as surface area A of a truncated cone plus the area under the plunger, and the initial area A_0 (Figure 1). Here the plunger penetration displacement was measured at a preload of 1 N.

$$\varepsilon_{CBR} = \left(\frac{A - A_0}{A_0} \right) \cdot 100\% \qquad (1)$$
Figure 1. Illustration of the stretched test specimen area in the static puncture test (CBR-test).
Figure 2. Illustration of tensile force vs uniaxial strain and static puncture force vs multiaxial strain.

Very good correlations between tensile forces and static puncture forces were found for all tested GTX-NWs. As an example (GTX ME 380) diagram shows tensile force $F_{Tensile,CMD}$ plotted on the uniaxial strain $\varepsilon_{Tensile,CMD}$ in cross-machine direction and F_{CBR} on ε_{CBR} (Figure 2).

In order to vary the installation situation of four GRKs, three different fill materials were selected, and these were combined with two different levels of loading due to construction operations. The installation and compaction of the fill material was carried out mechanically. The expected rut depths in the geotextile layer were between 5 cm and 15 cm. Round-grained fill material (sandy gravel) and angular fill material with and without stones (sandy, stony gravel and sand-gravel mixture) were used.

Large-scale test fields (TF) filled with uncompacted quartz sand 0/2 mm not driven on before installation of the GTX-NWs and placement of the base course material are shown on Figure 3.

The bulk material of the sub-base layers was poured onto the TFs with a wheel loader and distributed and levelled with a mobile excavator with a clearing bucket. The sub-base layer was compacted with a single-drum compactor in such a way that the test setup could be driven over with a three-axle truck loaded up to 40 t total weight (Figure 4). After the passes and the measurement of the ruts on the top of the sub-base layers, the top 10 cm to 15 cm of the sub-base layer material was carefully removed with a backhoe. A mobile suction excavator was then used to pick up most of the remaining fill material (Figure 5). The rest was removed manually.

Figure 3.   Four test fields at different stages of installation of GTX-NWs.

Figure 4.   Ruts of a fully loaded truck.

Figure 5.   Removal of fill material with a mobile suction excavator.

3   EVALUATION

All samples taken were subjected to a uniform visual sample approach. Damage was recorded as indentations or holes and cracks and assigned to a defined visual damage factor k_{vis}. Optical damage was found almost exclusively in the area of the ruts. Hardly any optical damage was found "between the wheels" (Figures 6 to 8).

Figure 6.   Stretched sample and relaxed sample after removal of fill material.
Figure 7.   Samples taken "under the wheels" (sec. 1 and 3) and "between the wheels" (sec. 2).

There was a more or less linear increase in the EA with the increase in the mass per unit area for all samples in the ADS as well as the removed samples. "Under the ruts", the samples showed greater damage here in the form of lower EA than the samples "between the wheels" (Figure 9). There, the GTX-NWs could also be tensioned as a result of the ruts forming on both sides, but the direct compressive load of the coarse grain of the sub-base layer on the GTX-NWs was not present there. The preliminary compaction of the sub-base layer by the single-drum compactor was able to cause the first damage. It was not possible to completely separate these successive influences in retrospect.
Figure 8.   Damaged samples of an un-treated (left) and of a thermally treated GTX-NW (right).
Figure 9.   Example of the EA in ADS W_{ADS}, after damaging "between the wheels" W_0 and after damaging "under the wheels" W_{1+2} shown as EA vs. mass per unit area.
Figure 10.   Illustration of the loss of EA, with EA W_{0+1+2} in ADS and EA W_3 of a damaged specimen. W_3' is equivalent with W_3.

The total damaging work (DW) resulted from the difference between the EA in the ADS W_{0+1+2} and the remaining EA W_3 including the reduction due to the visual damage factor. The "degree of damage" (DoD) was defined as the ratio of the DW and the EA taking into account also the visual findings using k_{vis}. DoD decreased with increasing mass per unit area.

Figure 10 shows the reduction in static puncture force and multiaxial strain of damaged specimens for one example and illustrates the loss of EA, here given as the "areas under the curves".

TF GRK3 showed that DoD was below 20% in 3 out of 5 samples (Figure 11). The other two samples were thermally surface treated and showed DoD between 40% and 50%. The samples in TF GRK4b were very severely damaged. DoD between 40% and 80% were found. In TF GRK5, the 5 lighter GTX-NWs with masses per unit area below 300 g/m² all showed relatively large damage, while the two heavier GTX-NWs only showed damage levels below 20%. All samples from the TF GRK6 showed DoD between 30% and 90%.

The evaluation for "robustness" was carried out for all products. Six of the 12 products met their assigned requirements for a permissible DoD of e.g. 20% in the respective test fields used. Five out of 12 products were installed exclusively in test fields that did not meet their classification. They did not meet the requirements for an allowable DoD of e.g. 20%. One out of 12 products was adequately installed in corresponding test fields according to its classification and did not fulfil the mentioned requirement. In a second observation, a permissible DoD of e.g. 50% was assessed. This criterion, in turn, was met by 11 of 12 products. In principle, it would be desirable that no damage whatsoever occurred to the geotextile separation layers in order to be able to ensure their complete and permanent functionality.

The damage caused by ruts and trucks passing over the surface exceeded the damage caused by backfilling and subsequent compaction with a compactor. Figure 12 shows the increase in DW starting from TF GRK3 on the left up to TF GRK6 on the right side of the diagram. It gives a clear trend of the DW "between the wheels" W_0 and the DW "under the wheels" W_{1+2}.
Figure 11. Example of DoD vs mass per unit area for test field TF GRK3.
Figure 12. Increase of DW "between the wheels" W_0 and "under the wheels" W_{1+2} shown for four TFs.

The total DW increased in the test fields TF GRK3 and TF GRK4b from approx. 10 to 24 kJ/m, whereby the grain size distribution of the sandy gravel in TF GRK3 and the sand-gravel mixture in TF GRK4 did not show any serious difference. But the grain shapes of the gravel were different. This showed that the grain form of the fill material played an important role in the damage of the geotextiles (Figure 13).
Figure 13. DW vs truck passes.

Another increase in DW from about 40 kJ/m to 45 kJ/m was observed when comparing TF GRK5 and TF GRK6. Here, the identical grain size was used in both TFs. The distinction between these TFs lay in the ruts produced. This again showed that both the construction operation in the form of backfilling and subsequent compaction and the truck passes damaged the GTXs.

A closer look at the stresses caused by the loaded truck passes showed that the effects on the GTX - expressed as DW - due to the grain shape of the angular sand-gravel mixture compared to a round-grained sandy gravel of the filling material was more decisive than the effects of the construction operation. Round or squat grain shapes were obviously less damaging than angular or pointed shapes of the gravel or stones.

The energy introduced by the truck passes correlated with the DW observed for the sharp-edged fill material. The primary selection of GTX separation layers should therefore preferably be based on the existing fill material. The duration and intensity of subsequent construction operations are less predictable. Consequently, the focus should be on sharp-edged fill materials. As a simplified approach, it would be enough to distinguish only between "normal construction operations" and "demanding construction operations".

The GTX-NWs with thermal surface treatment in TF GRK3 resulted in greater DW than the more stretchable products. They were not as good at evading the forces caused by the indentations of the coarse grains. They rather followed the resistance principle. Unlike more "stretchy" GTX filters, which have to safely span the cavities of the core layer in the case of drainage geocomposites, in the case of separation layers between fine-grained subsoil and the coarse fill layer on top of it, it is irrelevant if the GTX-NW deforms into the coarse structure

of the fill material. The essential thing is that this happens without damaging the filter. In cases where the separation function is of primary importance, this evasion principle appears to be more appropriate than the resistance principle.

4 PROPOSAL OF A CLASSIFICATION SYSTEM

Regarding the deformability, an easy pre-selection of GTX-NWs used for the separation function could be the penetration displacement in a CBR-test of at least 53 mm, if the penetration displacement is measured at a preload of 1 N (Figure 14). Furthermore, one could counteract the stress caused by dumping the base course material with limiting the permissible hole diameter of the GTX-NWs in the cone drop test to approx. 20 mm (Figure 15).

Based on the experience of this research project, classification systems should consider the strength and deformability of GTX-NWs. Therefore, the EA and DW should be used to evaluate the robustness. The requirements for the EA result from the fact that the required EA can compensate for the DW without the GTX-NWs being damaged. For "Class 3", this would require an EA based on CBR tests of 60 kJ/m, for "Class 4" 100 kJ/m, for "Class 5" 140 kJ/m and for a "Class 6" 180 kJ/m.
Figure 14. Penetration displacement in the CBR tests vs. mass per unit area.
Figure 15. Holes in a cone drop test vs. mass per unit area.

Recommendations for the protection of an earthen embankment from flooding on the Big Almaty Ring Road (BAKAD)

A. Zhussupbekov, N. Aidargaliyeva, A. Tulebekova & A. Yessentayev
L.N.Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The problem of construction of the Big Almaty Ring Road (BAKAD) in conditions of the possibility of flooding by ground and external waters is considered. The hydrogeological conditions of this site and general constructive solutions of the embankments, according to the working project, were considered. When designing structures on these collapsible soils, one should consider the possibility of increasing their moisture content by soaking the soil from above from external water sources. Taking this into account, it is necessary to provide for a set of measures, including the elimination of subsidence properties. Having studied the experience of road construction in Kazakhstan, as well as the design data and geological conditions of the project "BAKAD", as well as analyzing the results of laboratory soil studies and the results of field stamp tests. And regarding the test results was recommended constructive technological solution with using geosynthetics materials.

1 INTRODUCTION

The design and construction of civil and industrial buildings and structures on structurally unstable soils are one of the most important and difficult problems today. Such soils include collapsing soils, the feature of which is that these soils have a macroporous structure and exhibit additional deformation, called collapsing when soaking (Kalantari B., Reznik Y.). In this regard, in the design of buildings and structures, there is a need to study the bearing capacity and deformability of soils. Durability, cost, and terms of construction largely depend on the quality of the determination of these properties. Incorrect assessment of the deformability of soils may lead to the construction of unreasonably large foundations or to their excessive collapsing, which may cause an emergency condition of the entire building or structure.

To determine the deformability and bearing capacity of soils there are methods of field soil testing with piles and stamps used. In this regard, in the works, during the construction of buildings and structures on such soils, there are various construction measures to increase the load-bearing capacity of the collapsing soil base proposed. For example, tamping, ground piling, pre-soaking, and reinforcement with vertical elements (Rollins K. *et al.* 1994).

In the Commonwealth of Independent States (CIS), loess soils occupy about 35% of the European and 7% of the Asian parts. In Kazakhstan, loess and loess rocks are distributed mainly in the south and east of the country, which were formed under the influence of cytogenesis processes in the periglacial conditions of the mountain glaciations of the Tien Shan and Pamir.

Technological progress allows the use of artificial and man-made materials for reinforcement. Therefore, the search for new methods and techniques that meet all conditions of construction on collapsing soils is urgent.

2 MATERIAL AND METHODS

2.1 Research object: BAKAD

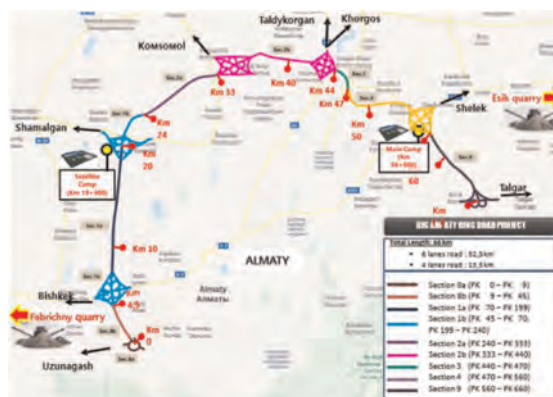
The road passes through the territories of the Almaty region's Karasay, Ili, and Talgar districts. The "Zero end of the survey" is located on the western side of Almaty city on the 23rd kilometer of the Alma-Ata-Uzyngash highway near the Kyrgauldy village. The end of BAKAD -on the eastern side of Almaty (Kazakhstan), on the 22nd kilometer of the Alma-Ata-Talgar-Yevgeniyevka highway (Figure 1).


Figure 1.   Location map of BACAD's.

The length of BAKAD is just over 66 kilometers. The route will consist of 21 bridges, 8 two-level interchanges, 18 overpasses, 2 elevated lines, etc. The road will have 4 to 6 lanes, designed for traffic speed up to 150 km/h. According to standard (SP RK, GOST) road belongs to category I a.

2.2 Engineering and geological conditions

Geomorphologically, the surveyed area is located on the gently inclined plain of the Zailiskiy Alatau foothills. The general direction of the plain slope - is the north.

The climate of the district is sharply continental. The climate features of the district are determined by the latitude and the presence of orographic elements on its surface. The combination of climate forcing causes the transformation of hot, dry weather with sharp seasonal and daily fluctuations in air temperatures. Summers are hot, and winters are moderately cold and mild. There are shower rains in spring and summer. Alluvial-proluvial deposits of Quaternary age (Q), represented by loams of different consistency and pebble soils covered with a soil-plant layer, take part in the geological and lithological structure of the site.

Below is a brief description of the engineering and geological conditions of artificial structures. Three wells up to 30.0 m deep were drilled to survey the soils of the overpass, 21 wells 36.0 m deep were drilled to explore the excavation soils, 13 wells 3.0 m deep, and 9 wells 6.0 m deep were drilled along the route axis.

Excavation:

1. EGE-1 - Loam, light hard, brown.

According to compression tests, the loams show collapsing properties from additional loads. Initial collapsible pressure makes 0.062 kg/cm^2. Coefficient of relative collapsing at specific pressure 0.5 kg/cm^2 – from 0.018 to 0.081; at specific pressure 1.0 kg/cm^2 – from

0.041 to 0.130; at specific pressure 2.0 kg/cm^2 – from 0.045 to 0.151; at specific pressure 3.0 kg/cm^2 – from 0.079 to 0.164.

Location line and Overpass bridge:

EGE-1 – Lbelongsoam, light, solid, brown. According to compression tests, the loams show collapsing properties from additional loads. Initial collapsible pressure makes 0.1 kg/cm^2. Coefficient of relative collapsing at specific pressure 0.5 kg/cm^2 – from 0.055 to 0.081; at specific pressure 1.0 kg/cm^2 – from 0.041 to 0.130; at specific pressure 2.0 kg/cm^2 – from 0.045 to 0.151; at specific pressure 3.0 kg/cm^2 – from 0.018 to 0.164. Geotechnical profile as to collapsing capacity belong to the first type.

EGE-2 – Loam, light, low-plastic, brown.

EGE-3 – Loam, light, high-plastic, brown.

EGE-4 – Coarse, brown, low moisture sand.

EGE-5 – Pebble soil with sand aggregate, water-saturated. Standard values of physical and mechanical parameters of strength and deformation properties of loams are given in Tables 1 and 2.

Table 1. Physical and mechanical properties of soils.

Parameter name	EGE-1 recess	EGE-1	EGE-2	EGE-3	EGE-4	EGE-5

[*]Characteristics are given for soils in a water-saturated state.

Normative and calculated values of the intercept cohesion (kPa), the angle of internal friction (degree), and the modulus of deformation (MPa) are shown in Table 4.

The calculated values of the characteristics are given, considering the coefficient of reliability on the ground.

Groundwater during the survey was penetrated at depths of 5.7–12.6 m. Amplitude of oscillations is 1.0–1.5 m. The estimated maximum groundwater level, considering the amplitude of fluctuations in the groundwater level, the influence of irrigation networks

during watering, and the flood period: the first end of February, the beginning of March, and the second end of March, the beginning of April, as well as atmospheric precipitation, should be taken above the measured groundwater level.

2.3 *Stamp tests*

The work was carried out to study the bearing capacity of the embankment and base excavation. The structure of the unit for soil testing by punch includes a stamp; a device for creating and measuring the load on the stamp; an anchoring device (for installations without a load platform); a device for measuring the sediments of the stamp; a device for soaking and control of soil moisture (when testing subsidence soils). The design of the unit provides the possibility of loading the stamp in steps (GOST) of the pressure of 0.01–0.1 MPa, centered transfer of the load on the stamp, and constancy of the pressure at each stage of loading. Stamp loading is carried out by a jack or calibrated weight. The load is measured with an error of no more than 5% of the pressure stage. Deflectometer for measuring stamp settlement are fixed on the reference system. The measuring system provides the measurement of settlements with an error of not more than 0.1 mm. To measure the stamp settlement, it is allowed to use of instruments that provide the measurement of settlements with an error of not more than 0.1 mm. The study of the bearing capacity of the foundation soil was carried out at 6 points of stamp tests. The research was carried out at 3 dry points and 3 wet ones (Zhussupbekov A.). Stamp tests are the most reliable method for determining the deformation modulus, elastic modulus, natural foundations, and structural layers of road pavements. To carry out the tests, a punching machine with a rotary arm was used, acting on the principle of the balance beam provided in Figure 2.
Figure 2. Field test process.

3 RESULTS

Stamping test results are presented in Table 3. Soil collapse is caused by the peculiarities of formation and existence of strata of these soils, because of which they are under consolidated. Under-compaction of loess soils can be maintained throughout the life of the strata unless moisture and load increase. In this case, additional compaction of soil in lower layers under the influence of its weight can take place. Therefore, the foundations formed by collapsing soils should be designed, considering the specific characteristics of such soils. Table 3 presented the compression ratio according to the results of stamp testing.

Soil collapse is caused by the peculiarities of formation and existence of strata of these soils, because of which they are under consolidated. Under-compaction of loess soils can be maintained throughout the life of the strata unless moisture and load increase. In this case,

additional compaction of soil in lower layers under the influence of its weight can take place. Therefore, the foundations formed by collapsing soils should be designed, considering the specific characteristics of such soils. Table 4 presented the compression ratio according to the results of stamp testing.

Table 4. Results of points.

Point name	Modulus of deformation, MPa	Modulus of elasticity, MPa	Compression ratio
Point1	46.74/ 10.75[*]	39.65/ 39.65[*]	0.99/0.94[*]
Point2	30.64/ 5.54[*]	37.08/ 37.08[*]	0.99/ 0.9[*]
Point3	25.05/ 5.42[*]	41.18/ 31.15[*]	0.99/ 0.9[*]

[*]Characteristics are given for soil at a water-saturated state.

On dry soil:
Average modulus of deformation of the structure for 3 points test is: Ed = 34.14 MP
Average modulus of elasticity of the structure for all 3 points test is Eel = 57.65MPa.
According to the tests carried out, the coefficient of compaction of soil layers the basis ranges from K ≈0.99.
The shape of the graph of general deformations corresponds to the linear dependence of the increment of total deformations on the increase in the load on the base. There is no loss of bearing capacity.
On wet soil:
The average modulus of deformation of the structure for 3 points test is: Ed = 7.24 MPa;
Average modulus of elasticity of the structure for all 3 points test is Eel = 35.96 MPa.
According to the tests carried out, the coefficient of compaction of soil layers in the base fluctuates within K <0.9. The design of the pavement consists of the selection of the most suitable materials based on local resources and the organization of the work, in the
Figure 3. General design solution.

appropriate dimensioning of the individual layers and their placement in depth. Construction solutions for the embankment are presented in Figure 3.

The choice solution of geosynthetic material presented the good filtration properties of geotextile (Tulebekova A.). Also, the economic effect was noted by reinforcing the soil with geosynthetic materials compared with other materials for improving the performance of roads.

4 CONCLUSION

When designing roads and road structures on collapsing soils, it is necessary to:

1. When designing structures on collapsing soils, the possibility of increasing their moisture content due to soaking the soil from external sources (rainwater, meltwater) from above should be considered. Taking this into account, it is necessary to provide a set of measures that include the elimination of subsidence properties (water protection and structural measures).
2. Provide measures to prevent the penetration of surface and anthropogenic water into the foundations.
3. Provide for runoff and channel-regulating structures and measures to prevent flooding and under flooding adjacent to unregulated medium and small rivers and to protect crossings under highways.
4. Provide waterproofing of foundations against aggressive soils. Provide joint corrosion protection for metal and reinforced concrete structures by providing laminated and rustproofing insulation on pipes and other reinforced concrete structures used in bridge construction, recreation, and stop areas buried in the ground, and the use of corrosion-protected, factory-made road signs and signposts.
5. To determine the bearing capacity of the soil foundations of the road highway under construction, one should rely on the results of the field tests (stamp experience). The results of which are as follows for soil at natural moisture, deformation modulus, Ed = 34.14 MPa, for water-saturated soil, deformation modulus, Ed = 7.24 MPa.
6. Lean clay can be used as an artificial embankment if it is well compacted, and a large amount of water is not allowed into the soil.

The following recommendations should be taken into account when strengthening collapsing soil bases with piles: pile foundations in areas with collapsing soils, if soaking of soils is possible, should be used in cases where it is possible to cut through with piles all the layers of collapsing and other clay soils whose strength and deformation characteristics are reduced by soaking; the reasonable choice of a particular geosynthetic material taking into account its physical and mechanical characteristics and functions that it is intended to perform.

Behaviour of biaxial geogrids in unpaved roads – research from Ireland

C. Reilly
Technological University Dublin, Ireland and Ciaran Reilly & Associates, Mullingar, Ireland

K. Nell
TerraTech Consulting, Portlaoise, Ireland

ABSTRACT: Biaxial geogrids are often used to reinforce unpaved roads over low strength subgrades. By allowing the unsuitable subgrade to remain in place and allowing for reduced road thicknesses, substantial reductions in cost and improvements in performance can be achieved. This paper reviews research undertaken at Technological University Dublin where small model testing boxes and instrumented geogrids have been used in combination with representative samples of weak subgrades and high-quality granular fill to simulate the response of biaxial geogrids to monotonic and cyclic plate loading. It was found that the tensile strain measured in the geogrid under test was only a small fraction of the geogrid's ultimate tensile strain, indicating that the ultimate strength of the geogrid is less important than its interaction with the fill. The magnitude of loading was found to have a more significant effect on displacement than the number of load cycles suffered. It was also found that increasing the number of geogrids in the road had a very significant impact on strain and displacement suffered.

1 INTRODUCTION

Geosynthetic materials, including geotextiles and geogrids, have seen extensive use for the reinforcement of unpaved roads, often for temporary access purposes, over low-strength or otherwise unsuitable subgrades. By allowing the unsuitable subgrade to remain in place and allowing for reduced road thicknesses, the appropriate use of geosynthetics can lead to substantial reductions in the cost while also improving the performance of such unpaved roads (Keller 2016). Other benefits include the reduction of rutting and increased road service life.

Unpaved roads are generally constructed by placing one or more layers of high-quality granular fill over a natural subgrade. The natural subgrade may have been stripped of topsoil or not. When specified, one or more layers of geotextile or geogrid are placed between the subgrade and the granular fill. These geosynthetics can act as separators and reinforcements. A typical reinforced unpaved road cross section is shown in Figure 1.

Many design methods have been proposed for unreinforced and reinforced unpaved roads over the years. A significant body of field test data, where unreinforced unpaved roads and airfields were tested under known loadings, was published in 1970 (Hammitt 1970), and various authors have developed design methods based on these and other data (Giroud & Noiray 1981; Giroud & Han 2004a, 2004b; Jewell 1996; Milligan *et al.* 1989a, 1989b). The majority of these methods take account of the confinement and lateral restraint of the granular particles which interlock with the ribs of the geogrid (Giroud 2009) rather than the
Figure 1. Typical unpaved road cross section.

"tensioned membrane" effect. This is because the deformations required to mobilise the "tensioned membrane" effect are larger than those typically tolerated for roadways.

The Giroud & Han (2004a, 2004b) design method has been widely used to design unpaved roads using biaxial geogrids in Ireland and the UK and, in the authors' experience, has proved suitable. However local experience is important to successful application. Several case histories are presented in Reilly & Nell (2018), although detailed quantitative measurements were not available for these projects. Calvarno *et al.* (2016) report on an analysis of the Giroud & Han design method alongside the more recent Leng & Gabr procedure, with field data also being analysed in the study. It was found the Giroud & Han design method predicted a greater design road thickness than the Leng & Gabr procedure, all other variables being held equal. The field testing found that the Giroud & Han and Leng & Gabr designs formed upper and lower bounds respectively to the measured performance of a road on a subgrade for CBR = 1.3%.

Jas *et al.* (2015a, 2015b) used discrete element modelling, calibrated with laboratory testing in a 1.0m (L) × 1.0m (W) box, to show the response of a geogrid in an unpaved road on a weak subgrade to loading due to a passing wheel. It was shown that the actual tensile stress and strain in the geogrid was very small (less than 0.3 kN/m and around 0.5% respectively) and a small fraction of the geogrid's ultimate capacity, achieved at around 6% strain. It was further concluded that the confinement of the granular particles in the apertures of the geogrid result in a residual stress in the first 8 to 10 cm above the geogrid, a possible explanation of the improved bearing capacity that geogrids provide.

2 RESEARCH ACTIVITIES

2.1 *Research at Technological University Dublin (TU Dublin)*

This paper reviews research conducted by Rutkauskas (2018), Aladwani (2019), and Flaherty (2020) under the supervision of the first author at TU Dublin (Dublin Institute of Technology up to 2019). Two designs of model testing boxes and instrumented biaxial geogrids (Thrace TG3030S) were used in combination with representative samples of weak subgrades and granular fill to simulate the response of biaxial geogrids to monotonic and cyclic plate loading. Testing was carried out with different subgrades, varied loading intensities and cycles, and varying numbers of geogrids in the simulated unpaved road. The granular fill used was locally known as "Clause 804" or "Cl 804" and was a well graded 0/31.5mm crushed rock fill intended as road sub-base. It is considered a high-quality material (Travers & Wyse 2022).

2.2 *Instrumented geogrid with foam subgrade*

Rutkauskas (2018) carried out research involving instrumenting the geogrid with strain gauges to show how the geogrid responded to loading when placed in contact with a weak

subgrade (in this case replicated by a foam used in furniture making) and covered by a surcharge of crushed rock, as would be the case in an unpaved road. The testing box was 0.6m (L) × 0.6m (W) × 0.6m (H) and fabricated from timber. Strain gauges were placed around one junction, located approximately midway in the left-right sense of the geogrid, and at the one third location in the up-down sense of the geogrid. Loading was applied monotonically using a 100mm × 100mm steel plate actuated by a hydraulic ram fitted with a load cell. Tests were carried out as follows:

– No geogrid, 300mm crushed rock directly on the subgrade
– One layer of geogrid on the subgrade, 300mm crushed rock over
– One layer of geogrid on the subgrade, one layer of geogrid at mid-height of the crushed rock

A cross section of the test apparatus is shown in Figure 2.
Figure 2.   Testing arrangement for two layers of geogrid. For tests with one layer, the second layer of geogrid was omitted while material thicknesses remained the same (Rutkauskas 2018).

Results of the testing showed that the presence of geogrid increased the loading sustainable for a given displacement, as shown in Figure 3. The load carrying capacity at 40mm defection was increased by 29% for one layer and 83% for two layers, and at 75mm deflection by 29% for one layer and 61% for two layers.
Figure 3.   Loading vs displacement for no geogrid, one layer of geogrid, and two layers of geogrid. (Rutkauskas 2018).

At the end of the test phase at 80kN loading, the plate penetrated the fill by a lesser amount when reinforced; plate penetration was reduced by 5% for one layer and 13% for two layers. Finally, the tensile strain measured was less than 0.31% at the end of the test phase at 80kN for both reinforced cases. For the case with two layers of geogrid, strains measured in the geogrid at mid height were smaller than the strains measured in the geogrid placed on the subgrade (0.13% vs 0.31%. Compression strain was measured in some strain gauges.

The results showed that the tensile strain measured in the geogrid was only a small fraction of the geogrid's ultimate tensile strain. The tensile force per meter in the geogrid was found to be 1.86kN/m for the test with one layer and 2.0kN/m for the test with two layers. These forces are only 6.2% and 6.67% respectively of the ultimate tensile strength of the geogrid of 30kN/m. This finding corresponds with the findings of Jas *et al.* (2015a, 2015b).

2.3 *Instrumented geogrid with natural soil subgrade*

Aladwani (2019) extended this research and built on lessons learned by Rutkauskas (2018), including the use of a more rigid model testing box and a real soft soil (peat) rather than a foam. Aladwani went further in increasing the numbers of geogrid layers used in the model road build up. Up to four layers of geogrid were placed in the model road and their performance assessed.

The testing box was 0.7m (L) × 0.7m (W) × 0.7m (H) and fabricated from mild steel. As a subgrade material, peat obtained from a peatland in the midlands of Ireland was used. Its properties were determined as follows: Von Post H5, unusually low moisture content of 10.5%, and lab vane strength 4.5kPa. The peat was placed and gently compacted to a layer 150mm thick before each test. Testing proceeded to a displacement of 120mm rather than 80mm. Otherwise, testing proceeded largely as per Rutkauskas (2018). The testing arrangement is shown in Figure 4.
Figure 4.   Testing arrangement (Aladwani 2019).

Results of the testing showed that multiple layers of geogrid, as expected, increased the loading sustainable for a given displacement, as per Rutkauskas (2018). The load carrying capacity at 60mm defection was increased by 245% by increasing geogrid layers from one to four, and at 120mm deflection by 516% for four layers.

At the end of the test phase at 120mm displacement, the loading plate penetrated the fill by a lesser amount when reinforced with four layers as against one layer; plate penetration was reduced by 21% for four layers.

The strain gauge readings showed that the average tensile strain measured was between 0.25% and 0.6% at the end of the test phase at 120mm displacement for both reinforced cases. The greater tensile strain measured by Aladwani as against the strain measured by Rutkauskas is explained by the greater displacement of the loading plate (120mm vs 80mm)

and the use of very soft peat as a subgrade. Again, compression strain was measured in some strain gauges.

The results again showed that the tensile strain measured in the geogrid (0.25 to 0.6%) was only a small fraction of the geogrid's ultimate tensile strain of 9 to 12%, corresponding with the findings of others.

2.4 *Instrumented geogrid with natural soil subgrade subjected to cyclic loading*

Flaherty (2020) built on the previous two studies by introducing cyclic loading conditions to the testing regime. Cyclic loading was intended to replicate traffic passing over the surface above the geogrid and to give a more accurate indication of how the geogrid will perform in a typical unpaved road.

The testing equipment and arrangement were largely the same as used by Aladwani (2019), except that a sheet of non-woven geotextile was introduced to separate the peat from the crushed rock. Thrace S8NW was used, which has a tensile strength of 8kN/m. As a subgrade material, again peat obtained from a peatland in the midlands of Ireland was used. Its properties were determined as follows: moisture content of 75% and lab vane strength 9.4kPa. The peat was placed and gently compacted to a layer 150mm thick before each test.

Tests were carried out as follows:

– one layer of geosynthetic, one layer of geogrid
– one layer of geosynthetic, two layers of geogrid
– one layer of geosynthetic, three layers of geogrid

The cyclic loading regime involved increasing the load intensity from 5kN to 25kN in increments of 5kN. For each 5kN loading phase, four load cycles were applied. Vertical deformation of 120mm was considered as failure. Loading was applied at a rate of 0.5kN per second. Graphs of load vs displacement are shown in Figures 5, 6, and 7.

The results showed that load magnitude has a greater influence on displacement than the number of load cycles. The most significant increases in displacement occur when the load magnitude was increased by 5kN at the start of each new loading phase. After the initial increase the displacement reduced and became more uniform throughout the remainder of each loading phase. The test with three layers of geogrid had the lowest maximum average increase in displacement due to additional load, indicating that increasing the number of geogrid layers improves the roads ability to resist temporary and permanent deformation.

During the unloading phase of each loading cycle, both the displacement and the strain in the bottom layer of geogrid demonstrated the ability to recover. The average strain recovery was 97.5%, and the average displacement recovery was 63%. Displacement recovery was greater as the number of geogrid layers increased, indicating that increasing the number of
Figure 5.   One layer of geogrid – displacement vs load (Flaherty 2020).
Figure 6.   Two layers of geogrid – displacement vs load (Flaherty 2020).
Figure 7.   One layer of geogrid – displacement vs load (Flaherty 2020).

layers of geogrid will help to reduce temporary and permanent deformation and thus increase the life of the road.

The highest strains were recorded at 40mm from the centre of the geogrid, which was directly under the plate load. This suggests that the lateral confinement of the aggregates results in a higher strain under the wheel load. Further research is required to clarify the mechanism causing this.

The results also indicated that lateral confinement occurs earlier when the number of geogrid layers increased. This could be as a result of the top layer of geogrid being closer to the plate load. Further research is required to determine the optimum placement of the geogrid.

3   CONCLUSION

Conclusions drawn from the work are as follows:

– small model testing boxes and instrumented geogrids were used successfully in combination with representative samples of weak subgrades and high-quality granular fill to simulate the response of biaxial geogrids to monotonic and cyclic plate loading;
– it was found that the tensile strain measured in the geogrid under test was only a small fraction of the geogrid's ultimate tensile strain, indicating that the ultimate tensile strength of the geogrid is less important than its interaction with the fill.;
– the magnitude of loading was found to have a more significant effect on road surface displacement than the number of load cycles suffered;

- it was also found that increasing the number of geogrids in the model unpaved road had a very significant positive impact on the strain and displacement suffered;
- further research is required to relate the thickness of the unpaved road in testing to design thicknesses from the design methods commonly in use;
- further work will use increased loading cycles and a larger testing box.

Quantifying geogrid reinforcement mechanism in roadway performance using Cyclic Plate Load (CPL) test

G.S. Ellithy
Assistant Professor, Department of Civil Engineering, Embry-riddle Aeronautical University, Daytona Beach, FL, USA

A. Crippa
Vice President, Tenax Corporation, Baltimore, MD, USA

ABSTRACT: For decades, geogrids have been used successfully to improve performance in both paved and unpaved roadway construction. Even though the current state of practice differentiates between the design methodology incorporating geogrids in paved and unpaved roadways, the true improvement contribution of geogrids is to the base layer, or to the layer that is placed directly on top of it. It has been established that the three reinforcement mechanisms by which geogrids enhance roadway performance are: lateral restraint, bearing capacity increase and membrane tension support. In order to quantify these mechanisms and their contribution to the roadway performance improvement, two Cyclic Plate Load (CPL) tests were carried out, one on a paved section with a hot mix asphalt (HMA) top layer, and the second on an unpaved section. The tests included control and reinforced sections. Each test was instrumented with Linear Variable Differential Transducers (LVDTs) at the surface and subgrade levels that measured the displacements at these levels while the cyclic loads were applied. The paper presents the results in terms of the Reinforcement Improvement Ratio (RIR) which is calculated as the ratio between the number of load cycles of the reinforced section divided by the number of cycles of the control section at the same level of displacement. It was found that RIR is almost identical for surface displacements for both paved and unpaved roadway sections indicating the similar lateral restraint effect of the used product. The bearing capacity increase and membrane tension support vary between paved and unpaved sections depending on the level of displacement at the base course and subgrade contact. The results of those two tests were used to put an emphasis on quantifying the mechanism by which the geogrid contributes to the roadway performance improvement regardless whether it is paved or unpaved. The results could be used empirically to modify the current state of practice for geogrid contribution in paved and unpaved roadways. It should be noted that the terms soil *reinforcement* and soil *stabilization* have been used interchangeably to indicate the above soil improvements using geogrids.

1 INTRODUCTION

As stated by Holtz *et al.* (1998) When an aggregate layer is loaded by a wheel, the aggregate tends to move laterally, as shown in Figure 1a, unless it is restrained by the subgrade or a geosynthetic reinforcement layer. Soft, weak subgrade soils provide very little lateral restraint, so when the aggregate moves laterally, ruts develop on the aggregate surface and also in the subgrade. A geosynthetic layer with good interlocking capabilities, like a geogrid, or frictional ability like a geotextile, can provide tensile resistance to lateral aggregate movement. Bearing capacity increase is another geosynthetic reinforcement mechanism as shown in Figure 5-2b.
Figure 1. Possible reinforcement functions provided by geosynthetics in roadways: (a) lateral restraint, (b) bearing capacity increase, and (c) membrane tension support (after Haliburton, *et al.*, 1981).

Similar to a footing, the use of geosynthetic reinforcement may force the potential bearing capacity failure surface to follow an alternate higher strength path. A third possible geosynthetic reinforcement function is membrane tension support of wheel loads, Figure 1c. In this case, the wheel load stresses must be great enough to cause plastic deformation and ruts in the subgrade. If the geosynthetic has a sufficiently high tensile modulus, tensile stresses will develop in the reinforcement, and the vertical component of this membrane stress will help support the applied wheel loads. Because tensile stress within the geosynthetic cannot be developed without some elongation, a significant rutting is needed to develop membrane-type support. Therefore, this mechanism is generally present in unpaved roads.

This paper presents the results from two Cyclic Plate Load (CPL) tests, one is performed on a paved section with a hot mix asphalt (HMA) top layer, and the second on an unpaved section. In both tests the California Bearing Ratio (CBR) of the subgrade was 2.0%. The testing conditions for the two tests were almost similar. Each test consisted of a control section and a reinforced section with the a geogrid layer placed on the subgrade where the base course layer was directly compacted on top of it. The tests were performed to investigate the geogrid reinforcement mechanisms in both paved and unpaved roadway sections and quantify these mechanisms if possible using the Reinforcement Improvement Ratio (RIR) which is calculated as the number of load cycles of the reinforced section divided by the number of load cycles of control section at the same displacement level.

2 CYCLIC PLATE LOAD (CPL) APPARATUS

The CPL test apparatus consisted of a rectangular concrete and steel test box that is 1.8 m deep, 2.3 m wide and 2.3 m long (6 ft × 7.5 ft × 7.5 ft). A stiff steel frame bolted to the top of the walls is used as a reaction for the servo-hydraulic actuator that provides the cyclic load to

the test surface. The servo-hydraulic system is programmed to continuously deliver individual load pulses having a trapezoidal shape and at a frequency of 1 Hz. The trapezoidal load pulse consists of four steps: ramp up to maximum load (0.3 s), hold maximum load (0.2 s), ramp down to minimum load (0.3 s), hold at minimum load (0.2 s). Max and min loads were 40 kN (9,000 lb) and 0.44 kN (100 lb), respectively, TRI (2019, 2022). The load was delivered to the road surface through a 2.5- cm (1-in). thick, 30- cm (12-in) diameter steel plate, designed to represent one equivalent single axle load (ESAL). Linear variable differential transducers (LVDTs) were positioned along the centerline of the load plate to measure vertical displacement of the surface as the test progressed, Figure 2. Information from these sensors was used to create a profile of the rut bowl resulting from the applied cyclic load. In addition, a single LVDT was also embedded in the subgrade to monitor displacement at the interface between the subgrade and base course (also the position of the geogrid for the reinforced tests). A data acquisition system was designed to monitor the applied load and displacement of all the LVDTs at a frequency of 25 Hz. From this data, a single max and min value was recorded for each of the sensors every 2 seconds.

Figure 2.   Typical surface sensor setup.

3   MATERIAL PROPERTIES

3.1   *Subgrade*

The subgrade soil was classified as a lean clay with sand (CL) according to the USCS classification system, and had a liquid limit (LL) of 40% and Plasticity Index (PI) of 19%, with an optimum moisture content and dry density of 18.6% and 16 kN/m^3(101.4 lb/ft^3), respectively. Subgrade construction consisted of placing and compacting the subgrade material in six 15-cm (6-in) thick lifts in the CPL box. The subgrade was thoroughly mixed and moisture conditioned to ensure the subgrade was uniform when placed. The target shear strength for the subgrade was 86.5 ± 3 kPa to achieve a California Bearing Ratio (CBR) strength of 2.0 ± 0.1%. This strength corresponded to a moisture content of about 28%. In place shear strength was measured using a hand-held vane shear to ensure consistency and strength during construction. Compaction of the subgrade was accomplished using a jumping jack compactor. The sixth and final layer of the subgrade was leveled to a tolerance of ±2.5 mm using a metal draw bar to cut the surface flat. The surface of the subgrade was covered with plastic during construction to prevent it from drying out.

3.2   *Geogrid*

A 3D structured geogrid was used in the reinforced test section. The geogrid in both tests was placed on the subgrade and the base course was compacted directly on top it. A single piece of geogrid was cut from the roll to fit within the width of the test box The material was cut out in a 45 degree orientation to allow instrumentation wires oriented in the machine and
Figure 3. Geogrid instrumentation.

cross-machine directions to exit from the two front corners of the test box. The geogrid was pulled taut to remove any wrinkles and wooden stakes were used to hold the materials in place. A photo of the installed geogrid is shown in Figure 3.

3.3 *Base course*

The base course consisted of crushed granite, and has a gradation as shown in Figure 4. The base course was classified as poorly graded gravel (GP) according to the USACS. It was constructed in four lifts for a total depth of 30 cm (12 inches) and was compacted using a vibrating plate load compactor. The in-place density of the base course was measured using a sand cone device. The dry unit weight averaged 22 kN/m^3 (138 lb/ft^3). The strength CBR of the base course was verified using Dynamic Cone Penetrometer (DCP) and averaged 10%.
Figure 4. Grain size distribution for the base course.

3.4 *Hot Mix Asphalt (HMA)*

The hot-mix asphalt (HMA) used in the testing of the paved section was purchased from a local HMA plant and stored in steel drums. HMA was installed in two layers, by reheating the mix for each layer, screeding it to a uniform depth and compacting it using a flat vibrating plate compactor. The final mix averaged a density of 19.5 kN/m^3 (124 lb/ ft^3) and a depth of 5.7 cm (2.27 inches).

4 RESULTS AND DISCUSSION

Figure 5 shows the results of the first test which included a 5.7 cm HMA layer (paved section/ Test 1). The results are presented by comparing the number of load cycles corresponding to the same displacement for control and reinforced sections. The compared displacements are those occurring at the surface of the subgrade. The load cycles are compared for the subgrade surface displacement at about 6 mm (0.25 inch), and the Reinforcement
Figure 5.   Subgrade surface displacement response for the paved section (Test 1).

Improvement Ratio (RIR) which is defined as the number of cycles for the reinforced section divided by the number of cycles of the control section, is about 13. An unexpected error occurred while measuring the displacement for the HMA surface and it is not presented in this comparison. As expected, the placement of a geogrid layer as a reinforcement inclusion between the subgrade and base course has significantly contributed to the performance of the paved section and increasing the number of load cycles, which could be translated to increasing design life.

Figure 6 shows the results of the second test which included a base course layer on top of the subgrade (unpaved section/ Test 2). Similar to the paved section, the results are presented by comparing the number of load cycles corresponding to the same displacement for control and reinforced sections. The compared displacements are those occurring at the surface of the base course and the surface of the subgrade. The load cycles are compared for the base course surface displacement at about 100 mm (4 inch), and the ratio is about 12. For the subgrade displacement which is at the level of 50 mm (2 inch), the ratio is also about 27. Similar to the paved section, the placement of a geogrid layer between the subgrade and base course has significantly contributed to increasing the number of load cycles, and hence design life.
Figure 6.   Base course and subgrade surface displacement response for the unpaved section (Test 2).

It is worth noticing the similarity between Test 1 and Test 2 RIR for the top surface displacements; top of subgrade in Test 1 (RIR = 13) and top of base course in Test 2 (RIR = 12), this indicates that for a given reinforcement level, or a given geogrid or geosynthetic product, the effect is almost identical for the lateral confinement mechanism which is the main mechanism responsible for geogrid reinforcement whether an HMA layer is present or not.

It was observed that the reinforced section in both paved and unpaved sections experiences less heave along the contact between base course and subgrade beyond the deforming area, and hence increase the bearing capacity of the reinforced section. The level of bearing capacity increases different between the paved and unpaved sections. The displacement

1231

along this contact was recorded and will be presented in the final submission of the paper to show the effect of bearing capacity increase mechanism as an effect of geogrid reinforcement.

It could be noticed that the membrane tension support mechanism is more dominant in the unpaved section (Test 2) where the RIR of the subgrade surface displacement is 27, higher than all other calculated RIR values. That is again, an expected result, but now it could be qualified and a clear contribution of the reinforcement through this mechanism can be quantified.

5 SUMMARY AND CONCLUSIONS

This paper summarizes the results from two Cyclic Plate Load (CPL) tests on two roadway sections. Test 1 was on a paved section that included a 5.7- cm thick HMA layer on top of 30- cm thick base course overlying a 2% CBR subgrade. Test 2 was on an unpaved section with configuration similar to Test 1 but without the HMA layer. In both tests, a 3D geogrid was placed at the contact between the base course and the subgrade. To quantify the three mechanisms of reinforcement; lateral restraint, increase in bearing capacity and membrane tension support, results were presented in form of a ratio between the number of load cycles of the reinforced section to that of the control section at the same level of displacement. This ratio is referred to as the Reinforcement Improvement Ratio or RIR. The RIR was calculated for the top surface, top of HMA for Test 1 and top of base course for Test 2, and for top of subgrade for both tests.

It was found that RIR is almost identical for surface displacements for both paved and unpaved roadway sections indicating similar base course lateral restraint effect of the 3D geogrid used in the tests whether the section is paved or unpaved. The bearing capacity increase mechanism varied between paved and unpaved sections depending on the level of displacement at the base course and subgrade contact beyond the deforming area. More data will be presented at the final submission of the paper with regard to this mechanism. RIR of the subgrade surface displacement in Test 2 (unpaved) was 27, higher than all other calculated RIR values. This indicates that the membrane tension support mechanism is more dominant in unpaved sections where high level of displacement leads to elongation in the geogrid which in return increases the resistance to further displacement.

The results of those two tests were used to put an emphasis on quantifying the reinforcement mechanisms by which the geogrid contributes to improvement of roadway performance whether it is paved or unpaved. The results could be used empirically to modify the current state of practice for geogrid contribution in paved and unpaved roadways.

The shear bonding of interlayer's effect on rutting parameters of an asphalt overlay

F. Moghadas Nejad, A. Noory & M. Khodadadi
Amirkabir University of Technology, Tehran, Iran

ABSTRACT: Using geosynthetic materials has noticeable effects on reducing the growth of reflective cracks in asphalt pavements. Meanwhile, some other parameters can be changed despite the positive effects and increasing the number of loads that the overlay can tolerate before cracking starts, and reducing the crack growth rate due to the reduction in shear strength between asphalt paving layers. One of the most important effects of changes in shear strength between pavement layers strengthened by geosynthetics is the change in resistance to other failures like rutting. In this study, the shear strength between the pavement layers was measured using the AUT-SFT device. Then, the resistance against rutting was tested for the same samples using a wheel-tracking machine. The results showed that the lower the shear strength of the geosynthetic reinforced specimens, the higher the rut depth in the AUT-SLT machine after the end of 600 load cycles.

1   INTRODUCTION

Hot mixed asphalt (HMA) overlay is a common solution for repairing degraded pavement. In fact, reflection cracks can propagate through the pavement and cause some distress in overlaid systems (Fallah & Khodaii 2015; Gonzalez-Torre *et al.* 2015). Reflective cracks are caused by the displacement of an underlying cracked layer due to shear and tensile stress induced by traffic loads or temperature changes (Amini 2005; Lytton *et al.* 2010). The environment and traffic conditions affect the propagation rate of cracking (Penman & Hook 2008; Sobhan & Tandon 2008). As it is well known, cracks in the lower layer can propagate through the upper layer due to concentrated strain at the top section of the old layer. There is currently no complete solution to prevent this phenomenon, but the occurrence of this cracking can be postponed (Khodaii *et al.* 2009).

Field reports indicate that geosynthetics can delay crack propagation in pavement systems and extend their service life (Shukla & Yin 2004). Some research has been conducted on the delaying solutions for reflection cracking in the overlay using various approaches at the field, experimental, and numerical scales (Austin & Gilchrist 1996; Baek & Al-Qadi 2006; Chen *et al.* 2013; Koerner 2005; Kazimierowicz-Frankowska 2008; Moreno-Navarro *et al.* 2014; Yang *et al.* 2011). Filtration, drainage, reinforcement, separation, and liquid barrier behavior are the primary uses of geosynthetic materials. Geosynthetic material reinforces the pavement structure by altering the pavement's reaction to loads (Koerner 2005). Among the different approaches, using an interlayer at the top of the old layer and the bottom of the overlay can provide better conditions to mitigate and delay the reflective cracking. This interlayer, like geosynthetics (geotextile, geocomposite, and geogrid), reduces stress or reinforces the pavement. Reinforcement occurs when the inter-layer's modulus is higher than that of the top and bottom pavement layers. On the other hand, stress relief happens when the modulus obtains a lower value (De Bondt 2000; Lytton 1989). The overlay's horizontal

tensile stresses created by loading and heat cycling should be reduced using the interlayer (Kim & Buttlar 2002).

Numerous numerical, experimental, and field studies have been conducted to propose various solutions for reducing the reflective cracking rate. The effect of fabric, as the stress relief layer, on pavement performance was evaluated by Amini (2005). It was reported that different factors, such as weather and subgrade conditions, traffic load, overlay thickness, and crack width, can affect pavement crack movement. Penman and Hook showed that the propagation rate of reflective cracking could be changed two-three times based on the glass-fiber geogrid inclusion within the overlay (Penman & Hook 2008). Sobhan & Tandon (2008) analyzed beam samples of asphalt mixture and found that stiff geosynthetic layers create more reflection cracking resistance. Khodaii *et al.* (2009) investigated the effect of different parameters on the propagation of reflection cracks, such as pavement type (asphalt mixture and concrete), the position of geogrids, test temperatures, and crack opening rate. They demonstrated that the position of one-third depth of overlay thickness from the bottom is more appropriate to increase the pavement fatigue life. Siriwardane *et al.* (2010) investigated the effect of glass fiber grids on asphalt pavement. Specifically, the results of their study and Fallah & Khodaii's work (2015) indicate that glass grids provide better pavement resistance to reflective cracking than other materials, such as polyester grids.

In addition, geosynthetics can also be used to reinforce pavements against rutting. Here, we present a summary of the related studies that assess the effects of geosynthetics on the rutting resistance of asphalt mixtures, even though limited research has been conducted regarding the effect of geosynthetics on rutting performance. Rutting distress of asphalt pavement accelerates with increasing the traffic load and pavement temperature (Bertuliene *et al.* 2011). As a result, lateral movement occurs in the pavement and creates a shear failure due to the shear strain (Kim & Park 2013). In addition, other factors, such as the thickness layer and its age, can influence the permanent deformation of the pavement (Abdullah Nur *et al.* 2013).

On the other hand, geosynthetics can reinforce the strength of the pavement against various distresses and changes its rheological model (Huang 1993; Perkins 1999). In this regard, Laurinavičius & Oginskas (2006) evaluated the rutting performance of reinforced pavement layers by geosynthetics and compared it to the control sample (with an equal thickness). They found that the rutting results are correlated with the elastic modulus of pavement, so a higher modulus indicates greater resistance to rutting. Regarding the higher elastic modulus of the reinforced layer, less permanent deformation was experienced. The reason is that geosynthetics reduce the shear strain of the asphalt layer (Laurinavičius & Oginskas 2006). Another study found that pavement reinforced with a smaller aperture geogrid size provides a better rutting resistance (Jenkins *et al.* 2004). The interlocking of asphalt mixture and geogrid contributes to the restraining effect and reduces the settlement of reinforced pavement compared with the control sample (Ling & Liu 2001). A field study was performed to investigate the role of geogrid on the rutting performance of asphalt pavement. The monitoring results proved the efficiency of geosynthetic materials (Sobhan *et al.* 2005). Compared to control samples, Komatsu *et al.* demonstrated that increasing geogrid adhesion to the asphalt mixture and reducing geogrid mesh size increased cutting and crack resistance by 30 and 10 times, respectively (Komatsu *et al.* 1998).

In 2018, Noory *et al.* developed a double shear bonding test named Amirkabir University of Technology Shear Lab Tester (AUT-SLT) for conducting dynamic shear loading on geocomposite-reinforced specimens. The device was able to apply normal load as well as dynamic shear loads (Noory *et al.* 2018). In other research, Noory *et al.* evaluated the effective parameters of shear resistance on the interface in a geocomposite-reinforced pavement. The parameters included product type, effective mesh size of geocomposite, the tensile strength of geocomposite, elongation at break, bitumen retention, and temperature (Noory *et al.* 2019a, 2019b).

Literature shows that different parameters can affect the shear bonding of geosynthetic reinforced overlays. Additionally, little research has been conducted on the effects of such parameters on the rutting resistance of asphalt overlay systems. This study is intended to comprehensively evaluate the effect of the most significant factors contributing to pavement performance through shear bonding strength and rutting phenomena. Here, the shear bonding between overlay and asphalt pavement is measured by the AUT-SLT device, and then the same samples were tested under the wheel track rutting device. An analysis of the results determined that specimens with greater shear bonding between layers were more resistant to rutting and showed less rutting depth.

2 SAMPLE PREPARATION

In order to figure out the relationship between the parameter of the rutting depth and shear bonding between layers of the geosynthetic reinforced specimens, two types of tests and specimens were designed and developed:

– Rutting of a geosynthetic reinforced overlay by a wheel-tracking machine
– Shear bonding between layers by AUT-SLT device

2.1 Rutting test

The specimens for the rutting test were prepared using the Press-BOX device, which applied shear side loading and compression loads from the upper actuator. A wheel-tracking machine is used to simulate the rutting process. The specimens consist of two layers reinforced by geocomposites with two 28 and 111-mm grid sizes. Also, a tack coat was applied at two rates of 0.5 and 1.5 kg/m^2. The specimens were fixed in (Figure 1a). The wheel-tracking machine mold and 600 load cycles were applied (Figure 1b). A side view of specimens is illustrated in Figure 1c. The rut depth was measured using an LVDT installed on the device.
Figure 1. Specimen preparation and rutting test set-up.

2.2 Specimen preparation test

The specimens used in the AUT-SLT device (Amirkabir University of Technology – Shear Lab Tester) are designed and built in three layers, as shown in Figures 2a and 2b. The samples were prepared in Press-BOX mold (Figure 2c), each cut into three samples. A servo-hydraulic actuator conducted the tests at a constant displacement rate of 12.5 mm/min. All the tests were done at two temperatures of 15°C and 30°C.
Figure 2. Specimen preparation and rutting test set-up.

Table 1 shows the experimental design of the tests. This analysis considered three factors: temperature, mesh size of the geocomposite, and application rate of the tack coat, all applied at two levels.

Table 1. Experimental design of the tests.

Specimen code	Temperature	GG size	Tack coat application rate
SP1	15	28	0.5
SP2	15	28	1.5
SP3	15	111	0.5
SP4	15	111	1.5
SP5	30	28	0.5
SP6	30	28	1.5
SP7	30	111	0.5
SP8	30	111	1.5

3 TEST RESULTS AND ANALYSIS

Table 2 displays the results of tests performed under predefined conditions.

Table 2. Test results for shear bonding and rutting tests.

Specimen code	Shear test results (kN/m^2)	600 cycles rutting (mm)
SP1	307.5	4.33
SP2	459.6	2.67
SP3	372.2	4.31
SP4	487.9	2.18
SP5	97.6	6.88
SP6	119.8	5.97
SP7	108.6	6.43
SP8	136.5	5.22

Before continuing with the analysis, the Anderson-Darling test was applied to the data to check whether the data was normal. As both rutting and AUT-SLT tests results had a P-Value greater than 0.05, it can be concluded that the test results passed the normality conditions.
Figure 3. Anderson-Darling test results for AUT-SLT-FFDS (kN.m^2).
Figure 4. Anderson-Darling test results for 600 cycles rutting depth (mm).

Figures 5 and 6 show that the difference between the lower and higher temperature levels has the greatest influence on both test results but in the opposite direction. As the temperature increases, the amount of rutting increases; on the other hand, the resistance to shear loads decreases. The next effective parameters are tack coat application rate and GG size.
Figure 5. Main effects plot for AUT-SLT results based on the factors.
Figure 6. Main effects plot for 600 cycle rutting depth results based on the factors.

The graph of 600 cycles of loading rut depth versus AUT-SLT results is shown in Figure 7. This graph illustrates that rut depth decreases with increasing shear bonding. In other words, the increase in shear bonding can prove a crucial factor in preventing rutting in the studied pavements.

A study of deformed overlays has revealed that the layers slide on top of each other, resulting in a reduction in strength against rutting.
Figure 7. Overlay shear bonding versus rut depth.

4 CONCLUSION

This study tested the shear bonding between layers of a geocomposite-reinforced specimen using AUT-SLT, a double shear test device developed at Amirkabir University of Technology. The rutting effect of the wheel path through pavement was also investigated, and the amount of rut depth was measured. After checking the normality of the data gathered, an analysis of the data was conducted, which resulted in the following conclusions:

− The temperature had the most significant impact both on the shear bonding between layers of a geocomposite-reinforced pavement and the rut depth.
− Tack coat amount was the second significant factor contributing to the dramatic change in shear bonding and rut depth.

- The mesh size of the geocomposite was the third effective parameter affecting shear bonding and rut depth. Greater mesh size can result in better bonding between layers and better action in rutting.
- There is a direct correlation between the shear bonding of layers and the rut depth after 600 wheel paths on the reinforced pavement. It was found that rut depth decreased as shear bonding increased. Consequently, the increase in shear bonding is an important factor in preventing the rutting phenomenon in the studied pavements.

ABSTRACT: Installation damage tests were carried out on several geosynthetics of various types and from different manufacturers. The testing procedures included conditioning products in a field installation at low temperatures, under specific Nordic conditions (crushed rock, compaction) followed by laboratory tensile testing of the exposed and unexposed geosynthetic samples. The results of the individual tests were evaluated, and the results interpreted anonymously regarding the different geosynthetic versus the typical design approach in similar Nordic conditions at positive temperature.

1 INTRODUCTION

In order to be able to propose recommendations for the use of reinforcement/stabilization geosynthetics in Nordic conditions, an investigation was carried out to collect information and provide data on their behaviour during installation in Nordic conditions (sub-zero temperatures, soil types and working conditions) (Rough project 2022). The investigation included a full-scale trial at a site in Northern Finland, 15 km southeast of Kemi along the E8/E75. The geosynthetics were installed at sub-zero temperatures ($-10°$C) under Nordic conditions, followed by tensile testing of the exhumed materials alongside non-exposed materials at temperatures of $+ 20°$C, $0°$C, $-10°$C and $-20°$C. Installation and recovery of the geosynthetics took place on 5th and 6th February 2020.

The installation replicated a typical subbase/base layer reinforcement/stabilization application. The geosynthetics were installed on a prepared subbase (compacted crushed rock) and a layer of crushed rock then dropped over the geosynthetic and compacted using typical construction plant. The trial was deconstructed, materials were exhumed, and samples taken for testing in the laboratory.

Several geosynthetics have been tested with different product structures and produced with different polymers: polyester woven coated geogrid, polyester strip geogrid, polypropylene strip geogrid, polypropylene punched and extruded geogrids, a polypropylene woven and geocomposites nonwoven with an extruded geogrid or a strip geogrid.

2 CLIMATIC CONDITIONS FOR THE INSTALLATION TRIAL

Temperature was recorded on site and compared with the data provided online by the Finnish Meteorological Institute (www.ilmatieteenlaitos.fi) from the nearest weather station at Kemi Airport (distance 20 km). Temperatures measured on site matched the weather data. For this reason, the data recorded hourly by the Finnish Meteorological Institute is used to indicate the temperatures during the installation conditioning of the geosynthetic products. During installation of the products and compaction of the layers of crushed rock material, the air temperature ranged between $-7°C$ and $-15°C$. No snow needed to be removed from the test section and no snowfall occurred during the installation and filling work. During the deconstruction/recovery of the samples on Thursday the 6th Feb. 2020 temperatures between $-4°C$ and $-7°C$ were recorded.

3 CRUSHED ROCK MATERIAL

The material used for the subbase and base layer was typical for Finnish road construction and unbound granular subbases. Figure 1 displays the particle-size distribution of the material used together with the limit values presented in Finnish guidelines InfraRYL for the base course. The material is named as "KaM 0/56" which means it is crushed rock GO 0/56 mm based on SFS-EN 13242.
Figure 1.   Particle-size distribution of crushed rock used and the Finnish limit values for subbase material.

4 TRIAL SET UP AND CONSTRUCTION

Construction of the trial sections followed Finnish specifications for road construction. Figure 2 shows the cross section of the setup for field conditioning. An imported fill material was placed and compacted over the entire trial area to level the site and provide a frost protection layer. This was a ferrochrome slag waste product from a nearby steel plant. The slag material had a temperature of approx. $+18°C$ on delivery to site. The temperature dropped to $+6°C$ one night after installation. Material temperatures were checked with a penetration thermometer approx. $5 – 10$ cm below each layer surface.

After placement and compaction of the slag layer, a subbase of 0/56 crushed rock was placed and compacted to a finished layer thickness of 30 cm. The reinforcement/stabilisation geosynthetics were then unrolled into place and finally the base layer of 0/56 crushed rock
Figure 2.   Cross-section of field trial setup.

was dropped with an excavator bucket on the geosynthetics with a measured height of 1.0 m and compacted to a finished layer thickness of 30 cm.

Compaction was done with a 12.6 ton dynamic roller. Five dynamic roller passes were used for compaction of each layer. Figure 4 shows the compaction level of each layer subsequently checked with a dynamic load plate testing device. During the compaction process the subsoil had a temperature of about – 6°C. Freshly delivered crushed rock material had a temperature of approx. – 6°C. Before installing the geosynthetics, subbase temperatures of about – 12°C were recorded.

Figure 3 shows the layout of the various geosynthetics and the compaction control verification (E_{V2} values). To minimize positional influences, each geogrid product was cut into half and installed at two different locations along the test field. For the subbase layer an average bearing capacity modulus of $E_{V2} = 132$ MN/m^2 was measured. The measured values ranged from $114 – 170$ MN/m^2. The base layer reached a bearing capacity modulus of $E_{V2} = 143$ MN/m^2 in average. The measured values ranged from $92 – 170$ MN/m^2. Before installation of the base layer, the locations of specimens for further laboratory testing were marked. This is to eliminate the possibility of bias by specimen selection. The pre-marked specimen locations can be seen in Figure 4.
Figure 3.   Arrangement of geogrid samples and results of compaction control (EV2 values).

Figure 4.   Installed geogrid materials with test samples pre-marked before base layer placement.

During installation no heavy equipment drove over the installed geogrid products. The tipping height out of the excavator bucket was controlled to a consistent drop of 1.0 m.

5   RECOVERY OF SAMPLES

Samples needed to be cut from the geogrid specimens for testing and evaluation of installation damage. To avoid additional damage to the samples during recovery a suction

technique was used. The upper 20 cm of the base layer was removed carefully by excavator and the remaining 10cm using a vacuum suction lorry.

After all the base layer had been removed, samples were cut from the previously marked locations and labelled. The marking included the product identifier and location on the installed test setup. For transport to the laboratory, the samples cut out were stacked in a robust wooden box with fabric between to avoid mechanical damage or other degradation during the transport.

6 LABORATORY TESTING

Tests were performed on conditioned samples returned from the field trial ('damaged') and also on samples taken from the same product specimens but not sent to site (non-damaged). Temperature conditioning of the non-damaged samples provided information on the effect of temperature on product behaviour.

6.1 Tensile testing in temperature-controlled environment

The damaged samples from Kemi were tested at + 20°C according to EN ISO 10319 to determine the corresponding evolution of the stress-strain characteristics.

Parallel, tensile testing on non-damaged samples was carried out in a temperature-controlled chamber (Figure 5). The test specimens were temperature conditioned for one hour before testing began. After clamping samples in the test rig, the chamber temperature was allowed to stabilize at the required test temperature before testing commenced. The tests were carried out on single ribs according to EN ISO 10319 to determine stress-strain characteristics.

Non-damaged samples were tested at – 20°C, – 10°C, 0°C and + 20°C.

Figure 5. Single rib tensile testing in a temperature-controlled chamber.

6.2 Results - Influence of temperature on tensile behaviour on non-damaged samples

Results from tensile testing of the non-damaged samples show the influence of temperature on product stiffness. Importantly, all products showed an increase in stiffness with reducing temperature. Using the representation of the reduction factor applied on stiffness ($RF_{ID, J}$) proposed by Allen and Bathurst (1994) the Figure 6 shows its evolution for the range of results for all product types tested.

Considering the average of all products tested, the increase of stiffness is $\geq + 30$ % (20°C to 0°C) $\geq + 40$ % (20°C to – 10°C) and $\geq + 47$ % (20°C to – 20°C).

6.3 Results – Influence of installation on tensile behaviour

Looking at the evolution of the different conditioning steps of the samples helps with the interpretation of the results:
Figure 6.   Effect of temperature on RFID, J (stiffness) - range of data from all products tested.

Samples damaged in Kemi:

– End of manufacturing of the product: temperature $\sim$ + 20°C (positive); undamaged
– Lay down on site in Kemi:temperature −10°C; undamaged
– Backfilling and compaction:temperature −10°C; damaged by installation
– Recovering of damaged samples:temperature −10°C; no extra damaging
– After transport, test in laboratory:temperature $\sim$ + 20°C (positive)

Samples undamaged tested at different temperatures:

– End of manufacturing of the product: temperature $\sim$ + 20°C (positive); undamaged
– Conditioning and testing in laboratory: temperature + 20°C, 0°C, −10°C, −20°C

The laboratory tests on undamaged samples at different temperatures allow evaluation of:

– The tensile strength and the tensile stiffness of the different geosynthetics at −10°C (equivalent to temperature during placement and backfilling and compaction).
– The evolution of tensile strength and the tensile stiffness of the different geosynthetics during the time when they are installed in the soil and submitted to temperature variations. It shall be noted that in this case the surrounding soil is also subjected to the same temperatures; this means that the increase (resp. decrease) of stiffness of the geosynthetics happens parallel to the soil stiffness increase (resp. decrease).

The laboratory tests on the Kemi damaged samples are realized at + 20°C:

– They allow evaluation of the influence of the installation realized at – 10°C on the product when it recovers to a positive temperature (+ 20°C).
– The characteristics (tensile strength, strain, or stiffness) obtained should not be compared with the ones measured at – 10°C on the virgin geosynthetics.

A quite large number of products have been tested in Kemi and considering the severe installation conditions (crushed rock and heavy compaction), some of the products were under-designed for the intended use at conventional conditions and positive temperatures. For this paper, it has been decided to focus only the finding on the geosynthetics which would normally have been used in the same geotechnical conditions at a positive temperature.

Considering the typical subbase/base layer reinforcement/stabilization application, the stiffness is the most important performance related parameter to be considered, not forgetting of course a sufficient robustness (resistance to installation damage).

The tests on the undamaged samples at + 20°C and −10°C show a significant increase in stiffness (Figure 6) as temperatures reduce and it is reasonable to assume that these higher stiffness values were present during installation at −10°C in the Kemi trial. Nevertheless, the effect of installation in Kemi Nordic conditions shows only a small variation of tensile

stiffness (-2% to $+7\%$) compared to the un-damaged samples. This variation is within the test accuracy and can be seen to be minor. The effect of installation in Kemi Nordic conditions measured on tensile strength was found to be a small reduction between 0% and 13%.

7   LABORATORY SIMULATION OF THE EFFECTS OF INSTALLATION AT SUB-ZERO TEMPERATURES

As part of this same study, an attempt was made to simulate installation damage at sub-zero temperatures in the laboratory. Impact conditioning using a specific device with a weight of $1000 \pm 5g$ with a round drop head falling from a height of 50 cm (same energy as defined in EN ISO 13433 - Geosynthetics - Dynamic perforation test) was carried out, on temperature conditioned samples. Single rib tensile testing (on the ribs and the junctions) was then carried out at $+20°C$ on the impact damaged samples. Comparison of the results with those from the actual installation damaged samples from the Kemi trial showed no correlation. It was concluded that while a laboratory method to condition samples that would replicate installation damage effects was desirable, the proposed method was not valid for this purpose.

8   CONCLUSIONS

For the defined Nordic conditions in the Kemi trial (soil type - crushed rock, drop height 1 m, compaction, etc.) geosynthetics correctly designed to have minimal installation damage at more common positive site temperatures (i.e., above zero $°C$)

a) Exhibit no detrimental effect on strength from installation at sub-zero temperatures of –$10°C$.
b) Exhibit no significant difference in stiffness (measured at $+20°C$) following installation at sub-zero temperatures of $-10°C$.

The stiffness of these geosynthetics increased significantly when measured at $-10°C$ compared to $+20°C$ (43% in average). These increased stiffness values will be the expected characteristics when installed in soil at $-10°C$. It should be noted that the soil also exhibits increased stiffness compared to higher temperatures.

ABSTRACT: Forest roads are fundamental infrastructures to provide the necessary access to the forest. Most forest roads are unpaved, formed using a superficial layer of unsealed gravel or aggregate, and often local soils or a mix of these two types of material. Herein, two local Portuguese soils were studied, assessing their potential use in unpaved forest roads, namely by including reinforcement with a geocomposite, and by performing CBR and triaxial tests, and estimating key design properties using proposals from the literature. The CBR test results indicate little improvement of the response due to the reinforcement. The triaxial test results show a clear effect of the reinforcement, namely for higher axial strains. The stiffness of the composite material increased relative to the unreinforced soil, particularly for higher strains, and decreased the post-peak softening. The correlations used for estimating the resilient modulus of the soils led to a large scatter of values. Thus, they must be quantified using tests or by proposing adequate relations to other geotechnical properties, extending existing databases.

1   INTRODUCTION

Forest roads are fundamental infrastructures to provide the necessary access to the forest. Their design must be efficient, cost-effective, and compatible with environmental values. Most forest roads are unpaved and, commonly, are formed using a superficial layer of unsealed gravel or aggregate (Institute for Commercial Forestry Research 2005). Such layer spreads the loads, decreasing the stress level at the subgrade and the associated displacement. In some cases, staged construction can be used to ensure higher shear strength, by consolidation of the existing soil (Timber Transport Forum 2020). The superficial layer corresponds to a significant percentage of the total road cost. Thus, adequate design and construction can lead to important savings (construction and maintenance). To perform its functions adequately, a good forest superficial layer should (Dawson 2001): provide a smooth-running surface, promoting efficient driving and low tyre wear; enable low transient (resilient) deformations under the vehicle wheels; lead to insignificant permanent deformation (rutting); minimise dust during dry weather, to provide safe driving conditions, environmentally acceptable air quality and very limited effects on tree growth adjacent to the pavement; enable limited loss of aggregate from the surface, maintaining the pavement thickness. Often, the superficial layer is formed by an aggregate, local soil or a mix of these two types of material. Herein, two local soils were studied, assessing their potential use in unpaved forest roads with a geosynthetic reinforcement, and estimating key design properties.

2 METHODODLOGY

2.1 *Experimental programme*

This paper includes results for two soils, residual soil from granite and fine soil, and one geosynthetic. The response of the reinforced soil was compared to that of the unreinforced soil tested under the same conditions, using triaxial and CBR tests. Table 1 summarises the test programme.

Table 1. Experimental test program.

Test	Soil	N° specimens	Conditions	H (mm)	D (mm)	Reinforcement layer N°	Position (re. top)
CBR	Residual	1	Soaked	125	152	0	–
	Residual	1	Soaked	125	152	1	2H/5
	Fine	1	Soaked	125	152	0	–
	Fine	1	Soaked	125	152	1	2H/5
Triaxial	Residual	3	Dry, UU	140	70	0	–
	Residual	3	Dry, UU	140	70	1	H/2
	Fine	3	Dry, UU	140	70	0	–
	Fine	3	Dry, UU	140	70	1	H/2

2.2 *Materials*

The soils studied represent two possible scenarios for using local materials to build unpaved roads in Portugal. The residual soil from granite is typical of the North of Portugal and was sampled in the region of Porto; the fine soil was collected from a saltpan in the Aveiro lagoon. The main properties of the soils are summarized in Table 2 and Figure 1. The residual soil was a poorly graded sand with silt, while the fine soil was a sandy silt.

Table 2. Properties of the soils studied.

Soil	% fines (%)	D_{50} (mm)	D_{max} (mm)	G_s (–)	γ_{dmax} (kN/m^3)	w_{opt} (%)	I_P (%)
Residual	8	1.000	12.70	2.55	18.88	11.5	11
Fine	65.7	0.023	4.76	2.64	18.10	13.9	10
Figure 1. Particle grain size distribution of the soils studied.

A geocomposite, GC, was used, formed by continuous filament non-woven geotextile, reinforced by high tenacity polyester yarns in the machine direction, MD. Some of its nominal properties include: tensile strength and strain of 55 kN/m and 10% in MD; 12 kN/m and 85% in the cross-machine direction; thickness of 2.14 mm; mas per unit area of 325 g/m^2.

2.3 CBR tests

The procedure used for the CBR tests is described in a specification by the *Laboratório Nacional de Engenharia Civil* (LNEC): LNEC E198 (1967). The procedure is very similar to that in ASTM D1883–07 (exceptions for the test velocity and the number of blows used to compaction the soil).

Cylindrical specimens were tested, with diameter D = 152 mm and height H = 125 mm. Each specimen was prepared by assembling 5 layers of soil, 25 mm high each, compacted with 25 blows of a hammer with 4.54 kg of mass and drop height of 457 mm. The soil was prepared to the desired water content (w = w_{opt}, modified Proctor test), and allowed to rest for 24 hours at a standard atmosphere (temperature 20°C; relative humidity 65%) within impermeable containers. Then, the specimens were soaked for 96 hours. The tests were performed applying an axial displacement of 1 mm/min. For the reinforced specimens, a similar procedure was used. The main difference was placing a disc of reinforcement horizontally at 2H/5 from the top of the specimen.

2.4 Triaxial tests

Unconsolidated undrained (UU) compression triaxial tests (ISO/TS 17892-8: 2004) were carried out using the following conditions: cylindrical specimens (70 mm diameter D; 140 mm height H); axial strain rate of 0.7 mm/min; dry specimens; confining stress of 50, 100 and 150 kPa. The residual soil was compacted to a density index, I_D, of 53% (dry unit weight of 14.05 kN/m^3). The fine soil was compacted to a compaction degree of 71% (dry unit weight of 12.85 kN/m^3).

All specimens were assembled in a similar way, by preparing layers of compacted soil (4 layers, 35 mm high each). To achieve the desired soil density, the total mass of soil necessary to remould a soil specimen was quantified and divided by the number of layers; then, each soil layer was build using the relevant mass of soil and compacted to the desired density. The compaction was done manually by vibrating the soil and applying cyclic normal forces to each layer. The reinforced soil specimens included a disc of reinforcement placed horizontally at mid height (H/2 = 70 mm). For these specimens, the mass of soil used to prepare the reinforced soil specimens was adjusted, to consider the volume of soil occupied by the reinforcement layer.

3 RESULTS

3.1 CBR tests

Table 3 summarizes the results of the CBR tests: target water content (w), real water content (w_{real}), CBR value for 2.5 mm and 5.0 mm penetration ($CBR_{2.5}$, $CBR_{5.0}$), maximum force (F_{max}). The force-penetration curves obtained are illustrated in Figure 2.

The results show that the inclusion of the reinforcement layer led to improvement of the response of both soils, when compacted to the optimum water content. The maximum force increased by 6% and 4% for the residual and fine soils, respectively.

Figure 3 shows the improvement factor of each soil reinforced with GC, for different values of the penetration during the CBR tests. For the residual soil, the largest improvement occurred for smaller values of penetration (up to 2.5 mm), while for the fine soil the improvement is more important for larger values of penetration (12.5 mm).

Table 3. Main results of the CBR tests.

Soil	Reinforcement	w (%)	w_{real} (%)	$CBR_{2.5}$ (%)	$CBR_{5.0}$ (%)	F_{max} (kgf)
Residual	–	11.5	11.4	22.1	25.1	1060.3
Residual	GC	11.5	11.0	22.4	25.4	1116.9
Fine	–	13.9	13.8	4.7	4.7	185.8
Fine	GC	13.9	13.6	4.7	4.9	192.9
Figure 2. Force-penetration response of residual and fine soils, unreinforced (UNR) and reinforced (R GC).
Figure 3. Improvement factor of the specimens of the residual and the fine soils reinforced with GC.

3.2 Triaxial tests

Table 4 summarizes the results of the triaxial tests: deviator stress (q), strain (ε), shear strength parameters (ϕ' and c'), secant stiffness modulus (E). The specimens of fine soil reinforced with GC did not fail; thus, no peak values are included. End of test values are designated as final (subscript fin), as critical state was not always reached. Figure 4 shows the stress-strain curves.

The reinforced soil specimens exhibited a response better than the soil. For the residual soil, the layer of reinforcement at mid-height of the specimens led an increase of peak deviator stress, q_{peak}, from 16% to 31%. The deviator stress at the end of the test increased 34% to 65% for the residual soil and 17% to 27% for the fine soil. Including the

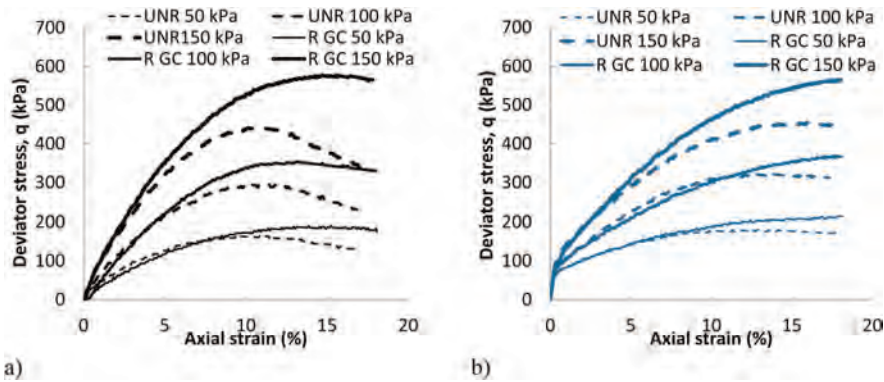

Figure 4. Stress-strain curves for unreinforced soil (UNR) and for soil with reinforcement layer at mid-height (R GC): a) residual soil; b) fine soil.

reinforcement layer changed the failure mechanism (Figure 5) from bulging, maximum at the centre of the specimens (unreinforced soil), to bulging between to top or the base of the specimen and the reinforcement layer (reinforced soil specimens). These changes confirm that the reinforcement was mobilised through friction as extension strains were induced at the centre of the specimens during the triaxial tests.
Figure 5. Observed failure mechanisms: a) unreinforced (UNR); b) reinforced (R GC).

4 ESTIMATES OF PROPERTIES RELEVANT FOR THE DESIGN OF UNPAVED ROADS

Mechanistic-empirical methods can be a way forward in achieving widely applicable unpaved roads designs. For that, the resilient modulus, M_R, of the materials is often a key parameter. For many countries where unpaved roads are used, particularly for low-volume roads, it may be challenging to assess the resilient modulus from experimental data. Thus, there are some correlations to other properties that can be used for an initial estimate of M_R. Mallela *et al.* (2009) presented some equations for that purpose, applicable to the design of flexible pavements. The quality of input data depends on the project level: level 1, requires the highest quality of data, obtained from direct testing on the project material; level 2, if a given parameter cannot be obtained from direct test results, it can be correlated to other test results; level 3, for lower volume roadways, where estimated input value for a given parameter are recommended, in the absence of test data. Equations 1 and 2 (level 2) refer to unbound aggregate materials, while Equation 3 (level 2), by AASHTO (1993), is applicable to for subgrade soils, namely fine-grained soils with a soaked CBR of 10. Table 5 shows recommended parameters for level 3, from Mallela *et al.* (2009).

$$M_R(MPa) = 17.6 \times CBR^{0.64} \tag{1}$$

$$CBR = \frac{75}{1 + 0.728(w \times PI)} \tag{2}$$

where PI = plasticity index of the soil and w = % of material passing the 0.075 mm sieve.

$$M_R(MPa) = 10.3 \times CBR \tag{3}$$

The fine soil is estimated to have M_R = 48.6 MPa (Equation 3). The soaked CBR of the soil is 4.7, smaller than the reference value of 10 for applicability of Equation 3. The fine soil can be classified as A-4, which leads to a level 3 estimate M_R = 75.8 MPa. The latter is 56% larger than the first, showing that this approach must be used critically. The residual soil does not meet any of the criteria, thus it is not possible to estimate its resilient modulus.

To promote the use of local soils in unpaved forest roads using mechanistic-empirical design methods, it is necessary to estimate key design parameters. Thus, the resilient modulus of local soils must be quantified using tests or by proposing relations to other geotechnical properties, extending existing databases.

5 CONCLUSIONS

This paper presents data on the shear strength and bearing ratio of two local soils (residual and fine) to assess their potential application in unpaved forest roads. The response of the unreinforced soil was compared to the soil reinforced with a geocomposite, using CBR and triaxial tests data. In addition, properties relevant for the design of unpaved forest roads were derived using proposals from the literature. From the results the following conclusions can be established:

- The CBR test results indicate little improvement of the response due to the reinforcement. The position of the reinforcement (at a depth equal to the width of the plunger used in the CBR test) is one of the causes of the small improvement observed.
- The triaxial test results show a clear effect of the reinforcement, particularly for higher axial strains. The stiffness of the composite material increased relative to the unreinforced soil, namely for higher strains, and decreased the post-peak softening.

Table 5. Recommended resilient modulus for level 3 applications of Mechanistic-Empirical Pavement Design Guide (MEPDG), Malella et al. (2009).

Material category	Base/subbase	Subgrade			
Soil / aggregate	Unbound	A-1[*]	A-4[*]	A-6[*]	A-7[*]
Resilient Modulus, M_R (MPa)	15.2	220.6	75.8	68.9	75.8

[*]AASHTO Soil Classification System (AASHTO M 145 1991)

- Conventional CBR tests may not be adequate for quantifying the mechanical response of the soil-geosynthetic composite.
- The correlations used for estimating the resilient modulus of the soils led to a large scatter of values (56% variation). Thus, they must be quantified using tests or by proposing adequate relations to other geotechnical properties, extending existing databases.

ABSTRACT: The methods for design and construction of high embankments on weak bases of geocell mattresses using geogrids have been developed and are successfully used in Ukraine. During construction of the road embankment near the bridge over the railway in Reni, Ukraine, geocell mattresses were used over the section of more than 5 km. The silted marshland, overgrown with reeds, could not serve as a good foundation for the 11 m high embankment. Difficult hydrogeological conditions and the threat of constant floods prompted to use the geocell mattress technology, which made it possible to reduce the cost and time of construction. After the embankment was reinforced with the geocell mattresses, the following was achieved: the total settlement of the embankment base was reduced by 30%; the calculated resistance of the base soil was increased by 25%; the bearing capacity of the base was increased by 33%. The field geodetic observations were carried out to confirm the reliability of the embankment reinforced with the geocell mattresses.

1 INTRODUCTION

The transport structures construction on weak bases creates many problems for designers and builders. Firstly, such construction is always associated with high costs, and secondly, it significantly increases the works execution time. Methods for increasing the base bearing capacity by removing a weak soil and replacing it with stronger materials or by arranging a pile field are not always feasible in practice and, as a rule, are not economically feasible. The modern technologies allow to solve the weak base problem and at the same time significantly reduce the construction time and obtain tangible financial savings (Jenner 1988), (Jewell 1988), (Kaliukh *et al*. 2013, 2021), (Slyusarenko *et al*. 2009, 2010), (Robertson 1987), (Trofymchuk *et al*. 2022), (Voloshkina *et al*. 2021). The base bearing capacity can be increased either by the groundwaters level lowering in water-saturated soils, or by the base soils preliminary compression by pressure (Dobie 2011). Today, the methods have been developed for the design and construction of high embankments on weak bases with the geosynthetic materials use (TENSAR 2023). Most of the calculation methods for the reinforced earthworks are based on limit equilibrium method. In the event of a seismic impact, the additional inertial loads caused by an earthquake are included in the equivalent static

loads and calculated as by the quasi-static analysis methods. The reinforced earthworks calculations shall be performed in two stages (TENSAR 2023). Stage 1 includes the analysis of the overall (external) structure stability, resulting in the determination of the overall dimensions of the reinforced earth structure and the length of the geogrids from reinforced earth with an allowance for the class of consequences (responsibility) of the structure. This is, in fact, the analysis of the gravity retaining wall for shear, overturning, and bearing capacity loss. The analysis of the overall structures strength is performed by the method of circular-arc slip surfaces or by the method of H.M. Shakhunyants (Terzaghi & Peck 1996). Stage 2 refers to the local (internal) strength analysis (a double-wedge method), when the geogrids strength and vertical step, as well as the strength of the geogrids junctions to the cladding are checked. If the structures are built in seismic areas, the stability analysis should consider the seismic actions. The design scheme according to stage 2 is conditionally divided between two wedges, namely, Wedge 1 and Wedge 2 (Figure 1a).

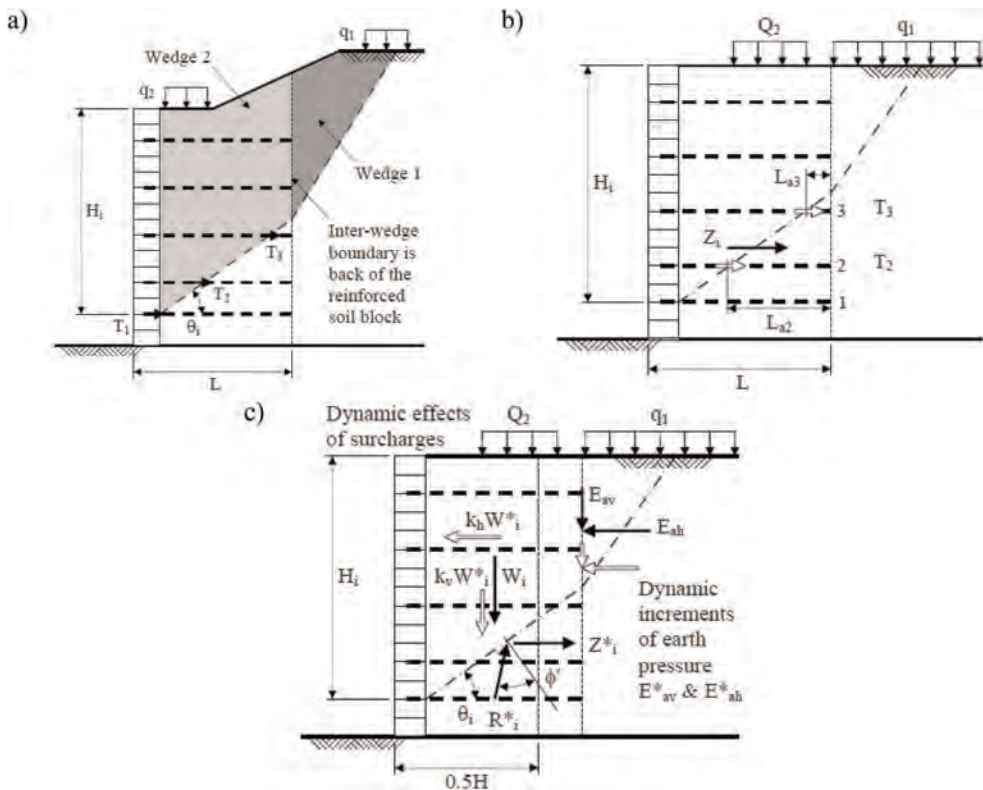
The purpose of the stage 2 analysis is to ensure that the resistance (frictional forces $T_1 + T_2 + T_3$) created by the cladding and soil reinforcement, which is intersected by the Wedge 2, is sufficient to avoid the local (internal) structure stability loss. The horizontal force Z_i required for the balance of two wedges is determined from the balance equation of forces applied to the Wedge 2 (Figure 1b): $Z_i = \sum H_i - \sum V_i \tan(\varphi' - \theta_i)$, where $\sum H_i$ is all horizontal forces sum equal to E_{ah}; $\sum V_i$ is all vertical forces sum equal to $W_i + Q_2 + E_{av}$; φ' is the internal friction angle of the backfill soil, degrees; θ_i is the variable angle of the Wedge 1 and


Figure 1. The internal stability analysis according to the stage 2: a - the scheme division into two wedges; b – forces acting on the structure; c – consideration of seismic effects (Dobie 2011). The symbols in Figure 1 correspond to the description of the program code TensarSlope version 1.13 (TENSAR 2023).

Wedge 2 inclination to the horizon, degrees. The analysis procedure for the seismic impact case is like that for static actions (Figure 1b), but with the additional action of seismic forces (Figure 1c). The main difference is the consideration of the additional seismic forces acting on the Wedge 2 (Figure 1c). A geomattress properly formed and placed in the embankment base keeps the overlying soil layers from displacements during the construction process and after its completion, until the base weak soils will gain sufficiently high mechanical characteristics due to consolidation and will stop to plastically deform. The paper purpose is to describe the geocell mattresses use for reinforcing the embankment of the approach to the viaduct over the railway laid through a silty swampy area overgrown with reeds (Bypass of the city of Reni on the km 0 + 000 – km 5 + 600 section with the area seismicity of 7 points on the Richter scale). Due to the complicated hydrological conditions and permanent flooding threat such soil originally could not serve as a good base for an 11-m high embankment. All that was a reason for the geocell mattress technology application by the Odesa highway service (TENSAR 2023). Such a structure was an alternative to the standard methods of the construction on weak soils, such as the soil replacement up to a mineral bed (1), and the pile foundation (2) or overpass (3) arrangement. The geogrids geomattresses in the bases provided a practical solution to the task of the embankments construction on the weak soils bases and promised the significant reduction of works execution time and their costs saving up to 31% compared to other options (TENSAR 2023).

2 MAIN PART

To study the engineering and geological conditions of the construction site at the international highway M15 (E87) Odessa - Reni (bypass of the city of Reni) section between the kilometer posts (KP) of 49 + 60-59 + 20 in the Odessa region, the surveys were carried out as the field, laboratory and office research parts. According to a plan, before the drilling operations start the road embankment base of sandy-loamy material was erected on the site. The natural relief was changed due to the elevations increase by 1.5–3.0 m. Absolute elevations at the wellheads along the road axis were 2.1–4.5 m. For boreholes drilling execution the portable drilling equipment "Geolog-15" was used. During the field works at the site, 6 boreholes of 10-m depth were drilled with soil sampling. In compliance with the general requirements to the soils characteristics determination methods (Ukraine Building Code. DSTU B V.2.1-3-96. 1996), the soils physical and mechanical properties were determined in the geotechnical laboratory, and the groundwaters chemical analysis was performed as well. Based on the office processing of the field and laboratory research data with the use of materials from surveys performed in the area in previous years, the engineering-geological elements (EGE) were defined, and the report was compiled with the corresponding text and graphic appendices. Sandy-argillaceous alluvial-estuarine deposits are the part of the geological succession, and modern Quaternary and Tertiary (ancient deluvium) alluvial and alluvial-estuarine deposits are the part of the site engineering geological structure up to the explored depth of 10.0 m (Figure 2).

If in the soils profile there are the soils belonging to the third category in terms of seismic properties, the site seismic activity should be increased by one point, and for the fourth category of soils in terms of seismic properties the site design seismicity should be determined by microseismic zoning (Ukraine Building Code. DSTU B V.2.1-3-96. 1996). The analysis of the soil physical and mechanical characteristics shows that the natural soils cannot serve as the highway embankment base because these soils deformations under the distributed load from automobile traffic will be very high. The deformations will lead to the road surface destruction. Due to the actual soils physical and mechanical characteristics and other conditions (silty swampy terrain overgrown with reeds), the natural terrain cannot serve as a good base for an 11-m high road embankment. The complicated hydrological conditions and constant flood threat lead to the need of transforming the initial physical and mechanical

properties of the base soil by means of the soil reinforcement to reduce the deformations of the future highway embankment bases. For this purpose, a TENSAR geocellular mattress is chosen (TENSAR 2023). It is a three-dimensional structure consisting of a TriAx 170 basic hexagonal geogrid laid directly on the weak soil and the vertical cells of RE570 uniaxial geogrids. The slow process of constructing the embankment structure reinforced with geo-mattresses allows to accelerate the rate of the base stability increase with loads applied to the embankment being considered.

3   THE EMBANKMENT STABILITY ANALYSIS

The stability, subsidence and consolidation time of the 11-m high embankment is analyzed in accordance with the EGE data for the borehole No. 1 on the KP-49 road section at the approaches to the viaduct. The embankment subsidence and consolidation time are analyzed for the pressure of 0.20 MPa. The embankment height is 11 m and $\gamma \sim 18$ kN/m^3, P $\approx$ 0.2 MPa. The total embankment subsidence is S = 0.39 m. Some soil layers characteristics taken for the analysis are given in Table 1.

Using the commercial software (program code TensarSlope version 1.13 (TENSAR 2023)), the following types of computations were performed: overall stability analysis for the embankment with a geocellular mattress at its base without any seismic impact (1); overall stability analysis for the embankment with a geocellular mattress at its base under the seismic load action (2); analysis of the embankment base subsidence without reinforcement (3); analysis of stresses reduction along the embankment bottom when the base is reinforced (4); base subsidence analysis in the case of the reinforcement with a geocellular mattress (5); analysis of the embankment base soil consolidation without the base reinforcement (6); base consolidation analysis for the embankment reinforced with a flat mattress (7). In Figure 3 the design scheme of the static analysis is presented.

Table 1. The soil layers characteristics used in the analysis.

№	Soil layer	Layer thickness, (kPa)	φ, (degree)	γ, (kN/m^3)	E, (MPa)	Initial c, (kPa)
0	EGE 2	1	18	19.5	14	4
1	EGE 2a	0.6	18	19.5	14	4
2	EGE 2б	0.4	18	8.4		4
3	EGE 2c	0.4	18	8.4		
4	EGE 3	0.9	10	17.8	10	8
5	EGE 4	2.4	13	19.5	13	4
6	EGE 5	2.4	11	19.2	9	8
Figure 3. Design scheme of the embankment with a stabilizing geocell mattress (Bishop's method, static analysis): Subgrade – the filled soil according to Table 1 (soil № 0); Geocell – the geocell mattress; 1-6 soils according to Table 1; Fmin/max – the minimum and maximum factors of safety.

The analysis shows that the ratio of the shear moment to the resisting one is 1.363 along the curve No. 1 (Fmin, Figure 3) and 1.561 (Fmax, Figure 3) along the curve No. 2. For a more detailed understanding, the additional seismic analysis (7 points on the Richter scale) is performed. The results of this analysis show that the factor of safety is by $\sim$ 18–20% less than (Fmin, Figure 3), but the minimum factor of safety in the seismic analysis is 1.12, which satisfies the Ukrainian building code (Ukraine Building Code. DBN V.1.1-12:2006. 2006). Such results are achieved due to a geocell mattress arrangement. The principle of the TENSAR geocell structure operation is that in this structure the mechanism of destruction along the circular-arc slip surfaces is not a critical factor. The main criterion of stability is the shear strength of the plastic layer below the geocell, which is maximally mobilized when the Tensar geomattress is used. The geomattress formed and laid in the embankment base keeps the overlying soil layers from displacements during the construction process and after its completion until the base weak soils will gain sufficiently high mechanical characteristics due to consolidation and will stop to plastically deform. The TENSAR geogrid application ensures the subsidence reduction (at least by 33%) and makes it uniform (TENSAR 2023).

4 GEOGRID GEOMATTRESSES ARRANGEMENT ON THE WEAK SOILS OF THE RENY BYPASS ROAD CONSTRUCTION SITE

The geogrid geomattresses installation is performed during two stages. The first one involves the structure formation of interconnected cells consisting of 1-m wide vertical uniaxial plastic geogrids and a horizontal biaxial geogrid as a basic surface (Figure 4). Then at the second
Figure 4.   The geomattresses formation.

Figure 5.   The general view of a geomatttress.

Figure 6.   Geomattress filled with a stone material.

stage the obtained 1-m high structure (Figure 5) is filled in with lumpy natural stone material (Figure 6) to create a rigid base for the deposited embankment.

The mentioned operations are carried out directly at the construction site by rolling out the biaxial geogrid along the day surface of the soil base and parallel to the weak soil layer along the embankment axis with adjacent rolls sheets overlapping by at least 300 mm. To shorten the processes of geogrid laying, subsequent vertical walls installation and geomattress filling with stone material, it is preferable not to stitch horizontal geogrids, but to place them with overlapping (Figure 4). The uniaxial geogrid should be rolled out in a direction perpendicular to the embankment axis and attached to a horizontal grid that operates as the geomattress base. To confirm the operational reliability of the embankment reinforced with geocell mattresses, the in-situ geodetic observations were carried out. The total subsidence of soil layers No. 4 and No. 5 (according to the soil profile (Table 1) was 0.009 m/h, which allowed to construct the 11-m high highway embankment with geocell mattresses in accordance with the requirements of construction standards and regulations in force in Ukraine.

5   RESULTS

The total length of the bypass road around the city of Reni is 6 352 meters. The maximum permissible speed on the road is 90 kilometers per hour, the estimated traffic flow is 7 973 cars per a day, the lane number is 2, their width is 3.75 meters. In 2018, under the OdesaHiprodor and Uniprom LLC project the construction of the international highway M15 (E87) Odesa - Reni part (bypassing the city of Reni) in the Odesa region was completed.

6   CONCLUSIONS

1. The total subsidence of soil layers No. 4 and No. 5 was 0.009 m/year, which made it possible to build the 11-m high road embankment from geocellular mattresses in compliance with the requirements of building codes and regulations in force in Ukraine.
2. The embankment reinforcement with geocellular mattresses allowed to achieve the reduction of the embankment base total subsidence by 30%, the increase of the base soil design strength by 25% and the base bearing capacity growth by 33%. Those effects were obtained due to the embankment soil reinforcement with TENSAR geocellular mattresses and their interaction with the embankment soil.
3. To confirm the operational reliability of the embankment reinforced with geocellular mattresses, the field geodetic observations were carried out, which confirmed the design solutions. In 2019, the President of Ukraine P. Poroshenko put the highway bypassing the city of Reni into operation.

M. Muthukumar
Associate Professor, Vellore Institute of Technology (VIT), Vellore, India

ABSTRACT: Pervious pavements are similar to conventional pavements with no fine or little content of fine aggregate. Pervious pavements are considered as sustainable pavements as it controls storm water runoff, mitigate urban heat island effect. The construction of pervious concrete pavement on soft soil subgrade is not feasible unless subgrade soil specially treated with some strengthening material. Geocell is a three-dimensional geosynthetic product that is a promising material to reinforce the soil, there are no prominent studies in the past on application of geocell in the pervious concrete pavement. The present research is focused on the pervious concrete pavement performance using geocell base under the static loading. The series of static plate load tests on geocell reinforced and unreinforced pervious pavements as per the Indian Road Congress standards. The test results have shown that the vertical deformation, was reduced when the pavement is reinforced with geocell.

1   INTRODUCTION

Pervious concrete has been the subject of numerous studies on a variety of topics, including material characterization, mechanical properties, strength qualities, and hydraulic properties. To assess the effectiveness of pervious pavement, field experiments have also been done. Below is a brief summary of these studies.

1.1   *Studies on materials, mechanical and strength properties*

According to the American Concrete Institute (ACI,522R - 2010), the porosity of pervious concrete/asphaltic pavement ranges from 15 to 25%. Usually, single-size aggregates are utilized to make the concrete pervious. To ensure enough voids in pervious concrete, the aggregate size prepared should be between 19 and 9.5mm. The mechanical, permeability, and durability characteristics of pervious concrete pavements are significantly influenced by the physical characteristics, such as shape, size, and size distribution (Keveren *et al*. 2010). The crucial role of the cementing agent is to produce adequate bonding around the aggregates to enhance pervious concrete's durability (Chandrappa & Biligiri 2014). Various cementitious materials, such as fly ash and silica fume as partial replacements, have also been researched in addition to cement. However, after a certain threshold of partial replacement, the strength starts to decline. Additionally, digital imaging techniques were used to investigate how cementing agent coating thickness affected results (Deo & Neithalath 2011). From the studies, it was found that smaller particles had thicker coatings than bigger aggregates and it has been found that when paste thickness increases, characteristics like porosity and permeability decreases.

Several mix designs were also put forth by various researchers based on various principles, but the most prevalent was to give the aggregates enough cement coating (Nguyen *et al.* 2014). According to these investigations, aggregate densities ranged from 1400 to 1800 kg/m^3, and the aggregate to cement ratio ranged from 4:1 to 12:1. The range of the water cement ratio was 0.20 to 0.42.

Realizing that pavement thickness affects pervious concrete, the mechanical and tensile attributes are of utmost significance. Many researchers have looked into these characteristics (Haselbach *et al.* 2005; Huang *et al.* 2009; Yang & Jiang 2002; Yahia & Kabagire 2014). According to the investigations, the strength characteristics can be enhanced to better sustain low traffic roadways. However, there are numerous restrictions on the hydrological properties. Debris and dust cause the pervious concrete pavement to get clogged, which reduces the pervious concrete's ability to withstand infiltration (Haselbach 2010). According to Kayanian *et al.* (2011), the top 25mm of pervious concrete is clogged.

1.2 *Structural integrity of pervious pavements*

In light of the fact that laboratory studies do not accurately reflect how pavement performs in the real world. As a result, a few investigations on the in-service pavement section were also carried out in the field. Geotextiles are used in fields to create a barrier between the subgrade and the aggregate base and the pervious concrete layer. Only a few research on the impact of geotextile on the performance of pervious concrete have been done, according to (Chandrappa & Biligiri 2014). There are not many studies that show the benefits of drainage or structural integrity are improved by the upper geotextile (Scholz 2013). Additionally, the structural stability of conventional concrete and pervious concrete pavements with various foundation conditions was examined (Abit *et al.* 2014). The investigations demonstrate that the structural integrity of pervious concrete pavements is significantly influenced by the aggregate base condition. It was discovered that pervious concrete pavements deflected between 1.7 and 4 times more than normal pavements.

From the literature review it is observed that the permeable concrete pavement system have become an important integral part of sustainable urban drainage system. In contrast, the pervious pavements are associated with clogging problems and are therefore not as much applied in practice. Further from the literatures it is also observed that the structural integrity of pervious pavement largely depends on the base and sub-base conditions. Hence this project aimed at studying to improve the performance of pavements by providing base course using textured geocells, with provision of perforations along the sides. Providing textured geocells the excess water which could not infiltrate will be drained laterally to the ditches through the perforation provided on the geocells. Hence, experimental and numerical investigations have been carried out to study the performance of pervious pavement with and without geocells under undrained conditions.

2 MODEL TEST AND NUMERICAL INVESTIGATION

2.1 *Model studies to evaluate structural integrity of the pervious concrete pavement*

Model test was conducted in a medium scale loading frame designed and fabricated in the laboratory. Subgrade soil was compacted in the test tank of size 1.0m × 1.0m to the desired density. Textured geocells was placed over a compacted soil deposit. The geocells was filled with 20 mm aggregates and compacted to a relative density of 70%. A prefabricated concrete panel of size 1.0m × 1.0m × 0.1m was placed over the geocell/geoweb base. After placing the concrete panel, rainfall is simulated continuously until the subgrade is saturated. The excess water which does not infiltrates in to the subgrade is drained by providing a reservoir on one end of the test tank. The saturation of the subgrade is monitored continuously using

tensiometer placed at three locations placed at top, middle and bottom of the subgrade soil. The saturation is continued for at least 4 days or till the subgrade is fully saturated. After saturation has taken place, load test was carried out to evaluate the structural strength of the pavement. Figure 1 shows the schematic diagram of the laboratory scale model test.
Figure 1.   Schematic diagram of experimental setup.

2.2   *Numerical investigation*

PLAXIS3D, finite element software was used to carry out the numerical analysis. For the purpose of solving this pavement numerical model, the linear strain problem-solving approach was used. The pervious pavement was modelled as a layered structure (Figure 2) and subjected to static loading. A model with a 1 m × 1 m plan was made using a 10-Noded Tetrahedral element.
Figure 2.   Numerical Model of the pervious pavement in Plaxis3D.

The load was applied to a rigid circular plate in each model. The loading plate size should be smaller than 1/6th of test tank width to prevent boundary effects (Hegde & Thallak 2016). Therefore, in this investigation, isotropic static compression was applied by positioning a hard plate with a 150mm diameter in the model's centre. Through the robust steel circular plate, 1130 kPa of uniform pressure was applied. Friction at the interface between the soil and the geocell as well as the soil and the geogrid was taken into consideration. The flow coupled deformation computation method was used to analyse the model. The equilibrium of pore water pressures is achieved in each step of the analysis.

2.3 *Model parameters*

The behaviour of sand subgrade soil and geocell composite layer was simulated using the completely elastic Mohr-Coulomb material model. For the clay subgrade, the soft soil model was used, while the linear elastic model was used for the loading plate and pervious concrete. According to IS: 800-2007, the steel plates' qualities were taken into account. According to the guidelines of IRC37-2012, the poisson's ratio of the subgrade soil in the under-drained case is taken into account as 0.3, and in the undrained situation, it is taken into account as 0.49. According to IS: 456-2000, the Young's modulus of pervious concrete is taken into account. Since the porosity of pervious concrete ranges from 15% to 35%, the void ratio is considered to be 0.25.

3 RESULTS AND DISCUSSIONS

Experimental and numerical investigations on the pervious pavement with geocell foundation under drained and undrained conditions were carried out in order to address the effectiveness of structural integrity of pervious pavement under geocell confinement. According to the study, by adding a geocell base, it is possible to reduce vertical displacement. Because of the increased pore pressure caused by the applied pressure in undrained conditions, the shear strength of the subgrade soil is decreased (Figure 3).

Using the geocell under the undrained conditions, the vertical displacement was reduced by over 47%. (From 4.97mm to 2.63mm).The mattressing effect of the geocell, which allows
Figure 3. Effect of geocell base on the vertical displacement of the pervious pavements.

for even stress distribution. Figure 3 demonstrates that the geocell not only distributes the stresses but also lessens their intensity over the subgrade.The interconnected geocells function like a wide mat to distribute the applied load across a wider region, thus reducing the pressures on the subgrade. In the area below the loading plate, there was a concentration of the most stress. Additionally, it has been found that the displacement at the top of the geocell is greater than the displacement at the subgrade level. This is because the geocell base's stiffness is aroused, which causes a measurable decrease in the vertical stress on the subgrade.

Geocell is manufactured with different types of polymeric materials, resulting in different order of magnitude of Young's Moduli. The stiffness of geocell plays a major role in parametric studies. Hence FE analyses were carried out to address this issue. The analyses were carried out for the geocell of 15cm height and different stiffness of the geocell. Leshinsky and Ling (2013) reported that the stiffness of the geocell ranges from 0.5GPa to 100GPa. Hence a similar range of geocell stiffness was considered in this parametric study. The analyses inferred that the use of geocell of higher stiffness yielded less reduction in the vertical displacement. This reduction might be significant at larger loading amplitudes, which the current study does not examine. However, the finding in the current study is quite intriguing and helpful that even the geocell with less stiffness is very effective in reducing the vertical displacement of the pervious pavement under any drainage conditions. According to studies on the height of geocell, the strength of the subgrade determines how much influence the height of geocell as a pavement base has. As a result, FE analyses were also carried out to investigate the impact of the geocell's height in both drained and undrained conditions. Under static or dynamic loading beneath the pavement in an undrained condition, excessive pore water pressure typically occurs, leading to increased displacement (Figure 4). As the geocell's height rises, it creates a solid foundation and dissipates stresses, which inhibits the development of pore water pressure in the subgrade. Beyond that point, there is no discernible decrease in the displacement of the pavement when the height of the geocell is raised by five times (from 50mm to 250mm)
Figure 4. Effect of geocell height on the performance of the pervious pavements.

4 CONCLUSIONS

Through PLAXIS3D modelling, the impact of different parameters on the functionality of pervious pavement is investigated. These conclusions are reached in light of the results.

1. Under an undrained state, the displacement of pervious pavement without geocell confinement is approximately four times larger. It makes intuitive sense that the large decrease in the bearing stratum's shear strength is the cause of this abrupt rise in vertical displacement. The bearing support for the pervious pavement decreases as a result of this loss in shear strength.
2. Providing geocell continues to have a big benefit. The vertical displacement was reduced by over 47% as a result of the installation of a geocell in an undrained environment.
3. The performance of the pervious pavement is greatly influenced by the height of the geocell. When the geocell's height is extended from 50mm to 250mm, the vertical displacement is reduced by 186%. As the strains inside the geocell are released, the pore water pressure in the subgrade under undrained conditions quickly dissipates, providing a firm foundation for the pervious pavement.
4. According to the numerical analysis, adding geocell base improves the pervious pavement's ability to withstand pressure under both drained and undrained conditions. The geocell aids in dispersing stresses over a larger region and in reducing pore water pressure that builds up in undrained circumstances.

ABSTRACT: Inclusion of geosynthetic reinforcements within the granular base layer has been shown to substantially improve the overall performance and life of pavements. This effect has been demonstrated in several applications, and the mechanisms through which such an improvement can be achieved have been clearly described for the past 40 years by many authors. However, because of the complexity of the reinforcement mechanisms, quantifying this effect, either in terms of increased design life or reduction of the pavement thickness, is not simple. Because of this, available design methods still rely heavily on empirical test results from large scale lab tests or field trials. The growing need for a sustainable use of plastic materials has led manufacturers to develop innovative geosynthetics capable to give the maximum possible performance with the lowest possible weight. This paper provides an overview of the development of a biaxial geogrid characterized by a three-dimensional shape designed to improve the interaction with the granular aggregate. Multiple laboratory tests were run on various biaxial geogrid designs to evaluate the performance in pavement applications. Laboratory tests included pull-out, composite stiffness tests, cyclic plate load tests, and full-scale rolling wheel load tests using an accelerated pavement tester (APT). This paper summarizes the results of these tests, which showed the advantage of the three-dimensional biaxial geogrids over traditional planar geogrids.

1   INTRODUCTION

Including a geosynthetic reinforcement layer within a granular base layer can substantially improve the strength and extend the life of pavement structures. This effect has been demonstrated in several applications, and the reinforcing mechanisms though which these improvements are achieved are known and have been clearly described over the past several decades by many authors (e.g., Cuelho *et al*. 2014; Hufenus *et al*. 2006; Fannin & Sigurdsson 1996; Tingle & Webster 2003).

   Biaxial geogrids are commonly used for base and subbase reinforcement. The global economic crisis that is affecting the world economy and the construction industry in particular, together with the growing need for a sustainable use of plastic materials, has motivated geogrid manufacturers to optimize the performance of their products by reducing weight and carbon emissions without sacrificing performance, which has led to several recent changes in the structure and geometry of geogrids.

Quantifying performance improvements solely through mechanical means is not easy due to the complexity of reinforcement mechanisms within pavements; therefore, available design methods rely on empirical data from laboratory performance tests. The most widely used road design for geosynthetic-reinforced pavements is based on a modified U.S. AASHTO 1993 design, which relies on empirical performance data from test sections run in accordance with AASHTO R 50-09 and GMA White Paper II (Berg *et al.* 2000). In-air tests on geosynthetics are not necessarily designed to directly quantify these effects; therefore, laboratory tests using geogrids embedded in soil were used to evaluate the effects that various geogrid rib shapes and strengths had on performance.

2 GEOGRID REINFORCEMENT IN PAVEMENTS

Geogrids used in road and rail applications primarily experience loading under plain strain-stress conditions, where the loads imparted in the geogrid perpendicular to the direction of travel (in the cross-machine direction of the geogrid) are significantly greater than loads imparted parallel to the direction of travel (corresponding to the machine direction of the geogrid), as illustrated in Figure 1. The accumulation of stresses in the cross-machine direction of the reinforcement is described in greater detail in Cuelho and Perkins (2016) based on extensive data from full-scale field test sections.
Figure 1.   Geogrid in plain strain-stress condition.

Tensile resistance in all directions is necessary when radial loads are applied; however, in most transportation applications stresses accumulate more significantly in the cross-machine direction of the geogrid (orthogonal to the direction of traffic) due to lateral spreading of the aggregate within the wheel path. Geogrids provide resistance to this movement by interacting with geogrid members oriented in the machine direction, which subsequently transfer stresses into tensile members oriented in the cross-machine direction. Lateral confinement of the aggregate is related to the capability of the geogrid to effectively interact with the aggregate, as illustrated in Figure 2. The shape and stiffness of the individual geogrid ribs and cross-members are important to ensure effective interaction with individual soil particles, resulting in positive stress transfer between the materials and a stiff composite system.

Structural T-beams are commonly used as load-bearing members in steel and reinforced concrete structures because they are able to resist stresses applied in two directions simultaneously. The horizontal member of the T-shaped cross section resists longitudinal stresses
Figure 2.   Illustration of effect of rib height on reinforcement zone of influence.

and horizontal bending moment, while the vertical section of the T-shape resists vertical stresses and bending moments. Utilizing the T-shape for geogrid ribs oriented in the machine direction will allow for greater heights, which will improve its ability to increase the reinforcement zone of influence, but maintain its stiffness to be able to transmit stresses to tensile members.

A series of geogrids were recently designed with modified ribs in the machine direction to improve the interaction with a granular base course in an effort to collect and distribute stresses being transferred by the wheel loads and into tensile members oriented in the cross-machine of the geogrid. Stiffer ribs in the machine direction help restrict horizontal movements of soil particles, thereby increasing confinement. Improving the lateral confinement of the aggregate directly improves the vertical strain resistance (in other words, inhibits rut). Alternate geogrid rib geometries were designed to compare to traditional flat biaxial geogrid ribs. An evaluation of the performance of conventional and redesigned geogrids was made in the lab and using bench-scale and full-scale tests, as described below. The material properties of the geogrids evaluated as part of this study are listed in Table 1. The BX geogrid incorporates the standard horizontal flange, the W-Grid incorporates an upright web, and the T-Grids uses an upside-down T shape, for ribs oriented in the machine direction, as shown in Table 1. T-Grids are ordered from weaker to stronger, T-Grid 1 to T-Grid 4, respectively.

Table 1.   Material properties of geogrids used in this evaluation.

Property	BX (MD/XD)	W-Grid (MD/XD)	T-Grid 1 (MD/XD)	T-Grid 2 (MD/XD)	T-Grid 3 (MD/XD)	T-Grid 4 (MD/XD)
MD Rib Shape

3   LABORATORY TESTS

There are a variety of tests that can be used to evaluate the performance of geogrids for roadway applications. AASHTO R50-09 (Standard Practice for Geosynthetic Reinforcement of the Aggregate Base Course of Flexible Pavement Structures) outlines the

necessary steps to effectively incorporate geosynthetics into the design of pavements. Reinforcement benefit in AASHTO R50-09 is defined as the traffic benefit ratio (TBR), which is "the ratio of the number of load cycles of a reinforced pavement structure to reach a defined failure state, to the number of loads for the same unreinforced section to reach the same defined failure state." TBR is most often determined using a Cyclic Plate Load (CPL) test or a Rolling Wheel Load (RWL) test. These tests were originally outlined in the GMA White Paper II (Berg *et al*. 2000). More recently, the CPL test method was codified in ASTM format (ASTM D8462). Other smaller laboratory tests can also be used to evaluate potential benefits of various geogrid designs. The Composite Stiffness (CS) test (Zornberg *et al*. 2012) and the monotonic pullout test (ASTM D6706) were also used in this study to investigate performance improvements of geogrids having ribs that incorporate the structural "T" shape when compared to traditional flat ribs associated with standard biaxial geogrids. Each of these tests was run by TRI Environmental, Inc., and their results on a variety of geogrids is detailed in the subsections below.

3.1 *Standard pullout test*

Monotonic pullout tests (EN 13738:2004) were run at 20 kPa confinement using CEN Standard sand and a 1 mm/min displacement rate to evaluate the pullout resistance of an early prototype of a three-dimensional geogrid (W-Grid) when compared to a conventional biaxial geogrid (BX), the results of which are summarized in Figure 3 (Recalcati 2012). Test results clearly show the effectiveness of the three-dimensional structure; however, the peak resistance is developed at a greater displacement. These results seem to indicate that a geogrid with taller ribs in the machine direction (W-Grid) is able to improve the interaction but may experience deformations larger than conventional biaxial geogrids (BX) that have shallower but wider ribs.
Figure 3.   Pullout test on the first prototype of three dimensional geogrids (Recalcati 2012).

3.2 *Composite stiffness test*

Composite stiffness (CS) tests were performed on two geogrids according to a draft version of the Texas Department of Transportation test procedure (Tex-136-E 2019). This test standard was developed based on research by Zornberg *et al*., (2012) for performance testing of geosynthetic used as reinforcement in pavements. CS tests are performed using a minia-ture pullout device (Figure 4) that applies small displacements to a geogrid embedded in an aggregate while under low-level confinement. The confining aggregate in this testing

Figure 4. Composite stiffness test apparatus (courtesy of TRI Environmental, Inc.).

program consisted of gravel between the 7.35 mm and 4.75 mm sieves and compacted in the test box in a dry state to a density of 1632 kg/m^3, as outlined in the test standard. A constant confining pressure of 20.7 kPa was applied using an air bladder in all tests. The resulting parameters derived from this test, the coefficients of soil-geosynthetic interaction (K_{SGC-1}, K_{SGC-2}, and K_{SGC-3}), are stiffness properties of the soil-geosynthetic composite. The average of these three parameters was used to compare the results from the three geogrids tested, where greater values indicate a stiffer/stronger composite. Three individual specimens were run on each material in the cross-machine direction. The average composite stiffness values were 44, 38, and 23 (kN/m)^2/mm for the T-Grid 3, T-Grid 1, and W-Grid geogrids, respectively, clearly showing the stiffer material shape having a positive influence on this property.

3.3 Cyclic plate load test

Full-scale unpaved CPL tests were conducted on two geogrid-reinforced test sections and one control (unreinforced) test section according to the ASTM D8462 test standard. Development of the ASTM test standard is based on the recommendations outlined in White Paper II (Berg et al. 2000). Tests were performed using a large test apparatus that was 2.3 m by 2.3 m in plan (Figure 5). A road prism was constructed by compacting a 0.9 meter thick layer of lean clay subgrade prepared to a strength of CBR = 2.0%, topped by 250 mm of compacted crushed base course (GP) having a maximum particle size of 25 mm. The geogrid reinforcement in these tests was placed directly atop the subgrade, beneath the base course. A 40 kN cyclic load was applied at a 1 Hz frequency to the surface of the base course using a 305 mm diameter steel plate to evaluate performance. Performance benefit was determined by calculating the TBR associated with 75 mm of vertical displacement (rut) beneath the load plate. Three materials were tested in comparison to the Control, resulting in TBRs of 9.5, 6.1, and 5.7 for the T-Grid 4, T-Grid 2, and BX geogrids, respectively. Performance results from the CPL tests showed the benefit of geogrids having the T-shape over a traditional biaxial geogrid, as well as the benefit of stronger T-shapes.

3.4 Rolling wheel load test

Full-scale paved RWL tests were constructed in an indoor concrete-lined test pit 1.2 m deep by 3.3 m wide and 15 m long and subsequently trafficked using an accelerated pavement
Figure 5.   Cyclic plate load test apparatus (courtesy of TRI Environmental, Inc.).

tester (APT). The subgrade (the same material as the CPL tests outlined above) was prepared and compacted to a final thickness of 0.9 m at a strength of CBR = 2.5%. Geogrids in reinforced test sections were placed directly atop the subgrade. A GW-GM aggregate base course with a maximum particle size of 37.5 mm was prepared and compacted to a total thickness of 312 mm. Hot-mix asphalt was constructed atop the base course at an average thickness of 74 mm. The APT trafficked the test sections (Figure 6) by applying a 40 kN bidirectional load via a dual-wheel assembly. The outcome from these tests, calculated at an average surface rut of 35 mm, resulted in TBRs of 3.2 and 1.9 for the T-Grid 3 and T-Grid 2 geogrids, respectively, showing that a strengthening the T-shape improves performance.

Figure 6.   Rolling wheel load APT (courtesy of TRI Environmental, Inc.).

4   CONCLUSIONS

Traditional biaxial geogrids are commonly used to reinforce the base layers of pavements; however, the growing desire for a sustainable use of plastic materials coupled with the desire to take into proper consideration sustainable civil design has motivated engineers to find more efficient and effective solutions for geogrids used as roadway reinforcement. In the spirit of environmental sensitivity, the structural design of biaxial geogrids was enhanced by stiffening members in the machine direction through the use of T shape in order to optimize and maximize geogrid properties directly linked to better performance. A variety of

interaction tests (pullout, composite stiffness, CPL and APT tests) were used to evaluate their performance when compared to one another.

In general, the results from these tests showed the ability of these geogrid enhancements to improve performance. The following observations were made using the interaction data produced as part of this study.

- Pullout interaction of W-Grid > BX, despite W-Grid being lighter and weaker
- Composite stiffness of T-Grid 3 > T-Grid 1 > W-Grid, despite the same strength in the cross-machine direction
- CPL results of T-Grid 4 > T-Grid 2 > BX, despite weaker strengths in the cross-machine direction
- APT results of T-Grid 3 > T-Grid 2, despite weaker strengths in the cross-machine direction

Additional future tests are planned to add to this analysis to further illustrate the importance of specific geogrid design attributes as well as their impact on the performance of geogrid-reinforced paved and unpaved roads.

ABSTRACT: Plate load test (PLT) is used frequently to evaluate the elastic modulus (E_{PLT}) of soils. However, this test is cumbersome, time-consuming and requires huge setup for reaction force. While Light Weight Deflectometer (LWD) devices are becoming very popular in earthwork quality control due to their swift evaluation of the deformation modulus (E_{LWD}) and non-destructive in nature. In this study, the effect of two contact pressures (q) to evaluate E_{LWD} were considered for both unreinforced and triaxial geogrid reinforced sandy soils were investigated, in order to successfully implement the use of LWD testing to replace plate load test (PLT). In addition, the correlations were proposed in terms of modulus improvement factors (MIF) of reinforced sandy soils. The findings show very good correlation of MIF obtained from these two tests.

1 INTRODUCTION AND CONTEXTUAL

Mechanical behaviour of unbound granular layers can be determined using a variety of lab and field tests (NCHRP 1-37A 2004). Field tests, such as plate load test (PLT) have some notable drawbacks because it requires large equipment for the reaction force. In-situ load and deformation characteristics are measured by PLT to evaluate elastic modulus (E_{PLT}) of the granular layers (Alshibli *et al*. 2005; DeMerchant *et al*. 2002; Li & Ronald 2005). Mechanical properties of granular layers can be estimated using a variety of laboratory testing methods such as monotonic and repetitive PLT. The limitations of these approaches are there loading patterns, specimen sizes, preparation process and time involved for testing (Consoli *et al*. 2009; Li & Baus 2005). Recent years have seen the development and use of a wide variety of devices to address these problems and provide a quick way to measure modulus (Moshe & Yair 2001; Park & Chung 2003). This implies that there has been a concerted effort to replace the PLT with a quick and portable device such as light weight deflectometer (LWD) (Fleming *et al*. 2007; Nazzal 2014; Sidhu *et al*. 2023; Umashankar *et al*. 2015).

LWD is a non-destructive testing (NDT) device, used for evaluating the deformation modulus (E_{LWD}) of granular layers. Its working principle is based on a dynamic

portable short impulse plate load bearing-deformation. LWD test has recently gained a lot of attention as a quick and easy way to check the quality of compaction and/or evaluation of modulus. LWD device offers a short duration of impulsive load and provides the same information as PLT but in a dynamic manner (Benedetto et al. 2012; Duddu & Chennarapu 2022; Mooney & Miller 2009; Vennapusa & White 2009). Static and repetitive PLT tests evaluate elastic, resilient modulus respectively and permanent deformations under the plate measured through displacement gauges. Owing to the inherent variability of compacted in-situ granular layers, one should think about the benefits of performing multiple testing points using LWD device rather than single PLT over the course of the project.

According to the literature studies, the elastic moduli (E_{PLT}) obtained from laboratory and field requires expensive setup and needs significant time and effort. These limitations have led authors to carry out the study to provide practicing engineers a new and low-cost approach using LWD device and to establish a reliable moduli and MIF evaluation of reinforced sandy soils that can be used in design of infra projects. In context, the objective of this study was discussed in the following section.

2 OBJECTIVES

The objective of this study is to assess the potential use of LWD device to evaluate: (a) deformation modulus (E_{LWD}) of unreinforced sandy soils for various relative compactions and two plate contact pressures (q) of 0.1 MPa and 0.15 MPa, (b) deformation modulus values of triaxial geogrid reinforced sandy soil for various embedded depth of reinforcements, and (c) modulus improvement factors (MIF) of reinforced sandy soils and to establish correlations between MIF_{LWD} and MIF_{PLT}.

3 MATERIALS

Locally available sandy soil was used to carry out a series of tests and its physical properties was determined as per ASTM specifications as shown in Table 1. Figure 1a shows the particle-size distribution curve of the sandy soil. Triaxial (triangular aperture) polypropylene geogrid reinforcement that satisfies the specification of European Organization for Technical Assessment (EOTA) and BS EN ISO 9001:2015 was selected to reinforce the sandy soils (refer to Figure 1b).

4 EXPERIMENTATION

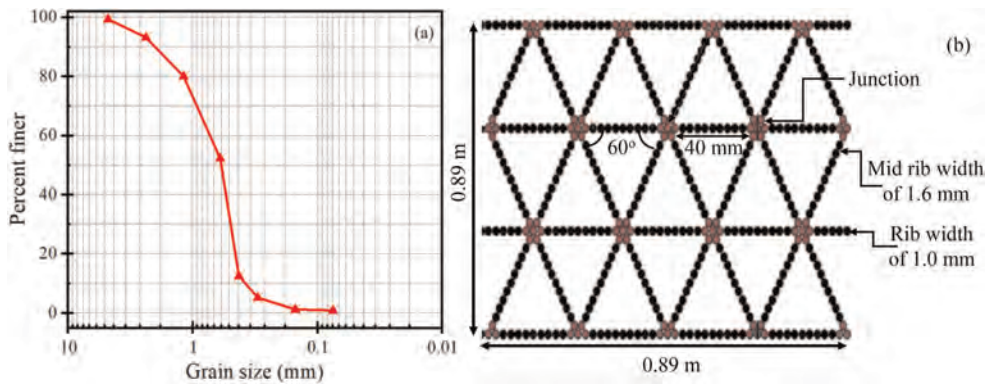
Locally accessible sandy soil was used for testing as unreinforced and reinforced cases for the test configurations with respect to the depth of reinforcement to plate diameter (u/a) ratios of 0.17, 0.25, 0.33, and 0.50. Two different plate load-based testing methods, namely LWD and


Figure 1. Details of materials used in this study: (a) Particle-size distribution curve of sandy soil, and (b) Schematic view of triaxial geogrid reinforcement.

PLT, were carried out to measure the load deformation responses of the test configurations. Figure 2 represents the LWD device with detailed components and two drop weights of 10 kg and 15 kg to simulate the contact pressures of 0.1 MPa and 0.15 MPa as considered in the study. The considered weights were dropped from a certain height of 0.72 m. The induced impulsive force is transmitted to the center of loading plate and mechanical contact is developed on the surface of sandy soils. An accelerometer is built inside the loading plate, which senses movement, transmits a signal to control unit and deformation of plate will be obtained. The measuring techniques start with the initial three preloading drops allowing for enhancing proper contact between the loading plate and surface of sandy soil. The next three consecutive measuring drops are used to register mean deformation ($\bar{w}$) to evaluate deformation modulus (E_{LWD}) (ASTM E2583, 2015). The E_{LWD} can be calculated by using well-known Boussinesq's elastic solution, Eq. (1), for loading over rigid base resting on an elastic half-space.

$$E_{LWD} = \frac{qr\,(1-r^2)f_r}{w} \tag{1}$$

where, E_{LWD} = Deformation modulus, MPa; q = plate contact pressure (equal to 0.1 MPa and/or 0.15 MPa);

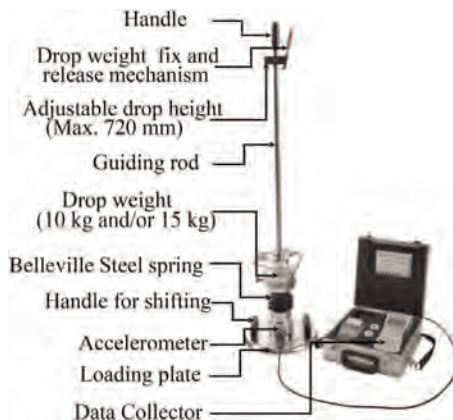
r = Radius of loading plate = 150 mm; v = Poisson's ratio of the sandy soil = 0.25; f_r = Plate rigidity factor (1.65); and $\bar{w}$ = mean deformation mm.


Figure 2. Schematic view of Light Weight Deflectometer (LWD) NDT Device and its components.

Large-scale experiments for PLT were carried out in a test chamber (0.9 m × 0.9 m × 0.9 m in size) using a loading frame of 10-ton capacity and equipped with actuator and load cell. A series of LWD and PLT tests were carried out using a 300 mm diameter circular plate that was placed in the centre of a test chamber, which is 450 mm away from the LSTC walls to ensure that the effects of boundaries were minimal. To achieve a relative density (R_d) of 85%, samples were prepared in layers in the LSTC using pneumatic plate vibratory device. More details of vibratory compaction process can be found in Hariprasad *et al*. (2016). Before compacting the sandy soil layers in LSTC, calibration studies were carried out to prepare a uniformly dense layer to obtain a relative density (R_d) of 45%, 65% and 85%. Relative compaction (RC) was estimated as 89%, 93%, and 97 % respectively from the correlation proposed by Holtz Gibbs (1979).

5   RESULTS AND DISCUSSIONS

Experimental results were represented in terms of deformation modulus (E_{LWD}), elastic modulus (E_{PLT}), and modulus improvement factors (MIF) for various test configurations as mentioned earlier.

5.1   *Influence of compaction and contact pressure on E_{LWD} value*

In the experimentation process, the repeatability tests were conducted to ensure the uniformity of results. Table 2 shows result of deformation modulus values for various relative compaction (RC) levels and contact pressures (q). It was clearly observed that the E_{LWD} value increases with an increase in relative compaction, due to increase in density of sandy soil. For instance, the E_{LWD} increased by 67% as the RC increases from 89% to 97% for the case of unreinforced sandy soil. In addition, due to the change in contact pressure from 0.1 MPa to 0.15 MPa, the LWD measured minimal change in the E_{LWD} value (i.e., variation of 1 to 2.5 MPa). Due to the reason of small increment in the applied contact pressures (i.e., a difference of 0.05 MPa). Similar findings was reported by Fleming *et al*. (2002); Lin *et al*. (2006); Camargo *et al*. (2006). Literature suggests to use the appropriate contact pressure (0.15 MPa) to mobilize elastic-plastic behaviour for reinforced soils and further test results were presented for 0.15 MPa of contact pressure (15 kg drop weight of LWD device).

	E_{LWD}, MPa					
	q = 0.1 MPa	q = 0.15 MPa	q = 0.1 MPa	q = 0.15 MPa	q = 0.1 MPa	q = 0.15 MPa
Test Configurations	RC = 89 %		RC = 93 %		RC = 97 %	
Unreinforced sandy soil	11.41	12.38	17.03	18.02	19.35	20.64

5.2   *Influence of embedded depth of reinforcement on $E_{LWD\ (0.15\ MPa)}$ value*

Table 3 represents the effect of embedded depth (u) of triaxial geogrid reinforcement on deformation modulus of sandy soil for various relative compaction (RC) levels. The deformation modulus (E_{LWD}) of the reinforced sandy soil increases with decrease in u/a ratio for various RC levels. It is due to passive resistance, lateral restraint and radial stiffness offered by the geogrid reinforcement and it will significantly mobilized when placed closely under the loading plate. Hence, a substantial improvement in the $E_{LWD\ (0.15\ MPa)}$ of the reinforced sandy soil was observed at an embedded depth (u) of 50 mm (i.e., embedded depth equal to

Table 3. Deformation modulus (E_{LWD}) for various embedded depth (u) of reinforcements and relative compaction (RC) levels.

Test Configurations	u/a	u, mm	E_{LWD}, MPa					
			q = 0.1 MPa	q = 0.15 MPa	q = 0.1 MPa	q = 0.15 MPa	q = 0.1 MPa	q = 0.15 MPa
			RC = 89 %		RC = 93 %		RC = 97 %	
Triaxial geogrid reinforced sandy soil	0.17	50	16.55	17.68	26.63	27.2	28.09	29.45
	0.25	75	15.43	16.53	22.6	23.87	24.83	27.37
	0.33	100	13.7	15.06	21.3	22.82	23.54	24.32
	0.50	150	12.44	14.09	20.52	21.99	22.08	23.23

one-sixth of the plate diameter) compared to the unreinforced case and other embedded depths (u) of triaxial geogrid reinforcements.

5.3 Modulus improvement factors of geogrid-reinforced sandy soil from LWD and PLT

Modulus Improvement Factor (MIF) is defined as the ratio of reinforced deformation modulus ($E_{LWD(r)}$)/elastic modulus ($E_{PLT(r)}$) to the unreinforced deformation modulus ($E_{LWD(ur)}$)/elastic modulus ($E_{PLT(ur)}$) and can be calculated using Eq. (2).

$$MIF = \frac{E_{LWD(r)} \quad or \quad E_{PLT(r)}}{E_{LWD(ur)} \quad or \quad E_{PLT(ur)}} \tag{2}$$

MIF and E_{LWD} values were represented for the relative compaction of 97% and contact pressure of 0.15 MPa. To compare the $E_{LWD\ (0.15\ MPa)}$ data measured from LWD tests, a plate load tests (PLT) were performed for the same test configurations of unreinforced and reinforced cases. In case of PLT, elastic modulus (E_{PLT}) was calculated at a settlement of 3 mm for both cases and represented in Table 4. MIF values were increased with an inclusion of reinforcement and decreases with an increase in u/a ratio. Improvement in MIF of sandy soil reinforced with triaxial geogrid can be attributed due to passive resistance, lateral restraint resistance offered by reinforcement in the radial directions against applied contact pressure. Figure 3 represents the linear regression analysis for MIF obtained from LWD and PLT and it represents a very good correlation. Equation 3 can be used to calculate the MIF of PLT from MIF of LWD test. The LWD device can be used to calculate the MIF value of reinforcements in the lab and field within a short time.

$$MIF_{PLT} = 0.7635 MIF_{LWD} + 0.2557 \tag{3}$$

Table 4. MIF calculations for $E_{LWD\ (0.15\ MPa)}$ and PLT.

6 CONCLUSIONS

This study presents the deformation modulus obtained from LWD test for unreinforced and reinforced sandy soils. Deformation modulus (E_{LWD}) values were found to be increased with an increase in compaction levels of sandy soils and minimal change was observed with increase in contact pressures from 0.1 MPa to 0.15 MPa. Due to the incorporation of triaxial geogrid, a substantial improvement in the E_{LWD} of the sandy soil was observed at an embedded depth of 50 mm (i.e., one-sixth of the plate diameter). Hence, it was considered as the optimum depth. Modulus improvement factors were found to be increased with decrease in embedded depth of reinforcement. The developed linear regression model correlates MIF obtained from LWD and PLT tests and was found to be in good agreement ($R^2 = 0.85$). Therefore, LWD device can be used as MIF value evaluating tool for the phases of RC levels and embedded depth of triaxial geogrid reinforcement instead of PLT.

The study is limited to a sandy soil and triaxial type of geogrid reinforcement used in the study. Further scope of this study can be extended to evaluate the E_{LWD} and MIF values for various types of granular soils, aggregates, and geogrids of different apertures.

Investigation of variability in large scale laboratory box testing

W. Jeremy Robinson* & Jeb S. Tingle*
US Army Engineer Research and Development Center, Vicksburg, USA

ABSTRACT: The ability to quantify the performance benefits of geosynthetic inclusions in granular pavement layers is a unique challenge. Geosynthetic products in the current market have varying aperture sizes, material types, and manufacturing processes that intend to improve pavement performance through a variety of mechanisms, making quantification of the potential of individual geosynthetic products and the development of a universal design procedure problematic. One approach to quantifying performance benefits is the assessment of geosynthetic inclusions in full-scale testing. While it could be argued that full-scale evaluations provide the most realistic assessment of anticipated performance, full-scale experiments can be logistically burdensome and, at times, cost prohibitive. On the other hand, large-scale laboratory box testing reduces the amount of required materials, reduces required testing time, and reduces required capital investments. Large-scale laboratory box testing has been used for well over 30 years to investigate geosynthetic stabilized pavement structures with well-documented success. However, a comprehensive testing program to assess the repeatability of large-scale laboratory box testing has not been conducted. In the absence of a comprehensive testing program, two historical studies with multiple test items conducted at the U.S. Army Engineer Research and Development Center were selected to assess the repeatability of current large-scale laboratory test procedures. The two historical studies included multiple pavement profiles representative of both a thick airfield pavement subjected to heavy loading conditions and an aggregate-surfaced pavement subjected to highway loading conditions. The assessment of the test procedure included a statistical and engineering evaluation of the reported surface deformation data to estimate repeatability in large-scale box test results and an investigation of potential sources of variability that could influence performance outcomes. The results of these assessments of the large-scale laboratory box experimental procedure represent an initial step to identify expected variability in large-scale box testing.

1 INTRODUCTION

The ability to predict pavement performance with the inclusion of a geosynthetic presents a unique challenge. There are a variety of geosynthetic products on the market that intend to improve pavement performance through mechanisms such as lateral reinforcement of the aggregate base layer, tensioned membrane effect, and bearing capacity improvement. The selection of an appropriate index property that adequately predicts performance is an industry-wide challenge. While some have suggested that certain index properties, i.e., aperture stability and tensile strength, among others, can provide an indication of pavement performance, widespread acceptance of a universal design procedure remains up for debate. An alternative to a universal design-procedure is the evaluation of geosynthetics in a

full-scale test section, which could be evaluated at an accelerated pavement test facility or at an in-service pavement. While it could be argued that full-scale evaluations provide the most realistic assessment of performance, full-scale experiments can be logistically burdensome and, at times, cost prohibitive. Alternatively, large-scale laboratory box testing reduces the required amount of materials, testing time, and capital investments. Large-scale laboratory box testing (example shown in Figure 1) is advantageous compared to small-scale laboratory testing, i.e., triaxial cell or direct shear benchtop testing, because more realistic geosynthetic/ pavement interactions can be expected. Tingle *et al.* (2021) recommended standardization of large-scale box testing and presented minimum equipment and instrumentation require- ments. Equipment standardization could improve the effectiveness of data sharing as well as support the ability to construct a shared database of experimental results. However, to the authors' knowledge, a comprehensive testing program to assess the repeatability of large- scale box testing has not been conducted. Like precision and bias statements found in small- scale laboratory test methods, an expected repeatability of large-scale box testing is needed to support data comparisons.

Figure 1.   Example of large-scale laboratory box test setup.

2   OBJECTIVES AND SCOPE

The objective of this paper is to take an initial step in quantifying variability in performance outcomes in large-scale box testing. Two historical studies performed at the U.S. Army Engineer Research and Development Center (ERDC) were found to provide a meaningful amount of data for comparison. The studies represented opposite ends of the pavement spectrum where one study evaluated thick airfield pavements subjected to high-contact pressure aircraft loading conditions, and one study evaluated aggregate-surfaced low- volume pavements subjected to highway loading conditions. Details regarding the airfield experiment can be found in Robinson *et al.* (2019), and details regarding the highway experiment can be found in Tingle and Jersey (2005). The experiments are briefly described in the following subsections.

2.1   *Airfield experiment*

Eleven test items consisting of a 127-mm-thick asphalt layer, a 178-mm-thick crushed limestone base layer, a 305-mm-thick sand subbase layer, and a 3-California Bearing Ratio (CBR) high-plasticity clay subgrade were evaluated. Two distinct phases of the experiment were conducted in which geosynthetics were placed at the subgrade/subbase interface in one phase, and geosynthetics were placed at the base/subbase interface in the second phase. Four unreinforced test items were evaluated with varying layer material properties that included changes in subbase layer material type and changes in subgrade CBR. Loading conditions

consisted of a 128-kN load applied to a 305-mm-diameter steel plate yielding a 1750-kPa contact pressure. Deformation data with load cycles is summarized in Table 1. TI-1, TI-7, and TI-8 had either different material types, different geosynthetic types, or drastically different performance, thus were omitted from the analysis.

Table 1. Summary of deformation data for airfield experiment.

Cycle	TI2	TI3	TI4	TI5	TI6	TI9	TI10	TI11
1	1.4	1.8	1.0	2.3	0.0	0.0	0.0	0.0

20,000	61.0	ND	34.1	ND	ND	41.9	ND	36.8

TI = test item; ND = no data; deformation reported in mm.

2.2 *Highway experiment*

The highway experiment consisted of six different aggregate surfaced test items constructed over a very weak high-plasticity clay subgrade. Five of the test items consisted of a 0.36-m-thick crushed limestone aggregate layer over a 1-CBR subgrade. A geogrid, geotextile, and geogrid/geotextile combination were included at the subgrade/aggregate interface. One unreinforced test item with a 0.36-m-thick crushed limestone aggregate layer, referred to as Item 3, was evaluated, and one unreinforced test item with a 0.51-m-thick crushed limestone aggregate layer, referred to as Item 1, was evaluated. A 40-kN load applied to a 305-mm-diameter load plate was targeted, however, the authors noted that the design load was difficult to achieve on the weak pavement layers resulting in varying loading conditions for each test item. Thus, the measured load was used to convert cycles to equivalent single axle loads (ESALs), allowing meaningful performance comparisons to be made. Deformation data with ESALs is summarized in Table 2. Note Item 1 had a thicker aggregate layer and was not included in the analysis.

3 ANALYSIS APPROACH

Permanent deformation data were used to assess the variability for each experiment. A statistical analysis was performed to determine whether the deformation performance between the control test item and the reinforced test items were statistically different. If the performance was not found to be statistically different, then it was assumed that measured performance was within the inherent variability of the box test and could be used to quantify variability. Further, the data were evaluated for practical significance from an engineering standpoint. For example, if the average difference between two test items was 3 mm, i.e.,

Table 2. Summary of deformation data for highway experiment.

Item 2		Item 3		Item 4		Item 5		Item 6	
ESAL	Def.	ESAL	Def.	ESAL	Def.	ESAL	Def.	ESAL	Def.
1	0.0	1	0.0	1	0.0	1	0.0	1	0.0

ND	ND	4,515	63.0	5,071	29.5	ND	ND	ND	ND

ESAL = equivalent single axle load; Def. = deformation (mm); ND = no data

within the accuracy of the measurement technique, then from a practical standpoint the performance of those test items was deemed equivalent.

3.1 Analyses of airfield experiment

Deformation data from the airfield experiment were appropriate for a paired statistical analysis, because data were obtained at the same number of load cycles. A paired t-test was deemed appropriate for the statistical comparison. The results of the statistical analyses (Table 3) indicated that all test items were statistically different from the control test item with the exception of TI6. Further, a practical evaluation of the data, i.e., the average difference between the item of interest (IOI) and the control, found that TI3 had practically equivalent performance. TI5 and TI10 (both containing geosynthetics) were found to have worse performance than the control item, which was not expected, and could be a function

Table 3. Statistical analyses of airfield experiment.

Comparison	n	p-value	Sig.	Average Control (mm)	Average IOI (mm)	Average Difference (mm) (Control-IOI)
TI3	13	0.009	Y	19.6	21.8	−2.1
TI4	13	<0.001	Y	19.6	14.0	5.6
TI5	13	0.001	Y	19.6	26.9	−7.3
TI6	14	0.830	N	22.2	22.2	0.1
TI9	15	0.001	Y	24.8	19.1	5.8
TI10	11	0.011	Y	16.2	25.1	−8.9
TI11	15	<0.001	Y	24.8	16.6	8.2

n = number of observations, Sig. = statistically significant, IOI = item of interest, Y = yes (statistically significant), N = no (not statistically significant)

of box test variability. However, a review of the experimental results indicated that TI5 had a lower subgrade density and a thinner asphalt layer than the control test item. TI10 had approximately 25 mm less base course than the control. These observations could explain the significantly poorer performance of these test items and highlight the importance of implementing strict construction quality control in laboratory box testing, more stringent than would typically be achieved in full-scale construction.

TI2 sustained 3,700 cycles to failure, TI6 sustained 4,100 cycles to failure, and TI3 sustained 3,000 cycles to failure, where failure was defined as 25 mm of permanent deformation. At 25 mm of deformation, the average cycles-to-failure was 3,600, and the standard deviation (SD) was 557 cycles. Coefficient of variation was 15.5%, which was considered relatively low. If a 95% confidence interval (2SD) is considered, then the expected range of cycles to failure was approximately 2,500 to 4,700.

Similarly, at 50 mm of permanent deformation, TI2 sustained 16,990 cycles to failure, TI6 sustained 17,600 cycles to failure, and TI3 sustained 14,000 cycles to failure. Average cycles to 50 mm of permanent deformation was approximately 16,200, and the SD was 1,930 cycles. The 95% confidence interval ranged from 12,350 to 20,050. Coefficient of variation was 11.9% at 50 mm of permanent deformation.

3.2 Analyses of highway experiment

Deformation data from the highway experiment were not found to be appropriate for a paired t-test. Recall that test cycles were converted to ESALs due to variations in load magnitude resulting in reported data at varying traffic levels. Thus, the reported data were first qualified using an F-test to establish if the variances for each sample set were statistically different. The results of an F-test indicated that the variances between the control test item and the other geosynthetic test items were statistically equivalent, indicating a pooled t-test was an appropriate statistical measure of the difference between sample means. The results of the statistical analyses where comparisons are made to Item 3 (Control) are shown in Table 4.

The results of the statistical analyses indicated that Item 4 and Item 6 were statistically equivalent to the control test item. It should be noted that Item 4 would be statistically different from the control at a lower level of confidence, i.e., alpha = 0.10. Further, the average difference between the control and Item 4 was 10.5 mm, which represented a meaningful difference from a practical standpoint. Item 6 was found to perform more closely to the control test item; the average difference between the control and Item 6 was 2.2 mm.

Item 3 sustained 831 ESALs to 25 mm of permanent deformation, and Item 6 required 1,212 ESALs to achieve 25 mm of permanent deformation. To reach 50 mm of permanent deformation, Item 3 required 2,832 ESALs, and Item 6 required 3,557 ESALs.

Item 4 and Item 5 were replicate test items, and both contained a geogrid/geotextile combination; thus, we used these results to evaluate the differences in the test items. A pooled t-test indicated that the average performance difference between the test items was

Table 4. Statistical analyses of highway experiment.

Comparison	N1	N2	p-value	Sig.	Average Control (mm)	Average IOI (mm)	Average Difference (mm) (Control-IOI)
2	15	12	0.007	Y	20.3	2.6	17.7
4	15	15	0.097	N	20.3	9.8	10.5
5	15	14	0.041	Y	20.3	7.2	13.1
6	15	13	0.792	N	20.3	18.1	2.2

N1 = number of observations (control Item 3), N2 = number of observations (reinforced test item), Sig. = statistically significant, IOI = item of interest, Y = yes (statistically significant), N = no (not statistically significant)

not significantly different (p-value = 0.571), and the average difference was 2.5 mm. Item 4 achieved 25 mm of permanent deformation at 3,921 ESALs, and Item 5 achieved 25 mm of permanent deformation at 6,925 ESALs. ESALs required to reach 50 mm of permanent deformation for Item 4 and Item 5 were 22,769 and 31,258, respectively.

4 SUMMARY OF LOAD CYCLE VARIABILITY

The results of a statistical analyses of the experiments described herein provided some meaningful, albeit limited data for the investigation of variability in large-scale box testing. In order to normalize observations from each experiment and summarize variability, the relative percent difference between maximum and minimum cycles to 25-mm and 50-mm failure criteria were determined. Relative percent difference (RPD) is the absolute difference between two values divided by the average of the two values, all multiplied by 100. These calculations were performed on the values from the airfield experiment, the highway experiment, and highway experiment geosynthetic replicate as summarized in Table 5.

It was found that RPD values for the airfield experiment and highway experiment were generally consistent compared to each other. RPDs at 25-mm rut were 31% for the airfield experiment and 37% for the highway experiment, suggesting that the variability observed in the drastically different experiments was similar. In both cases a reduction in RPD was observed from 25-mm rut to 50-mm rut. Notably, the RPDs at 50-mm rut for both experiments were nearly identical, suggesting that variability tends to decrease with an increase in deformation.

RPDs for the replicate geosynthetics (noted as Highway GEO in Table 5) were higher than the other comparisons at both 25-mm rut and 50-mm rut.

These data suggest that if three or more experiments are repeated with the same materials, same construction techniques, and same loading conditions that the coefficient of variation should be below 20%. If only two experiments are repeated with the same materials, then the analyses suggests that the RPD should below 40%.

Table 5. Summary of relative percent difference for analysis data.

Experiment	Minimum	Maximum	Absolute Difference	Average	RPD (%)
Airfield					
25-mm rut	3.000	4,100	1,100	3,550	31.0
50-mm rut	14,000	17,600	3,600	15,800	22.8
Highway					
25-mm rut	831	1,212	381	1,021	37.3
50-mm rut	2,832	3,557	725	3,194	22.7
Highway (GEO)					
25-mm rut	3,921	6,925	3,004	5,423	55.4
50-mm rut	22,769	31,258	8,489	27,013	31.4

RPD = relative percent difference; GEO = geosynthetic

5 CONCLUSIONS

Two laboratory box test experiments conducted at the ERDC were selected to assess the repeatability of performance tests. The experiments represented both heavily-loaded thick airfield pavements and aggregate-surfaced highway pavements providing a range of performance results. The analyses included both a statistical component, i.e., t-test, and a

practical component, i.e., observed differences, to assess similarities in surface deformation performance.

The results of the analyses suggested that variability, i.e., coefficient of variation, was relatively low in the airfield experiment, less than 20%. In the highway experiment, only one test item was found to have similar performance to the control, which limited a variability assessment. These data may suggest that a weaker pavement, in the case of a large-scale laboratory box experiment, may be necessary to obtain meaningful performance differences that could be attributed to geosynthetic inclusion.

A direct comparison of the airfield and highway experiment found that variability was relatively consistent. Relative percent difference was on the order of 35% at 25 mm of deformation and on the order of 22% at 50 mm of deformation. The data suggest that if three or more experiments are repeated, the COV should be expected to be less than 20%, and if two experiments are repeated the RPD should be less than 40%.

The data presented herein represent a limited analysis of anticipated repeatability in large-scale laboratory box testing. While numerous studies have been successfully conducted for well over 30 years at multiple test sites, the absence of a robust assessment of anticipated variability presents difficulty in comparing test results. Thus, we recommend that additional experimentation be conducted to include both with-in laboratory repeatability, as well as a round-robin style assessment of multi-laboratory variability. These data would improve confidence in data sharing and facilitate development of a performance database.

Effect of asphalt geogrid reinforcement on pavement response considering spatial variability in asphalt layer

L. Xiao & J.F. Xue
School of Engineering & Information Technology, The University of New South Wales, Campbell, Australia

A. Shahkolahi
Global Synthetics Pty Ltd, Virginia, QLD, Australia

ABSTRACT: Base and subgrade spatial variability can induce adverse effects on the structural response of pavements. However, few studies have investigated the impact of the spatial variability of the asphalt layer. The effects of asphalt geogrid reinforcement on pavement performance with spatially variable layers is still unknown, although geogrid reinforcement has been a common practice in pavement engineering. Random finite difference analysis (RFDA) is conducted in this study to evaluate the effect of spatial variability in asphalt layers on pavement responses and determine the effect of geogrid reinforcement under spatial variable situation. Several key conclusions are drawn: (1) the assumption of heterogeneity for the asphalt layer can induce a considerable underprediction of the critical pavement strain; (2) geogrid helps to mitigate the negative impact resulting from the asphalt spatial variability; (3) the low modulus dominating effect amplifies the mean strain of asphalt layer, thereby leading to a better mobilization of the geogrid reinforcement in the probabilistic cases.

1 INTRODUCTION

Spatial variability is one of the main sources of geotechnical uncertainties and has been proven to induce adverse effects on the structural response of pavements. Lua & Sues (1996) presented the first RFEM (random finite element method) application to study the impacts of spatial variability on pavement life. Ali *et al*. (2013) and Vaillancourt *et al*. (2014) investigated the effect of spatially varied modulus in subgrade on pavement responses. Titi *et al*. (2014) investigated the spatial variability of the base layer from FWD (falling weight deflectometer) tests and assessed their impact on pavement performance from existing pavement data. However, compared with studies regarding spatially variable base and subgrade layers, few studies have addressed the impact of spatial variability in the asphalt layer. On the other hand, inclusion of geogrid reinforcement in the asphalt layer has been used as a common practice to improve pavement performance. However, it remains unclear whether the presence of geogrid will aggravate or mitigate the impact caused by spatial variability.

Random finite difference analysis (RFDA) is conducted to: (1) assess the impact of spatial variability in the asphalt layer on the pavement response, (2) determine the role of geogrid reinforcement in the statistical effect of asphalt spatial variability, and (3) explore possible mechanical explanations for the effects of spatial variability and role of geogrid reinforcement. The maximum horizontal tensile strain at the bottom of the asphalt layer (denoted by

ε_h^{ac}) is selected as the critical pavement response variable. Note that, the location of this critical strain might not necessarily occur right below the tire centerline due to the impact of asphalt spatial variability. To avoid coupling effects from different sources of uncertainties, only Young's modulus of the asphalt layer is treated as a spatially varied property. All other parameters are assumed as deterministic.

2 RANDOM FINITE DIFFERENCE METHOD

2.1 Numerical modelling and key influence zone

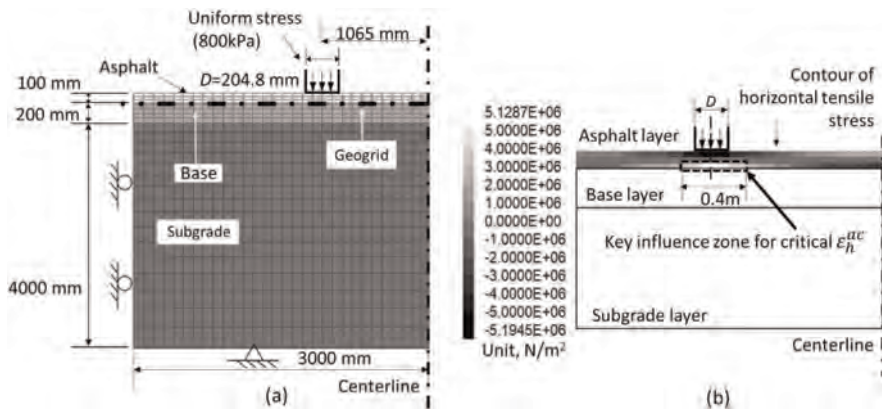
A typical three-layered pavement structure reported in Austroads (2017) guide is selected as the subject of this study. Figure 1(a) illustrates half of the pavement structure modelled with FLAC2D software. The mesh size is fine enough and further refining of the meshes will not greatly affect the results of the simulation. As shown in the figure, a uniform load of 800 kPa over a 204.8 mm (D) diameter area is used to simulate the tyre pressure. Table 1 lists the material properties.


Figure 1.   (a) Finite difference model (not to scale); (b) tensile stresses and key influence zone for ε_h^{ac}.

Table 1.   Material properties of the pavement model.

Material	Asphalt layer	Base layer	Subgrade layer
Constitutive model	Linear elastic	Mohr-Coulomb	Mohr-Coulomb
Thickness	100 mm	200 mm	4000 mm
Young's modulus	2000 MPa	200 MPa	10 MPa
Poisson's ratio	0.40	0.35	0.28
Cohesion	–	5kPa	30 kPa
Friction angle	–	40°	25°
Dilatancy angle	–	20°	0°
Unit weight	24 kN/m^3	20 kN/m^3	18.2 kN/m^3

To investigate whether the presence of geogrid below the asphalt layer will aggravate or mitigate the impact caused by the asphalt spatial variability, a parametric study was conducted by adopting three kinds of geogrid reinforcement (G1, G2, and G3) and one unreinforced (UR) case as reference. The secant stiffnesses (J) at 2% for G1, G2, and G3 are

3000 kN/m, 6000 kN/m, and 9000 kN/m respectively. The geogrids are simulated with geogridSEL in FLAC2D and placed at the interface between the asphalt and base layer. A linear shear behavior is assumed for the interface with cohesion of 30 kPa, friction angle of 45° and shear stiffness of 300 MPa/m.

Figure 1(b) presents the contour of tensile stresses in the asphalt layer of an unreinforced deterministic case. The induced tensile stress in the asphalt layer decreases rapidly with the horizontal distance measured from the centreline of the loading. At about $1D$ away from the centreline of the loading area, the tensile stress reduces to below 40% of the maximum value. Thus, large tensile stress and strain of asphalt layer mainly occur within this $2D$ (about 0.4m) region in the vicinity beneath the loading area. Accordingly, the $2D$ region is determined as the key influence zone for the critical horizontal tensile strain in the asphalt layer (denoted by ε_h^{ac}). As opposed to the deterministic situation, the overall modulus of this key influence zone varies with different realizations in spatial variable situations and therefore leads to different magnitudes of ε_h^{ac}. To measure the overall modulus of the key influence zone, a local modulus, E_{local}, is defined by calculating the arithmetic mean modulus of the 0.4 m wide region.

2.2 Modelling and discretization of random fields

As mentioned above, Young's modulus of the asphalt layer (E) is set as spatially variable. The spatial variability is represented by a continuous and stationary random field generated using the Karhunen–Loève expansion (Huang *et al*. 2001) with Monte-Carlo runs of 100. The lognormal distribution is adopted to characterize the variability of E with its mean μ_E = 2000 MPa, and coefficient of variation COV_E = 30%. The following exponential auto-correlation function, $\rho(x, y)$, is used:

$$\rho(x, y) = \exp\left(\frac{-2|x|}{\delta_x}\right)\exp\left(\frac{-2|y|}{\delta_y}\right) \tag{1}$$

where δ_x and δ_y denote the horizontal and vertical scale of fluctuation (SOF) respectively. In this study, the asphalt modulus is assumed as isotropic random field with $\delta_x = \delta_y$ =0.2 m.

3 RESULTS AND ANALYSIS

3.1 Effect of asphalt spatial variability on the critical tensile strain

Figure 2 presents the relationship of E_{local} versus ε_h^{ac} in the spatially varied (SV) unreinforced pavement. The power regression line shows that the critical stain ε_h^{ac} increases as E_{local} decreases. It is also found that ε_h^{ac} of most realizations (75 out of 100) are larger than the deterministic (DET) value (3.136 millistrain). Furthermore, the number of realizations with ε_h^{ac} greater than the deterministic strain (75 out of 100 realizations) is far more than that with E_{local} smaller than the deterministic modulus (59 out of 100 realizations). The gap between the two numbers is caused by the combined effect of local spatial variability within the influence zone and the low modulus dominating effect (Fenton & Griffiths 2005): the softer areas have a greater influence on the critical strain than stiffer ones do. This effect is manifested by the regression trend in Figure 2 where ε_h^{ac} grows more and more rapidly with decreasing E_{local}.

As shown in Figure 2, the maximum ε_h^{ac} deviates from the deterministic strain much further than the minimum strain does due to the low modulus dominating effect. All these factors make the mean value of ε_h^{ac} in the probabilistic cases higher than their corresponding deterministic ε_h^{ac}. Consequently, assuming the asphalt heterogeneity can induce an underestimation of the critical tensile strain in the asphalt layer and therefore an overprediction of the fatigue life.
Figure 2.   Relationship of E_{local} versus ε_h^{ac}.

3.2   *Effect of geogrid reinforcement on the statistical result of ε_h^{ac}*

Figure 3(a) shows the statistical distribution of ε_h^{ac} under different reinforcement conditions. Compared with the unreinforced case, the distribution of ε_h^{ac} with reinforcement (G2) is not only left-skewed but also narrower. This is due to the fact that the reinforcement induced reduction in the maximum strain is much greater than that in the minimum strain. Consequently, the geogrid reinforcement is capable of not only decreasing the mean value of ε_h^{ac} but also mitigating the variation in terms of standard deviation.

To quantify the relative increase of the mean strains in spatial variable cases as opposed to the corresponding deterministic strains, an amplification factor R_{mean} is defined:

$$R_{mean} = \left(\frac{\overline{\varepsilon}}{\varepsilon_{\text{det}}} - 1 \right) \times 100\% \tag{2}$$

where $\overline{\varepsilon}$ is the mean value of ε_h^{ac} in a spatial variable (SV) case, and ε_{det} is the corresponding deterministic (DET) strain.

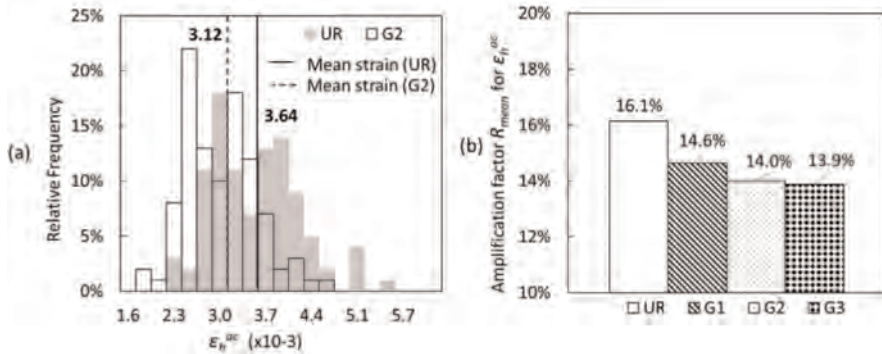
Figure 3(b) shows the value of R_{mean} for four kinds of geogrid reinforcement conditions. It shows that, under the unreinforced situation (UR), the spatial variability of Young's modulus in the asphalt layer can increase the critical strains by 16.1% compared with the


Figure 3.   Effect of geogrid reinforcement: (a) Distribution of critical strain; (b) Amplification factor R_{mean}.

1291

homogenous situation. Another indication is that the presence of geogrid can decrease the amplification factor. And the decreasing effect strengthens but not significantly with the geogrid stiffness. The narrower distributions of ε_h^{ac} and lower R_{mean} in reinforced cases imply that the presence of geogrid can mitigate the negative effect of the asphalt spatial variability, which will be detailed next.

3.3 Statistical and mechanical explanation for the role of geogrid reinforcement

Geogrid reinforcement decreases the critical strain in the asphalt layer in both deterministic and probabilistic analyses. To measure the relative strain reduction resulting from the geogrid reinforcement, a decreasing factor R is defined as the ratio of ε_h^{ac} in the reinforced situations to ε_h^{ac} in the corresponding unreinforced cases. According to this definition, in probabilistic situation, a smaller R suggests a better performance of geogrid reinforcement in mitigating the amplification effect of spatial variation.

Figure 4 shows the relationship of the decreasing factor R under G2 reinforcement in both the spatial variable (SV) case and the deterministic (DET) case. It reveals that the decreasing factor R in most realizations is smaller than that in the deterministic case. Moreover, the minimum R (81.9%) deviates from the deterministic R (87.4%) much further than the maximum R (88.8%) does. All these together contribute to an average decreasing factor R (85.8%) lower than the deterministic R (87.4%). In addition, the linear regression of data in Figure 4 indicates the decreasing factor R is negatively correlated with the asphalt strain level. This is consistent with well established findings that high levels of asphalt stain help to mobilize the geogrid reinforcement (Zornberg 2017).
Figure 4. Comparison of decreasing factor R with G2 reinforcement in SV case and DET case.

To mechanically explore the statistical result, the maximum tensile stress of the geogrid (denoted by σ_h^g) is extracted and plotted against the asphalt strain level in Figure 5(a), and against E_{local} in Figure 5(b). As illustrated in Figure 5(a), σ_h^g in most realizations (81 out of 100) is larger than the deterministic σ_h^g of 70.3 MPa. Moreover, the maximum σ_h^g (81.3 MPa) deviates from 70.3 MPa much further than the minimum σ_h^g (64.9MPa) does. All these together lead to an average σ_h^g (72.5MPa) greater than the deterministic σ_h^g. In other words, the geogrid reinforcement is better mobilized owing to the asphalt spatial variability than in homogeneous situation.

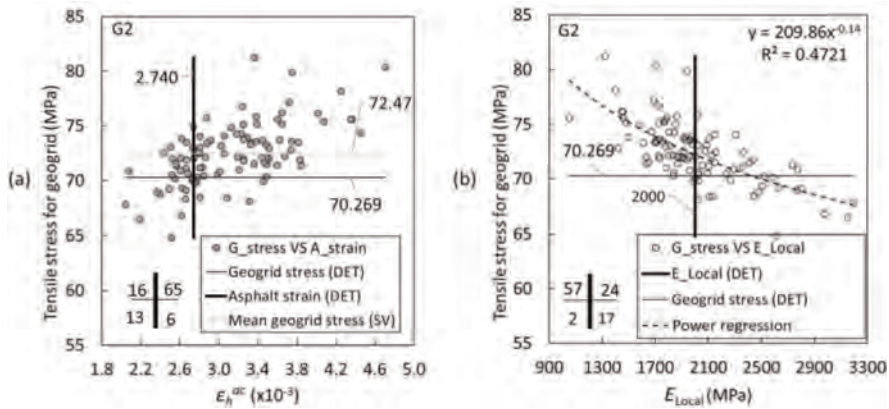
The variation of σ_h^g is ultimately induced by the asphalt spatial variability, especially the spatial variability within the key influence zone. As illustrated in Figure 5(b), the power


Figure 5. Distribution of the maximum tensile stress of the geogrid (G2): (a) σ_h^g versus ε_h^{ac}; (b) σ_h^g versus E_{local}.

regression trend indicates that σ_h^g grows rapidly as E_{local} decreases, meaning that a soft key influence zone contributes more to the geogrid mobilization than a stiff one does. Another interesting finding is that the number of realizations with σ_h^g greater than the deterministic σ_h^g is far more than the number of the realizations with E_{local} lower than the deterministic Young's modulus (i..e., 2000 MPa). For example, in Figure 5(b), there are 59 out of 100 realizations with E_{local} lower than 2000 MPa, but there are 81 out of 100 realizations with geogrid tensile stress greater than 70.269 MPa. The gap is not caused by the overall modulus (i..e., E_{local}) but by the local spatial variability within the key influence zone.

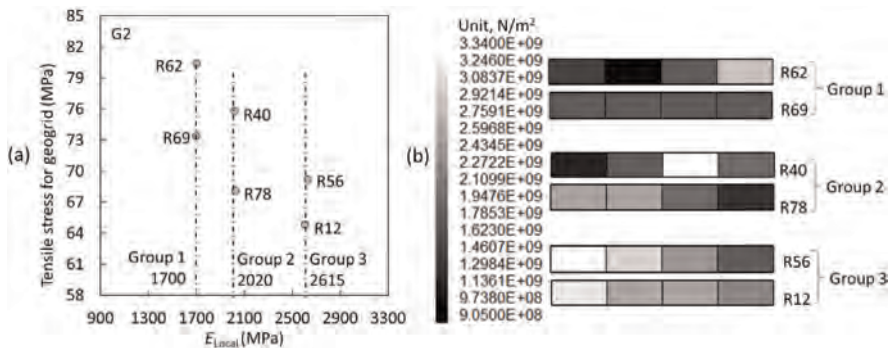
To demonstrate the effect of local spatial variability on the variation of σ_h^g, three groups of data are extracted from Figure 5(b) and their spatial distributions of Young's modulus within the key influence zone are shown in Figure 6. Each group consists of two realizations with approximate E_{local} but different magnitudes of spatial variability of Young's modulus within the 2D region. For example, with an approximate E_{local} (1700MPa), the spatial variation of Young's modulus in realizaiton No. 62 (R62) is more intense than that in realizaiton No. 69 (R69). In all the groups, a key influence zone with quickly varying modulus always corresponds to a large σ_h^g (or vice versa). This could be explained by the low modulus dominating effect which makes the softer area contributes more to the mobilization of geogrid reinforcement than the stiffer area does. As a result, even under the same E_{local}, the


Figure 6. (a) Realizations with approximate E_{local} but different σ_h^g; (b) corresponding distribution of Young's modulus with key influence zone.

geogrid is more fully mobilized by a key influence zone with large local spatial variability than one with less spatial variability.

4 CONCLUSIONS

Based on the analyses, it can be concluded that the asphalt spatial variability can induce a considerable amplication effect on the critical pavement strain and that the geogrid reinforcement can mitigate the adverse effect induced by the spatial variability. On the one hand, the presence of geogrid can decrease the amplification factor R_{mean} and reduce the variation of ε_h^{ac}. The variation of the geogrid stiffness within the selected range in this study makes a marginal difference in mitigating the negative effect. On the other hand, compared with the homogeneous situation, geogrid is more easily mobilized owing to the presence of the asphalt spatial variability. The amplication effect of asphalt spatial variability and the role of geogrid in that effect can be well explained by the low modulus dominating effect.

ABSTRACT: This study presents a laboratory study on seven different test configurations subjected to cycling moving wheels load by using an accelerated pavement test. Tests were conducted on lateritic clay mixed with gravel and unbounded granular material at two different thickness, in a geosynthetic stabilized and unstabilized sections. All test sections were constructed on a low CBR clay subgrade. Each pavement section performance was evaluated by measuring the surface rutting and the subgrade vertical pressure at different cycles. Findings indicated that the lateritic gravel base pavement sections had lower surface rutting than the granular base, mainly because the lateritic increases the material stability, delaying the occurrence of damage on the gravel. Furthermore, sections modified with geocomposite were found to have improved performance than the control sections.

1 INTRODUCTION

The use of high-quality crushed aggregates is becoming scarce and expensive, and, in some regions, they are not even found, especially when they are for low to medium traffic volume roads. In this context, it is essential to define alternatives that are both technical and economically viable for pavement construction. The use of geosynthetics can provide an alternative solution. The inclusion of geosynthetic provide tensile reinforcement through frictional interaction with base course materials, reducing applied stresses on the subgrade and preventing excessive permanent deformation (Koerner 2005). Therefore, the geosynthetic with the base/subgrade stabilization function can be a viable option that can extend the pavement service life, minimize maintenance costs, and reduce the demand for crushed aggregates (Palmeira & Antunes 2010).

Many researchers have investigated the performance of geosynthetics in pavement structures (Abu-Farsakh & Chen 2011; Leng & Gabr 2002; Palmeira & Antunes 2010; Qian *et al.* 2013; Tang *et al.* 2008). These studies reported that geosynthetic properties, the location of the geosynthetic, the strength of the subgrade, and the thickness of the base layer affect the geosynthetic effectiveness.

The use of non-conventional and alternative materials in sub-base and base layers to replace conventional granular materials are currently being studied for pavement structures (Rezende *et al.* 2015). Thus, since 1972 it has been common to use lateritic soils mixed with lime or gravel in base and sub-base for low to medium traffic volume in Brazil (Nogami & Villibor 1991). One of the questions is the effectiveness of the geosynthetic when comparing lateritic gravel and unbounded granular material.

This study presents an experimental investigation on the performance of a lateritic clay soil mixed with gravel and an unbound granular material as base materials using a large scale steel box with a moving wheel loading apparatus attached to it. The research scope is to compare these two different materials and the geosynthetic response in the stabilized sections.

2 TEST SETUP AND MATERIALS

2.1 *Materials*

A weak clayed silt subgrade soil classified as high plasticity silt (MH) and A- 7-5, according to the USCS and HRB classification system, was collected near the city of São Carlos, São Paulo, Brazil. Tests were performed, obtaining a CBR of 3.5, 34% moisture content and a density of 1.45 g/cm^3 at Standard Proctor compaction.

A crushed unbounded coarse granular aggregate and a soil-aggregate mixture were used as base materials in this study. The unbound granular base consists of basaltic crushed stone with a dry density of 2.16 g/m^3 at an optimum moisture content of 4.1%. The soil-aggregate is a granulometric stabilized base with 20% of lateritic clay mixed with 80% basaltic crushed stone on a dry mass basis, with a dry density of 2.33 g/m^3 at an optimum moisture content of 6.5%. The lateritic clay was classified as A-6, ML and LG', according to the HRB, USCS and Miniature Compaction Tropical (MCT) systems, respectively. Figure 1 shows the grain size distribution curve of these materials.
Figure 1.   Particle size distribution curve.

Two types of geosynthetics were used in the tests, a composite geogrid (consisting of a light polypropylene nonwoven geotextile with a polyester geogrid, CGG) and a geogrid (GG) were used to mechanically stabilize the base aggregate. Both geogrids are biaxial and have the same properties. The physical and mechanical properties of the geosynthetics are summarized in Table 1.

2.2 *Test setup*

A large steel testing box with internal dimensions of 1.8 m high, 1.6 m wide, and 1.8 m long available at the University of Sao Paulo was used in this experimental study, as shown in Figure 2. Seven different structures were constructed, and a rolling wheel system, first

Figure 2. Test setup.

developed by Correia and Zornberg (2016) and modified by Pedroso *et al.* (2022), was used to simulate traffic loading. The testing wheel consists of a one-tire configuration fixed in the centerline of the box, with a diameter of 540 mm and a width of 154 mm that applied unidirectional loading in a tracking length of 1.0 m. The equipment was set to a maximum rate of 600 wheel passes per hour. The wheel load consists of a linear load that increases from 0 to a peak of 16 kN in 0.1 s; then, it is maintained constant through the tracking length. At the end of the tracking length, the load is reduced to zero, the wheel is pulled up and returns to the starting point over 1.5 s.

The pavement performance was evaluated by earth pressure cells, LVDT's and tell tails, as explained in Pedroso *et al.* (2022). Six earth pressure cells with 30 mm diameter installed in pairs at different locations along the experimental section for monitoring the vertical stress distribution. The sensors were placed in the middle of base course, at the top of the subgrade, and 300 mm below the base and subgrade interface.

The surface transversal profile was measured using a manual profilometer. The wheel cycles were stopped, and the profilometer apparatus was installed on the surface, ensuring that all points were aligned. Measurements were made at 0, 100, 500, 1000, 2500, 5000 and 10,000 wheel passes, and then each 10,000 wheel passes. For these experimental conditions, tests were conducted until reaching a total of 100,000 load repetitions or 50 mm surface permanent deformation (half of the base thickness for 100 mm base tests).

Seven stabilized (S) and non-stabilized test sections with two different base materials, lateritic-aggregate (L) and unbond granular (G), and thickness were evaluated. All sections were constructed with the same subgrade and the same bituminous surface treatment. The tests setup, base materials type, stabilized condition, and construction control are specified in Table 2.

Table 2. Test sections, base materials type and stabilized condition.

Test Section	Base material	Thickness (m)	Stabilized condition
LB1	Lateritic-aggregate	0.1	Non-stabilized
LB1S	Lateritic-aggregate	0.1	CGG-interface
GB1	Unbound granular	0.1	Non-stabilized
GB1S	Unbound granular	0.1	CGG-interface
LB2	Lateritic-aggregate	0.2	Non-stabilized
GB2	Unbound granular	0.2	Non-stabilized
GB2S	Unbound granular	0.2	GG-middle of base

3 TEST RESULTS

3.1 *Surface profile*

Figure 3. Shows the surface profile for all seven test sections.

A rut deep and more extensive than the wheel width combined with heave along both sides is formed for the granular base. The repeated wheel shear stress causes a lateral spreading of the granular base material particles. This lateral displacement was one of the main deterioration mechanisms contributing to a thinner and less stiff material while leading to an increase in subgrade deformation. Opposed to the granular base sections, the effect of lateral spreading in lateritic base sections was not a significant deterioration mechanism since the surface profile did not show the formation of a heave beside the wheel path. This behavior is due to the decrease in the number of voids and the increase in density caused by the presence of fines in the soil-aggregate mixture. However, based on the observation after trenching at the end of each test, excess water was observed in the base/subgrade interface and contamination of the base by the subgrade fines. This intermixing are the major deterioration mechanisms for the lateritic base.

3.2 *Vertical stress*

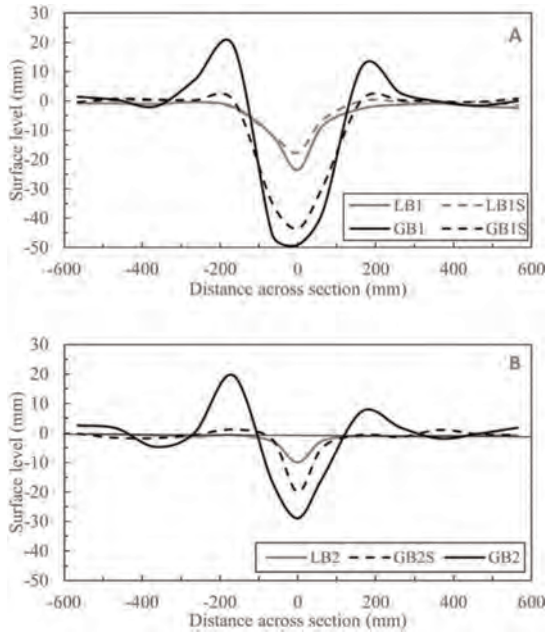
Figure 4 presents the maximum vertical stress for all test sections. The lateritic base, which is more rigid, showed lower vertical stress values at the top of the subgrade. As expected, the maximum vertical stress increased with the number of cycles showing that the repeated wheel loads progressively reduce the base stiffness, which is in agreement with (Qian *et al.* 2013;


Figure 3.   Surface transversal profile: (a) 10 cm thick base; (b) 20 cm thick base.
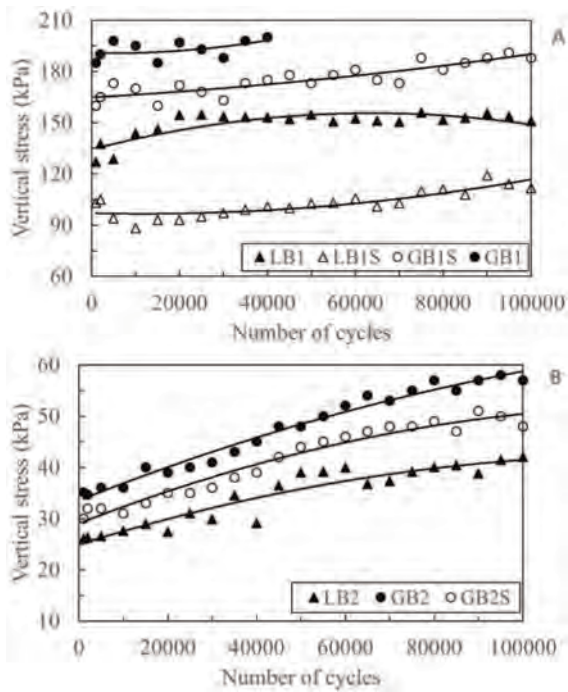

Figure 4.   Maximum vertical stress: (a) 10 cm thick base; (b) 20 cm thick base.

Tang *et al.* 2008). It is noteworthy that the increase in thickness of the base reduces the maximum vertical stress on the subgrade. However, sections with the same permanent deformation do not have the same vertical stress. For example, the GB2 section has lower vertical stress and a higher permanent deformation than LB1S.

The stabilized sections shows that the slope of the curve is less steep, in other words, the increase in vertical stress over the cycles is reduced when compared with the other sections. The same trend was observed for the accumulation of permanent deformation over time. This behavior can be results in the maintain of the base modulus over time.

4 CONCLUSIONS

This paper presented an experimental study on the performance of two base course materials unstabilized and stabilized with geosynthetic at different configurations under a moving wheel load. It can be concluded that the stabilized sections had a superior performance than the unstabilized sections, showing a decrease in superficial rutting and vertical stress at the subgrade. The base coarse deterioration mechanisms were different for the two materials. The primary mechanism for the coarse granular base was the lateral spread. On the other hand, the excess of water and intermixing between materials were the major deterioration mechanisms for the lateritic base. Therefore, the geosynthetic main function had different objectives for each base material.

NAUE GmbH & Co. KG, Germany

ABSTRACT: In order to quantify the effect of geogrid stabilisation/reinforcement, a full-scale pavement field trial was established upon a soft and expansive subgrade. Sections with variable geogrid arrangements were constructed in order to allow the quantitative assessment of geogrid stabilisation/reinforcement; both in terms of their initial contribution to composite insitu stiffness parameters and their benefit to the long-term performance of a pavement. On site testing was completed within all trial sections during the project's construction phase, such that the initial state (strength and stiffness) of performance the subgrade and each pavement layer was adequately characterised. Post construction, ongoing performance monitoring has included the use of embedded pressure cells. An analysis of the first 3 years of monitoring of this full-scale field trial was conducted, with selected results presented herein. The data demonstrates that the inclusion of geogrids successfully improves the bearing capacity of the pavement profile by reducing the traffic imparted vertical pressures being exerted upon the underlying materials. The results also demonstrate that the presence of two geogrid layers (with one placed at the subgrade-subbase interface and one at the subbase-base interface) offer a greater improvement of the bearing capacity than the installation of a single geogrid at the interface of subgrade-subbase materials. Additional observations relate to longitudinal cracking of the pavement, where greater control of cracking has been initially achieved in the test sections where geosynthetic reinforcement was installed.

1 INSTRUCTIONS

Geogrids are used to stabilize and reinforce the roads and improve the bearing capacity of pavements on soft subgrades. Additionally, geogrids installed within granular layers of a pavement formation are frequently used to control environmental distress and limit longitudinal cracking due to expansive subgrades by providing the stiffening, known as the new function of geosynthetic material to control deformations in the soil-geosynthetic composite.

In recent years, "Stiffening" has been introduced by Prof. Jorge Zornberg (2017a,b) as a function of geosynthetics to control pavement deformations (e.g. due to environmental loads) for applications such as pavements on expansive subgrades. "stiffening" refers to development of tensile forces in the geosynthetic material to control deformations in the soil-geosynthetic composite, while "reinforcement" refers to development of tensile forces in the geosynthetic material to maintain or improve the stability of the soil-geosynthetic composite.

Although both functions provide mechanical improvement, the required geosynthetic properties to achieve these functions are slightly different. The key property for "reinforcement" is the geosynthetic tensile strength and stiffness, while the main design parameter for "stiffening" is the stiffness of soil-geosynthetic composite (Zornberg, 2017a,b). Supported by more than 20 years of research and field monitoring, the use of stiffening geosynthetics has now become a standard practice in many countries specially in united states to mitigate cracks and improve pavements life on expansive subgrades. The use of geosynthetics was found to effectively minimise the detrimental effects of expansive soil subgrades on flexible pavements. Geosynthetic-stiffened pavement sections on expansive clay subgrades have showed significantly better field performance than control (non-stiffened) sections or even lime stabilised sections. On the other hand, geogrid-stiffened section with less gravel thickness could perform equal/better to the sections without geogrid and thicker gravel (Roodi & Zornberg 2020; Roodi et al. 2016; Roodi 2016; Zornberg et al. 2012, 2008). This verifies the benefit of geogrid stiffening in reducing the cover thickness for construction on expansive subgrades.

2 FULL SCALE FIELD TRIAL DETAILS

The trial included different sections with different geogrid and gravel combinations. Each test bed is to be 9.0m (length) × 4.85m (width). The main sections for this study are the control section (no reinforcement), single reinforced section and double reinforced section. Pressure cells were installed on top of the subgrade to measure the effect of geogrid stabilization/reinforcement and stiffening (Figure 1).
Figure 1.   Test cross sections.

The field was open to local traffic for at least 3 years to make sure the gravel-geogrid interaction and activation of geogrid is occurred. Measurements were conducted after 3 years and results of unreinforced, single reinforced and double reinforced sections were compared to each other.

Geotechnical investigations have shown a black silty clay subgrade with hi plasticity (PI = 86%) with soaked CBR of 2% and CBR swell of 5%. After excavation of the subgrade to the required level, onsite testing was conducted on the subgrade to measure the in-situ subgrade properties. These included DCP, Panda test, FWD and Static Plate Load Test according to DIN 18134:2012-04 (Figure 2). After installing gravel layers, Plate Load Testing was also conducted on top of every granular layer for each section.

Figure 2.   Subgrade preparation and testing.

To monitor the long-term performance of benefit of geogrid reinforcement in single and double reinforced sections, pressure cells were installed during the project and monitored beyond project completion. A total of three test beds were instrumented with pressure cells.

To isolate the study to the effect of geogrid only and provide separation between subgrade and granular layer for all sections, a laid and welded biaxial geogrid-geotextile composite with textured surfacing and with the geotextile integrated between geogrid bars was installed at the subgrade level for reinforced sections and a separation nonwoven geotextile was installed on the subgrade for unreinforced (control) sections. Subbase layers were placed and compacted according to standard installation practice to achieve minimum 98% compaction. Gravel used was type 2.3 according to QLD TMR specification MRTS04 (2021). The thickness of the gravel layer was checked and measured for each subbase layer. Where a second reinforcement layer was planned, a laid and welded biaxial geogrid with structured surfacing was used. A 40mm thin asphalt surfacing was placed and compacted on top of the base course layer. The road was then opened to the public local traffic. Figure 3 shows the placement and compaction of the materials.

Figure 3.   Installation of pressure cell, geocompsoite, geogrid, gravel and asphalt.

After 3 years of local trafficking, a full load water truck was used to apply pressure on the road surface in sections with no reinforcement, single reinforcement and double reinforcement. The water truck stayed on top of the pressure cell point for few minutes, so the pressure cell could have enough time to measure the transferred pressure to the subgrade. The data collecting intervals of the pressure cell was also reduced to few seconds for the time period of the testing. To be able to measure the pressure accurately and apply the load directly on the pressure cell, the exact location of pressure cells was determined and marked on the road surface using a Ground Penetrating Radar (GPR) system.

3   RESULTS & DISCUSSION

3.1   *Strain modulus*

Test result from in-situ Plate Load Testing during construction showed that the improvement in the strain modulus E_{v2} is higher in section with double reinforcement even with a thinner gravel layer compared to section with single reinforced, and both are higher than the unreinforced control section. The improvement has been calculated as E_{V2} on the top of the base layer for each section divided by E_{V2} of subgrade only. Figure 4 shows the results of these test sections.
Figure 4. Percentage of increase in Ev2 for different sections.

Results clearly showed that inclusion of one geogrid increases the strain modulus (E_{v2}) v.s. the unreinforced section, and the double reinforcement can increase the strain modulus even more compared to single reinforcement.

3.2 Subgrade deformation

The results from the pressure cell measurements after 3 years were also analysed for the above sections. Results clearly showed that a single reinforcement performed better than unreinforced section, and double reinforcement performed better than single reinforcement in terms of reducing the vertical stresses transferred to the subgrade even with a bit less gravel thickness. This can be due to the better load distribution because of the presence of the geogrid, especially in the double reinforced section compared to the single reinforced section. This can lead to less vertical deformation of the subgrade and longer service life of the pavement in the double reinforced section compared to the single reinforced section. On the
Figure 5. Pressure transferred to the subgrade for different sections.

other hand, the reduction in the vertical stress was higher for double reinforced section with thinner gravel compared to single reinforced and unreinforced sections. This means by using a double reinforcement, the thickness of the pavement can be reduced and still the same or better performance can be achieved.

3.3 *Controlling longitudinal cracks over expansive subgrade*

To study the 'stiffening' effect of the geogrid in controlling the cracks caused by expansive subgrade shrinkage and swell, a single reinforced section was considered between two double reinforced sections in the full-scale field trial to be studied along with the control section with no reinforcement. All sections had the same thickness and subgrade conditions. The single reinforced section had only one layer of geogrid-geotextile composite at the subgrade layer while the double reinforced sections had an extra geogrid within the granular layer. The same geogrid and geocomposite used in other sections were used here. After 3 years under local traffic, longitudinal cracks had developed in the section with no reinforcement. The sections with single and double reinforcement had no cracks on the surface. There was a minor crack in the section with single reinforcement, which was more towards the edge of the cross section in the longitudinal joint with the other road lane. Even this minor crack in the single reinforced section was stopped when reached to the double reinforced sections. Figure 6 shows then results.

Figure 6. Performance of unreinforced (left photo) vs single reinforced and double reinforced sections (right photo) on expansive subgrade.

4 CONCLUSION

In order to quantify the effect of geogrid stabilisation/reinforcement, a full-scale pavement field trial was established upon a soft and expansive subgrade. Sections with variable geogrid arrangements were constructed including control section with no geogrid, single reinforced section with on layer of geogrid-geotextile composite at the subgrade-subbase interface, and double reinforced sections with additional geogrid within the pavement between subbase and base layers. An analysis of the first 3 years of monitoring of this full-scale field trial was conducted. The data demonstrated that the inclusion of geogrids successfully improves the bearing capacity of the pavement profile by reducing the traffic imparted vertical pressures being exerted up-on the underlying materials. The results also demonstrated that inclusion of one geogrid increases the strain modulus (E_{v2}) v.s. the unreinforced section, and the double reinforcement can increase the strain modulus even more compared to single reinforcement. In addition, long term monitoring of longitudinal cracks due to the expansive nature of subgrade shows that the additional geogrid layer within the granular pavement between

subbase and base (stiffening geogrid) can successfully control the longitudinal cracks due to swell-shrinkage of the expansive soil.

ABSTRACT: Geosynthetic reinforcement of asphalt layers has been used for almost several decades but to this day a proper evaluation of influence of these materials on pavement fatigue life is still challenging task, especially for new types of geogrids composites. This paper presents the evaluation of fatigue performance of large sized asphalt concrete beams reinforced with new type of geogrid composite in which hexagonal (multiaxial) polypropylene stiff monolithic paving grid with integral junctions is bonded to the polypropylene non-woven paving fabric. Non reinforced samples were used as a reference. Fatigue testing was performed in the scheme of four-point bending test (4PB-PR) in the controlled strain mode at the constant temperature of +13°C and frequency of 1Hz. The specimens width (170 mm) was selected on the assumption that asphalt layers should cover at least 2 full hexagon pitches of multiaxial geogrid. The distance between axes of the end supports equalled to 740 mm. The distance between axes of the loading supports equalled 247 mm. Test results were analysed in several aspects, including the standardized approach based on stiffness reduction but also with the use of critical strain at one million cycles. The effect of the notch on the fatigue life and the ability of the reinforcement to crack propagation delay was also analysed. Based on the ε_6 critical strain, reinforced samples result in an increase of the critical strain from 30% (notched) to 40% (un-notched).

1 INTRODUCTION

Reinforcement of asphalt with use of geosynthetics is still a globally application where practice is ahead of science. Number of successful installations followed by improvement of asphalt pavements over time reported by various authors [Brown 1985; Canestari *et al*. 2015; Correia 2014; Pasquini *et al*. 2013] are sometimes compared with cases where geosynthetic inclusion did not provided expected performance improvement to the pavement. Mechanism of asphalt reinforcement was subject of research by [Al-Qadi 2006; Graziani *et al*. 2014; Ragni *et al*. 2020; Zieliński 2013; Zofka *et al*. 2017]. This paper is presenting results of implementation of recently developed geocomposite with multiaxial geogrid into double-layered asphalt beams and its impact on delay of fatigue performance under cycled loads. As cracking occurring at the bottom of asphalt layers significantly reduces the fatigue life [Mackiewicz 2013; Spadoni *et al*. 2021], analyzes of the double-layer system with inclusion of a notch were also carried out.

2 MATERIALS USED AND SAMPLES PREPARATION

2.1 Asphalt concretes

Two asphalt concretes were used in this study: bottom layer made of asphalt concrete AC 11 W 35/50 for levelling course, upper layer made of asphalt concrete AC 16 W 35/50 for binder course. Both mixtures were designed and produced in accordance with the European standard EN 13108-1 and the Polish technical guidelines WT-2:2014 for medium traffic load (for the range of 500,000 to 7,300,000 of 100kN ESALs). The mineral mixtures were composed of limestone filler and crushed gneiss/granite fine and coarse aggregate. Neat bitumen classified as 35/50 according to EN 12591 standard was used as a binder.

2.2 Geocomposite with multiaxial geogrid

AX5-GN geocomposite interlayer contains two components, i.e. (1) multiaxial (hexagonal) paving grid with integral junctions bonded to (2) a polypropylene non-woven paving fabric. Unit weight of the grid component is approximately 210 g/m^2. The unit weight of the fabric component is 130 g/m^2. Geocomposite was developed and produced by Tensar International Ltd., Blackburn, UK. Geocomposite interlayer AX5-GN is presented in Figure 1.

The grid is oriented in three directions. The size of hexagon pattern of the hexagonal grid has the nominal value of 80 mm. A geogrid performs the structural reinforcement function (R) of the asphalt interlayer. A geocomposite uses a non-woven fabric that acts as a bonding layer during installation. A non-woven fabric, after installation and saturation with bitumen, also acts as a SAMI layer, which means that it provides a stress relief function (STR). Another functions of the bitumen saturated non-woven fabric is a moisture interlayer barrier (B).
Figure 1. View of the double-layer sample preparation process and notching of beams with circular saw and the view of the middle part of the beam with a cut notch (sample inverted as it was positioned into the 4PB device), 1 – multiaxial (hexagonal) grid, 2 – polypropylene non-woven fabric, 3 – notch 2 × 10 mm, 4 – AC11W, 5 – AC16W.

2.3 Bitumen emulsion

Bitumen emulsion was used as a tack/bond coat for the layer interfaces. The direct shear test method proposed by Leutner was used to assess the interlayer adhesion of asphalt layers.

Based on the previous test results [Jaskula et al. 2021], the following types and amounts of bitumen emulsion for further testing was selected as the most optimal: C69 B3 PU (bitumen emulsion for surface treatments, bitumen content 69%) in quantity of 1.2 kg/m^2 (residue bitumen) for reinforced systems, C60 B3 ZM (bitumen emulsion for layer interfaces,

bitumen content 60%) in quantity of 0.2 kg/m^2 (residue bitumen) for non-reinforced systems. The higher value of the asphalt emulsion in the case of using a geocomposite results from the need to completely infiltrate the non-woven fabric with bitumen. Emulsions for layer interfaces (ZM) were produced from 70/100 bitumen, while emulsions for surface treatments (PU) were produced from 100/150 bitumen.

For the reinforced specimens, shearing failure always occurred at the interface between fabric and the lower asphalt layer and no debonding of the composite was observed, which proves good internal integration of the composite with upper asphalt layer. Introduction of reinforcement composite resulted in 75% reduction of inter-layer bond strength as compared to specimens without reinforcement from 1.5 MPa to 0.4 MPa.

2.4 Samples preparation

The specimens prepared for laboratory testing consisted of two layers of asphalt concrete (AC). They were bonded with bitumen emulsion applied as a tack/bond coat. Reference samples (in which two asphalt layers were used with no reinforcement) and reinforced samples (in which a multiaxial AX5-GN geocomposite was installed in between two asphalt layers) were prepared. The double-layer prismatic specimens preparation process is depicted in Figure 1. They contain the main steps, as: production of timber forms with internal dimensions of 240 × 135 × 1000 mm; laying and compacting of the bottom AC11W asphalt layer (compaction temperature 135 ± 5°C), up to a height of 45 mm after compaction; application of a tack coat of selected bitumen emulsion; installation of composite asphalt interlayer (if applicable); laying and compacting of the upper AC16W asphalt layer (compaction temperature 135 ± 5°C), up to a height of 90 mm after compaction; cutting the test beam from the compacted sample to the final sample with dimensions of 170 × 100 × 850 mm. The final AC11W levelling course thickness of 30 mm and AC16W binder course thickness of 70 mm was obtained. Standard Wacker Neuson walk-behind roller RS 800A was used to compact specimens. The beam samples were notched (2 mm width x 10 mm depth) in the middle of their span, using a high precision notching (circular) saw.

3 METHODOLOGY OF FATIGUE TESTING

3.1 Four-point bending scheme

Fatigue testing was performed in the scheme of four-point bending test (4PB-PR). To reflect actual working conditions of the pavement, the specimens used for a test were significantly larger than those recommended in typical procedures of the fatigue testing: 850 × 170 × 100 mm.

The assumption that the width of the reinforcement placed between asphalt layers must cover at least 2 full hexagon pitches of multiaxial geogrid resulted in a sample width of 170mm.

The test was performed in a climatic chamber at a constant temperature of +13°C, which is the equivalent temperature adopted in the design of flexible pavements in Poland. The scheme of the 4PB test configurations is presented in Figure 2.

Two sets of double-layered beam specimens were used in the 4PB fatigue test: without and with a notch. Fatigue tests on specimens without notches were performed to determine fatigue curves and compare fatigue characteristics of the reinforced systems against systems without reinforcement. Notches were introduced to initiate cracking, thus enabling monitoring of its propagation based on changes in stiffness of the tested systems as well as assessment of the effect of reinforcement on inhibition of crack propagation in asphalt overlay.
Figure 2. Scheme of the 4PB test configuration.

Beams were exposed to cyclic loading that caused a sinusoidal change in horizontal strain from 0 to the predetermined maximum value equal to 400, 500, 600, 700 and 800 μstrain. A single specimen was tested for each combination of parameters: presence of composite reinforcement of multiaxial geogrid, notching and strain value. Bending was applied in one direction only, and in combination with inverted position of the specimen, the reinforcement functioned in the tension zone. The loading frequency was 1 Hz. The maximum number of applied loading cycles was limited to 300,000, which resulted in a maximum testing time of 84 h per test [Jaskula *et al*. 2021, 2022].

3.2 *Metodology of fatigue life evaluation*

During the fatigue testing in the controlled predetermined strain mode, a gradual decrease in the stiffness modulus of asphalt mixtures occurs during the following load cycles.

The obtained results were analysed in terms of the number of cycles to failure, fatigue curves, strain at one million load cycles and observation of crack delay. A detailed description of monitored parameters is given below [Jaskula *et al*. 2021, 2022]. Stiffness in any given cycle may be calculated from Equation 1:

$$S_i = \frac{\sigma_i}{\varepsilon}$$

(1)

where S_i = stiffness in the i-th cycle of the test; σ_i = maximum tensile stress in the i-th cycle; and ε = maximum strain of the extreme tension fibres of the cross section (constant for controlled strain mode across all cycles).

Fatigue life N_f is a number of cycles required to achieve fatigue failure of the specimen. The most common definition of fatigue failure is the moment when the stiffness S_i is reduced by 50% in comparison of the initial stiffness S_{ini}, measured at 100th cycle.

Fatigue curve is determined by the N_f fatigue life results achieved at various strain levels. The curve enables to estimate fatigue life of the system at any assumed strain level (also outside of the tested range). The general form of the equation of the curve is as follows (Equation 2):

$$\varepsilon = A\left(N_f\right)^b$$

(2)

where ε = tensile strain; A = slope of the fatigue curve; b = coefficient based on the obtained fatigue test results and N_f = fatigue life of the system.

Critical strain at one million load cycles ε_6 means a parameter based on the fatigue curve, equivalent to strain at which fatigue life of the system is one million load cycles. This parameter is used to characterise asphalt mixtures in terms of fatigue resistance. High value of the ε_6 strain indicates better fatigue properties of the mixture (or the entire tested layered system) in comparison with the low ε_6 value.

4 TEST RESULTS

4.1 *Fatigue life evaluation*

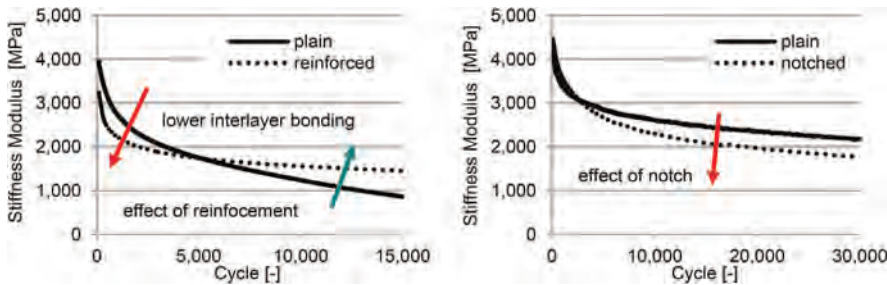
For specimens reinforced with geocomposite interlayers, it is visible that the decrease in stiffness modulus in the first phase is more rapid due to lower interlayer bonding. During second phase it is lower compared to reference systems, due to reinforcement. The effect is shown in Figure 3a. In case of inclusion of initial crack, the failure of the system occurs faster in comparison to the plain samples (Figure 3b). Parameters ε_6 were calculated based on fatigue curves and marked in Figure 4. The fatigue models were calculated with the least-square method, and they are presented in Figure 4 as well. Based on equations given in Figure 4, fatigue life can be extrapolated for level of strain, which occur in pavement structure, what is obviously related with some uncertainty.


Figure 3. A – schematic influence of reinforcement on fatigue characteristic of un-notched samples, B – schematic influence of inclusion of crack on fatigue characteristics.
Figure 4. Fatigue model diagrams obtained from the four-point bending test of systems without reinforcement and reinforced with geocomposite of multiaxial geogrid for plain samples: A – samples without notch, B – samples witch notch.

Reinforcement with composite results in an increase in the critical strain by 40% compared to unreinforced systems in case of un-notched specimens. Inclusion of initial crack resulted in decreasing ε_6 parameter in both systems, but it is still clearly noticeable that reinforced system increases in the critical strain by 30%.

4.2 *Delay of crack propagation for notched samples*

A phenomenon of a subsequent flattening of the stiffness curve slope for systems reinforced with geocomposite, which indicates that the process of crack development was relieved, was generally observed. The course of recorded changes in stiffness was compared with the

appearance of cracks in the samples after testing procedure. Images of cracks were presented in Table 1, in order to ensure the visibility of the progressing of the cracks their shapes were marked and highlighted in red.

In the case of systems reinforced with geocomposite, the bitumen saturated fabric starts to dissipate the stresses generated nearby the crack. Inhibition of crack propagation was observed in samples subjected to strain levels of 400, 500 and 600 µstrains, as was depicted in Table 1, hence the composite prevented crack propagation from the lower asphalt layer to the upper asphalt layer for the strain level equal to 600 µstrains. In case of the highest strain levels, i.e., 700 and 800 µstrains, the cracks propagated through the composite interlayer and then into the upper layer. It is suggested, based on the failure mechanism, that a local loss of an inter-layer bonding at the asphalt-composite-asphalt interface would appear. It would lead to the re-initiation of the cracking at the bottom of the upper asphalt layer. Nonetheless, no rupture of the geocomposite components was detected.

Table 1. A comparison of photographs of notched samples after fatigue testing with highlighted cracks.
5 CONCLUSIONS

Based on the analysis of the results of the performed fatigue tests carried out on the unreinforced beam samples and samples reinforced with the geocomposite of multiaxial geogrid, the following conclusions can be formulated:

- Enhancing the pavement with the geocomposite noticeably increases its fatigue life. This relative increase strongly depends on the level of horizontal tensile strain at the bottom of the asphalt overlay.
- The effect of asphalt reinforcement is more beneficial in case of new pavements with thick asphalt layers, where one can expect lower tensile strains at the bottom of these layers and fatigue cracks have not been initiated yet. This has been simulated by the tests carried out on plain samples. An increase in ε_6 up to 40% can be achieved, when compares to the control system.
- The effect of asphalt reinforcement is less beneficial in case of rehabilitated pavements, where fatigue cracks have been initiated yet and one can expect higher tensile strains at the bottom of asphalt layers. This process has been simulated by the tests carried out on notched samples. An increase in ε_6 parameter up to 30% can be achieved, when compares to the control system.

- A slight decrease in the initial stiffness modulus of the reinforced systems, as an effect of a reduction in interlayer shearing strength was observed and thus differential movement between asphalt overlay and composite can be expected. However, a 'control de-bonding mechanism' supposed to be a positive effect that provides the function of stress relief as well as SAMI function, created by the bitumen saturated fabric.
- An application of a composite of multiaxial geogrid in the asphalt pavement will significantly delay the occurrence of fatigue cracking and thus extend the pavement durability.

ABSTRACT: Asphalt pavements lose their bearing capacity when rainwater infiltrates the base course through cracked and damaged areas in the surface course and binder course. The decrease in base course bearing capacity causes progressive damage because of base course deformation, resulting in early deterioration of the entire pavement structure. Major pavement repairs have been limited to cutting overlays because the cost of pavement maintenance and repair notably drops with increased road stock volume. Thus, an experimental study was conducted to improve the base course durability of asphalt pavement by laying geotextiles to extend the long life of road pavements. As a result, geotextile was found to suppress the reduction of base course bearing capacity even when rainwater infiltrated the pavement.

1   INTRODUCTION

The durable setup life of major national roads and other roads in Japan is 10–15 years. However, asphalt pavements that deteriorate prematurely are increasing because of the increased number of large traffic vehicles and extreme weather conditions. Pavement repair to extend service life necessitates repair work up to the base course layer. Despite the need for costs related to pavement maintenance and repair as the pavement stock increases, the budget for road maintenance and repair is decreasing year by year, along with rising social security costs because of a declining birthrate and an aging population. Therefore, economical and efficient maintenance and management methods are required. Repair work, including a base course, is remarkably more than three times more expensive and four times longer than cutting overlay. Drastic repairs are also difficult to carry out on major national roads and highways in service because of high traffic volumes and strict traffic restrictions.

The general pavement structure of asphalt pavements comprises a lower base course, upper base course, binder course and surface course laid at a specified thickness from the subgrade top, depending on the subgrade strength. Although this structure provides a load-dispersing effect and keeps the road pavement sound, asphalt pavements are thought to

deteriorate over time, rainwater seeps through cracks and pavement joints, and the entire pavement structure begins to deteriorate prematurely because of the reduced bearing capacity of the base course. Therefore, maintaining a sound base course is a key issue that will be essential in the future for extending the service life of pavements and building a sustainable society.

In recent years, research and development have focused on base course reinforcement, especially the reinforcement of base courses using geotextiles (Zomberg *et al.* 2018). Geotextiles are important materials used in constructing soil structures and serve as tensile reinforcement (Takahashi *et al.* 2008; Yamauchi 1986). These have been used in pavement construction in Japan as a countermeasure for the soft base course in road pavements (Hirao *et al.* 1992). However, only a few instances exist in which geotextiles have been used to reinforce base courses. Thus, research on the application of geotextiles to base courses has received much attention. Hirakawa *et al.* (2014) showed that even a single layer of geogrid in the base course can significantly reduce the amount of residual subsidence. They also discovered that when combined with a highly dense base course, progressive residual settlements could be effectively restrained.

In this report, the effects of reinforcing the base course with geotextiles were investigated to understand (1) the effects of soil material and (2) the geotextiles on base course reinforcement during rainwater seepage. The results of constant strain loading tests on the effect of geotextiles laid in a model ground on the bearing capacity characteristics of the base course, which were conducted using a small soil tank test apparatus and two types of geotextiles of different geometries, were presented.

2 EXPERIMENTAL PROCEDURE

2.1 *Experimental materials*

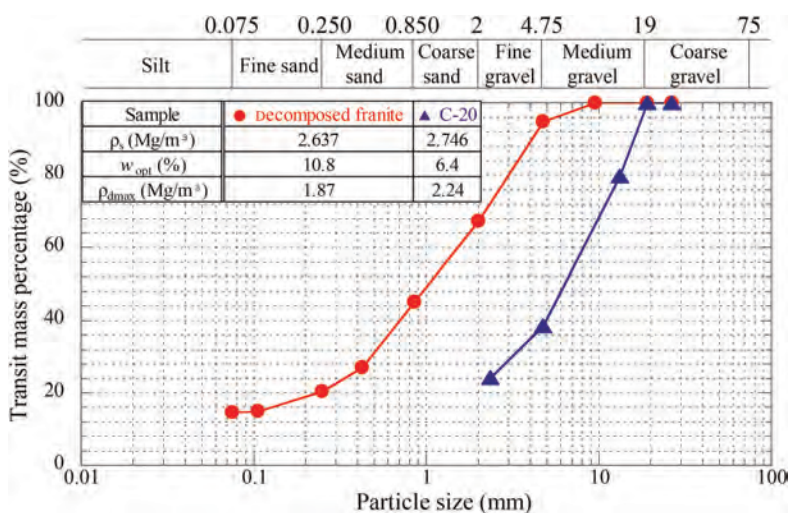
Decomposed granite and crushed stones (C-20) were used as experimental samples. The grain size additive curves are shown in Figure 1. The geotextiles used woven fabrics and triaxial geogrids. An overview of the 2 types of geotextile is presented in Table 1. Woven fabrics are used primarily to improve bearing capacity in soft roadbeds. It is a particularly


Figure 1.   Grain size accumulation curve.

Table 1. Overview of the geotextiles.

Reinforcement	Woven fabric	Geogrid

Tensile strength (kN/m)	89.0	10.0
Wastewater volume (l/min/m²)	3055.5	—

high strength material that combines reinforcement, separation, and drainage. Whereas, geogrid is a reinforcing material with a three-directional stretched shape and excellent restraint effect by interlocking with granular base course material.

2.2 Experimental method

A small soil tank, 90 cm high, 120 cm wide, and 20 cm deep, was used in this study. A schematic diagram of the experimental apparatus is shown in Figure 2. The loading plate was 10 cm wide, 19.8 cm deep, and 2.2 cm thick. A spring (spring constant $k = 3.75$ kN/mm) and plate were placed at the bottom of the small soil tank to determine the base course deformation because of loading. Here, the spring stiffness was set to the maximum strength at which the model ground was not deformed by the dead weight of the soil to be loaded. The model ground was prepared by the tamping method with a thickness of 30 cm under a specified compaction control by density, with the initial water content of the soil sample adjusted. Two layers of 10 cm thickness (1st and 2nd layer) each were compacted in the lower 20 cm of the model ground, and two layers of 5 cm thickness (3rd and 4th layer) were compacted in the upper 10 cm of the model ground to allow geotextiles to be laid at
Figure 2. Schematic diagram of the experimental apparatus.

shallower depths. Constant strain loading was carried out with a displacement of 50 mm at a rate of 1 mm/min as the termination condition to determine the characteristics of the base course bearing capacity. In addition, water was sprinkled from the top of the model ground before loading to understand bearing capacity behavior because of rainwater. Water was sprinkled by misting the top 5 cm of the geotextile, and the water content increased by 4% after sprinkling water.

2.3 *Experimental conditions*

The experimental conditions are listed in Table 2. In this study, the method of preparing the model ground differed depending on the sample, with a 95% compaction degree for decomposed granite and 90% for C-20, and the initial water content was set to the optimum water content for both. In addition, the length and depth of the geotextile bedding were standardized.

Table 2. Experimental conditions.

Sample	Initial water content (%)	Degree of compaction (%)	Reinforcement	Laying length (cm)	Laying depth (cm)
Decomposed granite	10.8	95	Unreinforced	–	–
			Woven fabric	120	5
C-20	6.4	90	Geogrid		

3 EXPERIMENTAL RESULTS AND DISCUSSIONS

3.1 *Effect of different soil samples on bearing capacity*

Figures 3(a) and (b) show the loading stress and settlement at the loading plate center from the constant strain loading test. In both soil samples, the loading stress relative to the amount of settlement increased with the geotextile. Here, the ultimate bearing capacity, q_u, is determined from the method of the intersection of the tangent line of the settlement curve at the beginning of the loading with the tangent line of the settlement curve at the end of the loading as shown in Figure 3 (Hirao *et al.* 1992). The ultimate bearing capacity shows that the reinforcing effect of the geotextile is demonstrated regardless of the soil sample.

The results of the bearing capacity reinforcement effect of the geotextile installation, which are calculated as the ratio of the ultimate bearing capacity to the unreinforced ultimate bearing capacity as a percentage increase in bearing capacity, are shown in Figure 4. The effect of support reinforcement by geotextile placement was higher for C-20 than for decomposed granite. This may be due to differences in the frictional and constraining effects of the geotextile because of the differences in grain size width. In addition, when comparing geotextile types for both soil samples, geogrids with lower tensile strength showed higher values than woven fabrics because the geogrids exerted tensile forces in all directions. Thus, the restraining effect was sufficient for crushed stones with large grain sizes, indicating that the bearing reinforcement effect of laying geotextiles was sufficient, irrespective of the geomaterial.

3.2 *Effect of rainwater infiltration on bearing capacity*

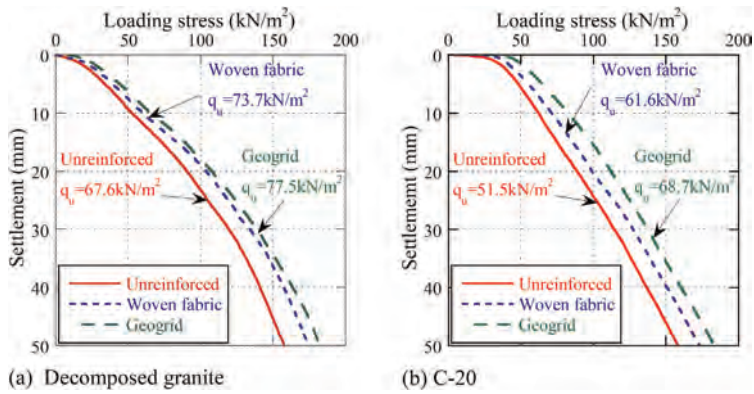
In this study, the water was sprinkled from the top of the model ground to assess the base course bearing behavior because of rainwater seepage through cracks in the pavement. Loading tests were conducted using two types of geotextiles and crushed stone (C-20). The


Figure 3. Loading stress and settlement.
Figure 4. Increase rate of bearing capacity.

loading stress–settlement relationship is shown in Figure 5. As in the case of no sprinkled water, the loading stress relative to the amount of settlement remarkably increased with geotextile laying. Moreover, the effect of sprinkled water on the ultimate bearing capacity is shown in Figure 6. Then, the ultimate bearing capacity remarkably decreased with water sprinkling in both conditions. This may be due to an increase in the degree of saturation of the ground and a decrease in suction because of watering (Figure 7). However, the geotextile-lined ground showed higher values than the unreinforced ground, indicating that geotextiles are effective as a stormwater seepage control measure.

3.3 Understanding bearing capacity behavior over time

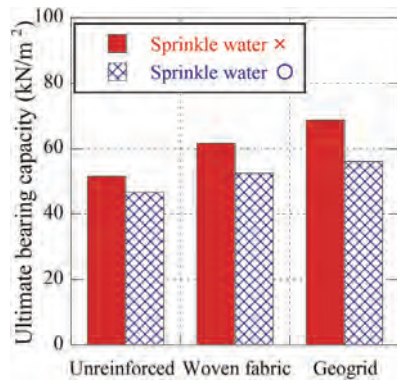
In this study, it was assumed that rainwater seeps into the base course and that the seepage water flows down into the ground, and the bearing capacity behavior over time from rainwater seepage was investigated. The experiments were conducted by varying the time between sprinkling water and loading to 0, 6, and 24 h. The effect of the water content state of the model ground because of water sprinkling on the bearing capacity was evaluated by measuring the water content at the end of the loading test. The change in ultimate bearing capacity over time after water sprinkling is shown in Figure 8. Notably, the ultimate bearing
Figure 5. Loading stress and settlement.


Figure 6. Effect of water infiltration on the ultimate bearing capacity.
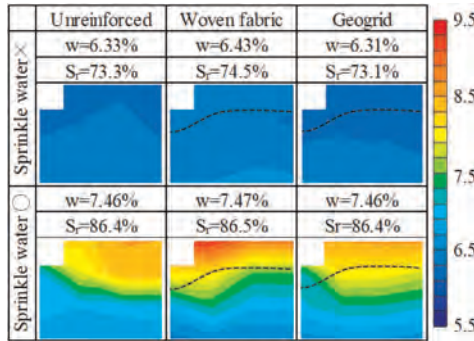

Figure 7. Distribution of water content on water infiltration.

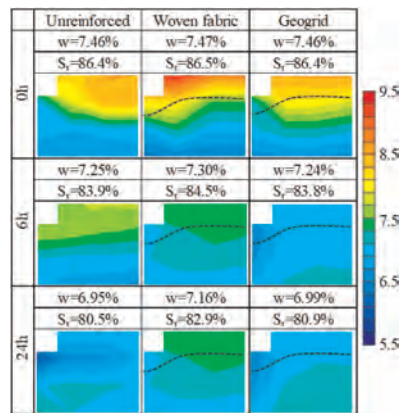
capacity decreased significantly after 6 h of water sprinkling in both conditions and then recovered gradually after 24 h. The geotextile showed a high bearing capacity and recovery because of its reinforcing effect. The water content distribution at the end of the test is shown in Figure 9. The water content was highest at 0 h immediately after water sprinkling, and as
Figure 8. Effect of elapsed time on ultimate bearing capacity.


Figure 9. Distribution of water content on elapsed time.

time passed over 6 and 24 h, thecontent decreased as water seeped down into the soil tank. However, the ultimate bearing capacity decreased significantly at 6 h, irrespective of the decrease in water content. This indicates that rainwater seepage through cracks in the road surface largely affects base course bearing capacity, leading to premature pavement degradation. The results also show that geotextile laying is effective in this bearing capacity reduction behavior.

4   CONCLUSIONS

1) The wider the grain size range of the geomaterial and the larger the grain size, the more effective the base course reinforcement by geotextiles.
2) The geotextile's type and shape influence its effectiveness in reinforcing base course bearing capacity.
3) The bearing capacity is once reduced by rainwater seepage, but recovers over time. The reinforcing effect of laying geotextiles is significant, and a high bearing capacity and resilience are demonstrated.
4) The reinforcing effect of geotextile laying on base course bearing capacity results in a longer service life for asphalt pavements.

Mechanistic analysis of a pavement with GRC (Geoweb Reinforced Concrete)

J. Schmalbach
Soil Protection, Bogota, Colombia

ABSTRACT: The operation of pavement with GRC (Geoweb reinforced concrete) can be analyzed through a mechanistic methodology of pavement design. This involves modeling the pavement system based on the initial variables, including applied loads, traffic, condition of the subgrade, properties of the concrete, and the Geocell base polymer. To model the pavement, a finite element analysis is used to simulate the behavior of the system. The finite element model can consider the different layers of the pavement, including the subgrade and the GRC layer. The properties of each layer can be specified, including the modulus of elasticity, Poisson's ratio, and thickness. To study fatigue, an analysis of forces and moments is carried out to determine the maximal deformation of the subgrade. The maximum tensile stress in the system is also determined, which is an important factor to understand pavement fatigue. By simulating the behavior of the pavement over time, it is possible to predict the onset of fatigue and determine the expected service life of the pavement. By considering these different variables, it is possible to design a pavement system that is durable, long-lasting, and capable of withstanding the expected loads and traffic conditions. Overall, pavement modeling through a mechanistic methodology of pavement design is a valuable tool for analyzing the behavior of pavement with GRC (Geoweb reinforced concrete) and predicting its performance over time. By taking into account the initial variables and simulating the behavior of the pavement system, it is possible to design and construct pavement that is safe, efficient, and cost-effective.

1 INTRODUCTION

1.1 *Structure*

GRC (Geoweb reinforced concrete) is a system that combines geocell and concrete to create a more efficient and effective way to construct roads and other transportation infrastructure. The system was first developed in Colombia in the 2000s through empirical methods, and formal study of the system began in 2018 by Professor Jie Hann. The key to the GRC system is the combination of geocell and concrete in a way that provides both the necessary flexural and elastic behavior, as well as compressive strength. The geocell provides the necessary flexibility and elasticity that concrete alone would not be able to withstand, while the concrete provides the strength needed to support heavy loads. The geocell also serves as a formwork for concrete, which makes installation faster and easier than other systems. This makes it an attractive option for complex accessibility roads in Pacific islands, as discussed by the World Bank in 2019 (World Bank 2019). Overall, the GRC system offers a promising solution for transportation infrastructure construction. Also, ongoing research and development could lead to even greater improvements in efficiency and effectiveness.

To ensure the long-term viability of GRC as a common construction technology, detailed studies of the technology are needed. By understanding the behavior of GRC pavement over time, it is possible to design and construct sustainable roads that will endure for generations.

One advantage of using GRC technology is that the stiffness of the concrete guarantees longevity, resulting in rigid pavements that have greater endurance and durability over their service life with lower maintenance costs. This is due to their more resilient development and better interaction with the wheel, leading to lower gas consumption per kilometer (Nilson 2001). Furthermore, concrete roads have been shown to perform better in high humidity conditions and over saturated soils, due to their hydraulic binders that are not deteriorated by water in the interface. This assures higher longevity of these types of structures. Overall, GRC technology has the potential to create sustainable and long-lasting roads that offer cost and time savings in construction, as well as improved performance and durability over their service life. Therefore, it is important to continue studying and developing GRC as a common construction technology for generations to come.

1.2 Methodology

The methodology outlined in this paper is aimed at comprehensively understanding the behavior of Geoweb reinforced concrete (GRC) pavements. The steps involved are as follows:

(a) A detailed study of the GRC system's materials, with a focus on understanding the relationship between Geocell Polymer and concrete.
(b) Development of a free-body diagram to analyze the system's loads, stresses, and strains and lay the groundwork for further investigation.
(c) Conducting a large-scale finite element analysis using Ansys software to create a model with a 9x9 matrix of GRC cells and provide design guidelines for GRC pavement designers.
(d) Reviewing existing GRC pavements to identify any shortcomings and gain insights into the failure mechanisms of this pavement type.
(e) Based on the data collected from the previous steps, developing a design approach for GRC pavements.

The primary objective of this paper is to provide a realistic review of the factors that must be considered when designing and building GRC pavements. The findings of this research will be useful for future research and practical applications of this innovative technology.

1.3 State of art

GRC typically consists of two main components: concrete, and geocells. Cement in the concrete acts as a binder to hold the materials together, while aggregates provide strength and stability to the structure. The geocells, on the other hand, are three-dimensional honeycomb-like structures made of high-density polyethylene (HDPE) that serve as a reinforcement to concrete giving the strain capability. The geocells interlock with the concrete, creating a strong composite material that can withstand heavy loads and harsh environmental conditions.

Geocells: Geocells were originally developed in the 1970s by Gary Bach and the US Army Corps, using welded polyethylene sheets to create a honeycomb structure that provided cohesion to soils with no natural stability. This technology was initially used for stabilizing beachheads during wartime landings, but over time, companies like Presto began marketing the product to private firms, leading to the development of the geocell market. Geocells have proven effective in providing cost-effective solutions for heavy load equipment on soft underlayment. (United States Patent nº US6395372 B1 2000).

Concrete: Although concrete has been extensively studied for centuries, with a primary emphasis on enhancing its durability and compression strength, this paper does not intend to explore in detail the tensile properties that are typically considered in the design of conventional concrete pavements. Rather, it focuses on investigating the interplay between concrete and geocell materials in GRC pavements. (World Bank 2019).

Empirical approach: The use of GRC began empirically, with GRC channels being built in Brazil's Amazon River to withstand the heavy equipment required for cleaning the river's muddy banks. Following the success of these channels, GRC was tested for use in road projects

Technical approach: Two distinct approaches have been identified from the projects analyzed and various developments made. The first approach, proposed by Professor Jie Han, involves a rigid slab solved using the Westergaard solution. However, when studying the second state of the slab, a different equation must be implemented due to the relative rigidity radius being less than the length of the concrete cell. The relative rigidity radius is assumed to be equal to the point of push-off test developed by Han. The second approach outlined in this paper evaluates the system in two dimensions by creating a free-body diagram, providing an approach for designing methodology. (Xiaoming Yang 2010).

2 METHODOLOGIC DEVELOPMENT

2.1 *Theoretical approach*

To study GRC, it is essential to begin with a free-body diagram that illustrates the forces present in the system. This diagram provides a clear understanding of where the most significant stresses or strains may occur.

Figure 1 illustrates that the stress in the system will only be in compression for concrete since the geocell will absorb the tractive stresses that may arise in the slab through elastic strain. This shows that the elastic strain caused by the elastic module of the polymer can withstand the strain and return to its original position. The compressive stresses are left for the concrete to withstand, making a high tenacity macro compound comprising a polymer matrix and concrete.
Figure 1. Free corps diagram stresses and strains in GRC system; individual block free corps diagram.

When examining the individual block, there will be a shear stress present in the complete perimeter between the concrete and the geocell. From this point, it is important to analyze stresses and deformations to determine the critical flexural moment that can be present in the concrete block, which is the one that will fail. This ensures that the concrete will not fracture.

To ensure a correct approach, it is important to note that the border elements can transfer shear stress, but they should not transfer torsional stresses. Thus, it can be concluded that:

$$\sum F_y = 0 \therefore R_{soil} + F_{frictionGRC} - P_{wheel} A_{wheel} = 0 \tag{1}$$

$$\sum M = 0 \therefore \quad F_{fCRG} = \frac{240}{N_{wheels}} \frac{h-7}{x \quad Axle} \tag{2}$$

$$M_{crit \quad concrete} = \frac{R_s}{2} \frac{L}{4} + \frac{F_{fCRG}L}{4} + \frac{F_{fCRG}L}{2} - \frac{P_l a^2 \pi}{2} \frac{a}{2} = L\left(\frac{R_s}{8} + \frac{3}{4} F_{fCRG}\right) - \frac{P_l a^3 \pi}{4} \tag{3}$$

$$M_{crit \quad concrete} = L\left(\frac{R_s}{8} + \frac{720}{4} \frac{h-21}{N_{ll}}\right) - \frac{P_l a^3 \pi}{4} \tag{4}$$

By analyzing the critical moment for concrete, it is possible to identify the point at which the concrete will fail. It is important to evaluate the wheel load in three different positions to determine whether the critical point has been identified. Once the moment has been determined, it is possible to calculate the stress at this point in the tension fiber.

$$\sigma_t = \frac{Mc}{I} = \frac{M\frac{h}{2}}{\frac{bh^3}{12}} = \frac{6M}{bh^2} = \frac{\frac{3L}{2}\left(\frac{R_s}{2} + \frac{720}{N_{ll}} \frac{h-21}{N_{ll}}\right) - \frac{3}{2} \frac{P_l a^3 \pi}{2}}{bh^2} \tag{5}$$

The equation shown can be used to determine the maximum possible stress in the system, which identifies the most critical point that the system can be exposed to when modeling the structure in 2D. The equations presented in this paper were developed solely by the author.

2.2 ANSYS model

To model the GRC system using a finite element program, it is important to consider that the honeycomb structure must be transformed into prismatic diamonds to enable the polymer to work within its elastic range with its initial strain, which will arrange the fibers of the structure. The model presented in the paper assumes that the soil is linearly elastic and that the interphase between the concrete and the polymer has the resistance depicted in Figure 2.

The values used for the finite element analysis (FEA) in this study were high density polyethylene (HDPE) and concrete. HDPE had an elastic modulus of 700 MPa, as obtained in a test conducted by the authors in 2018 on strain and stress analysis in a Geoweb cellular confinement cell. The concrete modulus used was 23.4 GPa, corresponding to concrete with a rupture modulus of 24.1 MPa. Boundary conditions were specified by fixing the rotation of the external blocks and using a foundation with known values ranging from 50 MPa/mm to 250 MPa/mm, with variations made every 50 MPa. The simulation utilized a wheel load of 0.69 MPa pressure applied to a circular area with a 12 cm radius to simulate the weight generated by a loaded truck wheel. It is important to note that the results discussed in the study are only a portion of the findings obtained. (Schmalbach 2018).

Based on the finite element solution of the total deformation, it can be observed that the soil deforms more than the slab. This will be further reviewed in the analysis, but it is important to note this initial observation. When analyzing the principal stresses in the
Figure 2. Punch concrete Cell test with GW30 cells redone as the methodology proposed (Han 2012).
Figure 3. FEA total deformation.
Figure 4. Stress in geocell matrix.
Figure 5. FEA strain in the geocell matrix.

geocell matrix, it can be inferred that they appear in the neutral axis, where compressive and tensile stresses govern the behavior of the evaluated zone in the model. When evaluating strain, the solution highlights the fact that the geocell absorbs stress as a strain, due to the differences in the elastic modulus of the two materials that are working in deformation equivalence. This is demonstrated in Figures 3 to 5.

2.3 *In situ analysis*

It should be emphasized that in Colombia, where GRC has been installed in over one million square meters, cases of deterioration and failure have been observed, with the predominant failure mode being illustrated in Figure 6. This failure mode is caused by the movement of fines underneath the GRC, which generates excessive pressure and degrades the interface between the Geocell and the concrete, resulting in water infiltration. This phenomenon, known as *broad radius rutting*, is characterized by a significant radius of failure, with the wheel paths being noticeably wider than the wheel itself, indicating a failure of the subgrade rather than the rolling layer. When the interface is breached, fines are pumped out of the granular layers, leaving the GRC layer without support. This is a common failure mode for rigid pavements, as evidenced by the AASHTO road test, in which 80% of concrete structures failed due to this type of failure. Adequate design considerations can help mitigate this failure mode.

Figure 6.   Fail presented in a soft soil with high fines and water presence.

3   ANALYSIS

To synthesize, a mechanistic analysis of the GRC system reveals that its monolithic structure generates high-pressure zones with minimal deflection, creating critical issues that require pressure control to avoid deterioration, particularly in low mechanical soil response areas. Two analyses can aid in designing a path that limits deflection, preventing suction caused by pressure in the deflected area and indirectly restraining the total deflection of the geocell to prevent it from reaching the polymer's plastic strain. The geocell must handle significant elastic strains within its elastic range, preventing permanent deformation accumulation that leads to rapid system deterioration. However, a too rigid geocell polymer becomes fragile and fails after only a few loading repetitions. It is crucial to return to equation 5, which determines the allowable stress in the GRC system, either because of the geocell's yield point limit or concrete rupture at a specific point.

4   CONCLUSIONS AND RECOMMENDATIONS

- The failure of the GRC system is caused by excessive deflections allowed in the structure, making the allowable total deflection a crucial designing parameter.

- The finite element analysis and mechanistic analysis show that the geocell can withstand tension stresses, and the tractive stresses are not affecting the concrete. Failure in the field also confirms that the concrete remains intact, while the polymer fails over time
- To better understand the interphase between the two materials, further studies are necessary to develop fatigue curves and predict the system's behavior over time.
- Despite the challenges, GRC pavements can revolutionize the infrastructure industry, offering more durable and cost-effective roads. GRC roads can be the future, particularly in developing countries that need to improve their road systems rapidly and steadily, as the World Bank suggests.
- GRC has proven to be a viable option for pavement construction due to its durability and longevity, as well as its ability to reduce slab thickness, construction time, and costs. Its use in Colombia has been driven by the country's specific geographic and weather conditions, as well as its infrastructure needs. However, further research and development are still needed to fully realize GRC's potential as a sustainable and cost-effective construction material.

ABSTRACT: The incorporation of geosynthetic interlayers during the asphalt overlay construction has proven successful in mitigating the reflective cracking and enhancing the pavement structural capacity. However, milling an asphalt layer reinforced with geosynthetic interlayer is a huge concern, since there is a possibility of geosynthetic interlayers compromising the reclaimed asphalt pavement (RAP) quality and characteristics. On the other hand, inclusion of RAP into the hot mix asphalt (HMA) is a common practice. Hence, it is important to understand the characteristics of RAP collected from geosynthetic-reinforced asphalt layers (referred herein as GRAP) and their influence on the performance of asphalt mixtures. The objective of this study is to understand the characteristics of GRAP and subsequently, investigate the performance of asphalt mixtures with 15% and 30% GRAP contents. Additionally, the performance of asphalt mixtures with 15% and 30% RAP contents, and 100% virgin aggregates (referred as control mixture) was evaluated for comparison with that of asphalt mixtures combining GRAP. The characterization of GRAP and RAP included particle size gradation and binder extraction tests, while the performance evaluation of the asphalt mixtures included indirect tensile strength, and moisture susceptibility tests. Comparison of binder extraction test results revealed that the GRAP samples had binder content slightly higher than that of the RAP samples. While the comparison of indirect tensile strength and moisture susceptibility test results indicated the performance of asphalt mixtures with GRAP similar to that with RAP, where both mixtures outperformed the asphalt mixtures made solely of virgin aggregates. This indicates the potential of incorporating GRAP and RAP up to 30% into the asphalt mixtures without compromising the performance of asphalt mixtures.

1 INTRODUCTION

The search for sustainable and innovative solutions gave rise to a new material in paving works, the reclaimed asphalt pavement. Specifically, during the rehabilitation program, the

*Corresponding Authors: saxena_ashray@utexas.edu, vinay.vasanth@utexas.edu, ncorreia@ufscar.br and zornberg@mail.utexas.edu

pre-existing asphalt layer is either partially or completely milled resulting in tons of aggregate-sized particle material, commonly known as RAP. This material has been transforming paving works in many countries around the world since late 30's. Additionally, with waste reuse and recyclability policies, a great intensification on the utilization of RAP in recent years has been observed. Consequently, there is less waste generation and reduction in the extraction of raw materials required for pavement construction, thereby providing significant environmental and economic benefits.

The Texas Department of Transportation (TxDOT) promotes using RAP on a larger scale in many pavements works, including composition of a new asphalt mix, extra widening of roadways, replacement of granular base course and subbase materials, construction of shoulders, residential driveways, parking lots, bicycle paths, gravel road rehabilitation, trench backfill, and embankment's design. Previous literatures (Plati & Cliatt 2018; Saxena *et al*. 2023) have reported that the pavement containing RAP could perform equally well when used in base course and in some instances better than the conventional granular base course comprising virgin aggregates (VA), in terms of its structural performance.

Additionally, due to the increased binder cost and scarcity of virgin aggregates, the demand for using RAP in asphalt mixtures has increased. In 2010, the utilization of RAP in asphalt mixtures conserved approximately 20.5 million barrels of asphalt binder (NAPA 2011). Moreover, the advantages of using RAP in asphalt mixtures are not limited to only economic and environmental benefits. Research studies (Shu *et al*. 2012; Uribe *et al*. 2022) have shown that the replacement of virgin aggregates with RAP can improve the indirect tensile strength of asphalt mixtures by about 50% and additionally improve the resistance against moisture damage (Shu *et al*. 2012). However, Singh *et al*. (2017) reported that moisture damage of asphalt mixtures containing RAP improves only up to the addition of 30% RAP content, and further increase of RAP content makes the asphalt mix vulnerable to moisture damage.

In recent decades, the incorporation of geosynthetic interlayers during the asphalt overlay construction has proven successful in mitigating reflective cracks and thereby, enhancing the pavement performance (Saride & Kumar 2017, 2019). Thus, it is possible to mill asphalt layers that may include geosynthetic interlayers within them. Therefore, it becomes crucial to conduct experimental research studies to comprehend the characteristics and behavior of RAP obtained from milling such asphalt layers that have been reinforced with geosynthetic interlayers. Although the literature on this topic is very limited, it is important to note that the growing trend of incorporating geosynthetics within asphalt layers may increase the prevalence of RAP containing geosynthetic fragments. Recently, Gu *et al*. (2021) demonstrated that a 30% RAP containing milled polypropylene geotextile fragments presented an excellent resistance to moisture damage, rutting and cracking. In addition, they reported that geosynthetic RAP and control RAP asphalt mixtures had comparable flexibility index values.

In summary, studies on the recyclability of geosynthetic-reinforced asphalt millings are very limited in number, which requires more attention. Hence, this study is undertaken to understand the characteristics of RAP containing geosynthetic fragments (GRAP) and consequently, investigate the performance of asphalt mixtures with 15% and 30% GRAP. Moreover, performance of asphalt mixtures with 15% and 30% RAP contents, and 100% virgin aggregates was determined to answer whether the presence of geosynthetic fragments in RAP has an adverse impact on the quality of asphalt mixtures. The characterization of GRAP and RAP included particle size gradation, and binder extraction tests, while the performance of asphalt mixtures has been investigated through indirect tensile strength, and moisture susceptibility tests.

2   CHARACTERIZATION OF RAP AND GRAP

The RAP with and without geosynthetic fragments were collected during the milling program conducted along the US 70/84 Highway at Muleshoe, TX. The roadway comprised of

a sandy subgrade, 300-mm-thick granular base, and 110-mm-thick asphalt layer that comprised of a 50-mm thick first lift and a 60-mm thick second lift with a paving fabric between them. The paving fabric was a polypropylene nonwoven geotextile used as a stress relieving interlayer to mitigate reflective cracking. The milling process involved two stages: the top 50 mm of the 110 mm thick asphalt layer was first milled to obtain RAP samples, followed by milling of the remaining 60 mm thick asphalt layer (having geosynthetic 10 mm below the first milled surface), to obtain GRAP samples. The collected RAP and GRAP samples were completely dried out in the laboratory and need of crushing them was identified before characterization tests. Specifically, 3 kgs of sample was crushed each time by dropping a modified Proctor hammer weighing about 4.5 kg, from a height of 450 mm for about 100 times. Figure 1 shows the RAP (Figure 1a) and GRAP samples (Figure 1b) collected from the site which were crushed into the laboratory due to their bigger sizes, and crushed GRAP samples (Figure 1c) used in characterization tests.
Figure 1. Collected RAP samples: (a) RAP; (b) RAP with geosynthetic fragments (GRAP); and (c) GRAP after crushing process.

The crushed RAP and GRAP samples were first sieved to determine their grain size distribution. Moreover, this analysis allowed for the determination of whether screening of the geosynthetics fragments is required for GRAP samples. Finally, bitumen extraction tests were conducted on RAP and GRAP samples, using centrifuge method with trichloroethylene, per AASHTO T164, to obtain the percentage of binder in the collected samples.

3 MIX DESIGN

The asphalt mixture investigated in this study was a TY-D binder course mix typically used by TxDOT for pavement construction. In order to evaluate the recyclability of GRAP samples as a potential aggregate material for surface course, five different asphalt mixtures are designed. These mixtures included 0% (control mixture), 15% and 30% RAP and GRAP samples. All mixtures were found to fit well within the gradation limits of TY-D surface course mixture, as specified by Item 341 TxDOT. It should be noted that all the specimens were prepared using the same virgin aggregate, procured from the Marble Fall Quarry - Texas Material in Texas. Virgin aggregate used was primarily crushed rock. Moreover, Performance Grade (PG) 64-22 was used as the virgin binder for the sample preparation. In this study, the notation used for mixtures containing only virgin aggregate is VA (control specimen) and mixtures containing RAP and GRAP are respectively denoted as 15-85 RAP/ 30-70 RAP and 15-85 GRAP/30-70 GRAP, where the first term represents the percentage of

RAP or GRAP, the second term represents the percentage of virgin aggregate, and the last term indicates the type of RAP used in a given mixture. An optimum binder content corresponding to 7% air void content for all the prepared mixtures was determind to be 4.45 (VA), 4.10 (15-18 RAP), 4.00 (15-85 GRAP), 3.70 (30-70 RAP), and 3.55 (30-70 GRAP), respectively. This implied that the asphalt mixtures containing GRAP samples require less virgin binder to compose the hot mix asphalt as compared to mixtures containing RAP or virgin aggreagtes.

4 LABORATORY TESTS

4.1 Indirect tensile strength (IDT) test

The indirect tensile strength of asphalt mixtures is used to evaluate their rutting and cracking potential by characterizing the tensile strength and viscoelastic properties of the mixtures. The indirect tensile strength test was performed on five different asphalt mixtures designed herein at different test temperatures (5, 10, 25°C), per ASTM D6931. The cylindrical specimens were prepared in dimensions of 150 mm diameter and 95 mm thickness at a target void content of 7%, using Superpave gyratory compactor. The compacted specimens were then conditioned in a temperature controlled chamber at test temperatures for a period of 24 h prior to testing. Three specimens were prepared for each mix design and tested until failure using a loading rate of 50 mm/min.

4.2 Moisture susceptibility test

Moisture susceptibility tests are conducted to evaluate the moisture-induced deterioration of asphalt mixtures subjected to moisture over extended periods. The moisture susceptibility of the asphalt mixtures is evaluated in terms of tensile strength ratio (TSR), per ASTM D4867. Specifically, tensile strength ratio is defined as the ratio of indirect tensile strength of specimens at wet condition to the indirect tensile strength of specimens at dry condition. Six specimens of 150 mm diameter and 95 mm thickness were prepared for each of the five different asphalt mixtures at a target air void content of 7%, using Superpave gyratory compactor. The specimens (six in number) of each mixture were then separated into sets of three to test them under both dry and wet conditions. The dry condition specimens were conditioned at 25°C for about 2 h prior to testing, while the wet condition specimens were partially saturated through vaccum-saturation until 70% to 80% of the voids were filled with water and then immersed in water bath at 60°C for 24 h. The wet condition specimens after moisture damage were then conditioned at 25°C in a water bath for 2 h before testing. Indirect tensile strength test were conducted on both the dry and wet specimens at a loading rate of 50 mm/min. The load-displacement characteristics were recorded for all the specimens tested and the corresponding maximum load was used to calculate the indirect tensile strength of the respective asphalt mixtures evalauted in this study, which in turn was used to calculate the tensile strenth ratio of the respective asphalt mixtures. A high TSR value (>80%) indicates better resistance to moisture and vice-versa.

5 RESULTS AND DISCUSSIONS

5.1 Characterization of RAP and GRAP

During the sieve analysis of crushed GRAP sample, geosynthetic fragments were observed only up to 12.7 mm sieve, after which no traces of geosynthetics were observed in the mix. This may be due to the fact that geosynthetic particles were bigger in size and the presence of mastic asphalt on their surface has increased their size. Table 1 shows the design gradation of RAP and GRAP samples used for the preparation of asphalt mixtures. Table 1 demonstrates

that the crushed RAP and GRAP samples were almost similar, with no significant change in their volumetric or gradation requirements. On the other hand, while considering the binder extraction test on the collected samples, the binder content of RAP and GRAP samples is determined to be 4.92% and 5.87%, respectively, indicating that there was a difference of 0.95% in binder content for the collected RAP and GRAP samples. The higher binder content of GRAP can be attributed to the application of tack coat during installation of paving interlayer at the site.

Table 1. Design gradation of collected materials.

Sieve size*	Percentage Passing (%)	
	RAP	GRAP
19.05	100	100
12.7 mm	99	99
9.53 mm	90	95
4.75 mm	60	65
2.36 mm	40	44
0.6 mm	20	25
0.3 mm	13	15
0.075 mm	5	5

*Sieve size in millimeters.

5.2 Indirect tensile strength test

5.2.1 Effect of temperature on the indirect tensile strength of asphalt mixtures

The indirect tensile strength for the five different asphalt mixtures evaluated in this study at different test temperatures are reported in Table 2. The results show that the indirect tensile strength of the asphalt mixtures decreases rapidly with increase in test temperature. For example, the indrect tensile strength of 30-70 RAP was reduced by 22% and 65%, when the test temperature changed from 5 to 10°C and 5 to 25°C, respectively. These reduction in indirect tensile strength values was due to the reduction in the viscosity and cohesion of the asphalt binder particles at higher temparature, thereby causing lower resiatnce to tensile forces. Moreover, specimens containing RAP and GRAP samples has shown less reduction in indirect tensile strength value with increasing test temperature compared to control specimens. The reason behind this was the presence of aged binder on the surface of RAP and GRAP samples providing greater stiffness to the mix, which in turn causing higher resistance to tensile stresses.

Table 2. Tensile strength of asphalt mixtures at different temperatures.

Mixture type*	Temperature (°C)		
	5	10	25
VA	2223	1487	589
15–85 RAP	2343	1679	733
15–85 GRAP	2231m	1614	722
30–70 RAP	2722	2113	955
30–70 GRAP	2433m	1826	859

*Tensile strength is in kPa.

5.2.2 *Effect of RAP and GRAP content on the indirect tensile strength of asphalt mixtures*

The indirect tensile strength test results for the specimens containing different percentages of RAP and GRAP samples are reported in Table 2. As can be seen in the table, the average indirect tensile strength value was highest for 30-70 RAP specimen at any given test temperature, followed by 30-70 GRAP, 15-85 RAP, 15-85 GRAP and VA specimens respectively. The higher indirect tensile strength of specimens containing RAP or GRAP samples compared to control specimens was due to the presence of aged asphalt binder on the surface of collected samples, imparting higher stiffness to the asphalt mixtures. Moreover, the indirect tensile strength of control specimen was observed to be 30%, 19%, 11%, and 8% lower than the indirect tensile strength of 30-70 RAP, 30-70 GRAP, 15-85 RAP and 15-85 GRAP, respectively, at test temperature of 10°C. In contrast, no significant difference between the indirect tensile strength of specimens containing RAP and GRAP samples (at any given percentage) were observed. While addition of GRAP samples resulted in lower tensile strength of specimens compared to those containing RAP samples, which can be attribute to the presence of geosynthetic fragments that might have reduce the stiffness of the asphalt mixtures.

5.3 *Moisture susceptibility test*

The moisture susceptibility of the five different asphalt mixtures evaluated in this study was determined in terms of the tensile strength ratio by evaluating the indirect tensile strength of dry and wet specimens. Table 3 shows the moisture susceptibility results (tensile strength ratio values) of the tested specimens. As can be seen in the table, 30-70 RAP specimen has shown the highest TSR value followed by 30-70 GRAP, 15-85 RAP and 15-85 GRAP specimens, respectively. While the control specimen has shown the lowest TSR value. These results indicate that the replacement of VA with RAP or GRAP samples can improve the stability of asphalt mixtures against moisture damage. Specifically, the RAP and GRAP samples contains aged, hardened asphalt binder which increases the stability of asphalt mixtures due to the higher viscosity of aged binder. In addition, oxidized binder is hydrophobic in nature and absorb less water, thus causing RAP and GRAP specimens to absorb less water than control specimens. Moreover, the TSR value of 30-70 RAP and 15-85 RAP was found to be slightly higher than that for 30-70 GRAP and 15-85 GRAP, respectively, because the geosynthetic fragments can absorb moisture. However, asphalt mixtures evaluated in this study, containing either RAP or GRAP samples were found to perform better against moisture damage compared to control specimen.

Table 3. Moisture susceptibility results.

Mixture type	TSR (%)
VA	81
15-85 RAP mm	85
15-85 GRAP m	82
30-70 RAP mm	90
30-70 GRAP mm	87

6 CONCLUSIONS

This study is performed to present the characteristics of RAP containing geosynthetic fragments and its suitability with virgin aggregates as surface course material. The following conclusions can be drawn from this investigation:

(1) The binder content of GRAP samples was observed to be 0.95% higher than that of RAP samples which can attribute to the presence of tack coat used during the installation of geosynthetic interlayer.

(2) The indirect tensile strength of the asphalt mixtures decreases rapidly with increasing test temperature. However, specimens containing RAP and GRAP samples results in less reduction in the indirect tensile strength values with increasing temperature compared to control specimens due to the presence of aged binder.

(3) The addition of RAP and GRAP samples (up to 30% by weight) can improve the indirect tensile strength and moisture susceptibility of the asphalt mixtures compared to control specimens.

ABSTRACT: Road cave-ins associated with hidden cavities are one of key issues in road maintenance. Field model tests were carried out to develop and improve methods of detection, diagnosis, and repair of hidden cavities at the prototype scale test road, 30 m long and 6 m wide. Hidden cavities were made artificially by burying bags filled with fine gravel in well-compacted base course layers. Fine gravel was removed by a vacuum cleaner after the completion of the surface course. FWD tests and plate loading tests were carried out to investigate stability of hidden cavities in base course. A series of laboratory model tests was also carried out to investigate the effect of type of geosynthetics and their depth in the base course on the stability.

1   INTRODUCTION

Road cave-ins associated with hidden cavities are one of key issues in road maintenance. Cavities in ordinary conditions are caused by various factors such as breakage of sewer pipes. Subsurface cavities of this type are formed when subgrade soil particles or subbase materials are washed away into the pipe. A cavity thus formed from a certain depth of the ground expands with time, and when the strength of the pavement is not enough, a sudden cave-in finally occurs. About 5,000 to 10,000 cave-ins are found every year in Japan. Such hidden cavities are usually detected by a ground penetrating radar often mounted on a car which runs as fast as 100 km/hour. Mechanism of cavity formation and stability of the ground have been studied mainly by laboratory model. Mechanism of cavity formation and stability of the ground have been studied mainly by small scale laboratory model tests on clean sand (e.g., Indiketiya *et al.* 2019; Karoui *et al.* 2018; Kuwano & Ohara 2021) but not on crushed stones due to the limitation of model scale. However, experimental study on hidden cavity in prototype scale road pavement is hardly found. This paper reports stability of hidden cavity in base course layer reinforced by geosynthetics through prototype scale field model tests. A series of laboratory model tests was also carried out to investigate the effect of type of geo-synthetics and their depth in the base course on the stability.

2 PROTOTYPE SCALE FIELD MODEL TESTS ON STABILITY OF HIDDEN CAVITY IN BASE COURSE REINFORCED BY GEOSYNTHETICS

2.1 *Test outline*

Field model tests were carried out to develop and improve methods of detection, diagnosis, and repair of hidden cavities at the prototype scale test road, 30 m long and 6 m wide, constructed in the Saitama University campus as shown in Figure 1(a). A cross section of the test road with hidden cavities is shown in Figure 1(b). The test road consisted of 100 mm surface course. Layers below the surface course were 250 mm upper base course with M-30 mechanically stabilized crushed stones ($D=0\sim30$ mm), 100 mm lower base course with C-40 crusher-run stones ($D=0\sim40$ mm), and 200 mm subgrade with decomposed granite sandy soil.
Figure 1.   Prototype scale test road. (a) Aerial view of prototype scale test road. (b) Typical cross section.

Hidden cavities were made artificially by burying bags filled with crushed stone #7 ($D=2.5$-5 mm) in well-compacted base course layers. Fine gravel was removed by a vacuum cleaner through the $\phi=50$ mm hole after the completion of the surface course as shown in Figure 2. About 60% crushed stone #7 could be removed from the buried bags. Although the bags could not be made completely empty, the ceilings, which are key in the stability problem, were thought to be made properly. Size and depth of the cavities were measured by radar. Figure 2(c) is an example of a photograph taken by a borehole camera.

Geogrid TX, geotextiles PET and WF were used. Their rupture strengths are 16 kN/m, 600 kN/m, 80 kN/m, respectively. TX could not be used at the depth of 100 mm, just below the surface course, because TX geogrid melts at the high temperature of about 150 °C when asphalt is used for pavement. Geosynthetics of 2,800 mm×2,800 mm were set at respective depths as summarized in Table 1. Figure 3 shows placement of geotextile PET at 200 mm from the road surface. FWD tests and plate loading (PL) tests were carried out to investigate stability of hidden cavities in base course.
Figure 2.   Formation of a hidden cavity in the base course layer. (a) Crushed stone #7 in a bag. (b) Removal of fine gravels by a vacuum cleaner from the pavement surface.(c) Example of a photograph taken by a borehole camera.

Table 1. Hidden cavity IDs in prototype scale field motel tests.

Depths of cavity and reinforcement	Geogrid TX	Geotextile PET	Geotextile WF	No reinforcement
D100 = D100	—	5–8	—	5–10
D200 = D200	5–6	5–7	—	3–5
D350 > D200	7–6	7–5	7–7	3–3
D350 = D350	5–5	—	—	—

Figure 3. Placement of geotextile PET at 200 mm from the surface of prototype scale model test road.

2.2 *Results of prototype scale field model tests*

Prototype scale field model tests were carried out in some phases. In the first series of tests, only cavities were made without geosynthetics reinforcement in base course layers. Some of the cavities at the shallower depth collapsed due to their deadweights before loading tests. Cavity 5-6 was planned so that the geosynthetics would support the asphalt surface course. As the geogrid TX melts at the temperature of 150 °C, which is expected when asphalt is placed over the base course, only the geotextile PET was placed at the bottom of the asphalt layer at the cavity 5-8. FWD tests and PL (plate loading) tests results at the cavity 5-10 (Cavity@100 mm from the asphalt surface, No geosynthetics) and at the cavity 5-8 (Cavity@100 mm, PET@100 mm). As seen in Figure 4, there was not clear difference in the loading tests results of 5-10 and 5-8 cavities, though the 5-8 cavity was reinforced by the geosynthetics PET. It is probably because the PET was not attached firmly to the bottom of the asphalt layer because it melts at 250 °C and does not have large apertures for good interlocking with aggregate.

When the cavities were at 200 mm deep and the geosynthetics were just above the cavities, FWD deflection and load-settlement relationships of PL test were almost the same for the cavity 5-6 (geogrid TX) and the cavity 5-7 (geotextile) as seen in Figure 5. Those for the cavity 3-5 showed also almost the same, though FWD deflection was slightly high.

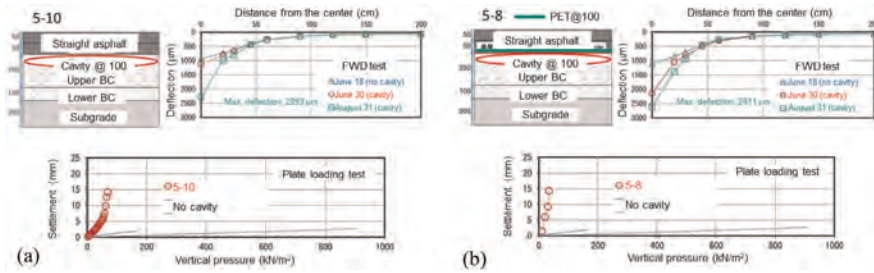
When the cavities were deeper at 350 mm but no reinforcement, settlement increased rapidly when the vertical pressure exceeded about 500 kN/m^2 as seen in Figure 6(a). Although this vertical pressure was much higher than the values shown in Figure 5 (cavity@200, reinforcement@200), sudden increase in the settlement indicated that the collapse (road cave-in) took place. According to the observation made in the laboratory model tests, the ceiling of the cavity collapsed with load and deformation, the cavity approached the surface, and resulted in the cave-in of the cavity. On the other hand, when the cavities were at 350 mm and the geosynthetics were at 200 mm, 150 mm above the cavities, sudden increase was not observed to the high vertical pressure of more than 800 kN/m^2 as seen in


Figure 4. Loading tests on the cavities at 100 mm. (a) 5-10 (No reinforcement). (b) 5-8 (PET at 100 mm).
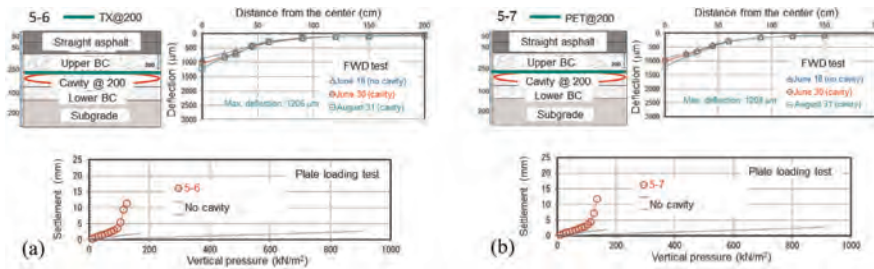

Figure 5. Loading tests on the cavities at 200 mm. (a) 5-6 (TX at 200 mm). (b) 5-7 (PET at 200 mm).
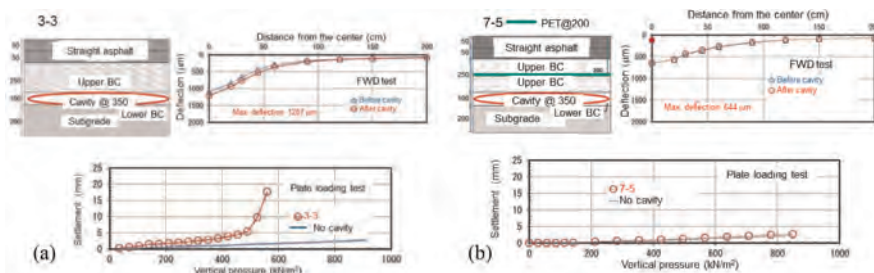

Figure 6. Loading tests on the cavities at 350 mm. (a) 3-3 (No reinforcement). (b) 7-5 (PET at 200 mm).

Figure 6(b). FWD deflections and PL test results were almost the same for the cavities with the geogrid and geotextiles. It is presumed that the pavement is stable enough if the thickness of the base course layer is kept by the geosynthetics.

3 LABORATORY MODEL TESTS ON STABILITY OF HIDDEN CAVITY IN BASE COURSE REINFORCED BY GEOSYNTHETICS

3.1 *Test outline*

In this series of tests, hidden cavities were made in the base course, and surface loading tests were carried out in a large square tank of size 1 m x 1 m in plan and 0.8 m in height. The schematic diagram of the test layout is presented in Figure 7(a). The 350 mm thick model

1338

subgrade of silica sand #5 was placed in the bottom layer and the 300 mm thick base course of compacted C-40 crusher-run stone was placed in the top layer of model ground. This is of a prototype scale of road structure around a cavity. The dry density of base course and subgrade was 1.73 g/cm^3 and 1.55 g/cm^3 respectively. Geogrid TX or geotextile WF, shown in Figure 7(b) and (c), was placed at different depth, d, from the surface of the base course. TXd or WFd indicates a test case reinforced by geogrid or geotextile at the depth d. For example, if geogrid was placed at the depth of 150 mm, the test was identified as TX150. A circular sandbag with a diameter of 120 mm was fully filled with fine gravel to the thickness of 60 mm. It was placed on a funnel (ϕ =130 mm x h=100 mm) at the interface of base course and subgrade. A funnel was connected to a 20 mm hose in the subgrade as shown in Figure 7. The base course was well compacted over the fully filled sandbag. Then, fine gravel in the bag was sucked out by a vacuum cleaner to simulate the cavity formation process in road. The 300 mm base course was made by compacting C-40 crusher-run stones.

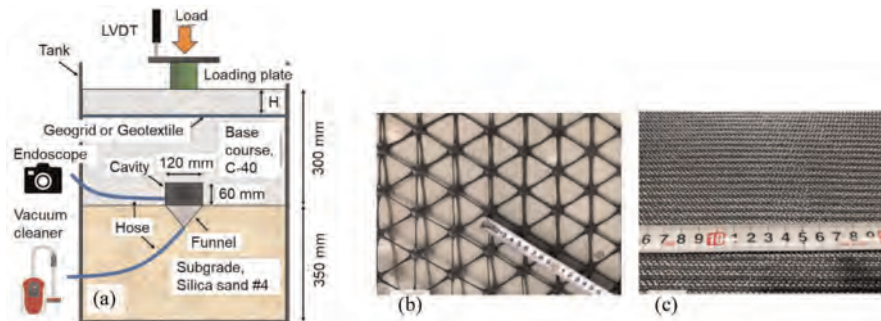
Plate loading tests were carried out. Load was increased stepwise until the settlement reached about 100 mm. Besides the monotonic loading tests, some cyclic loading tests were performed. Vertical stress was changed between the minimum stress of 100 kPa and the maximum stress with a period of 10 seconds. The maximum stress was increased stepwise after every 500 cycles. Cyclic loading tests were indicated by "*" such as TX150*. Test cases are summarized in Table 2.


Figure 7.   Outline of laboratory model test. (a) Test setup. (b) Geogrid TX. (c) Geotextile WF.

Table 2.   Test conditions.

Test ID	Reinforcement	Reinforcement depth, d (mm)	Type of loading
NR	No reinforcement	N.A.	Monotonic
TXd	Geogrid TX	d=50, 100, 150, 240	
NR*	No reinforcement	N.A.	Cyclic
TXd*	Geogrid TX	d=50, 100, 150, 240	
WFd	Geotextile WF	d=50, 100, 150, 240	Monotonic

3.2   *Results of laboratory model tests*

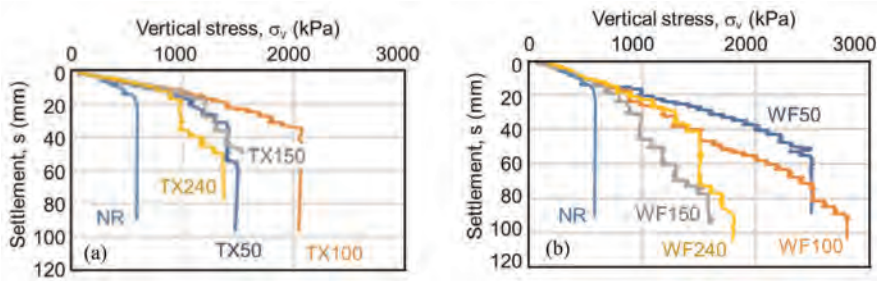
Vertical stress – settlement relationships obtained by monotonic loading tests on base course with a cavity are shown in Figure 8(a). The base course layers were reinforced by the geogrid TX at respective depths or without reinforcement (NR). Vertical stress to cause sudden increase of settlement is different for the different depth of geogrid reinforcement. The stress


Figure 8.   Monotonic loading test results. (a) Geogrid TX. (b) Geotextile WF.

to cause collapse of the reinforced base course was higher than 1000 kPa and the highest for the base course reinforced at the depth of 100 mm. Figure 8(b) shows the results of monotonic loading tests on the base course layers reinforced by geotextile WF laid at the different depths. Similar to the geogrid cases, base course layers reinforced by geotextile showed higher stability than the base course layer without reinforcement.

Result of cyclic loading test on the model base course without reinforcement, GN*, is shown in Figure 9(a). Settlement increased gradually for the smaller vertical stress. But it increased suddenly and collapsed when the vertical stress reached 900 kPa, as there was a cavity at the depth of 240 mm. This sudden increase of surface settlement was observed also in monotonic loading tests. If TX was laid at the depth of 50 mm or 240 mm (just on the cavity), settlement increased gradually to the maximum stress of around 2000 kPa even after a limited amount of sudden increase at around 900 kPa as shown in Figure 9(b). Geogrid TX changed the base course behavior with a cavity from brittle to ductile. It was also seen for TX100 and TX150.

Figure 10 indicates the vertical stress, σ_v, to cause 20 mm settlement and collapse for the geosynthetics embedded at different depths in the base course. It is seen that the geogrid supported the base course on the cavity better than the geotextile.

Figure 11 shows photographs of endoscope taken in the cavity within the base course (a) WF150 and (b) NR*. Both the pictures were taken when the top of loading cylinder was pushed to the surface of the ground. In the case of WF150, the cavity was still remained though some red C-40 aggregates laid at the ceiling of the cavity dropped to the cavity
Figure 9.   Cyclic loading test results. (a) No reinforcement. (b) Geogrid TX50 and TX240.
Figure 10. σ_v to cause S=20 mm and collapse.

(a) TX150   (b) NR*
Figure 11. Views in the cavities at the end.

bottom. In the case of NR*, the cavity was filled with the collapsed C-40 aggregate. It indicates that the reinforcement prevented the cavity from collapsing completely.

4 CONCLUSIONS

The following results were obtained from the field and laboratory model tests:

(1) If a cavity without reinforcement is shallow and approaches surface course, the asphalt layer cannot support its own weigh and cave-in occurs.
(2) Effect of reinforcement becomes less obvious when the cavity is shallow.
(3) Geosynthetics contribute more to increase stability of the cavity in base course by maintaining the thickness of well-compacted base course layer above it rather than mechanical reinforcement such as confining effect and tensioned membrane effect (hammock effect).

ABSTRACT: Roadways include stiff aggregate layers, which support and dissipate traffic loads before reaching the subgrade soil. The aggregate stiffness must be preserved to reduce rutting severity. Geosynthetic-stabilisation can preserve the aggregate stiffness through aggregate-geosynthetic interaction at small strains. The performance of geosynthetic-stabilised roadways depends on the properties of both the geosynthetic and the selected aggregate. A study was completed at the University of Saskatchewan to determine the relative performance of two geogrids used to stabilise two types of aggregate. A recently built full-scale wheel trafficker system applies accelerated traffic loading to 1.5 m wide unsurfaced test sections. Accelerometers were installed on the surface to measure changes in the aggregate stiffness with traffic loading using multichannel analysis of surface waves (MASW). This method facilitates non-destructive measurements of stiffness at numerous depths throughout the aggregate. The average shear wave velocity and rutting performance are presented for each soil-geogrid composite.

1   INTRODUCTION

Rutting is the result of permanent deformations in the road structure and subgrade, which are caused by lateral spreading of the aggregate and bearing capacity failure in the subgrade (Zornberg *et al*. 2017). The subsequent decrease in particle confinement causes the aggregate stiffness to degrade; thus, resulting in less resistance to subgrade shearing and heave (Lees 2017).

The aggregate layers can be stabilised with geosynthetics to help preserve the initial stiffness of the aggregate (Zornberg & Roodi 2021). Through aggregate-geosynthetic interaction, stress transfer is mobilised at small strains/displacements in the geosynthetic which are initiated during construction and initial traffic loading. Effective particle interlock also helps counterbalance any potential bearing capacity failure in the subgrade (Lees 2017). Consequently, the cost and frequency of road maintenance and rehabilitation is decreased.

Geosynthetic stabilisation can also reduce the thickness of aggregate required for design; thus, providing a sustainable solution to preserve non-renewable aggregate resources (Zornberg & Roodi 2021).

Geosynthetic-stabilised roadway design and performance is traditionally evaluated using traffic benefit ratio (TBR) and/or base course reduction (BCR). Geosynthetic manufacturers often provide TBR and BCR values within their product specification sheets. However, these values depend on the interaction between the selected roadway materials and geosynthetic for a given project. Many researchers and transportation agencies have completed independent studies to predict and quantify the stiffness enhancement achieved through geosynthetic stabilisation. These studies are usually completed through index testing, analytical and numerical models, laboratory testing and/or performance testing (e.g. Archer & Wayne 2012; Cuelho *et al*. 2014; Kang *et al*. 2022; Lees 2017; Zornberg & Roodi 2021; Zornberg *et al*. 2017). It is important that the current knowledge base is continually expanded by testing geosynthetics with a variety of aggregates and subgrade soils, subject to traffic loading (Cuelho & Perkins 2017).

The objective of this research is to determine a near-continuous profile of stiffness with depth through the entire aggregate layer, both before and after traffic loading. Traffic loading was applied to unsurfaced road test sections using a full-scale wheel trafficker system. Two types of road base aggregates were used for this study: a locally sourced prairie aggregate, and a high-quality, crushed rock. Two geogrids, with similar aperture geometry and varying rib thickness, and two non-stabilised control sections were assessed. Preliminary estimates of shear wave velocity through geogrid-stabilised and non-stabilised aggregates were obtained directly beneath the applied traffic load using multichannel analysis of surface waves (MASW).

2 SURFACE WAVE ANALYSIS

Of the several types of waves generated during siesmic testing, shear waves are often used to characterize the stiffness of soil. Shear waves can only be transmitted through the soil skeleton, while compression waves can travel through both soil and water. Equation 1 relates the small-strain shear modulus, G_{max}, to the soil density, ρ, and shear wave velocity, V_s (Kang *et al*. 2022).

$$G_{max} = \rho V_s^2 \tag{1}$$

Various seismic techniques can be used to measure V_s within the aggregate layer (Park 2011). Surface wave analysis is a non-destructive test method which maximizes the ease and versatility of sensor installation. This analysis depends on the dispersive nature of surface waves travelling in a vertically heterogenous soil medium. Rayleigh waves are used for surface wave analysis as they are easy to generate and detect, and will disperse in a heterogenous soil profile with varying stiffness (Everett 2013). The Rayleigh wave phase velocity will depend on the soil properties across the entire depth through which the wave travels. Lower wave frequencies (f) provide measurements of V_s at greater depths than higher wave frequencies, which provide measurements of V_s at shallower depths (Park *et al*. 2018), as shown in Figure 1.

MASW has been selected for this research to measure the stiffness profile through the aggregate layer. MASW is an ideal method for analyzing pavement structures, as soil stiffness can be measured at high resolutions over shallow depths (Park *et al*. 2018). MASW also allows for simple detection and separation of multiple modes, as well as mitigation of near-field effects (Olafsdottir *et al*. 2018).
Figure 1. Surface wave analysis through aggregate.

3 EXPERIMENTAL PROGRAM

3.1 *Full-scale wheel trafficker system*

A full-scale wheel trafficker system was built at the University of Saskatchewan, as shown in Figure 2. The system has a structural steel exoskeleton which houses an epoxy-laminated, four-layer marine plywood box. The box dimensions are 6.10 m long by 2.82 m wide, which can accommodate 4 – half-lane test sections per trial. The geogrids were installed in different lane locations for each trial to account for any systematic variability.

A pneumatic loading system provides simulated traffic loading through 2 carriage houses, each equipped with a pneumatic cylinder pressurized to 620.5 kPa. The applied pressure is equal to 40 kN, which is one-half of an equivalent single axle load (ESAL). Two 255/70R22.5 semi-truck tires, each pressurized to 620.5 kPa, apply channelized traffic load to the aggregate surface.

Using an adjustable head reservoir, consistent subgrade conditions (i.e., suction and undrained shear strength) are achieved for each test section. Tensiometers were inserted along the box wall to provide real-time readings of subgrade suctions. A MEXE Cone
Figure 2. Full-scale wheel trafficker system.

Penetrometer was also used to measure the subgrade California Bearing Ratio (CBR) immediately before and after traffic loading. From the suction and CBR values, the undrained shear strength (Su) is estimated. The design, construction, and operation of this apparatus are detailed further by Landry *et al* (2022).

3.2 Materials

A low-plasticity kaolinite clay subgrade was selected for this research. The clay was purchased as bricks from Plainsman Clays in Medicine Hat, Alberta. Table 1 shows the properties of the clay subgrade. Atterberg testing was completed to obtain the liquid limit and plastic limit of the clay according to ASTM D2487-17. The moisture content, dry density, and Su of the clay was measured immediately after opening the clay samples.

Table 1.   Properties of clay subgrade material.

Characteristics	Values
Liquid Limit (%)	34.5
Plastic Limit (%)	16.9–17.7
Moisture Content (%)	20.8–24.7
Dry Density (kg/m^3)	1520
Undrained Shear Strength, S_u (kPa)	22–43

The Su was measured using a laboratory shear vane. The clay subgrade was hand placed in four lifts (600 mm total) as to minimize any disturbance to the clay. Smoothing and leveling was then carefully completed as to not exceed the bearing capacity of the clay. The clay surface was periodically wetted to prevent desiccation.

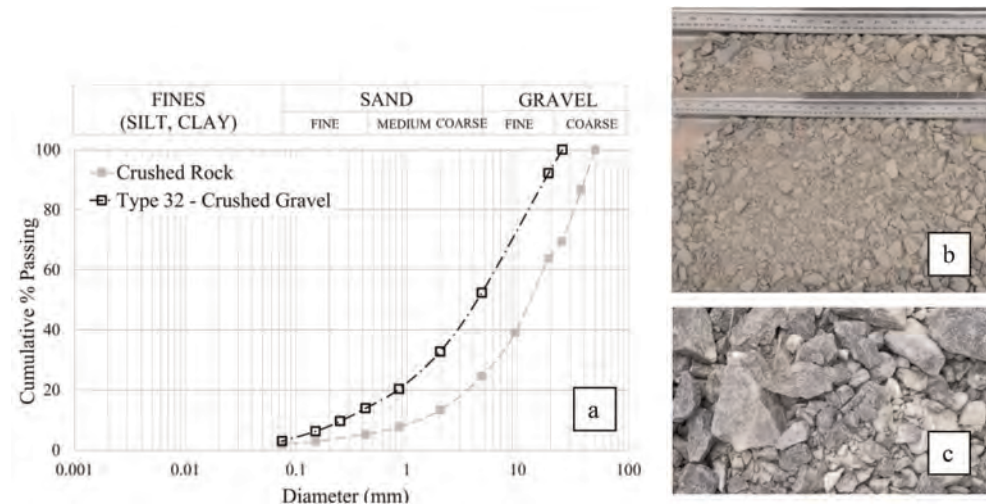
Two types of aggregate were selected for this research: Type 32 – crushed gravel (T32-CG), and crushed rock (CR), as shown in Figure 3. The T32-CG is a prairie aggregate,


Figure 3.   (a) Grain size distribution (b) Type 32 – Crushed Gravel (T32-CG), and (c) Crushed Rock (CR).

crushed to 90% one-face and 60% two-face fracture. The CR material is a crushed granite bedrock sourced from the Precambrian shield in northern Manitoba, which is intended to represent a high quality, angular aggregate (100% fracture) used by road agencies (where available).

The aggregate is placed and compacted in three 100 mm lifts (300 mm total) using a plate tamper. The maximum dry density (MDD) for the T32-CG and CR is 2100 kg/m^3 and 2350 kg/m^3, respectively. The optimum moisture content for the T32-CG and CR is 8% and 7%, respectively. Compaction was verified through nuclear densometer testing. Each lift was compacted to an average dry density not less than 95% of the aggregate MDD.

In this study, two variable aperture shape geogrids (VASG), GG1 and GG2, were evaluated with each aggregate type. The geogrid properties are identical, with the exception of the node thickness (GG2 > GG1). A control section with no geogrid was also assessed for each aggregate type.

3.3 Instrumentation plan for MASW

The test parameters for MASW must be optimized for each test site. These parameters include the source type/size, source offset, sensor type, number of sensors, and sensor spacing (Ferreira *et al.* 2014). In 2021, a study was completed to inform the equipment requirements and layout for MASW (Yesnik *et al.* 2022). The finalized instrumentation plan is shown in Figure 4.
Figure 4. Finalized instrumentation plan for MASW in full-scale wheel trafficker.

4 RESULTS AND DISCUSSION

In Summer 2022, the T32-CG test sections were constructed. For this trial, the average subgrade Su was measured as 22 kPa. To exercise caution in this first trial, and avoid possible failure in the soft clay, each lane was trafficked to only 1200 load cycles at a reduced pneumatic load of 20 kN. MASW was completed at 0, 400, and 1200 load cycles.

In Fall 2022, the CR test sections were constructed. For this second trial, the average subgrade Su was measured as 32 kPa. With stiffer subgrade conditions, each lane was trafficked up to 4000 load cycles (or until reaching 70 mm of rutting) at the full pneumatic load of 40 kN. MASW was completed at 0, 450, 1350, and 4000 load cycles.

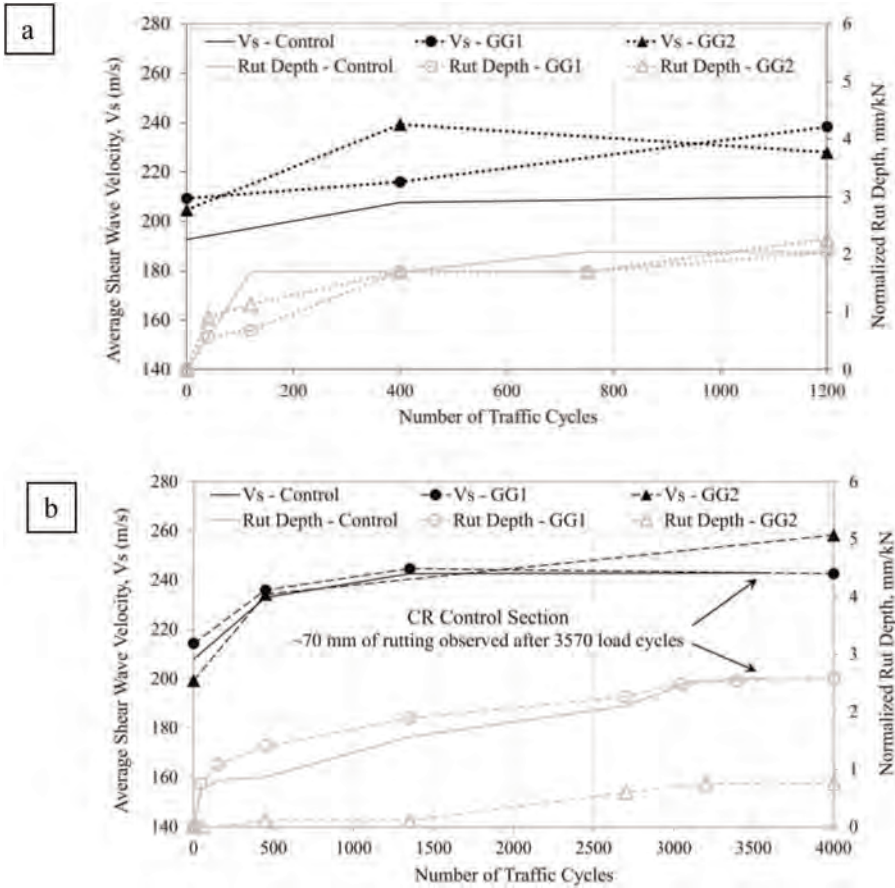
To complete MASW, the raw signal transmitted by the hammer strike is recorded by the 15- accelerometer array. Multiple hammer strikes were recorded at each array for every load cycle interval. The raw signal, recorded in the space-time domain (*x-t*), is transformed into the phase slowness-frequency domain (*p-w*) to generate an experimental dispersion image.


Figure 5. Average V_s and normalized rut depth vs. number of traffic cycles: (a) T32-CG, and (b) CR.

Multichannel data processing is completed using slant stacking in the slowness-frequency method to identify multi-mode dispersion curves (Park *et al*. 1998). Once these experimental modes are selected, inversion analysis is completed to create a profile of V_s and G_{max} with depth in the aggregate. MATLAB is used for all data collection and processing.

The performance of two VASG products used to stabilise T32-CG and CR aggregates, is shown in Figures 5a and 5b, respectively. The control section performance is also shown. MASW was completed for the accelerometer array located in the wheel path. The average V_s was obtained from the velocity model determined through inversion analysis. The rut depth was measured using a rut wedge, and normalized according to the applied traffic load for each trial.

For the geogrid-stabilised T32-CG, there is both a short- and long-term increase in V_s with trafficking. The control section also experiences an initial increase in V_s, which eventually plateaus. The normalized rut depth is initially lower for geogrid-stabilised T32-CG than for the control section, which aligns with the short-term trend in V_s. After long-term trafficking, the rut depth is comparable for all test sections, which varies from the long-term trends in V_s. After 1200 load cycles, the normalized rut depth only varies slightly - ranging from 2 - 2.3 mm/kN.

For the geogrid-stabilised CR, the short-term V_s is comparable to that measured in the control section. With increased trafficking, V_s increases and eventually plateaus for both the

control section and GG1-stabilised CR. However, V_s continues to trend upward with increased trafficking in the GG2-stabilised CR. The normalized rut depths are comparable for both the control section and GG1-stabilised CR; though, rutting is drastically reduced in the GG2-stabilised CR. The rutting performance aligns with the observed trends in V_s for the CR aggregate. After 4000 cycles, the normalized rut depth ranged from 0.8-2.6 mm/kN.

5 CONCLUSIONS

This paper presents an accelerated trafficking device and non-destructive test method to quantitatively assess the stabilisation performance of various aggregate-geogrid composites. The average V_s and normalized rut depths are presented for two trials. The performance of each unsurfaced test section is dependent on the properties of the subgrade, geogrid, and aggregate. Both geogrids mitigate the time-dependent degradation of stiffness (i.e., V_s) in the finer, less fractured T32-CG aggregate. There is a reduced rate of stiffness degradation also observed in the GG2-stabilised CR aggregate. The overall rutting performance over soft clay (after 1200 cycles) was comparable to that of the slightly stiffer clay (after 4000 cycles). Accordingly, the control and monitoring of subgrade strength is important to ensure consistent subgrade conditions during trafficking.

Geogrid reinforced pavement design

W.S. Alexander
Southern Geosynthetics Supplies Pty. Ltd., Australia

D. Alexiew
Dr, Alexiew Geoconsulting, Germany

ABSTRACT: Geogrid reinforcement of pavements is becoming common practice in civil engineering. But in Australia no design method was available that relates directly to Australian pavement design methodology. A design method has been developed that allows rapid, effective geogrid-reinforced pavement design with reference to Austroads pavement design methodology. A case history is presented to demonstrate the usefulness of this method.

1 INTRODUCTION

This procedure evaluates the required thickness of a geosynthetic reinforced bearing layer (base) for permanent roads. It is related to stiffness (bearing capacity, CBR), and not to rut depth.

The procedure is based on Austroads empirical pavement design method (2017) using additionally the Swiss design code, SVG (2003) to model the reinforcing effects of a geosynthetic and Voss R. (1961) to calculate aggregate subbase capping layer thickness. The goal is to reduce the bearing layer thickness resulting for a given situation from Austroads (2017) by application of geosynthetic reinforcement.

2 DESIGN METHOD

In Austroads (2017) Figure 8.4 the required thickness t of a granular layer (base) depends on the CBR of the subbase (subsoil) and on the traffic cycles (DESA). For design traffic of 10^5 to 10^8 axle load cycles (DESA) the relation is given in Figure 8.4 inclusive of the corresponding equation in the form t = t(CBR, DESA). For clarity this t is called here later tAUS.

$$t_{AUS} = [219 - 211.\text{logCBR} + 58.\text{log(CBR)}^2].\text{log(DESA/120) in mm} \qquad (1)$$

The principle of this method is to create a higher CBR than the one available on site at the bottom level of the "Austroad-base", thus reducing the required tAUS above. For this purpose a geosynthetic-reinforced granular layer is being implemented below the "Austroad-base"; it consists of the same fill.

The Swiss Code SVG (2003) defines a procedure how to achieve a second loading plate modulus EV2=45 MPa corresponding to a CBR=11% (BAST2017; SVG 2003) on the surface of a compacted granular layer using reinforcement.

t = [219 – 211(logCBR) + 58(logCBR)^2]log(DESA/120)
EV2=45 MPa is a kind of benchmark across Europe allowing the application of standard road structural layers above.

Input in SVG (2003) is the CBR of subsoil in the range CBR = 0,5 - 5,0%, and output is the required thickness of the layer.

For CBR>5% reinforcement makes no sense according to SVG (2003): no further thickness reduction. This corresponds approximately to the German State-of-the-Art:
no sense of reinforcement for EV2 >35 MPa (about CBR=7%).

Note that SVG (2003) is product and/or company independent.

It is based on intensive research and trials with different geosynthetics. It is stated therein that the graphs, recommendations etc. are quite conservative.

Note the following preconditions for the reinforcement according to SVG (2003):

P1. The reinforcement has to be biaxial.
P2. The reinforcement has to mobilize a tensile force of F2% >=8 kN/m at 2% strain ε (i.e. a tensile stiffness J2% >=400 kN/m at ε=2%).
P3. This has to be fulfilled in both directions. If it is not the case, the value for the "weaker" direction is decisive.
P4. The minimum Ultimate Tensile Strength (UTS), kN/m, has to be (examples for some typical products):
biaxially stretched geogrid from PP: 25 to 35 kN/m
woven geotextile from PP: 50 to 75 kN/m
woven geogrid from PET: 30 to 45 kN/m etc.

The procedure is using graphs (SVG 2003, Figures 183 & 184). For the purpose of this method the graphs were digitalized, and analytical formulations for the curves were derived. Based on them a Thickness Reduction Factor called here TRFSVG1 was formulated and derived

$$TRF_{SVG1} = t_{SVGR} / t_{SVGNR} \qquad (2)$$

$$t_{SVGR} = t_{SVGNR}. TRF_{SVG1} \text{ in mm} \qquad (2a)$$

1350

$$t_{SVGR}, \text{ in mm, is the thickness of are in forced layer} \qquad (3)$$

$$t_{SVGR}, \text{ in mm, is the thickness of an on} - \text{reinforced layer} \qquad (4)$$

For crushed fill the derivation results in

$$TRF_{SVG1} = 0,0164.CBR^2 - 0,0156.CBR + 0,6662 \qquad (5)$$

For CBR = 0,5 to 5,0% TRFSVG1 varies from 0,66 to 1,0 correspondingly.

The thickness of a non-reinforced layer can be assumed based on Voss (1961). After intensive research and test series Voss published graphs for the required layer thickness of well graded, well compacted gravels (rounded material) to achieve an EV2 from 25 to 250 MPa on the layer surface for an EV2 of subsoil in the range of 5 to 40 MPa (approximately CBR 0,5 to 9%, BAST(2017)).

Although a couple of years has passed, Voss (1961) is still being used and cited due to its basic character e.g. in Grundbau Taschenbuch (2009) or the ZTVE-Series for road construction ZTVE (2006).

For the purpose of this method the Voss-curves were digitalized, and an analytical formulation was derived for the required thickness tVOSS, mm, to achieve EV2 = 45 MPa (CBR= 11%) for CBR of subsoil from 0,5 to 5,0%, see explanations above and SVG (2003):

$$t_{VOSS} = -6,8048.CBR^3 + 88,175.CBR^2 - 402,86.CBR + 844,8 \text{ in mm} \qquad (6)$$

It is obvious due to geomechanical common sense and experience that for a well graded crushed fill the required thickness will be smaller than for rounded gravel as in Voss (1961), and consequently a reduction of tvoss is possible if crushed fill is used.

In SVG (2003) there are graphs for both crushed and rounded fills. Their analysis, comparison and evaluation result in a Thickness Reduction Factor TRFCRUSH if crushed fill is used instead of a rounded one.

$$TRF_{CRUSH} = t_{CRUSH}/t_{VOSS} = 0,8 \qquad (7)$$

$$t_{CRUSH} = t_{VOSS}. \ TRF_{CRUSH} \qquad (7a)$$

$$t_{CRUSH}, \text{ in mm, is the thickness of an on} - \text{reinforced layer from crushed material} \quad (8)$$

$T_{RFCRUSH}$ is almost independent from CBR and can be assumed as constant.

3 DESIGN PROCEDURE SUMMARY

The design can be performed as follows:

a) Calculate tAUS according to Austroad (2017) using Equation (1).
   Note: this is needed only if savings due to an added reinforcement have to be evaluated, see Equation (11) below.
b) Calculate the required layer thickness to achieve a CBR=11% at the level of the bottom of the "Austroad-base" called here tCBR11
   (additionally marked as a red dotted line here in Figure 8.4 from Austroads (2017)).
   2.1 Calculate tVOSS using Equation (6).
   2.2. Calculate tCRUSH using Equation (7) & (7a).
   2.3.

$$\text{Set } t_{SVGNR} = t_{CRUSH} \qquad (9)$$

Figure 1.   Subgrade condition.

Figure 2.   Geogrid with capping layer.

Figure 3.   Installing crushed rock capping layer over geogrid.

Figure 4.   Final pavement ready for asphalt wearing course.

2.4. Calculate TRFSVG[1] using Equation (5).

2.5. Calculate tSVGR using Equation (2a).

2.6. Set tCBR11 = tSVGR.

This is the required thickness of an implemented layer to achieve a CBR=11% at its surface (i.e. at the bottom level of an "Austroad-base" to be installed above).

c) Calculate a new tAUS acc. to Austroad (2017) using Equation (1) for a CBR=11%: This new value is called here tAUS11.

d) Calculate the final new required "reinforced" base thickness tFIN:

$$t_{FIN} \; = \; t_{CBR11} + t_{AUS11}, \; mm \tag{10}$$

Figure 5 Example Design

If from interest, the saving due to the use of reinforcement tSAVING, mm, can be now calculated as:

$$t_{SAVING} = t_{AUS} - t_{FIN}, mm \qquad (11)$$

Note that although this procedure is using mm due to formal reasons (Figure 8.4 in Austroad (2017) is using mm) a precision of 1 mm for a base thickness cannot be practically achieved.

4 EXAMPLE

At the new Essendon FC base, "The Hanger" at Tullamarine, designer Aurecon was faced with a real dilemma. The very soft reactive clay subgrade had repeatedly failed proof-rolling. Traditional options of dig-out and replacement with good quality fill, or in-situ cement-stabilisation were not possible due to the presence of a wide shallow service trench along the middle of the roadway alignment. With very little cover over services no further excavation was possible.

Assuming a design CBR of 1%, and design traffic of 100,000 ESA, the design program solution called for placement of DUX CG30, a 30kN/m biaxial geogrid combined with a non-woven geotextile at subgrade together with a 280mm "stabiliser" layer of crushed rock; this would then provide a working platform with CBR=11% and allow compaction of a second 180mm thick crushed rock pavement layer. The total pavement thickness of 460mm represents a saving of some 200mm, or 30% over traditional design.

To be extra-conservative designer Aurecon opted for reduced thickness of 180mm of cement-treated first lift, followed by 200mm of Class 2 FCR and a wearing course of 40mm AC. Upon setting after a few days the cement increases the strength and stiffness of the first stabiliser layer and provides an improved base for compaction of the second lift. But even on initial placement, before the cement "went off", the grid and 180mm layer virtually eliminated rutting under construction truck traffic.

One of the concerns of the contractor was how to achieve satisfactory compaction of pavement layers. Standard road construction practice requires satisfactory "proof-rolling" of the sub grade, with no visible movement or cracking of the subgrade. Any soft, "unsuitable" areas are dug out and replaced with engineered fill to achieve a typical CBR of 15%. However, when building on very soft soils, construction practice must be modified. Roadbase must be placed more carefully, dump trucks should avoid directly trafficking the grid wherever possible. Materials should be spread with light, low ground- pressure, such as the tracked bobcat such used here.

5 CONCLUSIONS

A design method has been developed to permit design of geogrid-reinforced pavements. The method draws on the Austroads pavement design method, with further input from the Swiss Code SVG for the reinforcing effect of geogrid and the work of Voss relating to aggregaFigure 6. Design Spreadsheet.

te pavement layer thickness. This method assumes a two step procedure, first a geogrid-reinforced subbase capping layer is designed to effectively increase the subgrade bearing strength, then the pavement is designed based on this improved subgrade. For subgrades of CBR<2% up to 30% reduction in total pavement thickness is achieved.

This method was first introduced in 2018 and has been used on numerous projects. Based on this experience the method appears useful and appropriate. One area for further research is regarding the use of cement-treated crushed rock with geogrids.

ABSTRACT: Railway has multiple advantages of reliable service, fast and versatile to both passenger and cargo as compared to other modes of transportation infrastructure. However, the efficiency and safety of railway engineering are dependent on the track structure. This paper evaluates the contribution of the multi-functional composite geotextiles to the railway track, through a laboratory test carried out at Southwest Jiaotong University, Chengdu, in collaboration with international industry practitioners. The contributions are assessed through the quantification of the traffic improvement as well as the reduction in ballast and sub-ballast fouling for three sets of simulated cyclic train loading test model, Model 1 as control, with Model 2 and Model 3 using different types of multi-functional composite geotextiles. The findings validate the reduction of vertical deformation and reduction of fouling by using multi-functional composite geotextiles, ultimately allowing the railway track to support additional train traffic and longer lifespan.

1 INTRODUCTION

Railway engineering is a comprehensive industry; comprised of many components including railway track, station, drainage, etc. to ensure the railway smoothly serves the global society without disruption. Among all components, railway track (i.e. track structure and track subgrade as shown in Figure 1) is considered the primary component that governs the efficiency and safety of the railway (Li & Selig 1995; Selig & Li 1994; Tan & Shukla 2012).

The railway track is a more complex field than roadway with a few important considerations including increasing the bearing pressure (capacity) of the subgrade soil,
Figure 1. Typical section of railway track.

1359

preventing contamination of the ballast by subgrade fines, dissipating the high pore water pressures built up by cyclic train loadings, and moisture management for expansive or frost heave and thaw susceptible subgrade (adapted from Indraratna *et al*. 2006). It is rarely seen that one geosynthetic type can fit all the above considerations, so multi-functional composite geotextiles are needed. In this paper, the contribution of multi-functional composite geotextiles to the railway track is evaluated through a full scale laboratory model tests. These tests study the vertical deformation behaviour, bearing pressure response, pore pressure variation, and fouling condition of the track structure under cyclic train loadings in different test conditions, for one control section (without geosynthetics) and two reinforced sections (with different composite geotextiles laid below subballast).

2 MODEL TEST

2.1 *Test box and loading apparatus*

The research is conducted at Southwest Jiaotong University (SWJTU) in Chengdu, which is a top research center for the railway engineering industry in China. The test box setup simulates the actual cyclic train loadings exerted on the top surface of 300 mm thick ballast. The loading of 20 tonnes railway axle load on sleeper was simulated using a steel loading plate measuring 1.1 m length and 0.3 m width, which represents half effective areas of the common sleepers utilized in Asia. As a result, the actuated cyclic train loadings were applied in a sinusoidal form with 48 kN as peak load and 4.8 kN as trough load at a frequency of 3 Hz. Besides that, a 20 mm thin rectangular sandbag was laid below the steel loading plate to ensure a uniform loading exerted on the ballast. The test box size was carefully determined through the ABAQUS and Plaxis 3D finite element methods (FEMs), to achieve an optimal box size with the least influence on the test results by the boundary condition. The FEMs suggest that the distance between the edge of the steel loading plate and the steel test box should be kept at a minimum of 0.15 m, and 50 mm thick polystyrene should be added along the inner edge of the steel test box. Meanwhile, the height of the test box should be a minimum of 1.2 m. As a result, the actual steel test box (Figure 2) measured 1.5 m length, 0.7 m width and 1.3 m height, equipped with the mechanism to accommodate the sophisticated requirements of tests was adopted for this research.

The test sections are illustrated in Figure 3, with different types of composite geotextiles laid in between the subballast and subgrade in the reinforced section, and without geosynthetics for a control section. Three loading stages were applied, each to 200,000 cycles of peak load. Stage 1 loading involved the initially prepared subgrade to 90% compaction lifts according to Modified Proctor Test at near optimum moisture content overlaid by 150 mm thick subballast and 300 mm thick ballast, subsequently 200,000 cyclic train loadings were applied. After completion of Stage 1 loading, water was sprayed on the top surface of the ballast to simulate rainfall. The rainfall simulation was applied over a 12 hours period that
Figure 2. Cyclic train loading test box.

1360
Figure 3. Typical section of steel test box and loading apparatus.

consisted of 6 cycles of 1 hour rainfall and 1 hour rest period. The average rainfall rate is 50 liters/hr. The test box was designed with a side window slot that allowed some water infiltration into subgrade soil while excess water could drain horizontally through the ballast and exit through the side window slot. Stage 2 loading started after 12 hours rest period at the end of the rainfall simulation. At the end of Stage 2 loading, the side window slot was sealed and then the test box was flooded to allow the subgrade soil to be soaked for 10 days until fully saturated. After 10 days, the side window slot was opened to allow excess water in the ballast to be drained off, and the Stage 3 loading was then initiated after that. Upon completion of Stage 3 loading, subballast and ballast were carefully extracted to measure the degree of fouling. The test box was then emptied before a second test was conducted. The second and third tests were identical to the control test, with the only exception of Mirafi® HPC2000 and Mirafi® HPC5000 being placed in between the subgrade and sub-ballast.

2.2 *Instrumentation*

Instrumentations were being installed for a variety of purposes, and properly calibrated before the commencement of tests as shown in Figure 4.
Figure 4. Instrumentations installed in each model.

2.3 *Subgrade soil*

The subgrade used for the test is a synthesized soil consisting of quartz powder (90%) and montmorillonite powder (10%) and is classified as low plasticity clay (CL) under the Unified

Soil Classification System (USCS), with more than 85% soil particles finer than 75 microns, PI = 13.1 and LL = 36. The purpose of using synthesized soil in the research is to ensure the consistency of subgrade conditions for each model. An exercise to calibrate the subgrade CBR against moisture content was also conducted (refer Figure 5).
Figure 5.   Subgrade soil and its calibrated CBR vs. moisture content curve.

2.4   *The ballast and sub-ballast*

The ballast and sub-ballast used in the research are both classified as well-graded gravel (GW) under USCS and generally conform to most country standards in Asia (Arema 2010; KTM 2015; RDSO 2007; SNI 2018; TB2897 1998; TB2140 2008). They are stiff basalt and granite, readily available in Sichuan province.

2.5   *Geosynthetics*

TenCate Geosynthetics has invented composite geotextiles (a combination of woven and nonwoven geotextiles mechanically connected by parallel stitching thread at close intervals), namely Mirafi[®] HPC2000 and Mirafi[®] HPC5000 which have a combination of the reinforcement, dynamic separation, drainage and moisture management functions (moisture management function only for Mirafi[®] HPC5000). Their actual test data and photos are shown in Table 1 and Figure 6

Table 1.   Properties of Mirafi[®] HPC composite geotextiles.

3 TEST RESULTS AND DISCUSSIONS

3.1 Soil moisture

The subgrade soil moisture contents are summarized in Table 2 as below. The moisture content in Stage 1 was controlled close to OMC, averaged at 17.9%. And then, the moisture content in Stage 2 is determined at the end of 12 hours rest period after rainfall simulation, averaged at 21.2%. Lastly, the moisture content in Stage 3 is determined after 10 days of full saturation averaged at 28.4%. With the average moisture content determined, the CBR for Stage 1, 2 and 3 are estimated as 30, 12 and 1 by using Figure 5.

Table 2. Subgrade moisture content and CBR.

*M= Model; **Refer Figure 4 for details

3.2 Vertical deformation

The vertical deformation is largest at ballast (average of W1 and W2 in Figure 4), followed by subballast (W3 in Figure 4) and least at subgrade (W4 in Figure 4) for all stages and models. This phenomenon is reasonable as the cyclic train loadings induced stress is highest at ballast. The stress reduced gradually when being transferred down to subballast and then subgrade. Besides, the differences in vertical deformation of each model in Stage 1 and Stage 2 are negligible. However, the differences in vertical deformation between each model in Stage 3 are obvious, especially for ballast layer, whereby Model 1 = 49.84 mm, Model 2 = 21.38 mm (reduced by 57.1%) and Model 3 = 19.03 mm (reduced by 61.8%). This phenomenon indicates that the Mirafi® HPC2000 and Mirafi® HPC5000 are effective to minimize the vertical deformation of railway track on low CBR subgrade.
Figure 7. Cumulative plastic vertical deformation prediction at subgrade CBR=1.

By replotting the graph of vertical deformation of all models in Stage 3 (CBR = 1) to a normal scale as shown in Figure 7, the traffic benefit ratio (TBR), which is the train loading cycles of a reinforced section divided by the train loading cycles of a control section to reach the same settlement. The vertical deformation for track structure is normally controlled within 20 mm to 30 mm depending on the individual country's requirement. The train loading cycles and subsequent TBR (average TBR = 8.8 to 13) are tabulated in Table 3.

Table 3. Predicted train cycles and TBR with the inclusion of Mirafi® HPC composite geotextiles.

*M= Model

3.3 *Ballast and subballast fouling*

Both ballast and subballast were cleaned with water before the test, the fine materials were washed away, and the smallest particle size of subballast is 0.25 mm. As such, the percentage of soil material smaller than 0.25 mm is considered fouling, being assessed at a few locations. After the sampling, the samples were oven-dried and the weight was measured as *m1*. After that, they will be washed in the sieve of 0.25 mm, and then oven-dried again, and the weight is measured as *m2*. The *fouling, μ* is defined as

$$Fouling~(\%),~\mu = (m1 - m2)/m2 \qquad (1)$$

Figure 8 showed the fouling of subballast in all three models at the end of the test, in which the subballast fouling is 3% in Model 1, 1.4% in Model 2 and 0.8% in Model 3. This showed that Mirafi® HPC2000 and Mirafi® HPC5000 composite geotextiles are very effective to prevent subballast fouling (reduced by 53% in Model 2 and 73% in Model 3). For the ballast fouling, it is very minor and there are negligible differences among all the models.

Figure 8. Fouling's observation in Model 1, Model 2 and Model 3 (from left to right).

4 CONCLUSION

In conclusion, this research proves that Mirafi$^{\circledR}$ HPC composite geotextiles effectively reduced vertical deformation and minimized fouling, thus prolonging the service life of railway track.

Reducing the settlement of railway ballast by random fibre reinforcement

E. Ferro

ABSTRACT: Random fibre reinforcement of granular soils with flexible polymeric fibres increases their shearing resistance and ductility. However, the potential advantages of fibre reinforcement are not limited to monotonic loading conditions. Recent research has shown that fibre reinforcement has the potential to reduce the permanent settlement of granular materials subject to cyclic loading, such as railway ballast. Ballast is still widely used on railways, as ballasted tracks are still predominant worldwide and are compatible with high-capacity and high-speed applications. Under repeated train passages, ballasted track settles differentially hence costly maintenance operations are required periodically to restore the correct rail level. Full-scale tests in the Southampton Railway Testing Facility (SRTF) have shown that the addition of a moderate amount of thin polyethylene strips to ballast can reduce the permanent settlement with marginal influence on track stiffness, provided that the fibres are sufficiently narrow not to disturb the natural arrangement of the ballast grains. As with fibre reinforced soils, the performance of fibre-reinforced ballast is expected to be influenced by the characteristics of both the host material and reinforcement. This study presents the results of full-scale tests carried out in the SRTF using different materials for the fibres and ballast. The fibres were obtained from polypropylene rope to replicate at a much larger scale the polypropylene filaments often used for the reinforcement of sands. The ballast was coarser and settled significantly less. The design of the reinforcement was informed by packing tests, as suggested by earlier tests using strip fibres. Thin fibres, with a small influence on the packing of the grains, were found to reduce the permanent settlement and had little influence on track stiffness.

1 INTRODUCTION

Reinforcement by randomly-placed flexible polymeric fibres can increase the shear strength of granular materials ranging from sands to gravels, while inhibiting dilation and post-peak strength loss (Ajayi *et al.* 2017b; Diambra *et al.* 2013; Gray & Ohashi 1983; Heineck *et al.* 2005; Lirer *et al.* 2012; Michalowski & Čermák 2003; Santos *et al.* 2010). The reinforcing effect provided by the fibres is attributed to them stretching with the deformation of the soil, hence providing additional confinement (Ajayi *et al.* 2017a; Diambra *et al.* 2010; Gray & Ohashi 1983; Mandolini *et al.* 2019; Michalowski & Čermák 2002). In contrast, at relatively small vertical strains of 1% to 5%, the fibres may reduce the mobilised shear strength (Ajayi *et al.* 2017b; Diambra *et al.* 2013; Heineck *et al.* 2005; Michalowski & Čermák 2003; Santos

et al. 2010). This may be explained by the fibres increasing the void ratio by disrupting the natural packing of the grains (Ajayi *et al.* 2014a; Ferro *et al.* 2022; Lirer *et al.* 2012; Santos *et al.* 2010). Moreover, the fibres require a small initial strain, inversely proportional to the initial density, to become effective (Consoli *et al.* 2009).

Recent research has investigated the potential of fibre reinforcement to improve the performance of railway ballast, as used on most railways (Ajayi *et al.* 2014b; Ferro *et al.* 2022). Modern ballast consists of uniformly-graded, coarse gravel obtained by crushing of high-quality rock, e.g. granite. In response to the stresses induced by the passage of trains, ballast deforms plastically leading to the accumulation of permanent differential track settlements. Costly maintenance operations, e.g. mechanical tamping, are required periodically to restore the correct track level. Considering that ballast settlement is the main source of the overall track settlement (Selig & Waters 1994), fibre reinforcement of ballast, if effective, could extend ballast service life and reduce maintenance costs. Moreover, random fibre reinforcement should be less sensitive to tamping operations than geogrids, also used on railways, which must be placed at a sufficient depth to avoid damage by tamping (Bathurst & Raymond 1987).

Full-scale cyclic tests in the Southampton Railway Testing Facility (SRTF) have shown that, under controlled laboratory conditions, the addition of a moderate proportion of narrow strip fibres can reduce the permanent settlement of ballast by approximately 20% with a negligible influence on the unloading-reloading stiffness. In contrast, excessively wide fibres may increase the settlement and should therefore be avoided, as they disrupt significantly the packing of the ballast grains reducing the initial density of the material (Ferro *et al.* 2022). Wider fibres would anyway be more problematic to mix uniformly with ballast and more prone to segregation during ballast placement.

This paper will present the results from full-size tests carried out in the SRTF to investigate the performance of fibres obtained from polypropylene rope, a scaled-up version of the polypropylene filaments often used as a reinforcement in sands.

2 MATERIALS AND METHODS

The ballast consisted of uniformly-graded, freshly-crushed granite aggregates from Mountsorrel quarry (Leicestershire, UK). The main characteristics and grain size distribution are shown in Figure 1(a), where G_s is the specific gravity, D_{50} is the average grain size, C_u is the coefficient of uniformity, e_{max} is the maximum void ratio; and e_{min} is the minimum void ratio. The fibres were obtained from general purpose three-strand polypropylene rope, of length L_f 300 mm and diameters d_f between 4 mm and 12 mm (Figure 1(b)).
Figure 1. (a) Grain size distribution, standard specification range (Cat. A, BS EN 13450:2002) and key characteristics for Mountsorrel ballast; (b) photo of ballast grains and polypropylene rope fibres with L_f = 300 mm and d_f = 4, 6, 8, 10, 12 mm).

To take account of the relative sizes of the fibres and the grains, the fibre-ballast composite was characterised in terms of fibre/grain ratio N_{fg}, normalised fibre length L_N and normalised fibre diameter d_N (Ajayi *et al.* 2017a):

$$N_{\text{fg}} = N_{\text{f}}/N_{\text{g}} \tag{1}$$

$$L_N = L_{\text{f}}/D_{50} \tag{2}$$

$$d_N = d_{\text{f}}/D_{50} \tag{3}$$

where N_{f} is the number of fibres and N_{fg} is the number grains (calculated as the weight of the ballast divided by the average weight of a single grain, $\sim$0.12 kg). For a given fibre length and diameter, N_{fg} is indicative of the number of grains that can be potentially engaged by each fibre.

The testing apparatus (Figure 2) is a full-size, plane-strain representation of a one-sleeper bay, which has been used previously to investigate the influence of ballast and sleeper interventions on railway track performance (Abadi *et al.* 2018, 2019; Ferro *et al.* 2020; Le Pen & Powrie 2011). The specimens were prepared from bottom to top by placing a 12 mm rubber mat that mimics the resilience of the subgrade, a 30 cm layer of ballast as typical in real railways, a G44 concrete sleeper with two short rail sections for load application, and further 20 cm of ballast to reach the upper surface of the sleeper. The fibre reinforced ballast was prepared by mixing the desired proportions of ballast and fibres manually in buckets, which were then gently poured into the testing rig to avoid fibre segregation. LVDTs were installed at several locations along the sleeper to measure vertical displacements. In each test a cyclic, vertical load representative of a 20-tonne train axle was applied evenly to the rails at 3 Hz for 3 million cycles using a hydraulic actuator. A more detailed description of the testing apparatus and preparation protocols is provided in Ferro *et al.* (2022).
Figure 2.   Schematic of test set-up with dimensions in mm; (a) cross-sectional view; (b) plan view.

3   RESULTS

Results are presented in terms of permanent settlement and resilient deflections for the 4 full-scale tests listed in Table 1.

Table 1. List of tests.

Test	L_N	d_N	N_{fg} (%)
M1	–	–	0
M2	7.1	0.14	7.6
M3	7.1	0.24	7.1
M4	7.1	0.14	13.4

In all the tests L_N was set to 7.1. This gives a fibre length equal to the depth of the ballast bed (300 mm) and should be sufficient to mobilise tension in fibres (Ajayi *et al.* 2017b). Fibre diameters were selected based on the results of the packing tests on the ballast/fibre composite (not reported in this paper, owing to limitations of space). At a given N_{fg}, the fibres with $d_N \leq 0.14$ did not inhibit significantly the packing of the ballast grains, hence were more likely to reduce the ballast settlement under cyclic loading (Ferro *et al.* 2022). For this reason, relatively thin fibres with $d_N = 0.14$ were used in test M2. For comparison, thicker fibres were used in test M3. For the thinner fibres, the effect of the fibre content N_{fg} was also investigated (test M4). The maximum fibre content used ($N_{fg} = 13.4\%$ in test M4) corresponds to approximately 60% of the maximum number of fibres that, based on visual inspection, could be added to ballast without extensive fibre overlapping.

For all the tests, the increase in average permanent settlement of the sleeper (calculated by weighted area) with the logarithm of the number of loading cycle is shown in Figure 4. The thinner fibres with $d_N = 0.14$ reduced the final settlement compared with the baseline test without fibres. At $N_{fg} = 7.1\%$ (test M2) they reduced it by ~10%, at $N_{fg} = 13.4\%$ by ~20% (test M4). This suggests that larger fibre contents may further reduce the settlement. However, previous full-size tests using strip fibres showed that the addition of too many fibres may in fact worsen performance (Ferro *et al.* 2022). The thicker fibres with $d_N = 0.24$ (test M3) were ineffective, increasing (very slightly) the settlement. This was attributed to the fibres disrupting significantly the natural packing of the ballast grains, hence increasing the ballast propensity to exhibit permanent settlement, as already observed for strip fibres (Ferro *et al.* 2022).
Figure 3. Settlement vs no. of loading cycles.

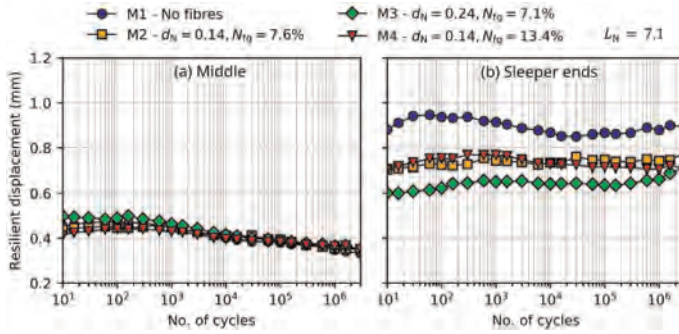
For each load cycle, the resilient deflections of the sleeper were calculated as the difference between the maximum and minimum displacements. The change in resilient deflection at the middle and at the ends of the sleeper with the logarithm of the number of loading cycles is shown in Figure 4. Overall, the fibres had no adverse effect on resilient deflections. At the middle, their effect was negligible (Figure 4(a)). At the sleeper ends, they reduced the resilient


Figure 4. Resilient displacement (a) at the middle of the sleeper and (b) at the sleeper ends, vs no. of loading cycles.

deflections (Figure 4(b)). Therefore, the rope fibres reduced the gapping between the sleeper ends and the ballast, which is responsible for the larger displacements measured at these locations (Ferro *et al*. 2020).

4 CONCLUSIONS AND FINAL REMARKS

Previous full-scale laboratory tests carried out in the Southampton Railway Testing Facility (SRTF) had shown that the addition of narrow, polyethylene strip fibres to ballast can reduce its permanent settlement without affecting significantly its stiffness (Ferro *et al.* 2022). Building on this, further full-size tests were carried out to investigate the potential of a different fibre material, comprising polypropylene rope, and improve understanding of the performance of fibre reinforced ballast. These new tests have shown that:

— relatively thin rope fibres with $d_N = 0.14$ at a content of $N_{fg} = 13.4\%$ reduced the ballast settlement by $\sim$20%
— thicker rope fibres with $d_N = 0.26$ were ineffective; this was attributed to the thicker fibres inhibiting the packing of the ballast grains, hence increasing ballast propensity to settle
— the settlement reduced approximately linearly with increasing fibre content, at least for $N_{fg} \leq 13.4\%$
— ballast stiffness was not adversely affected (reduced) by the addition of fibres and both the thinner and thicker fibres reduced the resilient displacements at the sleeper ends, i.e. they reduced gapping between the sleeper and the ballast.

Qualitatively, the effect of the rope fibres on ballast performance was consistent with that observed for the strip fibres. Neither fibre type adversely impacted the stiffness and both reduced ballast settlement if their dimensions were selected to avoid significant disturbance of the natural arrangement of the ballast grains. Rope fibres may be more effective than strip fibres. Although both types of fibre reduced the settlement by $\sim$20%, the rope fibres improved a particularly good ballast, which on its own exhibited very small settlements. However, further research is required to fully understand the behaviour of fibre reinforcement ballast and evaluate the optimal fibre characteristics for ballast improvement.

Bituminous geomembranes used for waterproofing in various transport applications

N. Daly
Axter Coletanche Inc., Montréal, Canada

T. Aguirre
Axter Coletanche Inc., Vancouver, Canada

B. Breul
Axter, Paris, France

ABSTRACT: Bitumen is a natural product, in which its use for waterproofing dates back to ancient times. A bituminous geomembrane (BGM) is manufactured by impregnating a polyester geotextile with an elastomeric bitumen compound. The geotextile provides a high mechanical resistance, while the bitumen provides the waterproofing properties and ensures longevity of the framework by protecting the geotextile. The durability of a BGM is measured in terms of how its key components, their mechanical and low permeable properties are subject to biodegradation by bacteria in various buried applications. Some example project applications in the domain of transportation will be described to illustrate these advantages where the bearing capacity of subgrades of over-consolidated soils can be improved by waterproofing unstable foundations in the presence of water. The infrastructure of the main tarmac runway at St. Georges airport in Utah and a railway track in Nebraska, both in USA will be described.

1 INTRODUCTION

Bitumen is a dense, highly viscous, petroleum-based hydrocarbon that is found in deposits such as oil sands and pitch lakes or it is obtained as a residue of the distillation of crude oil (refined bitumen). This natural substance has been used by humans for a wide variety of tasks and tools for at least the past 40,000 years. It was used in Mesopotamia, 5,000 years ago, to waterproof canals, Babylon gardens, etc. (Schwartz & Hollander 2005).

The first application of an in-situ BGM in transport construction was done to construct aprons for airplanes on low bearing soils, to cover radioactive waste in Texas, USA and a reservoir in the Alps realized with JP. Giroud in 1974.

The first fabrication of BGM in a factory was in France in 1975. This evolution was essentially driven by the need for the ability to control the quality of the product and to have better independence from the weather conditions.

2 BGM STRUCTURE

Bituminous Geomembranes (BGM) have a composite structure consisting mainly of a non-woven polyester long fiber geotextile, impregnated by a compound with a certain mass of elastomeric bitumen (Figure 1). The geotextile provides resistance and bitumen provides watertightness. Every roll manufactured is tested following CEN and ASTM standards for thickness, unit mass, resistance to tearing, static puncture, tensile strength, and elongation.
Figure 1. BGM structure.
Figure 2a. Apparatus for the test

Figure 2b. BGM after test with aggregates

2.1 *Reasons to use a geomembrane in transport construction application*

The first reason is for waterproofing. Permeability for BGM following ASTM E96 is 6. 10^{-14} m/s. The second reason is for resistance to aggregates puncture (Figure 2a and 2b). Static puncture for BGM following ASTM D4833 ranges from 3.9 kN to 4 kN, while puncture by aggregates following NFP 84-510 ranges from 20 kN to 40 kN.

The third reason is to have a low thermal expansion coefficient to avoid wrinkles during temperature variations. This allows for welding and placing cover materials can be done any time of day with fluctuating temperatures. BGM's low thermal expansion coefficient following ASTM D 696-08 is 0.22. 10^{-2} mm/m/°C, so it remains flat.

3 CASE STUDIES IN TRANSPORT APPLICATIONS

3.1 *Airport, runway reconstruction at the St. George Airport in Utah (USA)*

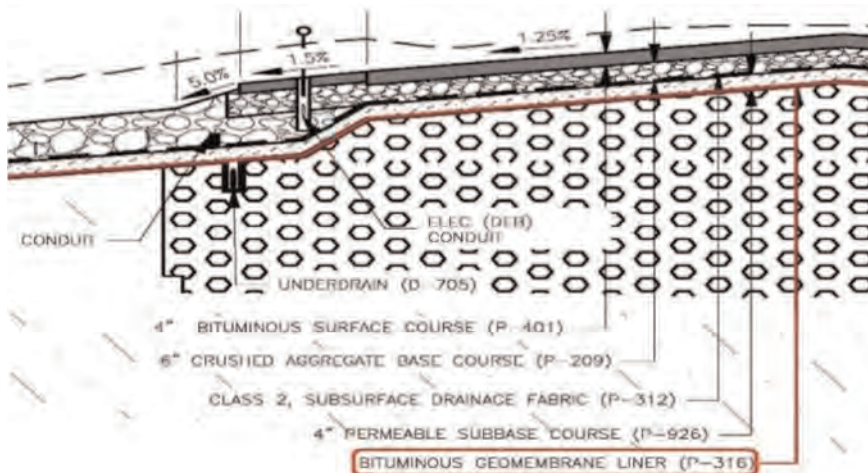
When the Saint George regional airport in Utah first opened in 2011, it was said the runway would last 20 years, but it only lasted 8 years due to the presence of blue clay under the runway and heavy rains. The runway needed a watertight barrier above the blue clay to avoid contact with water with this soil. This would help maintain the physical and


Figure 3.   Cross-section adopted for the reconstruction under the layer of asphalt concrete.

mechanical properties of the runway during varying weather conditions. The consultant had selected to use a BGM liner of 4.8 mm of thickness following ASTM D 5199, in order to accept gravel with high grain size and asphalt (temperature of application: 140°C) to be applied directly on top. See Figure 3 for design cross section.

BGM acted like an umbrella covering the blue clay with a wide overhang to avoid any water getting in contact with the structure supporting the runway. Only 130 calendar days were required to complete the entire project (Figure 4a). Figure 4b shows the large grain size of aggregates directly levelled above the BGM. The work was 200 m wide for over 1,600 m long. A team of six workers installed 6,000 m^2 of BGM per day, with an excavator equipped with a special hydraulic beam working 10-hour days in summer (temperature in the shade up to 40°C), for a total amount of 384,000 m^2 of BGM installed over 4 months.

Figure 4a.   General view of the site.

Figure 4b.   Equipment and material over BGM.

3.2   Use of BGM in railways construction and maintenance

BGM is used to protect railway platforms since it prevents clay from contaminating the ballast with water infiltration. The SNCF (French Railways) tested BGM using a in-house test called Vibrogyr (Figure 5), which simulates pulsed loading on the axles of railway sleepers and its foundation. It checks the puncture resistance of BGM with the aggregates on

Figure 5. Vibrogyr testing simulating rail traffic on ballast by SNCF (French Railways).

the ballast. This test showed that BGM could be placed directly on the platform and covered with ballast, without the need of protective layers.

Under half a sleeper, the ballast rests directly on the clay, under the other half, a BGM 5.6 mm thick following standard ASTM 5199 was placed. After estimated testing equivalent to at least 20 years of traffic on the busiest railroad of the S.N.C.F.(Paris-Tours-Bordeaux), it was found that as-is, the clay migrates into the ballast. If there is a BGM protection layer installed, there is no ballast pollution since some ballast aggregates are embedded inside the BGM without piercing the geomembrane. So BGM was used near Limoges, France in 1974, to shelter rainwater and altered granite substratum, to prevent the contamination of the ballast by clay. The construction site was in a deep trench serving as access to a tunnel. The level of the side ditches could not be changed, and it was therefore not possible to put in place thick layers of gravelly materials. It was noted that BGM had a strong resistance to puncture by these materials. BGM was verified after periods of 5 and 10 years till today. It was then found that the stones of the ballast had become embedded into BGM without piercing it, thus confirming the conclusions of the Vibrogyr test (Potvin 2016). The positive results observed on this test section led to the French Railways SNCF to continue the use of BGM on its railway tracks.

This technique therefore allows to save the cost of a deep stripping, followed by the installation of layers of selected materials. In addition, this geomembrane can be set up during a track and ballast renewal operation, which allows the saving of a prior heavy sanitation site.

3.2.1 High speed european train

East European High Speed Line (LGV Est) is a French high-speed rail line that connects Paris to Strasbourg, Germany and Luxembourg. During construction, engineers must pass over swelling shale soil near Reims. Shale tends to degrade from a hard rock-like material to a fine-grained soil mass. This degradation occurs over a long period of time, and many engineering problems such as settlements and slope failures are evident only several years after construction. The major difference between shale and clay is the lithification and diagenesis experienced by the shale in contrast to the clay, which is affected only by consolidation process. The lithification and diagenesis process affect geotechnical properties like in-situ void ratio, initial shear modulus, cohesion, apparent pre-consolidation stress, and shear strength (Gutierrez et al. 2008). On the other hand, factors that influence the swelling potential are type and amount of clay, initial placement conditions, stress history, nature of pore fluid, and temperature (Nayak & Christensen 1970). The solution found by French railways (SNCF) engineers was to do an umbrella above the shales to avoid any contamination by water by doing a watertight barrier with BGM of 5,6 mm of thickness.

TGV North (Paris-Brussel-Amsterdam-London) crosses a region with the presence of loess and chalk. BGM was used to avoid any diffusion of rainwater and thus avoid any risk of collapse. But this was done only after derailment of a TGV without injury and discovery of caverns under the line already built (Cuiet al. 2008).

3.2.2 *The Burlington Northern and Santa Fe Railway co. (BNSF)*

In Nebraska, the BNSF identified several sections of the existing track requiring refurbishment due to swelling soils (clay). Extensive engineering investigations found that the problem was the result of water in contact with the clay soil causing softening of the clay surface, which lubricated the bottom of the sub ballast. (Hyslip & McCarthy 2000). Under the repeated loading from train traffic, the sub ballast extruded out the sides of the track bed. The sub ballast layer thinned causing the outer rail to settle. In order to improve track performance in the section of track, the clay subgrade required stabilization and protection from further water contact.

Based on the geotechnical investigation, the alternative selected was a BGM of 5.6 mm thick following ASTM D 5199 (Figure 6a). Some of the subgrade clay contained sulfate which in the presence of lime and water could develop a tendency for substantial expansion over a period of time from a process known as "sulfate attack". In the location of this clay type, lime treatment of the clay without eliminating contact with water was unsatisfactory. Also, lime treatment could result in the development of flexural cracks in the stabilized clay. Water entering these cracks would result in the formation of the mud under repeated train loading.

The existing foundation was removed before adding the lime mixed with secure soil in place and BGM. Sub ballast was placed directly on top of the geomembrane without the use of geotextile protection, which BGM allows without a geotextile layer for protection (Figure 6b) (Selig & Waters 1994).
Figure 6a.   Designed cross section for BNSF.

Figure 6b.   Sub ballast placement directly on BGM.

3.3 *Use of BGM in road construction*

Some projects that will be described are for the application of the European Water Law in road construction. The respect of water quality in Europe is managed within the European Water Framework Directive. There is a directive for Ground water: the Groundwater Directive 2006/118/EC has been developed in response to the requirements of Article 17 of the Water Framework Directive. This includes the protection of the quality of groundwater under roads or highways. Vulnerable areas, fractured soils, and nearby water catchment areas, require waterproofing traffic areas and pavement platform areas, to treat water collected in such watertight basins that separate the water from the light pollutants and heavy elements.

3.3.1 *Protection of potable water on an Aquifer in Switzerland under N16 in Switzerland*

Under the N16 highway, there is the aquifer which supplies potable water for the town of Porrentruy, Switzerland with its 10,000 inhabitants. The fear of the Swiss Ministry of Transport was to have a truck carrying benzine, chemical liquid and having an accident by spilling discharges transported and polluting the ground water. So, they covered the complete exit and a superhighway by BGM to protect the aquifer (Figure 7a and 7b).

Figure 7a.   Exit on Swiss motorway N16.

Figure 7b.   Exit covered by BGM.

3.3.2 *Sustaining the ecosystem of a pond near a bypass*

In Ireland, a 3.5-km-long section of highway runs below the water table. Authorities wanted to make sure that the highway did not disturb the hydrogeological conditions and ecosystem of a marsh some 5 km from the Kildare bypass. On average, 30,000 vehicles, 20% of which are heavy trucks, pass through Kildare town every day. A 13-km-long bypass should put an end to the long bottlenecks in Kildare. The highway passes in front of one of the most famous racetracks in Ireland. As such, traffic noise would negatively impact breeding, disturb the horses before the races, and bother the spectators.

The solution was to bury the highway surface so that the berm would act as a natural noise-absorbing wall. Because of this, the highway surface was 4.5 m below the water table over a 3.5 km stretch. Of course, it could not pollute the water table nor interfere with the flow of water.

Technical solutions proposed during the call for tenders, and they chose to go with a BGM after a series of tests performed. See Figures 8a and 8b below for BGM installation.

Figure 8a.   Membrane installation.

Figure 8b.   Membrane over central collector.

4 CONCLUSIONS

The principle in protecting these transport applications is to build an umbrella above water-sensitive soils that avoids clay, gypsum, and inflating shales to be in contact with water. The described examples demonstrate the successful use of a BGM by a proven adequate strength, durability, and low permeability solution over 40 years.

Reinforced embankments for the Perranporth to Newquay Cycleway project at Newlyn Halt Railway Station, Cornwall, UK

Rozhan Saeed*
Geosynthetics Ltd, UK

ABSTRACT: Perranporth to Newquay Cycleway project is the solution for a ramp construction to be formed on top of an existing historic railway embankment. The ramp is located in tree root protection to provide the approach to footbridges. According to the British Standard BS5837:2012, the design in Tree Root protection areas should not need any excavation and compaction of the soil. The area close to existing tree roots should be protected and undisturbed during construction. Therefore, it is required to use systems to prevent tree and their root during and after construction traffic. A Cellweb system was designed to protect the tree root zone that allows drainage, nutrient and gas exchange necessary for root growth. The system decreases the pressure effect on soil and tree roots by dissipating the loads and transferring laterally to subgrade soil instead vertically. Therefore, the reinforced embankment with a stack Cellweb system filled with clean angular stone was used as a solution for a footbridge that allowed tree roots growth at the same time. The height of the embankment was 1.5m with a slope angle of 70deg. The Rivel Mesh system as a rigidity-formed face was used to achieve slope stability during construction and protect the embankment face against sliding. In the other hand, embankment slope faces were filled with top soil and vegetated. while the face was protected from erosion by covering with Erosion Contol landlok and wrapped around at each layer of soil. The design is included some key elements. Cellweb system to protect tree roots from excavation and compaction also reduces pressure on subgrade soil. Rivel Mesh systems were used to achieve slope side stability. Also, Erosion control landlock was used to protect slope sides against erosion in long term. Geotextile was used as a pollution and separation control and Sleeve-It was used as a supported fence for the ramp.

1   INTRODUCTION

The project is a design for a new ramp on top of an existing historic railway embankment to provide the approach to footbridges at multiple locations on the project to support the new cycleway from Perranporth to Newquay located at Newlyn Halt Railway Station, Cornwall, UK as shown in Figure 1.

The construction of the ramp would require a build-up of approximately 1.5m height in the Tree root Protection Area as shown in Figure 2. Construction of the embankment utilising conventional, compacted subbase materials would prevent continued water permeation and gas exchange between the atmosphere and roots beneath. This may ultimately cause root death, reducing the tree's ability to obtain the water and nutrients that it requires. Therefore, the embankment would need to be constructed using multiple layers of Cellweb.

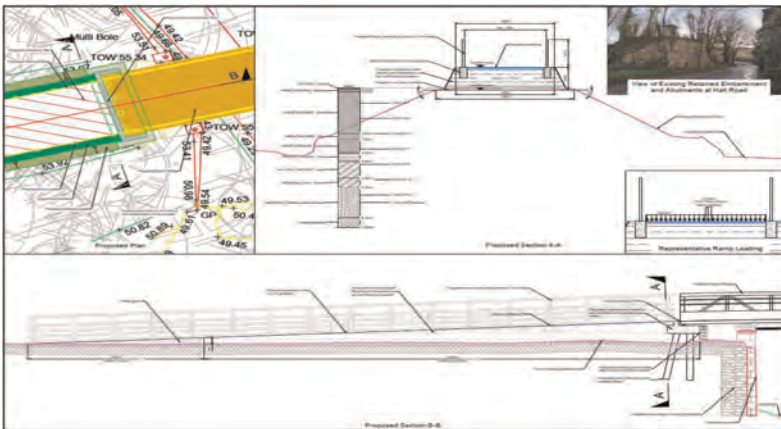
Figure 1. Existing historic railway embankment.


Figure 2. Site plan location and sections of embankment.

This would ensure the continued health of the tree and comply with the arboricultural method statement.

Cellweb TRP is a cellular confinement system used for tree root protection in construction. Cellweb offers a no-dig solution for subbase construction within tree root protection areas. Also, the system prevents the compaction of subgrade soil and allows water permeation and gas exchange between rooting and the environment and atmosphere. The system is filled with clean angular stone which is the confinement material infill to prevent tree roots severance and to allow water and oxygen to go through it. In addition, Nonwoven geotextile is used for separations and pollution control as shown in Figure 3.

Figure 3. Cellweb system with clean angular stone & geotextile for separation beneath it.

2 DESIGN METHODOLOGY

2.1 *Design method and standards*

Initially, the calculation was carried out by using the Cellweb TRP system infill with clean angular material to reduce the pressure on the subgrade and increase bearing capacity. The Cellweb system provides a stable structure to distribute the vertical loads and minimises soil compaction. The structural reinforcement design using Cellweb is based on the guidance provided by Webster (1981) which uses conventional bearing capacity analysis to determine the applied and allowable pressure below the road pavement. However, In this project, Cellweb is used as a multi-layers for building up the embankment and has been checked for slope stability.

The Embankment has been checked according to Standard – EN 1997 – DA1, In the design approach reduction factors are applied to actions and soil parameters as shown in Table 1.

Table 1. Partial factors on actions and soil parameters.

Partial factors on actions (A) Permanent design situation					
		Combination 1		Combination 2	
		Unfavourable	Favourable	Unfavourable	Favourable
Permanent actions :	$\gamma_G =$	1.35 [–]	1.00 [–]	1.00 [–]	1.00 [–]
Variable actions	$\gamma_Q =$	1.50 [–]	0.00 [–]	1.30 [–]	0.00 [–]
Water load :	$\gamma_w =$	1.35 [–]		1.00 [–]	
Partial factors for soil parameters (M) Permanent design situation					
			Combination 1		Combination 2
Partial factor on internal friction :		$\gamma_\phi =$	1.00 [–]		1.25 [–]
Partial factor on effective cohesion :		$\gamma_c =$	1.00 [–]		1.25 [–]
Partial factor on undrained shear strength :		$\gamma_{cu} =$	1.00 [–]		1.40 [–]
Partial factor on Poisson's ratio :		$\gamma_v =$	1.00 [–]		1.00 [–]
Partial factors for variable actions Permanent design situation					
Factor for combination value :		$\psi_0 =$		0.70 [–]	
Factor for frequent value :		$\psi_1 =$		0.50 [–]	
Factor for quasi-permanent value :		$\psi_2 =$		0.30 [–]	

Material of blocks – filling

No.	Name	γ [kN/m³]	φ [°]	c [kPa]
1	Clean Angular Stone 4/20	18.00	35.00	0.00
2	Subbase Type 3	18.00	35.00	0.00

First, the geometry of the embankment was produced and soil property was specified then the embankment was checked for global stability. The stability check included active and passive earth pressure calculation, check for overturning and check for slip stability, the shape of earth wedge and dimensioning check, allowable eccentricity and Bearing capacity of foundation and global slope stability with bishop method as shown in Figure 4.
Figure 4. Embankment stability check.

3 DESIGN CONSIDERATIONS

3.1 *Geometry and cross-sections*

The design analysis is based on the worst-case scenario with a maximum height of 1.5m and 70deg slope face. The embankment is along the bridge of around 26m with the different layers of 200mm Cellweb as shown in the following cross-sections. The embankment base width is 6.3m and the path on the top is 4.5m as shown in Figure 5.

Figure 5. Cross section of the embankment.

3.2 *Soil parameters*

The Cellweb infill material shall be a clean angular stone with a size of 20mm to 4mm complying with BS EN 12620. The property of fill material shown below
Cellweb Fill properties:

– Clean angular stone Type 4/20
– Particle sizes: 4mm to 20mm
– Friction angle $\phi' = 35$deg,
– Unit weight $\gamma = 18$kN/m3

The existing embankment was assumed Made of Ground Ballast and stable. The parameters used in the analysis are:
Foundation soil properties:

– Made of Ground Ballast
– Friction angle $\phi' = 30$deg,
– Unit weight $\gamma = 18$kN/m3
– Cohesion C' = 0 kPa

Topsoil and seeded topsoil were used on the face for the vegetated face.

4 DESIGN SOLUTION

The final solution included the results for embankment reinforcement with Cellweb and a vegetated face with a face support framework and erosion control.

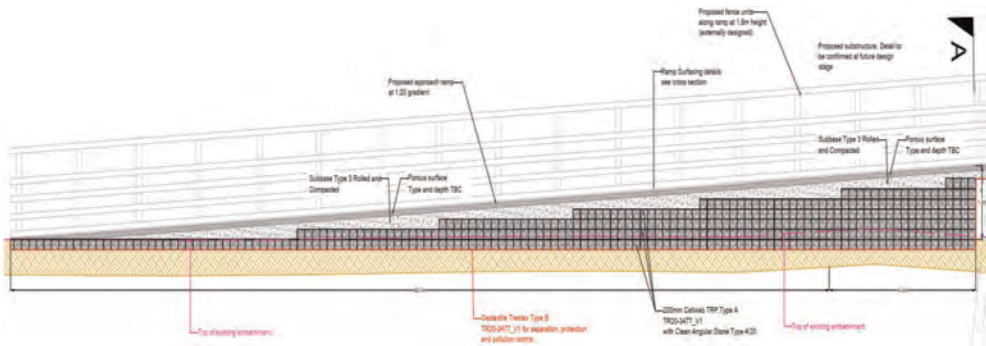
In the worst-case scenario, as shown in Figure 6 below, seven layers of 200mm Cellweb were used for the reinforcement which is filled with clean angular stone to protect tree roots protection and as a reinforcement for the build-up embankment up to 1.5m height. However, the layers are reduced along the bridge according to 1:20 slope ramp.


Figure 6. Long section of the reinforcement embankment final solution.

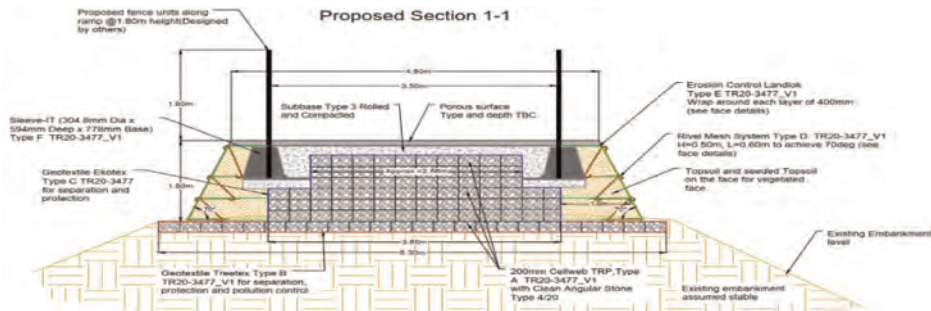
In this project layers of Cellweb have two roles, first as a system to reduce the loads on the tree roots against any compactions while giving permission of water and gas to exchange between roots and the atmosphere. second, Cellweb is used as a reinforcement layer to build up the embankment with a 70deg slope angle. To support the face, the Rivel mesh system has been used to achieve 70deg slope face and Erosion Control Landlok has been used to protect the face form erosions as shown in Figure 7 below.


Figure 7. Cross section of the reinforcement embankment final solution.

5 CONCLUSION

The use of reinforced embankments with Cellweb layers and filled with clean angular stone Type 4/20 allowed the construction to build up the new bath on the bridge with no-dig or compactions to the existing embankment to prevent damage to existing tree roots.

The main challenge for the design of the reinforced embankments was to keep the existing embankment to prevent damage and to achieve slop stability of a vegetated face with step angle of 70deg. For this purpose, the Rivel mesh system was used to support slope stability and achieve the angle and erosion control Landlock was used to protect the face from erosions.

In addition, a layer of Geotextile Treetex was used for separations and protections between the existing embankment and the proposed one. Also, between Cellweb layers and the face of the slope.

In conclusion, the beneficial effects of Cellweb system to build up the embankment are as follows:

– Minimizes compaction of the existing embankment.
– No-dig construction solution.
– Allow water and gas exchange between tree roots and the atmosphere.
– Use as a reinforced layer to build the embankment and achieve stability.
– Distribution loads and reduced effect on the existing embankment.

ABSTRACT: This paper focuses on evaluating local stiffness enhancement near a geogrid installed at the base/subbase interface of full-scale pavement test sections at the FAA's national airport pavement test facility (NAPTF) in the USA. The investigated test pavements comprised of the north section stabilized with a square aperture geogrid and the south control section with no geogrid. Inductive coil sensors and pressure cells were embedded in both sections. A full-size dual-tridem gear applied realistic moving wheel loads on the pavement surface. Pavement responses including layer deformations from coil sensors and applied pressure from earth pressure cells were measured during traffic loading. Modulus characteristics of the subbase layer were then estimated based on the sensor measurements during traffic passes. The study findings indicate higher layer stiffness consistently estimated in the geogrid-stabilized pavement section when compared to the values in the control section due to heavy aircraft gear loads.

1 INTRODUCTION

Geogrids used for unbound aggregate stabilization in flexible pavements increase lateral confinement, prevent excessive rutting under vehicular loading, and as a result, extend pavement service life. Despite the widely recognized benefits of geogrid stabilization, the application of geogrids in airport pavements has been limited (Norwood 2019). In the US, the Federal Aviation Administration (FAA) Reauthorization Act of 2018, sec. 525, required FAA, to the extent practicable, to encourage the use of durable, resilient, and sustainable materials and practices, including the use of geosynthetic materials. For decades, FAA has been operating the National Airport Pavement Test Facility (NAPTF) to provide high quality, accelerated pavement test data from rigid and flexible pavements subjected to simulated aircraft traffic. In the NAPTF Construction Cycle 9 (CC9) full-scale pavement tests, a 13.7 m long geosynthetics test section was included as a test item to evaluate related performance improvements of geosynthetics in airport pavements.

Numerous research studies reported that using geogrids to stabilize unbound aggregate layers effectively reduced surface deformation (Al-Qadi *et al*. 2008; Tingle & Jersey 2009). Geogrids installed in unbound base or subbase layers provide lateral restraint through geogrid-aggregate interlocking and create a stiffened zone in the proximity of the geogrid location. Experimental research using various test methods, including dynamic cone penetrometer (DCP) and direct shear tests, have shown that the base/subbase layer became stiffer near the geogrid location (Horvát *et al*. 2013; Kwon & Tutumluer 2009). Furthermore, recent research efforts using innovative bender element (BE) sensors successfully quantified

the stiffness enhancement and the extent of the geogrid-stiffened zone in the vicinity of a geogrid through direct measurement of shear wave velocity (Byun *et al.* 2019; Kang *et al.* 2022a, b).

The objective of the research effort described herein is to quantify localized stiffness characteristics of an unbound aggregate subbase layer installed with two types of embedded sensors, i.e., coil sensors and earth pressure cells, in the NAPTF CC9 geosynthetics experiment subjected to aircraft traffic loading. Comparisons are made between the subbase layer moduli of a geogrid-stabilized section with those of the control section during the accelerated pavement testing, and the performance improvement of the geogrid installed in the unbound aggregate base is highlighted.

2 TEST SECTION

Accelerated pavement testing of two full-scale airport pavement test sections was conducted in the fully enclosed NAPTF; utilized by the FAA to perform airport pavement research. The test track at NAPTF is 274 m (900 ft) long and 18.3 m (60 ft) wide and can accommodate various pavement thicknesses depending on the test objectives. The Construction Cycle 9 (CC9) pavement test sections consisted of 127 mm (5 in.) of P-401 asphalt surface course underlain by 203 mm (8 in.) of P-209 granular base and 737 mm (29 in.) of P-154 granular subbase layers. The paper focuses on the test results obtained from the first 330 vehicle passes for the geosynthetics test item, referred to herein as the low strength flexible conventional (LFC-3), which consists of a north section (LFC-3N) mechanically stabilized with a punched and drawn biaxial geogrid installed at the interface of the base and subbase, and a control section in the south (LFC-3S), which is unstabilized (see Figure 1). The embedded sensors were installed towards the upper part of the subbase layer near the geogrid location.

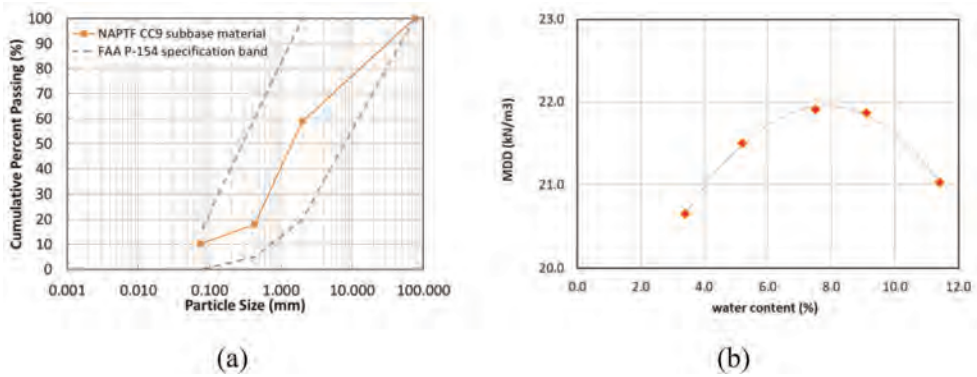
The properties of the P-154 subbase course, carbonate-based manufactured aggregate screenings, are illustrated in Figure 2. Sieve analysis in accordance with the ASTM C136 procedure was conducted to determine the grain size distribution curve shown in Figure 2(a). The subbase material is classified as A-1-b (stone fragments, gravel, and sand) according to the AASHTO soil classification system, and as SP-SM (poorly graded sand with silt and gravel) according to the Unified Soil Classification System (USCS). The mean grain size (D_{50}) of the aggregate material is 1.42 mm (0.056 in.) and the particle fraction passing No. 200 (0.075 mm) sieve size is 10.2%. As shown in Figure 2(b), the maximum dry density
Figure 1. Airport pavement cross-sections of FAA's NAPTF CC9 geosynthetics test item: (a) LFC-3N geogrid stabilized section, (b) LFC-3S unstabilized control section.


Figure 2. Properties for the P-154 subbase course aggregate: (a) grain size distribution, and (b) moisture-density relationship.

(MDD) and optimum moisture content (OMC) determined by the modified Proctor compaction test (ASTM D1557) were 21.96 kN/m^3 (141 pcf) and 7.9%, respectively.

3 EMBEDDED SENSORS

3.1 Coil sensor

A pair of inductive coil sensors was installed at the top of the subbase layer of both LFC-3N and LFC-3S test sections, as shown in Figure 1. The inductive coil, referred to herein as coil sensor, consists of a transmitter coil and a receiver coil, which are inductive circuits made of a copper wire winding a circular thermoplastic polymer disk [see Figure 3(a)]. A magnetic flux field generated around the transmitter coil by an input alternating current creates an output current to the receiver coil via mutual induction (Greenslade 2016). The distance between the transmitter and receiver coils can be estimated from the magnitude of the received signal using the following parabolic fitting equation.

$$y = ax^2 + bx + c \tag{1}$$

where x is the voltage and y is the relative displacement between coil pairs. The coefficients a, b, and c were obtained from the calibration process using the linear variable differential
Figure 3. Embedded sensors at NAPTF CC9: (a) Inductive coil pairs, and (b) Pressure cell.

transformers (LVDTs). Therefore, the coil pairs serve as a non-contact strain-measuring sensor that measures the local strain in a certain range. The average resolution of the coil sensors is 75 micro-strain (0.0057mm). Two coil sensor pairs were installed free floating with a target 76.2 mm (3 in.) gap, as recommended by the manufacturer. During each vehicle pass, dynamic pavement deflection responses were monitored using the sensors.

3.2 *Pressure cells*

Pressure cells were installed in the subbase layer, two in LFC-3N and one in LFC-3S sections. Pressure cells measure the dynamic pressure changes in the surrounding material through the internal pressure change in a thin hydraulic fluid cell between the two flat metal plates. A transducer in the pressure cell converts the fluid pressure change into an electrical signal. The output voltage collected by the data acquisition system is converted to a pressure measurement according to an established correlation from the calibration. To minimize local plate deflection due to pressure exerted from surrounding particles, the pressure cells used in this research are equipped with additional thick plates on each side [see Figure 3(b)]. Throughout 330 vehicle passes, dynamic pavement responses, i.e., applied pressure levels, were monitored using pressure cells. The LFC-3N pressure values were calculated by averaging the pressure from the two installed pressure cells in an effort to obtain an accurate estimate of the pressure at the same depth of the coil sensor.

4 TEST PROCEDURE

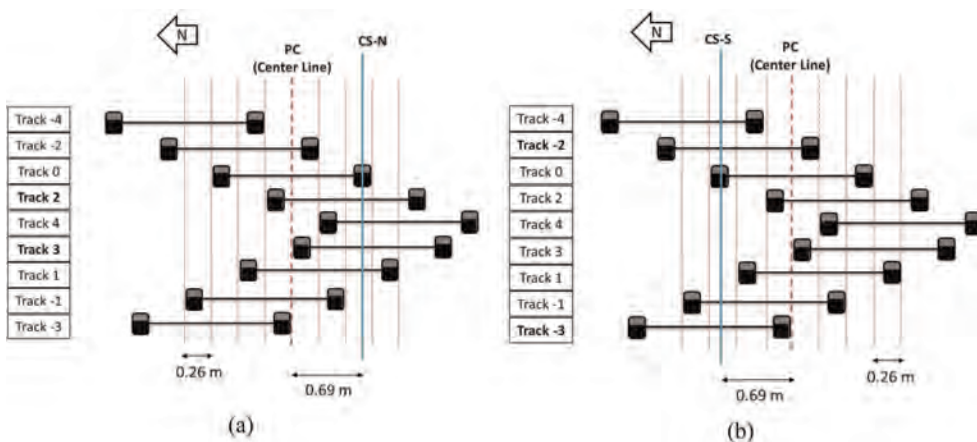
The National Airport Pavement Test Vehicle (NAPTV) applied a dynamic gear loading of 26.3 tons (58 kips) per wheel using a dual-wheel tridem-axle gear configuration (3D) module; equivalent to a total of 157.8 tons (348 kips) to simulate heavy aircraft gear loading. Figure 4 illustrates the NAPTV gear wander positions consisting of 66 vehicle passes, normally distributed and arranged in nine wander positions with different offset distances. The offsets are the distances from the centerline of the test section to the centerline of the loading module, located midway between the two wheels. The thick red dashed line indicates the pressure cell location at the centerline of the test section, and the blue solid line shows the coil sensor location for each test section. The remaining lines show the centerline of the loading gear at each wander position, which are equally spaced with a 0.26 m (10.2 in.) shift. As illustrated


Figure 4.   Traffic loading procedure with wander patterns: (a) LFC-3N, and (b) LFC-3S test sections.

in Figure 4, coil sensors are located at a 0.69 m (2.25 ft) from the centerline, while pressure cells are at the centerline. Data obtained from test tracks 2 and 3 for LFC-3N and from test tracks -2 and -3 for LFC-3S were analyzed and compared considering the identical loading condition at the coil sensor and pressure cell locations. Two passes of the loading module consist of an eastbound passage and a westbound passage at the same offset location. The complete wander pattern consisting of 66 passes is summarized in Table 1. Data from 5 complete wander patterns are presented in this paper.

5 RESULTS AND DISCUSSION

Figure 5 shows a sample dynamic response from a coil sensor and a pressure cell during pass No. 320 of the traffic testing. The three peaks observed from both sensors correspond to loads from the three wheels of the tridem-axle gear of the NAPTV passing over the sensors. The resilient modulus (M_R) of the unbound aggregate material is determined using the following equation.

$$M_R = \frac{\sigma_d}{\varepsilon_r} \qquad (2)$$

where σ_d is deviator stress, and ε_r is the recoverable resilient strain. Hence, the resilient modulus of the subbase layer can be calculated using the wheel load deviator stress obtained from the pressure cell and the recoverable resilient strain collected from coil sensors.

The stress states induced in the subbase layer will vary as the NAPTV loading is applied at different wander positions. Track 2 of LFC-3N and track -2 of LFC-3S induce the same stress state at the sensor locations. Figure 6(a) shows the resilient moduli estimated from vehicle passes at track 2 of LFC-3N and at track -2 of LFC-3S. Clearly, the estimated

(a) Coil sensor   (b) Pressure cell
Figure 5. Typical dynamic responses collected from embedded sensors at pass No. 320.

moduli at the geogrid-stabilized section indicate higher values with an average resilient modulus improvement of 68.7%. Therefore, it could be concluded that the geogrid-stabilized subbase layer has higher stiffness near the geogrid location. The authors previously reported that the extent of the geogrid-stiffened zone in the CC9 test section base layer is approximately 102 mm (4 in.) from the geogrid location (Kang *et al.* 2022b). The sensors located within the geogrid-stiffened zone captured the stiffness improvement achieved through geogrid-aggregate interlocking (see Figure 1). Note that the coil sensors were located 0.69 m (2.25 ft) apart from the pressure cell (see Figure 4). Whereas the vertical pressure values were collected near the wheel path, the coil sensor deflections were measured 0.52 m (1.71 ft) apart from the wheel path and thus the estimated moduli values could be higher than the actual values.

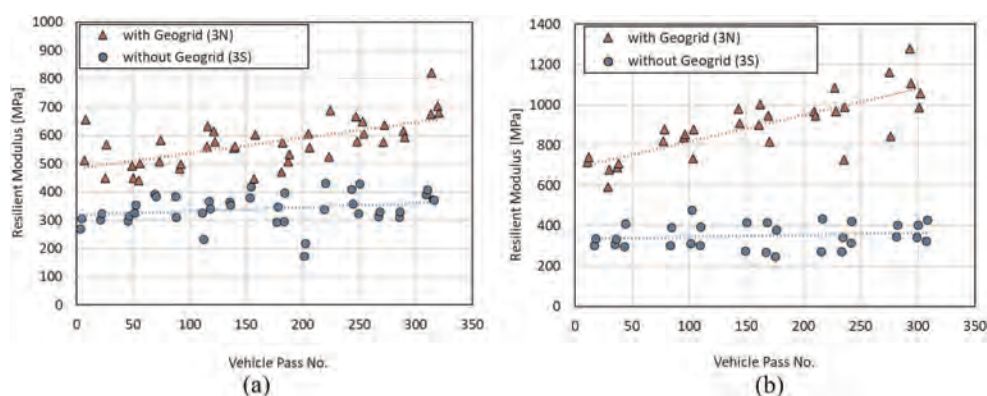
Figure 6(b) presents the resilient moduli estimated from vehicle passes at track 3 of LFC-3N and at track -3 of LFC-3S, which have the same stress state. Similarly, the estimated moduli at the geogrid-stabilized section were higher, with an average improvement of


Figure 6. Resilient moduli estimated using embedded sensors: (a) moduli from track 2 of LFC-3N and track -2 of LFC-3S, (b) moduli from track 3 of LFC-3N and track -3 of LFC-3S.

155.3%. The estimated moduli from tracks 3 and -3 were higher than those from track 2 and -2 due to the larger horizontal distance of the coil sensor from the wheel path, which is 0.59 m (1.94 ft), meaning the measured vertical strain is an underestimate of the actual strain at the pressure cell location. Interestingly, the estimated moduli increased as the number of load repetitions increased, especially at the geogrid-stabilized section. This could be attributed to the stabilized unbound aggregate layer by rearranging the aggregate particles during load repetitions, especially during the first few load repetitions (Kang *et al.* 2022a). Han *et al.* (2020) reported that from a falling weight deflectometer (FWD) test performed before and after accelerated pavement testing (APT), the modulus of the unbound base course for a geogrid-stabilized pavement after APT was considerably higher than the unstabilized section owing to the fully mobilized benefit of geogrid. A higher modulus increase observed in the geogrid-stabilized section was likely due to the gradual mobilization of the geogrid during vehicle passes.

6 CONCLUSION

This paper presented recent research findings on geogrid-stabilized airport pavements. The unbound aggregate subbase layer was instrumented with embedded inductive coil sensors

and pressure cells. A full-scale airport pavement test section, including a geogrid-stabilized section and an unstabilized control section were constructed in US Federal Aviation Administration's (FAA's) national airport pavement test facility (NAPTF). The 3D loading module of the national airport pavement test vehicle (NAPTV) applied dynamic gear loading of 26.3 tons (58 kips) per wheel, with a wander pattern consisting of 66 vehicle passes arranged in nine wander positions. Dynamic responses from coil sensors and pressure cells were collected for the first 330 NAPTV passes (5 complete wander sets). The local stiffnesses as resilient moduli at the top of the subbase layer were analyzed with and without geogrid stabilization using the dynamic sensor data.

The estimated subbase moduli from the geogrid-stabilized section were on average 68.7% to 155.3% higher than those for the unstabilized section. A stiffness improvement was therefore achieved within the 102 mm (4 in) geogrid-stiffened zone. The resilient moduli increased as the number of passes increased, especially for the geogrid-stabilized section, which could be attributed to the gradually increasing effect of stabilization during vehicle passes. These research findings clearly demonstrate the benefit of geogrid stabilization in airport pavements through the mechanisms of unbound aggregate base/subbase lateral restraint and stiffness enhancement.

Geosynthetics coated with pure polyurea to create a waterproofing membrane for railways bridge decks

E. De Ambri & C.P. Longoni
Mapei S.p.A., Italy

ABSTRACT: Geosynthetics are materials currently used in the railway's applications. The system developed with the Italian railways infrastructure manager, is using the geosynthetic as a base layer where to spray a pure polyurea membrane, a fast-curing waterproofing product used since decades all over the world to waterproof roofs, decks and hydraulic structures. The system is specifically designed to renovate the waterproofing performance of existent railways bridge decks. Purtop 1000, Mapei pure polyurea membrane, has been tested at a thickness lower than the one prescribed and it has passed all the required tests.

1 INTRODUCTION

Every railway bridge deck needs a waterproofing system to be protected from water which is one of the main causes of structure's decay.

There are a lot of waterproofing technologies suitable to waterproof new railway bridge decks made of concrete or steel; on the contrary it is difficult to find suitable waterproofing systems to renovate existent structures, where fast-track solutions adaptable to different substrate's conditions are required.

In Europe there is still in place the development of new infrastructures, but it is a matter of fact that the renovation market is an upcoming business which will surely increase in the next decades.

With a future wise perspective, in Italy the Italian railways infrastructure manager, developed in the 90's an innovative system to re-waterproof arched bridges. Later this system has been recognized as a valid solution for several kind of railway bridge deck and it has become one of the possible solutions for maintenance works on the Italian railways bridge decks.

The performance expected from the waterproofing layer in such a context are very high because it must keep its performance in a lot of different weather conditions and under multiple stresses (static and dynamic loads, puncture deriving from ballast, friction, etc.). Therefore, a premium waterproofing technology is required to assure watertightness and durability to the structure.

Moreover, the waterproofing system must assure a rapid installation because the service interruption cannot be long in operating infrastructures.

2 THE WATERPROOFING SYSTEM DESIGNED BY RFI (RETE FERROVIARIA ITALIANA)

The specification prescribes the use of resin-based waterproofing product (like polyurethane, polyurea, methacrylate, etc.) free of solvents, plasticizers, inert materials or bitumen. The chemical reaction which leads to the cured waterproofing membrane should last maximum 15 seconds and the waterproofing layer must allow pedestrians' traffic after not more than 5 minutes. Moreover, the product must be spray applied to be fast and to be applied during scheduled service interruptions.

The waterproofing product used for renovations can be the same one used for the new structures, what differs is the application thickness and the layering of the system, as described in the below table.

Table 1. RFI system layering according to the type of deck.

	New decks	Existent decks
Application thickness (mm)	≥ 4	≥ 5
System's layers (bottom-up)	1. Concrete/metal substrate 2. Primer 3. Waterproofing membrane 4. Asphalt-based protection layer	1. Existent structure 2. Geotextile (1500 g/m^2) mechanically fixed to the structure 3. Waterproofing membrane 4. Protective geotextile (800 g/m^2)

The design's logic is increasing the thickness from 4 to 5 mm when the waterproofing membrane is not fully adherent to the structure since it must anyhow withstand all the heavy mechanical actions deriving from the rails' functioning.

Furthermore, it must be also noticed that on new railway bridge decks the membrane protective layer is asphalt-based, and it is poured on the waterproofing membrane's surface at 130°–140°C, adding an additional performance required: the resistance to high temperatures.

2.1 Renovation system's advantages

The system developed more than 20 years ago by RFI is still actual because it presents a lot of advantages.

During renovation works it is always difficult to clearly know before in which conditions the railway bridge deck will be once exposed to be re-waterproofed. Therefore, a system which is using a geotextile, mechanically fixed, as a formwork for the spray applied membrane, prevents problems related to the substrate conditions, such us irregularities or moisture presence. Moreover, such a system can also be laid, properly anchored, on a stone chippings layer, reducing the excavation operations, especially at the sides of the bridge. At the same time such a "detached" system is demanding a high-performance waterproofing product which can withstand the mechanical stresses related to not uniform substrate.

A second important advantage is the absence of joints and/or fixing holes on the waterproofing membrane: the spray applied waterproofing product in fact guarantees seamless joints. Thanks to the chemical adhesion provided by a primer, two layers of product sprayed in different times are monolithically welded one to each other.

Thirdly, the spray application easily follows the geometry of the bridge deck and can easily adapt to the waterproofing details typically present on this kind of structures.

The last important advantage of such a system is the fast-track application. As previously mentioned, the use of the geotextile as a formwork prevents all the problems related to the substrate preparation and at the same time the use of a fast-curing material dramatically reduces the time linked to the waterproofing membrane application. The combination of these two factors allow to work in a night span time without causing service interruption during the day with all the related costs and inconveniences.

2.2 Waterproofing membrane's required characteristics and performance

The specification characterizes the waterproofing membrane through two types of tests: technological tests to be performed on the standard membrane and on an aged one, and functional tests to be performed only on the membrane as it is.

The following table shows the entire test programme and the related requirements.

Table 2. Test programme and requirements.

Test n.	Performance characteristic	Test method	Requirement
Technological tests on the waterproofing membrane			
1	Density	UNI EN ISO 1183-1	$1 \pm 0,1$ g/cm^3

2.3 *Test on the supply and on the applied product*

The specification does impose not only initial tests, but also tests related to the specific supply delivered at the jobsite. For this reason, samples 50×50 cm must be collected on the jobsite to perform the following tests (3 times each): density, tensile strength and elongation at break, Shore A hardness, watertightness test, absorption test at $1°C$ and IR spectrum.

Moreover, also a destructive test must be performed: a piece of the spray applied membrane each 50 m^2 must be cut to check the applied thickness.

2.4 *Execution phases*

The renovation of the waterproofing system implies always the same working phases, specifically:

(a) jobsite's set up;
(b) preparation of the support for the second track and rail's cut of the first one;
(c) rail's removal;
(d) ballast's removal and substrate's regularization;
(e) geotextile (1500 g/m^2) application and fastening;
 (f) waterproofing membrane spray application;
(g) protective geotextile (800 g/m^2) application;
(h) arrangement of the transversal and longitudinal overlaps' protection;
 (i) rail's repositioning, ballast's dumping and tamping.

Figures 1 – 2 – 3   Typical application phases on site.

3   THE MAPEI SYSTEM TO SATISFY RFI'S REQUIREMENTS

Mapei is waterproofing since years Italian railways bridge decks with Purtop 1000, two-component, solvent-free pure polyurea membrane applied by spray with a high-pressure, bi-mixer type pump, to form waterproof coatings on site.

Mapei waterproofing products' range is wide in terms of technologies and within this range Mapei selected polyurea for railways bridge decks as a top-quality solution, fast-track and highly durable.

The company experience in various infrastructures jobsites all over the world (such has tanks, dams, highways bridge decks, etc.) has in fact confirmed the high-level performance of this material. Moreover, a complete set of tests were performed over the years not only to assure its CE marking according to EN 1504-2 ("Products and systems for the protection

and repair of concrete structures - Definitions, requirements, quality control and evaluation of conformity - Part 2: Surface protection systems for concrete") but also to satisfy specific designers' requirements. The R&D department has consequently developed a formula able to withstand all the most severe stresses and conditions, positioning Purtop 1000 as a high technological solution for waterproofing.

In 2019 Mapei has decided to make one step further: it has started a qualifying process together with RFI technicians to apply Purtop 1000 in 3 mm thickness, both in new and existent railways bridge decks. This decision was taken to optimize the price-performance balance of the technology offered to the market, moreover a reduction in thickness is also saving time on site.

3.1 *The pure polyurea chemistry*

A polyurea is the product obtained by the polyaddition reaction of a polyfunctional isocyanate with a polyfunctional amine.
Figure 4. Polyurea reaction.

Thanks to the high reactivity between isocyanates and amines, it is not necessary the use of any catalyst for the reaction and this allows the formation of a continuous film with no bubbles caused by the humidity of the environment (that usually affects the quality of alternatives technologies).

The high reactivity also insures a very fast setting of the product (the pedestrian traffic is possible after only a few minutes and the product gets its final mechanical properties after only 24 hours).

Moreover, the formation of the urea groups leads to a very high number of intermolecular hydrogen bonds, that, after the preliminary selection of the isocyanate and the right mixture of amines, allow to achieve very good mechanical properties, in particular high elasticity, high tensile strength and high tear resistance (the Purtop 1000, for example, has more than 20 MPa as tensile strength, more than 300% of elongation and more than 80 N/mm as tear resistance).

Purtop 1000, as other hot spray polyureas, due to high reactivity of the two components, must be applied by spray, using special pumps, typically with mixing ratio by volume 1:1.

3.2 *Mapei's experience with Purtop 1000*

As already mentioned, Purtop 1000 is CE marked according to EN 1504-2 as a coating for concrete, but a lot of additional tests were performed over the years according to various projects' needs and they all have led to the conviction that the membrane could be applied in 3 mm thickness complying all the requirements of RFI's specification.

Every railway infrastructure is exposed to high temperatures in summer, but especially to low ones in winter and this is the critical condition where the waterproofing coating must maintain its mechanical performance assuring to be able to withstand all the possible loading stresses. Within the European regulatory framework, the EN 1062-7 is classifying coatings according to their crack-bridging ability, both static and dynamic, at different temperatures. As shown in the table below, Purtop 1000 in a thickness between 2 mm and 3 mm is reaching the highest classes at -20°C.

Table 3. Purtop 1000 crack-bridging properties.

Performance characteristic	Test method	Classification	Average samples thickness	Purtop 1000 performance
Static crack-bridging at -20°C	EN 1062-7	from class A1 (> 0.1 mm) to class A5 (> 2.5 mm)	2 mm	A5 > 2,5 mm
Dynamic crack-bridging at -20°C	EN 1062-7	from class B1 to class B4.2	2,9 mm	B4.2 w_o = 0,5 mm w_u = 0,2 mm w_L = ± 0,05 sinus n = 20.000 f = 1 Hz w = 0,3 mm

Another important mechanical characteristic for under ballast applications is the dynamic puncture resistance. Purtop 1000 has been tested by SNCF Réseau (the French rail network manager) according to their internal test method and it has been verified that a 3 mm coating is still continuous and watertight after the dynamical indentation it has been subjected to.

Moreover, for a dam project, Purtop 1000 has been tested, according to the requirements of the designer, in terms of static crack-bridging ability and puncture resistance under a hydrostatic pressure of 25 bar. During this test campaign it has been verified that a 2,16 mm thick sample is assuring the watertightness on an open static crack of 4 mm at 25 bar and that a 2,30 mm thick sample can withstand the puncture of a 5 mm asperity, always under a hydrostatic pressure of 25 bar.

Finally, another important performance, that a waterproofing membrane exposed to the environment should have, is the root penetration resistance, because there is always the possibility that some seeds start germinating in the ballast layer. Purtop 1000 has been tested according to the CEN/TS 14416 ("Geosynthetic barriers - Test method for determining the resistance to roots") method and it has been checked that after two years of roots' action a 2 mm thick film is completely insensitive to this type of stress.

3.3 Obtained results according to RFI specification

Based on the above-mentioned experience, Mapei Spa has approached the test campaign with RFI technicians to qualify the 3 mm thickness according to the specification.

All the tests listed at paragraph 2.2 were successfully passed except for the brittleness limit temperature, which was verified till -38°C and didn't reach the -40°C requirement. Despite this result, polyurea based materials are well-known to be still elastic at low temperature, therefore, the glass transition temperature of Purtop 1000 has also been checked and it has been verified that it is -47,9°C, confirming that the material is still elastic also below -40°C.

The test campaign has led to a fruitful discussion with RFI technicians in order to evaluate alternative test methods for the future, in addition to the ones prescribed by the specification, in order to take into consideration the physical and mechanical properties of each material which is allowed to use for this purpose.

4 CONCLUSIONS

Purtop 1000, pure polyurea membrane spray applied, is suitable to be used as a water-proofing layer for railway bridge decks satisfying the requirements of RFI (Rete Ferroviaria Italiana).

The test campaign which has lasted more than 2 years has verified that this reduced thickness of Purtop 1000 (in comparison to what prescribed by the specification) is able to assure the needed performance both alone and in combination with a geotextile in renovation cases.

This will lead to an improvement in the market because the use of Mapei Purtop 1000 with a reduced thickness is a plus not only from an economical point of view, but also from a practical one: it implies less time to be applied and this is generating a gain also from job-site's timing point of view.

Influence of geosynthetics in the structural layers on the railway track geometry

A. Petriaev

Emperor Alexander I St. Petersburg State Transport University, Saint-Petersburg, Russia

ABSTRACT: The paper presents research result of geosynthetics applications in railway structure with focus on ballast and subballast stabilization. Previous investigations have indicated the influence of geosynthetics on ballast bearing capacity and its deformation behavior, but field results of railway track geometry needs to be made. In addition, long-term behavior of stabilized track structure has not clearly indicated yet. In this study the influence of geosynthetics in ballast layer on long-term behavior estimated by the state of the track geometry. For this purpose, rail spotter and track leveling were used. The results have shown that deflection accumulation rate over time on the section with geosynthetics is 1.8 times lower than on the usual one, and the unevenness of track lowering is 1.7 times lower. Ballast stabilization with geomaterials in any case reduces the cost of current maintenance, the most complete difference in labor costs is felt starting from 4 years of post-repair operation.

1 INTRODUCTION

Recent year's information shows that on the railways where the heavy-duty and high-speed trains are being introduced, there is an increase in the number and length of sections of track with limiting train speeds. The appearance of these sections in many cases is due to the inability to ensure the stability of the track geometry.

Recently, geogrids have been increasingly used to strengthen the rail track. The benefits of geogrid reinforcement have been highlighted by some researches (Brown *et al*. 2007; Esmaeili *et al*. 2017; Gobel & Weisemann 1994; Indraratna *et al*. 2011; Ishikawa T. *et al*. 2019; Kwan 2006; Sharpe *et al*. 2006). Geogrids have rigidity, significant tensile strength, high modulus of deformation (low elongation at break), high resistance to temperature, chemical and biological influences and, due to this, are characterized by a long service life. Long-term behavior of track, stabilized by geosynthetics, has a considerable interest.

2 METHODS

Tensar SS30 polypropylene geogrids were laid at a depth of 40 cm under the sleeper during the track overhaul on the top of subgrade, which was presented by fine-grained sand . Granite crushed stone of a 40–65 mm fraction was laid on the top of the geogrid. The influence of geosynthetic materials under the sleepers on the track behavior was assessed by the number of deviation of track geometry from the standard. The evaluation of the track by the track measuring cars was carried out using the WAY software product.

The analysis of the track variations helps to identify problem areas in the sleeper's base. In addition to assessing the state of the track by the number of deviations from the standard, the "average mark" indicator was used to assess the geosynthetics effectiveness. The methodology for determining this indicator is given in the CP515 Instruction. The studies were

carried out at the two railways. The sections of the track were divided into sections, that do not have geosynthetic materials in the base ("standard") and sections that have geosynthetic materials in the base ("geosynthetics"). The evaluation used data for the period from the year following the ballast repairingдевяностотысяч to the tenth year of operation. More than ninety thousand records were used on the state of the track geometry to analyze the railway track. The summative indicator of the geometry state was the adjusted mean of deviations degree (AMDD) indicator. The calculation of the AMDD indicator was carried out according to the next equation:

$$\sum \text{IIst} + 1.35 * \sum \text{IIIst} + 1.71 * \sum \text{IVst}$$

where $\sum$IIst, $\sum$IIIst, $\sum$IVst = amount of railway track geometry deviations of the second, third and fourth degrees according to the instruction CP515.

Deviations that do not require work to eliminate them and the established train speeds do not decrease with such deviations belong to the I-st degree. Grade II also includes deviations that do not require a reduction in the governed trains speed, but affect the smoothness of the rolling stock and the intensity of the disruption of the track. They serve as an indicator of the need for preventive maintenance. The III-rd degree includes deviations, which, if not removed after detection, can significantly worsen the smoothness of train movement and increase the accumulation intensity of residual track deformations and some of them may even develop into deviations that cause a decrease in the train speed during the period before the next measuring car track inspection. Therefore, such deviations are eliminated as a matter of priority. The IVth degree includes deviations that cause an increase in the forces of interaction between the track and the rolling stock to values that can lead to train derailment. Therefore, when deviations of the IV degree are detected, the speed decreases or the movement of trains is closed. The assessment of the track gauge condition for track sections also is determined based on a score assessment of deviations from the standards of the track up-keep. according CP-436 Instruction. The quantitative evaluation of a section is set as the sum of all penalty points issued on a track section, given its length. The average mark of the rail track geometry deviation is set depending on its amplitude and length, the greater the deviation, the greater the value of the score assessment.

3 DISCUSSION

The assessment of the track state at the high-speed railway over time is shown in Figure 1.
Figure 1. Change in the average value of the AMDD.

The analysis of the obtained dependence clearly shows that the total number of deviations in the post-repair period is steadily decreasing. In the two year after the repair, the track stabilization is going at the same pace, regardless of the presence of geosynthetic material and by the third year of operation, the level of AMDD indicator is on average 4.9 pcs/km. Further, the standard design stabilizes at this value with a slight regression to the to the value 5.9 pcs/km by 6 years of operation. After the track adjusting, it is stabilizing for two years and the level of AMDD indicator reaches a value of 3.95 pcs/km by the by the eighth year. For a railway track with geosynthetic material, the level of AMDD indicator steadily decreases after the repair operation and by the 7th – 10th year reaches a value of 3.45 pcs/km.

Thus, the changes dynamics in the deviations number favorably distinguishes sections of the line with geomaterials.

A graphical representation of the third degree deviations changes dynamics is shown on the Figure 2.
Figure 2. Change in the average number of the third degrees' deviations by year.

Figure 2 clearly shows the effect of laying geomaterials in the sleeper bearing. On the "standard" sections, the same degree of track stabilization is achieved on the two year later compere to the "geosynthetics" sections. Deviations of the third degree, in the sections where geomaterials were laid, for the first year of post-repair operation should be associated with the stabilization of ballast materials after the technology of deep cleaning of crushed stone without removing the track. In addition, it is necessary to pay attention on additional repairs work, which was made on the fourth and seventh years on the "standard" sections.

An additional confirmation of the greater stability of the railway track with geomaterils in the substructure can be the dependences, which are shown in Figure 3.

Despite the fact that the average mark is steadily decreasing during the years after repairing works, the "standard" sections rating is always higher than "geosynthetics" sections. After the fourth year of operation, average mark for sections reinforced with geomaterials is no more than 80% of the same indicator for sections of the track without reinforcement.

To verify the geosynthetics effectiveness, the track stability of heavy-duty railway line was carried out. This line was used by trains with an axle load of 230 kN and speeds up to 80 km/h. The dynamics of changes in indicators of the state of the geometry of the track showed that both for the extracurricular high-speed first line and for the heavy–duty second line, the nature of changes in these indicators is the same.
Figure 3. Change in the average Change in the average grade by year by year.

Table 1. Changes in track geometry indicators before and after laying geomaterials.

| | Construction | |
Period	Standart	Geosynthetics
	AMDD indicator, pcs/km	
In the year before the repair	53.2	50.2
For the fifth year after the repair	20.2	14.1
Ratio, before / after	2.6	3.6
	Average mark	
In the year before the repair	90	141
For the fifth year after the repair	40	22
Ratio, before / after	2.3	6.4
	Average number of 3 degrees' deviations, pcs/ 10 km/	
In the year before the repair	6.33	15.6
For the fifth year after the repair	2.27	0.75
Ratio, before / after	2.8	20.8

The assessment generalized results of the track conditions on the second railway are shown in Table 1.

The data from the table show that the use of geomaterials is typical for problematic line sections. A year before the repair on these sections, the AMDD indicator was no more than in the "standard" sections and on the "geosynthetics" sections the number of deviations of the 3rd degree in the pre-repair year was 2.5 times more. Accordingly, the average mark of these sites was more than 1.6 times compared to "standard" sections.

The sections, where the geomaterials were laid demonstrate greater stability. In the fifth year after the repair, the average mark of this sections are 22 units, compared with 40 units for "standard" sections. The presence of third-degree deviations for sections with geosynthetic materials is characterized by an average value of 0.75 pcs / 10km. For "standard" sections, this value is 2.3 pcs/10 km, the values are given for the fifth year of operation after repairing.

To assess the impact of geomaterials on the track settlement five level control operations were carried out on "standard and "geosynthetics" sections. The length of the work section was 408m. The reinforced part was located in the center of the section.

In order to identify the effect of stabilization by geosynthetics on the long-term behavior of the track geometry, high-precision level control of railhead was carried out. After the completion of repair work in 21 days, the average track deformation on the "standard" section was 11 mm, compare to 8 mm at the "geosynthetics" section. After the stabilization of the track for 51 days, the track deformation was 20mm on the "standard" section and 7 mm on the "geosynthetics" section. Such differences in the values of rail deformations may be due to the different time elapsed between the tamping and the leveling work. Thus, at the initial stage of railway track stabilization, the track settlement in the section, stabilized by geosynthetics, decreases by 1.6 times, and after track stabilization by 2.9 times.

Therefore, it can be said that afterwards the track stabilization after repair work, on average, in one day, the track settles are by 0.38 mm on the non-reinforced section and by 0.14 mm on the reinforced one. Thus, the accumulation degree of residual deformations over time at the section, stabilized by geosynthetics, is 2.7 times lower than in the usual one.

The uniformity assessment of the track depression along its length showed that the deformation is more uniform on the reinforced segment of the railway line than on the non-reinforced one. Indeed, within the "standard" section maximum deviation from the average settlement was 9 mm after 21 days and 22 mm after 51 days, which is 2.4 times higher. Consequently, the longer the time interval, the greater the difference in track lowering in individual sections. On the "geosynthetics" section the maximum deviation from the average settlement was 5 mm and 7 mm, respectively, i.e. 1.4 times more. Thus, the subsidence unevenness in the "geosynthetics" section is 1.7 times lower compared to the usual one.

This is one of the positive properties of geomaterials, allowing achieving deflection uniformity in the longitudinal direction, which naturally will not lead to a significant longitudinal profile distortion and of course will reduce the cost of the current maintenance of the railway track by reducing the number of surfacing works by about half.

Landfills and remediation of contaminated sites

Hydraulic performance of Na CMC-added GCLs permeated with a simulated leachate at different temperatures

H.O. Ozhan*
Civil Engineering Department, Yeditepe University, Inonu Mah., Kayisdagi Cad., Atasehir-Istanbul, Turkey

ABSTRACT: In this study, triaxial permeability and free swell tests were performed on a geosynthetic clay liner (GCL) that had Ca bentonite and was enhanced with the biopolymer, sodium carboxymethyl cellulose (Na CMC) with a concentration of 0.25, 0.5, 1, 2, 5 and 10% by dry mass respectively. The GCL specimens were permeated with a simulated acidic leachate at a temperature of 20, 40, 60 and 80°C. Test results indicated that the temperature increase leaded to an increase in both the permeability and the swell index. As the temperature was increased from 20 to 80°C, the permeability increased by up to 1.5 orders of magnitude. Furthermore, 2% Na CMC was found to be the optimum concentration in the bentonite component of the GCL. 2% Na CMC addition caused the permeability to decrease from 9.81×10^{-7} to 2.24×10^{-8} m/s and the swell index to increase from 8.5 to 13.5 ml/2g at 80°C.

1 INTRODUCTION

Geosynthetic clay liners (GCLs) are barrier materials that are typically placed in landfills and other waste containment areas such as heap leach pads and mine tailings dams (Kang & Shackelford 2010; Rowe & Abdelatty 2012). Due to the biological decomposition of the organic substances in a waste containment area, the temperature of the leachate might exceed 60°C (Reinhart *et al.* 2020) and in some cases, might increase up to 80°C (Bouazza *et al.* 2014). Ishimori and Katsumi (2012) conducted permeability tests on a GCL that consisted of Na bentonite and permeated with 0.4 M NaCl solution. Permeability coefficient of the GCL was measured almost 1 order of magnitude higher at 60°C than at 20°C. Generally, Na bentonite is preferred to be used as the bentonite component of a GCL due to its lower permeability and higher swell index than Ca bentonite. However, polymer-enhanced Ca bentonite can effectively be used as a barrier material in waste containment facilities (Ozhan 2022; Razakamanantsoa *et al.* 2012). The primary reason for adding a polymer to Ca bentonite is to decrease the permeability in order to provide sufficient barrier capability.

Biopolymers are the organic products that are obtained from the bodies of plants or animals. They don't contribute to the carbon emission and thus, don't contaminate the environment. Carboxymethyl cellulose (CMC) is an anionic biopolymer and a derivative of cellulose obtained from the cell walls of plants (Chen 2015). De Camillis *et al.* (2016) performed hydraulic conductivity tests on Na bentonite. The bentonite specimens were enhanced with Na CMC and permeated with seawater. According to the test results, 2% Na CMC addition by dry mass caused approximately 3 orders of magnitude decrease in hydraulic conductivity when the specimens were subjected 4 wet-dry cycles in a permeation period of almost 100 days. Di Emidio *et al.* (2015) conducted hydraulic conductivity tests on Na CMC-added GCLs that consisted of Na bentonite. The GCLs were permeated with CaCl$_2$ solutions during a period of

*Corresponding Author: hakki.ozhan@yeditepe.edu.tr

more than 800 days. Test results indicated that Na CMC enhancement caused decrease in the hydraulic conductivity and increase in the swell index.

One of the primary objectives of this study was to investigate the effect of temperature increase of a simulated leachate on the hydraulic properties of a GCL that was composed of Ca bentonite. The other main objective was to determine the optimum concentration of Na CMC in the Ca bentonite of the GCL in terms of permeability and swell index. For these reasons, triaxial permeability and free swell tests were conducted on the GCLs that were enhanced with 0.25, 0.5, 1, 2, 5 and 10% Na CMC by dry mass respectively. The GCLs were permeated with a simulated leachate for 50 days at a temperature of 20, 40, 60 and 80°C respectively.

2 MATERIALS

The GCL used in this study was manufactured without any reinforcement. The Ca bentonite layer was placed between a woven and a nonwoven geotextile. The woven geotextile component of the GCL was a woven slit-film polypropylene geotextile whereas the nonwoven geotextile had needle-punched polypropylene texture. The bentonite component of the GCL was a powdered Ca bentonite. The engineering properties of the geotextile components of the GCL were listed in Table 1. The Ca bentonite component of the GCL had swell index of 20 ml/2g and montmorillonite content of 85%. The liquid limit and plastic limit of the bentonite were 141 and 41% respectively.

Table 1. Engineering properties of the geotextiles used in the GCL.

Property	Woven Geotextile	Nonwoven Geotextile	Test Method
Mass per unit area (g/m^2)	108	203	ASTM D5261
Apparent opening size (mm)	0.425	0.212	ASTM D4751
Tensile strength (kN/m)	12.2	15.4	ASTM D4595
Elongation (%)	10	45	ASTM D4595

The biopolymer that was added to the bentonite component of the GCL was chosen as Na CMC. CMC is manufactured by the catalytic reaction between cellulose and chloroacetic acid. Na CMC is the salt obtained from CMC. Na CMC is an anionic water-soluble polymer that is primarily used as a thickener and stabilizer in food, textiles, cosmetics and oil. Na CMC has molecular weight and formula of approximately 90000g/mol and $[C_6H_7O_2(OH)_2CH_2COONa]_n$ respectively (Chen 2015).

The fluid that was permeated through the GCL specimens in both the triaxial permeability and the free swell tests was chosen as a simulated leachate that had ion concentrations of 1700 mg/l Mg^{2+}, 240 mg/l Ca^{2+}, 45 mg/l K^+, 27 mg/l Al^{3+}, 5200 mg/l SO_4^{2-}, 430 mg/l NO_3^-. The simulated leachate represented an aggressive acidic leachate that could be collected in a waste containment area. The simulated leachate had pH value of 3.7.

3 TESTING PROCEDURE

3.1 *Triaxial permeability tests*

In order to prepare the GCL specimens, the geotextiles were cut with a diameter of 100 mm. The Ca bentonite that had mass/area of 4800 g/m^2 was placed on the nonwoven geotextile and wetted with tap water homogeneously. Afterwards, the woven geotextile was placed over the bentonite. Both of the geotextiles were bounded to the wetted bentonite without any reinforcement (Ozhan & Guler 2016, 2013; Ozhan 2011). The predetermined amount of Na CMC was poured into deionized water at a temperature of 60°C. Then, the water with the Na CMC was shaken for 30 minutes with a paddle mixer. The predetermined amount of Ca

bentonite was mixed with the Na CMC-added water homogeneously for 3 hours by using a paddle mixer. Then, the mixture was oven-dried for 24 hours at a temperature of 105°C. Afterwards, the dried Na CMC-added Ca bentonite was sieved through #200 sieve (Di Emidio 2010). The Na CMC-enhanced Ca bentonite was also bounded to the geotextile components of the GCL by following the same procedure as described for the Ca bentonite without any polymer addition. The concentration of Na CMC in the bentonite component of the GCL was taken as 0.25, 0.5, 1, 2, 5 and 10% by dry mass respectively.

After the specimen preparation, the GCL was placed in the flexible wall permeameter cell. From top to bottom, the test setup consisted of the top cap, porous stone, filter paper, GCL specimen, filter paper, porous stone and the base cap. The permeameter cell was filled with tap water and then, saturation and consolidation of the GCL specimen were completed by increasing the cell pressure to 550 kPa and the back pressure to 515 kPa. During these stages, the pressures remained constant for a period of 48 hours. Then, the permeation of the simulated leachate from the top of the GCL specimen to the bottom was initiated by increasing the influent pressure at the top to 518 kPa while the effluent pressure was kept constant as 515 kPa (ASTM D 6766 2012). The permeability values of the GCL specimens were measured according to Equation 1 as follows:

$$k = \frac{\Delta Q.L}{\Delta h \cdot \Delta t \cdot A} \tag{1}$$

Where k (m/s) is the coefficient of permeability of the GCL, ΔQ (m^3) is the average of leachate flow rate through the GCL for a specific period time, L (m) is the thickness of the GCL specimen, Δh (m) is the leachate head acting on the GCL, Δt (s) is the period over which the leachate is permeated through the GCL and A (m^2) is the cross-sectional area of the GCL that is perpendicular to the flow.

In order to set the temperature of the leachate to the desired values, the permeameter cell was placed in a stainless steel tank that had heater inside. The tank was filled with the simulated leachate and the permeameter cell was kept in the fluid. Afterwards, the temperature of the leachate was set to 20, 40, 60, and 80°C respectively. The temperature was able to be measured by a digital thermometer that was placed in the outlet tube of the effluent pressure valve.

3.2 *Free swell tests*

For evaluating the hydraulic performance of Na CMC-added GCLs at different temperatures, free swell tests were also conducted on the bentonite components of the GCLs (ASTM D5890 2011). The oven-dried Na CMC-Ca bentonite mixtures were prepared according to Di Emidio (2010). Each mixture that had a mass of 2 g was poured into the graduated cylinder that was filled with the simulated leachate. The swell index (2g/ml) values of the Na CMC-added bentonite specimens were measured after a period of 72 hours due to a possible ongoing swell even after 24 hours (ASTM D5890 2011). Similar to the temperature programming that was conducted in the triaxial permeability tests, the graduated cylinders were also sunk into the water tanks that were filled with the simulated leachate and the temperature of the leachate was set to 20, 40, 60, and 80°C respectively.

4 TEST RESULTS AND DISCUSSION

4.1 *Triaxial permeability tests*

As shown in Figure 1, temperature increase in the simulated leachate leaded to an increase in the permeability of the GCLs. The rate of increase was higher between 20 and 40°C. As a
Figure 1. Coefficient of permeability change with respect to Na CMC concentration at different temperatures.

result, when the temperature of the simulated leachate was raised from 20 to 80°C, the permeability of the GCL increased almost 1.5 orders of magnitude. For instance, 2% Na CMC-added GCL had permeability of 7.32×10^{-10} m/s at 20°C whereas the permeability of 2% Na CMC-added GCL was measured as 2.24×10^{-8} m/s at 80°C.

The increase in the permeability of the GCL due to the temperature increase of the simulated leachate can be attributed to the weaker interaction between the leachate and the bentonite grains. Temperature increase might lead to a repulsive zone among the colloids in the leachate (Wang *et al.* 2016). Moreover, the weak interaction between the simulated leachate and the bentonite grains of the GCL might cause the frictional resistance of the leachate to decrease. This behavior can be explained by a decrease in the viscosity of the simulated leachate due to an increase in the temperature (Wang *et al.* 2016).

The optimum Na CMC concentration in the Ca bentonite of the GCL was found to be 2% by dry mass as shown in Figure 1. The permeability of the GCL without Na CMC enhancement decreased by 1.7 orders of magnitude when 2% Na CMC was added to the GCL. However, further increase in Na CMC concentration caused almost no change in permeability. For example, the permeability of the GCL was measured as 9.81×10^{-7} m/s at 80°C. 0.5% and 2% Na CMC-added GCLs had permeability values of 2.34×10^{-7} and 2.24×10^{-8} m/s respectively. However, the permeability of 10% Na CMC-added GCL was measured as 2.01×10^{-8} m/s.

The interaction of Na CMC with the simulated leachate might have resulted in the formation of hydrogels and these hydrogels have the capability to clog the pores among the bentonite grains. The decrease in the permeability of Na CMC-added GCLs can be attributed to the clogging of these pores. 2% of Na CMC by dry mass was found to be the approximate concentration for clogging the pores among the bentonite grains.

As can be seen in Figure 2, the permeability of the tested GCLs increased drastically during the first 20 days of permeation due the ion exchange between the cations in the simulated leachate and the bentonite component of the GCL. The rate of increase in permeability was even higher at higher temperatures. The permeability of 2% Na-CMC-added GCL was almost 1.8 orders of magnitude higher after a permeation period of 20 days at 80°C. Although the rate of increase in permeability decreased as time passed, the permeability of 2% Na CMC-added GCL was measured 0.5 order of magnitude higher at a permeation period of 50 days when compared with that of 20 days as shown in Figure 2. However, the change in the permeability value of the GCL was even lower than 0.1 order of magnitude during the last 10 days of permeation. As a result, a permeation period of 50 days could be considered as the optimum period for the termination of the ion exchange between the bentonite and the simulated leachate. Furthermore, the stable trend after a period of 40-50 days of permeation could indicate that almost no biodegradation occurred within this period. Otherwise, a significant increase in permeability could take place.
Figure 2. Coefficient of permeability change with respect to time at different temperatures for 2% Na CMC-added GCL.
Figure 3. Swell index change with respect to Na CMC concentration.

4.2 Free swell tests

Due to an increase in the temperature of the simulated leachate, the swelling capability of the GCL was enhanced and the rate of increase in the swell index was found to be the highest up to the concentration of 2% Na CMC by mass as shown in Figure 3. The swell index of the GCL without Na CMC enhancement was measured as 8.5 ml/2g at 80°C. 2% Na CMC addition caused the swell index to increase up to 13.5 ml/2g. Finally, the swell index of 10% Na CMC-added GCL was found to be 14.5 ml/2g. On the other hand, 2% Na CMC-added GCL had swell index of 9, 10.5, 12.5 and 13.5 ml/2g at 20, 40, 60 and 80°C respectively. The test results showed that the behavior of the permeability was inversely proportional with that of the swell due to an increase in the temperature of the permeation fluid. This correlation was because of a possible decrease in the viscosity of the permeation fluid that caused both increase in the void size and expansion of the bentonite grains (Ishimori & Katsumi 2012).

5 CONCLUSIONS

An increase in the temperature of the simulated leachate caused the permeability of the GCL to increase. The rate of increase was higher between 20 and 40°C when compared with that between 40 and 60°C or 60 and 80°C. As a result, when the temperature was increased from 20 to 80°C, the permeability increased by a magnitude of almost 1.5 orders.

The deterioration of the hydraulic performance of the GCL was due to the increase in the temperature and also due to the interaction of the GCL with the simulated leachate. Na CMC addition to the GCL resulted in a decrease of 1.7 orders of magnitude in permeability. A concentration of 2% Na CMC by dry mass was found to be the optimum amount.

Due to the increase in the temperature of the simulated leachate, the swell index of the Ca bentonite in the GCL increased.

Na CMC addition leaded to an increase in the swell index of the Ca bentonite. 2% Na CMC addition caused the swell index to increase from 8.5 to 13.5 ml/2g at a temperature of 80°C.

In conclusion, the temperature increase of the simulated leachate deteriorated the hydraulic performance of the GCL by increasing the permeability. Na CMC is an environmentally friendly organic polymer that does not contribute to the carbon footprint. Na CMC addition to the Ca bentonite component of the GCL resulted in an enhancement in the hydraulic performance of the GCL by decreasing the permeability and increasing the swell index even at high temperatures.

Contaminant transport through landfill composite liners due to geomembrane defects

N. Guarena, A. Dominijanni & M. Manassero
Politecnico di Torino, Torino, Italy

ABSTRACT: Although a number of studies have been devoted to the assessment of the leachate flow rate through defects in geomembranes, which are routinely used in conjunction with low-permeability mineral layers for the lining of waste disposal facilities, relatively little attention has been paid to the mechanisms that control the transport of contaminants. A theoretical framework is here presented to model the advective-diffusive transport of inorganic contaminants through defects of uniform width and infinite length (holed wrinkles, defective seams, etc.), whereby imperfect contact conditions between the geomembrane and the underlying mineral layer are considered, and the mass conservation condition is imposed for both the solvent and the solute phases. Closed-form analytical solutions have been derived to assess the contaminant mass flow rate for the cases of pure advection and pure diffusion, with a view to quantifying the error associated with the simplified calculation approaches that are currently adopted for the performance-based design of landfill composite liners.

1 INTRODUCTION

Composite liners that include a high-density polyethylene (HDPE) geomembrane (GM), placed over a compacted clay layer (CCL), are prescribed throughout the world for the bottom lining systems of waste disposal facilities, with the goal of minimising the migration of contaminants from the waste fill to the surrounding environment. The regulations in force in many countries typically define a set of minimum requirements that have to be satisfied by both the GM and the CCL layers, depending on the type of waste that has to be disposed of in the landfill. In some cases the presence of a natural or engineered attenuation layer (AL), i.e., a layer of soil placed between the composite liner and the underlying aquifer or water resource that needs to be protected, represents an additional requirement.

The use of alternative lining systems, such as those in which the CCL is replaced with a geosynthetic clay liner (GCL), is permitted in most regulations, provided that equivalency with the prescribed composite liner is demonstrated on the basis of a selected performance criterion. Some of the common performance criteria, which are adopted to demonstrate that the proposed alternative liner is equivalent to, or better than, the prescribed composite liner, include: (1) the leachate flow rate under steady-state conditions; (2) the mass flow rate of a given contaminant under steady-state conditions; (3) the time required for the concentration of a given contaminant to reach a specified value at the bottom of the barrier; and (4) the time required for the mass flow rate of a given contaminant to reach a specified value at the bottom of the barrier (Katsumi *et al.* 2001; Manassero *et al.* 2000; Rowe & Brachman 2004; Shackelford 1990).

As far as the first of the aforementioned performance criteria is concerned, which is closely related to the steady-state advective travel time through the composite liner (Shackelford 1993), several approaches have been developed to calculate the leachate flow rate since the pioneering study of Giroud & Bonaparte (1989), who recognised that intact GMs are nearly impervious to the

liquid flow and, therefore, the only accessible pathway by which the leachate can migrate through landfill composite liners is through defects in the GM layer (e.g. defective seams between adjacent panels, punctures caused by sharp materials beneath and above the GM, and tensile failures induced by the landfilling operations). Rowe (1998) and Touze-Foltz *et al.* (1999, 2001) derived analytical solutions for the leakage rate under the assumption that, after infiltration through the GM defect, the contaminated liquid spreads horizontally in the interfacial zone between the GM and the low-permeability mineral layer up to a certain distance from the defect, prior to percolating vertically through the low-permeability mineral layer. The ability of Rowe's (1998) solutions to represent the actual three-dimensional (3D) flow regime within the composite liner was verified numerically by Foose *et al.* (2001a), who observed that analytical and numerical models yield nearly identical results for the values of the hydraulic transmissivity of the interface and the hydraulic conductivity of the low-permeability mineral layer that are representative of field scenarios. Other numerical studies have addressed specific issues, such as the effects related to the spatial variability in the hydraulic transmissivity of the GM/CCL interface (Cartaud *et al.* 2005a), to the change in the degree of saturation of the mineral layer and to the shape of longitudinal defects of finite length in the GM layer (Cartaud *et al.* 2005b; Saidi *et al.* 2006), to the hydraulic interaction between adjacent defects in the GM layer (Saidi *et al.* 2008), and to the different hydraulic properties of the geotextile and bentonite components of GCLs under unsaturated conditions (Bannour *et al.* 2016). Empirical (Giroud 1997; Touze-Foltz & Giroud 2003, 2005) and semi-empirical solutions (Foose *et al.* 2001a; Giroud & Touze-Foltz 2005) were developed using interpolation methods that combine theoretical (both analytical and numerical) and experimental results, thus providing design engineers with simple equations that allow the leachate flow rate to be assessed once a limited number of input parameters (i.e. the hydraulic head on top of the GM, the area of circular defects or the width of longitudinal defects, and the hydraulic conductivity of the mineral layer) and the contact conditions between the GM and the mineral layer are known.

Compared to the numerous attempts that have been made to propose a rational method to assess the leachate flow rate through composite liners, relatively few studies have been aimed at quantifying the advective-diffusive transport of contaminants in the presence of defects in the GM layer. The latter issue is particularly relevant in the case of inorganic compounds, which, unlike many organic compounds, do not readily diffuse through intact portions of the GM layer. Therefore, although the transport of organic compounds can be modelled under the hypothesis of molecular diffusion being the primary migration pathway over the entire surface of the composite liner (Foose 2002; Foose *et al.* 2002) when GMs are installed under strict construction quality assurance conditions (i.e. with a defect frequency ranging from 2.5 to 5 holes/ha, as reported by Rowe (2012)), the transport of inorganic compounds should be recognised as a 3D process that involves migration through the GM defects, through the interfacial zone between the GM and the underlying mineral layer and, finally, through the mineral layer itself, via a combination of advection and diffusion.

A simplified approach to model the advective-diffusive transport of inorganic contaminants through composite liners was proposed by Katsumi *et al.* (2001), who identified an equivalent one-dimensional (1D) system for which analytical solutions to the contaminant breakthrough time and mass flux exist. This approach, which has since been implemented in a number of analytical studies that have dealt with the performance-based design of landfill lining systems, allows both steady-state (Dominijanni & Manassero 2021; Dominijanni *et al.* 2021; Foose 2010; Guarena *et al.* 2020) and transient-state contaminant transport analyses (Foose *et al.* 2001b; Kandris & Pantazidou 2012) to be carried out using typical spreadsheet applications and hand-held calculators, and the equivalence between the prescribed and alternative lining systems to be assessed on the basis of performance criteria (2) to (4), which are preferable over the advective travel time criterion (1) since diffusion is a significant, if not the dominant, transport mechanism through composite liners (Foose *et al.* 2002; Manassero & Shackelford 1994; Shackelford 2014). Furthermore, such an approach may be used as an effective tool to verify the results of more complex (fully 3D) and computationally rigorous numerical models.

Despite its simplicity and versatility, the Katsumi *et al.* (2001) approach is not devoid of drawbacks, the most serious of which can probably be ascribed to the way the equivalent 1D system is defined. Although, on the one hand, satisfaction of the mass conservation condition for the solvent phase is guaranteed with regard to the analytical or empirical model that is selected to calculate the leachate flow rate, on the other, the mass conservation condition for the solute phase is disregarded, and an error is therefore made in the predicted contaminant mass flux relative to the theoretically correct solution. With the aim of covering this modelling gap, a novel theoretical framework is outlined in the present paper, in which the 3D advective-diffusive transport of inorganic contaminants within the composite liner is conceptualised as a horizontal flow along the interface between the GM and the low-permeability mineral layer and then a vertical flow in the low-permeability mineral layer, in a similar way to the reference scheme that was considered by Rowe (1998) with a view to approximating the actual leachate flow network under imperfect contact conditions at the GM/CCL or GM/GCL interface. The error that can arise from the adoption of the Katsumi *et al.* (2001) approach is estimated on the basis of closed-form analytical solutions to the contaminant mass flow rate for the cases of pure advection and pure diffusion, assuming that steady-state conditions have been achieved for both the liquid and solute transport.

2 MODELLING THE ADVECTIVE-DIFFUSIVE TRANSPORT OF INORGANIC CONTAMINANTS THROUGH COMPOSITE LINERS

The containment performance of landfill composite liners is known to be affected by the areal density of wrinkles in the GM layer, whose formation is mostly controlled, during construction of the liner, by the thermal expansion of the GM upon heating by solar radiation, as well as by its placement and protection procedures (Chappel *et al.* 2012; Giroud & Morel 1992; Rowe 2005, 2012). Indeed, because of the greater hydraulic transmissivity of the gap beneath the wrinkles than that associated with the interfacial zone between the GM and the low-permeability mineral layer, contaminants preferentially migrate through holes that are located in correspondence to the wrinkles rather than through holes that occur in flat areas. The following theoretical framework has thus been developed only for the case of a damaged wrinkle, whose width, $2b_w$, is defined as the width of the zone where the GM is not in contact with the underlying mineral layer (Figure 1), as this is the one of the greatest concerns about the problem of assessing the ability of the selected composite liner to limit contaminant transport from the waste fill. Nonetheless, if the liquid and contaminant transport rates are not controlled by the size of the actual holes in the wrinkle, the case of a damaged wrinkle is perfectly analogous to the case of a cut, tear or defective seam of width $2b_w$ occurring in a flat area of the GM layer, so that the two types of defects can collectively be referred to as defects of uniform width. Moreover, if the
Figure 1. Reference scheme for the liquid and contaminant transport analyses through a composite liner with a defect of uniform width and infinite length in the GM layer and imperfect contact conditions between the GM and the low-permeability mineral layer (not to scale).

length of the defect, L_w, is much greater than its width (i.e. defect of uniform width and infinite length), the liquid and contaminant transport analyses can be treated as two-dimensional problems (Giroud & Touze-Foltz 2005; Touze-Foltz *et al.* 1999).

Provided the spacing between adjacent wrinkles is high enough for their mutual interactions to be neglected, Rowe's (1998) analytical solution to the steady-state hydraulic head profile, h, beneath the GM can be written in the following form:

$$h(\xi) = \begin{cases} h_p & \text{if } \xi \le b_w \\ \left(H_f + H_m - h_b + h_p\right)e^{-\alpha(\xi - b_w)} - \left(H_f + H_m - h_b\right) & \text{if } \xi > b_w \end{cases} \tag{1}$$

The α parameter that appears in Equation 1 is given by:

$$\alpha = \sqrt{\frac{k_s}{(H_f + H_m)\theta_h}} \tag{2}$$

where θ_h is the hydraulic transmissivity of the interfacial zone between the GM and the low-permeability mineral layer, and k_s is the equivalent hydraulic conductivity corresponding to the low-permeability mineral layer (saturated hydraulic conductivity k_m) and the attenuation layer (saturated hydraulic conductivity k_f):

$$k_s = \frac{H_f + H_m}{\frac{H_f}{k_f} + \frac{H_m}{k_m}} \tag{3}$$

The horizontal leachate flow rate in the transmissive layer, Q_ξ, at a distance $\xi > b_w$ from the longitudinal axis of the wrinkle, can be expressed as:

$$Q_\xi(\xi) = L_w i_s \frac{k_s}{\alpha} e^{-\alpha(\xi - b_w)} \tag{4}$$

where i_s is the maximum mean hydraulic gradient through the low-permeability mineral layer and the attenuation layer:

$$i_s = 1 + \frac{h_p - h_b}{H_f + H_m} \tag{5}$$

The vertical leachate flow rate, dQ_s, that infiltrates the strip of the mineral layer between the ξ and $\xi + d\xi$ coordinates can be expressed as:

$$dQ_s(\xi) = \begin{cases} L_w i_s k_s d\xi & \text{if } \xi \le b_w \\ L_w i_s k_s e^{-\alpha(\xi - b_w)} d\xi & \text{if } \xi > b_w \end{cases} \tag{6}$$

and the corresponding vertical volumetric leachate flux, q_s, at a distance ξ from the longitudinal axis of the wrinkle, is obtained directly as the ratio of dQ_s to $L_w d\xi$:

$$q_s(\xi) = \begin{cases} i_s k_s & \text{if } \xi \le b_w \\ i_s k_s e^{-\alpha(\xi - b_w)} & \text{if } \xi > b_w \end{cases} \tag{7}$$

Finally, the leachate flow rate, Q_s, that infiltrates the low-permeability mineral layer at a distance ξ from the longitudinal axis of the wrinkle is given by:

$$Q_s(\xi) = 2b_w L_w i_s k_s \left\{ 1 + \frac{1}{\alpha b_w}\left[1 - e^{-\alpha(\xi - b_w)}\right] \right\} \tag{8}$$

which yields the total leachate flow rate through the damaged wrinkle, Q, if ξ tends to infinity:

$$Q = 2b_w L_w i_s k_s \left(1 + \frac{1}{\alpha b_w}\right) \tag{9}$$

2.1 *Katsumi* et al. *(2001) equivalent 1D system*

The approach that was proposed by Katsumi *et al.* (2001), with the aim of providing a simple calculation tool to analyse the transport of inorganic contaminants through composite liners when the leachate flow is at steady state, consists in computing an equivalent area, A_e, which conducts the same (total) leachate flow rate as the considered defect for the same hydraulic head drop across the composite liner, thereby ensuring that the mass conservation condition for the solvent phase is satisfied:

$$A_e = \frac{Q}{k_s i_s} \tag{10}$$

The equivalent area that is computed according to Equation 10 is here observed to correspond to the definition of the wetted area originally provided by Giroud *et al.* (1992, 1997). Furthermore, if Rowe's (1998) conceptual model is adopted to assess the leachate flow rate, the following expression results from substitution of Equation 9 in Equation 10:

$$A_e = 2b_w L_w \left(1 + \frac{1}{\alpha b_w}\right) \tag{11}$$

and the contaminant mass flow rate through the damaged wrinkle, J_{app}, which approximates the theoretically correct one, can then be obtained from the contaminant mass flux, j_s, which in turn is calculated according to the existing analytical solutions to the partial differential equation that governs the 1D solute transport through multi-layered barriers via advection, diffusion, sorption and degradation:

$$J_{app} = A_e j_s \tag{12}$$

When the contaminant transport is dominated by advection, and steady-state conditions are achieved for both the liquid and the solute transport, the following expression of Equation 12 holds true:

$$J_{app} = 2b_w L_w k_s i_s c_p \left(1 + \frac{1}{\alpha b_w}\right) \tag{13}$$

where c_p is the contaminant concentration in the leachate drainage layer, which is located directly above the GM layer.

If the diffusive component of contaminant transport prevails over the advective one, Equation 12 assumes the following form:

$$J_{app} = 2b_w L_w \Lambda (c_p - c_b) \left(1 + \frac{1}{\alpha b_w}\right) \tag{14}$$

where c_b is the contaminant concentration at the bottom of the composite liner, and Λ is the equivalent diffusivity (Manassero & Shackelford 1994; Manassero *et al.* 2000):

$$\Lambda = \frac{1}{\frac{H_f}{n_f D_f^*} + \frac{H_m}{n_m D_m^*}} \tag{15}$$

being n_m and n_f the porosities of the low-permeability mineral layer and the attenuation layer, respectively, and D_m^* and D_f^* the effective diffusion coefficients of the low-permeability mineral layer and the attenuation layer, respectively, which are obtained as the product of the apparent tortuosity factor (< 1) and the free-solution diffusion coefficient of the contaminant, $D_{s,0}$.

2.2 *Novel theoretical framework*

The theoretical framework outlined in this section should be interpreted as an attempt to overcome the limitations encountered in the Katsumi *et al.* (2001) approach, and to investigate

the extent to which this latter approach approximates the actual transport mechanisms of inorganic contaminants through landfill composite liners with defects in the GM layer.

Satisfaction of the mass conservation condition for the solute phase is guaranteed under steady-state conditions, with reference to the control volume in the interfacial zone between the GM and the low-permeability mineral layer (Figure 1), if the following relationship is verified:

$$dJ_s(\xi) + \frac{dJ_\xi(\xi)}{d\xi}d\xi = 0 \tag{16}$$

The vertical contaminant mass flow rate, dJ_s, that infiltrates the strip of the mineral layer between the ξ and $\xi + d\xi$ coordinates can be expressed as:

$$dJ_s(\xi) = q_s \frac{ce^{\frac{q_s}{\Lambda}} - c_b}{e^{\frac{q_s}{\Lambda}} - 1}L_w d\xi \tag{17}$$

or, substituting Equation 7 in Equation 17, in the following alternative form:

$$dJ_s(\xi) = \begin{cases} i_s k_s \dfrac{c_p e^{\frac{i_s k_s}{\Lambda}} - c_b}{e^{\frac{i_s k_s}{\Lambda}} - 1}L_w d\xi & \text{if } \xi \leq b_w \\[3em] i_s k_s e^{-\alpha(\xi-b_w)} \dfrac{ce^{\frac{i_s k_s}{\Lambda}e^{-\alpha(\xi-b_w)}} - c_b}{e^{\frac{i_s k_s}{\Lambda}e^{-\alpha(\xi-b_w)}} - 1}L_w d\xi & \text{if } \xi > b_w \end{cases} \tag{18}$$

where c is the contaminant concentration beneath the GM.

The horizontal contaminant mass flow rate in the transmissive layer, J_ξ, at a distance $\xi > b_w$ from the longitudinal axis of the wrinkle, can be expressed as:

$$J_\xi(\xi) = Q_\xi c - L_w \theta_d \frac{dc}{d\xi} \tag{19}$$

or, substituting Equation 4 in Equation 19, in the following alternative form:

$$J_\xi(\xi) = L_w i_s \frac{k_s}{\alpha}ce^{-\alpha(\xi-b_w)} - L_w \theta_d \frac{dc}{d\xi} \tag{20}$$

where θ_d is the diffusive transmissivity of the GM/CCL or GM/GCL interface.

Substituting Equations 18 and 20 in Equation 16 and collecting terms yields the following homogeneous, second-order, linear ordinary differential equation with non-constant coefficients:

$$\frac{d^2c}{d\xi^2} - \frac{i_s k_s}{\theta_d \alpha}e^{-\alpha(\xi-b_w)}\frac{dc}{d\xi} - \frac{i_s k_s}{\theta_d}\left[\frac{e^{-\alpha(\xi-b_w)}}{e^{\frac{i_s k_s}{\Lambda}e^{-\alpha(\xi-b_w)}} - 1}\right](c - c_b) = 0 \tag{21}$$

which has to be solved for $b_w \leq \xi < +\infty$ in conjunction with the following set of boundary conditions:

$$\begin{cases} c(b_w) = c_p \\ \lim_{\xi \to +\infty} \dfrac{dc}{d\xi}(\xi) = 0 \end{cases} \tag{22}$$

Once the steady-state contaminant concentration profile beneath the GM has been determined, either analytically or numerically, the contaminant mass flow rate, J_s, that infiltrates the low-permeability mineral layer at a distance ξ from the longitudinal axis of the wrinkle is given by:

$$J_s(\xi) = 2b_w L_w i_s k_s c_p \left\{ \frac{e^{\frac{i_s k_s}{\Lambda}} - \frac{c_b}{c_p}}{e^{\frac{i_s k_s}{\Lambda}} - 1} + \frac{1}{\alpha b_w}\left[1 - \frac{c(\xi)}{c_p}e^{-\alpha(\xi-b_w)}\right] - \frac{\theta_d}{b_w i_s k_s c_p}\left[\frac{dc}{d\xi}(b_w) - \frac{dc}{d\xi}(\xi)\right]\right\} \tag{23}$$

which yields the total contaminant mass flow rate through the damaged wrinkle, J, if ξ tends to infinity:

$$J = 2b_w L_w i_s k_s c_p \left[\frac{e^{\frac{i_s k_s}{\Lambda}} - \frac{c_b}{c_p}}{e^{\frac{i_s k_s}{\Lambda}} - 1} + \frac{1}{\alpha b_w} - \frac{\theta_d}{b_w i_s k_s c_p} \frac{dc}{d\xi}(b_w) \right] \tag{24}$$

2.2.1 Closed-form analytical solution for the case of pure advection

A first case of interest, for which a closed-form analytical solution to the total contaminant mass flow rate is easily obtained, is that of the advection that represents the main transport mechanism through the composite liner. Under such an assumption, Equations 21 and 22 reduce to a condition of constant solute concentration beneath the GM (i.e. $c = c_p$ for $b_w \leq \xi < +\infty$), and the total contaminant mass flow rate through the damaged wrinkle is then given by a relationship that is identical to Equation 13. Therefore, for the limiting case of purely advective transport, the Katsumi *et al.* (2001) approach leads to a prediction of the contaminant mass flow rate that can be regarded as the rigorous one from the mass conservation condition viewpoint, for both the solvent and the solute phases.

2.2.2 Closed-form analytical solution for the case of pure diffusion

When diffusion is the controlling mechanism of contaminant transport, as might be the case of composite liners that include mineral layers with very low hydraulic conductivity values (e.g. GCLs or bentonite-amended CCLs), the steady-state contaminant concentration profile beneath the GM assumes a form that is analogous to the hydraulic head profile given by Equation 1:

$$c(\xi) = \begin{cases} c_p & \text{if } \xi \leq b_w \\ (c_p - c_b)e^{-\beta(\xi - b_w)} + c_b & \text{if } \xi > b_w \end{cases} \tag{25}$$

where:

$$\beta = \sqrt{\frac{\Lambda}{\theta_d}} \tag{26}$$

The following expression can then be derived for the total contaminant mass flow rate through the damaged wrinkle:

$$J = 2b_w L_w \Lambda (c_p - c_b) \left(1 + \frac{1}{\beta b_w} \right) \tag{27}$$

Finally, the error that arises when the Katsumi *et al.* (2001) approach is used, relative to the theoretically correct solution for the limiting case of purely diffusive transport, is assessed by finding the ratio of Equation 27 to Equation 14:

$$\frac{J}{J_{app}} = \frac{1 + \frac{1}{\beta b_w}}{1 + \frac{1}{\alpha b_w}} \tag{28}$$

With the aim of quantifying the aforementioned error for a real pollutant containment scenario, the two landfill composite liners described by Dominijanni & Manassero (2021) have been considered herein, and cadmium (Cd^{2+}) has been selected to represent the inorganic leachate constituent of interest ($D_{s,0} = 7.17 \cdot 10^{-10}$ m²/s). The first lining system consists of a 1.5 mm thick GM and a 1 m thick CCL, which overlies a 3 m thick AL. The second lining system consists of a 1.5 mm thick GM and a 1 cm thick GCL, which overlies a 4 m thick AL. Further details about the physical, hydraulic and transport parameters assigned to the two composite liners can be found in Dominijanni & Manassero (2021), while an

assessment of the diffusive transmissivity, in the absence of experimental studies devoted to its measurement, can be obtained as follows:

$$\theta_d = D_{s,0}s \tag{29}$$

where s is the thickness of the GM/CCL or GM/GCL interface, which in turn can be related to θ_h, if Newton's viscosity law for the flow between two parallel plates applies to the transmissive layer (Giroud & Bonaparte 1989):

$$s = \sqrt[3]{\frac{12\theta_h\mu_w}{\gamma_w}} \tag{30}$$

being γ_w and μ_w the unit weight and viscosity of water, respectively.

The use of Equation 28 leads to a calculated error, J/J_{app}, equal to 0.022 for the composite liner that comprises the CCL, and 0.763 for the composite liner that comprises the GCL, as illustrated in Figure 2. Therefore, the Katsumi et al. (2001) approach overestimates the contaminant mass flow rate for both the considered lining systems, with an error that is greater in the case of the GM + CCL + AL composite liner than in the case of the GM + GCL + AL composite liner. Such an overestimation can be expected, considering the values of the decay constant, β, for the solute concentration profile beneath the GM (Equation 25), which are greater than the corresponding values of the decay constant, α, for the hydraulic head profile (Equation 1) and, thus, cause the footprint of the low-permeability mineral layer, over which contaminant diffusion takes place, to be smaller than the equivalent area that is given by Equation 11.
Figure 2. Iso-value curves of the error associated with the use of the Katsumi et al. (2001) approach, which is defined as the ratio of the theoretically correct contaminant mass flow rate, J, to the approximate one, J_{app}, under the hypothesis that diffusion is the controlling transport mechanism. The open symbols refer to the landfill composite liners considered by Dominijanni & Manassero (2021).

3 CONCLUSIONS

An original theoretical framework has been developed to calculate the steady-state mass flow rate of inorganic contaminants through landfill composite liners, which are made up of a GM overlying a low-permeability mineral layer, under the restrictive hypotheses that the transport of both the liquid and the solute only occurs through GM defects of uniform width and infinite length (e.g. holed wrinkles and defective seams), and that all the soil layers maintain fully-saturated conditions, even when negative pore-water pressures build up. The migration pathway within the lining system has been conceptualised as a horizontal flow along the interfacial zone between the GM and the underlying mineral layer, and then as a vertical flow in the mineral layer itself, as in the reference scheme considered by Rowe (1998) for the calculation of the leachate flow rate. Closed-form analytical solutions to the contaminant mass flow rate have been derived for two specific cases, namely pure advection and pure diffusion, with the aim of quantifying the error associated with the use of the simplified calculation approach that was proposed by Katsumi *et al.* (2001). In the case of purely advective transport, the latter approach has been proven to be consistent with the mass conservation condition for both the solvent and the solute phases, while satisfaction of the mass conservation condition for the solute phase is no longer guaranteed when diffusion represents the main transport mechanism, leading to an overestimation of the contaminant mass flow rate if the composite liners described by Dominijanni & Manassero (2021) are considered.

Further research is recommended on the aspects dealt with in the present paper. From a theoretical viewpoint, the possible existence of an analytical expression for the solute concentration profile beneath the GM should be investigated, also considering different defect types (e.g. circular holes in a flat GM), boundary conditions (e.g. parallel interacting damaged wrinkles) and transport properties of the soil layers (e.g. change in the degree of saturation for positive suction heads) from the working hypotheses of this study. Furthermore, the ability of the assumed migration pathway to represent the actual 3D advective-diffusive transport in composite liners should be verified with the aid of computationally rigorous numerical models. From an experimental viewpoint, the development of a laboratory apparatus, which allows the newly introduced θ_d parameter (i.e. the diffusive transmissivity of the GM/CCL or GM/GCL interface) to be measured, is of the utmost importance.

ABSTRACT: Desiccation-induced cracking and associated potential damage of geosynthetic clay liners has been the subject of numerous recent studies. In a previous study by the authors, crack propagation in GCLs was systematically investigated using an X-ray scanner. Based on this, the constitutive relationship between water content and crack intensity factor (CIF) for GCLs under combined impact of drying and wetting with divalent salt solutions has been derived. In the current contribution, the X-ray images of the aforementioned study are examined with respect to their crack width distribution. For this purpose, the experimental results were idealised as a Gaussian distribution and the median and variance were analysed. It was shown that there is a unique relation between median and variance independent of the hydration fluid.

1 BACKGROUND

The increase of drought and sequences of hot days associated with climate change has raised the question of the robustness of clay-based barrier systems under those new boundary conditions. The shrinkage induced by changes in water content and associated cracking can potentially yield cracks that could not be closed by swelling upon rewetting. To investigate this process is particularly complex for geosynthetic clay liners (GCLs) because, on the one hand, the needling and the carrier materials influence the potential cracking of the bentonite filling and, on the other hand, direct investigation of potential cracks through the carrier textiles is not possible.

In a previous study presented by Lieske *et al.* (2020) [2] desiccation-induced cracking in GCLs was investigated using an X-ray scanner. A commercially available GCL was used to prepare four different specimens, hydrated with DI-Water and CaCl$_2$ solutions of different molarity. The X-ray images revealed marked differences in the drying and cracking behaviour of the different specimens. However, based on the analysis of the crack propagation at different water contents it was found, that within the measuring accuracy the crack intensity factor (CIF) was mainly a function of water content, independent of the hydration fluid. The analysis of the CIF over gravimetric water content showed that the shrinkage can be

dedicated to four different stages. The desaturation of a fully saturated GCL is starting with the release of water from large inter-aggregate pores and water that has been absorbed by the geotextile, commonly causing only insignificant shrinkage and, thus, no cracks. In the second stage named linear shrinkage water is released from the inter-aggregate pores and the decrease in water volume is proportional to the decrease in volume. This cracking regime is associated with the most pronounced development of cracks. When the water content falls below a material-specific value, residual shrinkage is observed with a shrinkage much less pronounced than in the linear shrinkage phase. The released water is originating from the intra-aggregate pores and much more energy is needed to remove this water from a sample. The last stage is termed zero-shrinkage where a further water content decrease is not associated with further pore volume reduction.

The study also revealed that with increasing drying, cracks occur that were not closed by swelling upon rehydration. Although the study proves the risk of desiccation-induced damage to GCLs, from an application point of view the question arises, whether the experimental desiccation scenarios can become relevant in practice. GCLs are typically installed as a system with protection and buffer mechanisms which affects the dessication behaviour of the GCL [4,5,7,9]. It is also unclear at which level of desiccation cracks lead to a permanent change in the barrier performance of GCLs [2].

The aim of the present study is to shed more light on the risk of permanent cracks and thus damage to GCLs due to desiccation. The study by [2] was focusing on the crack intensity, i.e. the proportion of the crack area in relation to the entire considerd area. However, this and other studies revealed a wide range in the distribution of cracks [1,2,8]. Considering that large cracks are more likely not to be closed by swelling than smaller ones, it becomes clear that the distribution of cracks might be more important than the total volume of cracks (CIF) for the assessment of potential drying-induced damage. In this paper, the evolution of the crack width distribution of the X-ray experiments presented in [2] is investigated. For this purpose, the crack widths were idealised as normal distributions, and were analysed based on the median and the variance.

2 MATERIALS AND METHODS

The results were obtained from drying tests carried out with commercially available GCLs filled with sodium bentonite. The product data specified by the manufacturer are: Mass per area of 4800 g/m2, a thickness of ≥ 6 mm in the dry state and a hydraulic conductivity $k \leq 3 \cdot 10^{-11}$ m/s in the water-saturated state. Four GCL specimens in the size of 42.5 cm $\times$ 30.5 cm were cut and taped at the corners to prevent loss of bentonite. The raw bentonite was present as granules.

The four GCL specimens were hydrated with DI water (SP1), 0.05 mol/l CaCl2 solution (SP2), a 0.5 mol/l CaCl2 solution (SP3) and a 0.05 mol/l CaCl2 solution after prehydration with DI water (SP4). After hydration, the GCLs were dried in an oven at 30°C. The duration of the drying intervals was increased gradually to achieve different drying intensities. In all experiments, a 3.92 kPa load was applied to the GCLs both during hydration and drying. The profile of the water content of the different GCLs over the duration of the experiment is shown in Figure 1.

After each drying and wetting interval, the samples were examined by means of X-ray imaging. The 2D image of the GCLs obtained in this way was investigated with respect to crack patterns using the digital image processing software PCAS (Particles (Pores) and Cracks Analysis System). It should be noted, however, that the resolution of the device was limited. It was therefore not possible to analyse the GCLs with very fine cracks (e.g. SP3).

The probability density functions f(cw) of the crack widths obtained from the different X-ray images in Figure 2 give an impression of the variability of the detected cracks. The
Figure 1. Gravimetric water content over time of the different GCL samples during the drying/wetting cycles.

probability density f(cw) is defined according to equation 1, where n is the total number of cracks and Δn the number of cracks with a width in the interval of Δcw.

$$f(w) = \frac{\Delta n}{n \cdot \Delta cw} \tag{1}$$

The data obtained can be idealised by using the Gaussian distribution (also referred to as normal distribution) given in equation 2, where σ is the median and σ is the variance. The median is giving an impression about the most frequent encountered crack width. The variance μ is a measure of the distribution of the values with respect to the mean value. The larger the value of μ the flatter the Gauss curve, or in other words: the larger the difference between the smallest and the largest encountered crack width.

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \tag{2}$$

The dashed line in Figure 2 shows the idealised Gaussian curve while the bars represent the experimental data. Even though the Gauss curve has a quite good match with the experimental observations, a certain discrepancy between idealisation and experiment is noticeable, especially for the measured values of SP1 in the relatively wet state (w = 89 \%) and w = 162 \%). This may be attributed to the generally rather fine cracks that could hardly be measured by the device. Vice versa, as the mean crack width increases, the Gaussian distribution of the crack widths becomes more and more pronounced and the fit between experiment and idealisiation gets better.

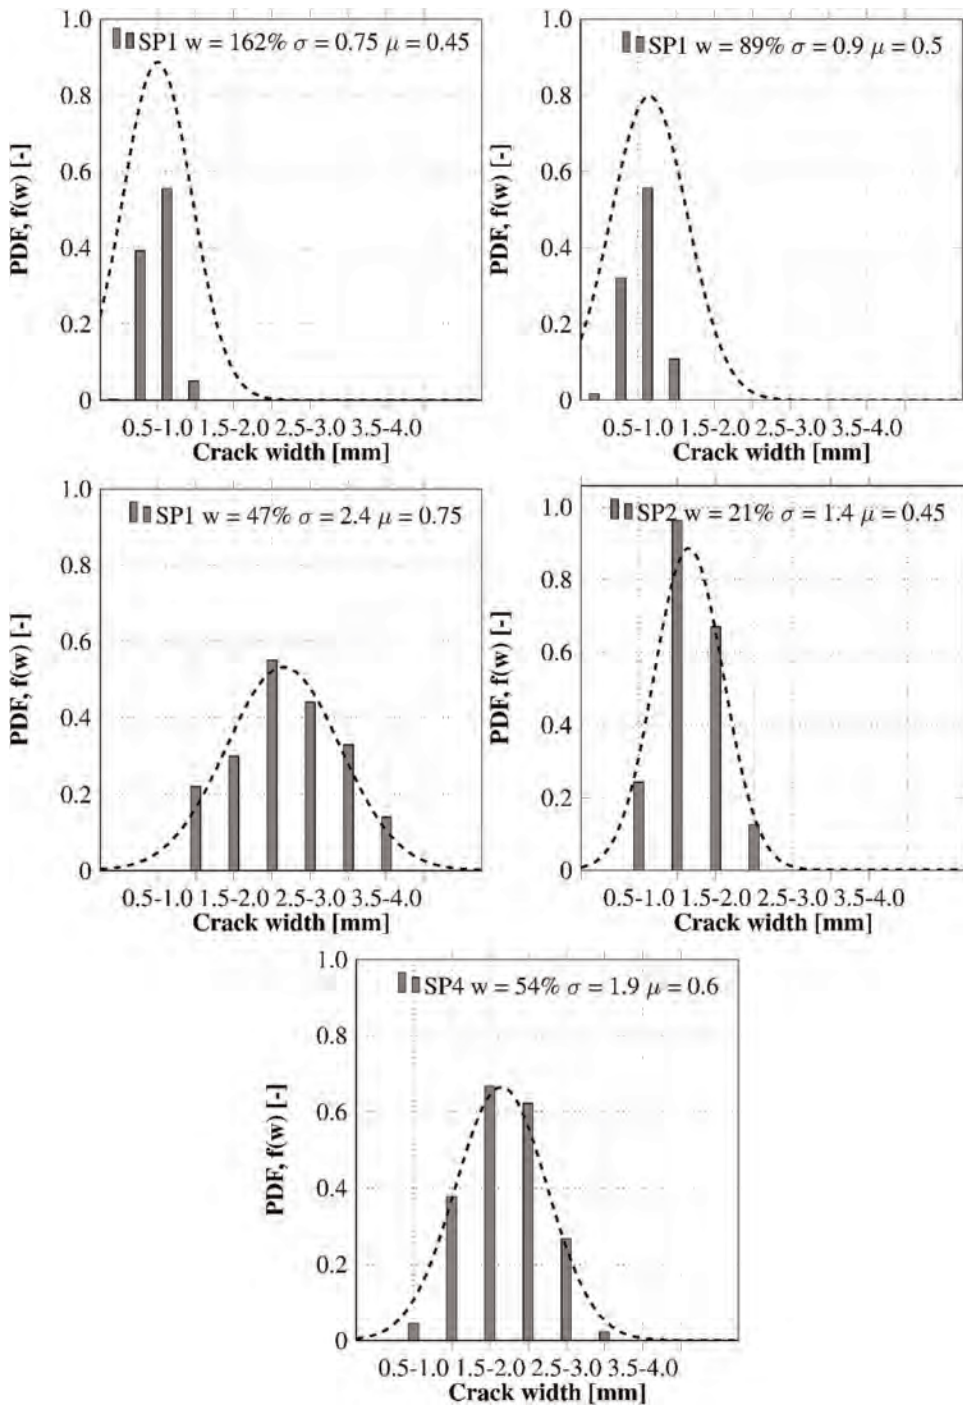
The importance of the mathematical analysis of the crack distribution for assessing the risk of damage due to drying can be illustrated by means of an example. If a discrete value for a critical crack width cw_{crit} is considered, above which the swelling properties under the given boundary conditions (surcharge load, mineralogical composition of the GCL filling, pore water chemistry, to name just a few) are no longer sufficient to close all cracks induced by drying, then all cracks widths $cw > cw_{crit}$ are associated to an damage of the GCL.


Figure 2. Probability density function of crack width for SP1, SP2 and SP4 at different water contents.

The potential of occuring cracks larger than cw_{crit} is given by the following three σ - μ combinations: (I) $\sigma \ll cw_{crit}$ μ is very high, (II) $\sigma < cw_{crit}$, μ is moderate and, (III) $\sigma > cw_{crit}$ (μ is not decisive in this case). In case (I), the average crack width is clearly below cw_{crit} but due to the wide range of crack widths (μ very high), damaging cracks have also to be expected. In the second case (II), the average crack width is below cw_{crit} but part of the Gaussian curve is located in the area of damage. In case (III) the average crack width is above the damage threshold cw_{crit}. The distribution μ is therefore not decisive for the analysis of the damage in this case.

3 RESULTS AND DISCUSSION

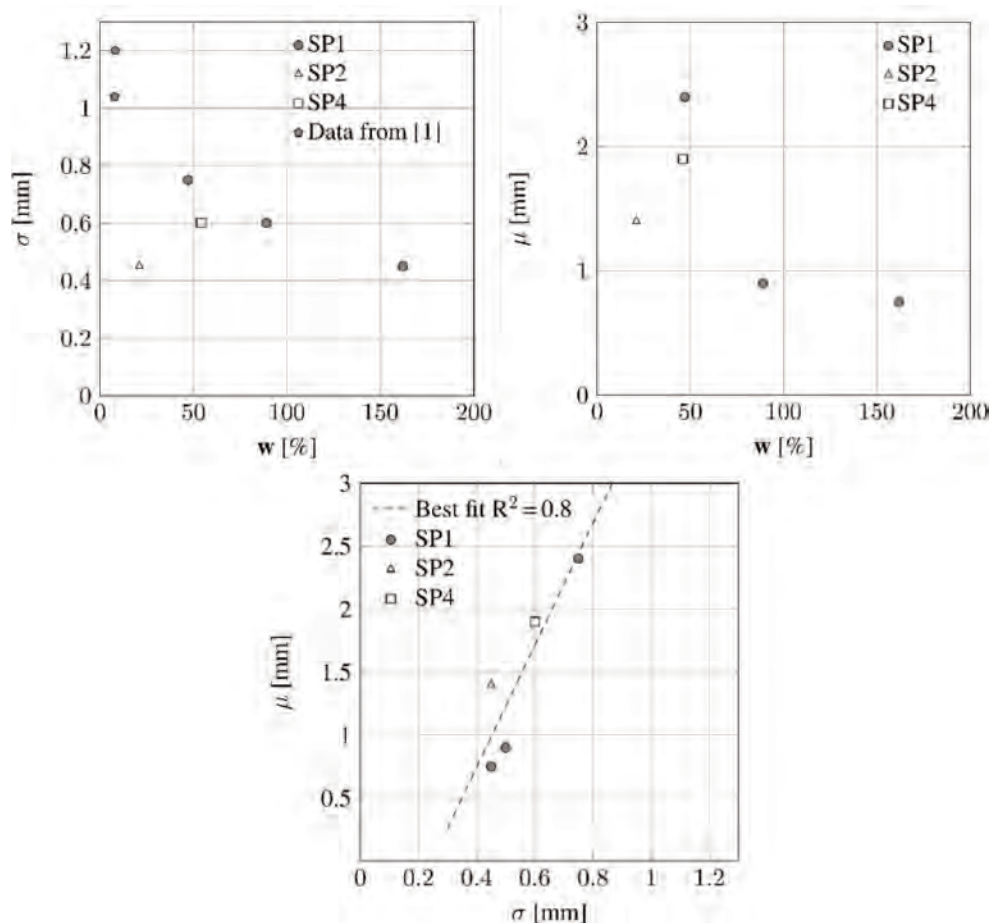
Figure 3 shows the evolution of the mean value μ and the standard deviation σ over the water content, as well as the correlation between σ and μ. Considering only SP1, i.e. the sample hydrated with DI water, an increase of σ with decreasing water content can be observed. Some experimental data given as average crack width in [1] was added in the σ-w plot, supporting the strong correlation between average crack width and water content. This


Figure 3. Correlation between σ, μ and w for different specimens.

trend shows that with increasing drying intensity, or decreasing water content, not only the average crack width increases but also the diversity of the crack widths.

When comparing SP1, SP2 and SP3, i.e. samples hydrated with different fluids, the order SP1 > SP3 > SP2 is observed for both μ and σ with similar water content. Dissolved salts cause the clay minerals to aggregate, which leads to a decrease in tensile strength on the macroscale. During drying the decrease in tensile strength manifests itself in the formation of rather fine cracks, since suction-induced stresses lead to cracks at relatively small strains. However, it must be taken into account that this does not provide any information about the number of cracks. The analysis of the CIF in Lieske *et al.* (2020) showed that under the boundary conditions considered, the CIF is only a function of the water content. It follows that for a given water content μ is smaller for a GCL hydrated with a salt solution than for one hydrated with DI water, but at the same time the total number of cracks is larger.

Figure 3(c) shows the relationship between σ and μ. It reveals a strong correlation (coefficient of determination = 0.8), whereas the mean crack width increases, the variability of the cracks also increases, which is mathematically indicated by a flatter Gaussian curve. The σ-w and μ-w plots in Figure 3(a) and (b) show a strong dependence on the hydration fluid, as this affected the tensile strength of the clay. However, the relationship between σ and μ is independent of the hydration fluid for the data considered. For the consideration of the damage potential, this correlation indicates that of the three σ - μ combinations described above that can lead to the formation of permanent cracks, only two are likely. The combination of a mean crack width significantly below the damage threshold and a very flat Gaussian curve as described in (I) seems unlikely in view of the experimental results, since small mean crack widths are associated with a small range of crack widths.

However, at the same time this consideration raises the question of a critical limit value for the crack width cw_{crit}, from which permanent structural damage to the sealing performance of a GCL is likely to occur. This limit is a complex function of material-specific parameters (such as the mineralogy of the GCL fill, mass per m2), installation conditions (load, nature of the surrounding soil) but also the exposure (wet-dry cycles, drying rate, chemistry of the hydration fluid) [1,2,6,8]. Further research is needed to derive such a criterium based on comprehensive understanding of the underlying soil mechanical constitutive relations to include all the aforementioned parameters.

4 CONCLUSION

This contribution is addressing the morphology of drying-induced cracks in GCLs. The global context is the risk assessment of permanent cracks and thus loss of barrier performance caused by extensive drying. Based on the assumption that wide cracks tend to exceed the self-healing capacity of bentonite rather than small ones, the crack width distribution was analysed. For this purpose, the crack width distribution was idealised using a Gaussian distribution and the median (σ) and the variance (μ) were analysed as parameters to describe the crack distribution. Three main observations were made:

– Both, the median and the variance of the Gaussian curves increased with decreasing water content for the samples tested with DI-water only.
– The samples that were hydrated with divalent salt solutions deviated from this trend.
– Regardless of the hydration fluid, there was a clear correlation between μ and σ.

However, these findings are only a first step towards a final risk assessment of drying events. To predict permanent damage, a critical crack width is required, beyond which the swelling capacity of the bentonite filling is no longer capable to fill existing cracks. The derivation of this limit value based on soil mechanics constitutive relations that take into account both material properties and installation boundary conditions is the subject of future research.

ABSTRACT: The paper presents some results of settlement calculations performed after completion of a municipal solid waste landfill built on collapsible soils (sensitive soils). The results of the calculations are compared in the hypothesis of maintaining the conditions of natural moisture content of the collapsible soil and in the hypothesis of flooding the collapsible soil as a result of an imperfect sealing system. Starting from the requirements of the national legislation in force which imposes a slope of at least 1% of the drains that take the leachate from the landfill, after consuming the settling of the deposit, the position of the drain is analyzed to ensure the transport capacity of the leachate from the moment of opening the landfill and until its filling and consumption of the settlement under the load transmitted by the stored waste. Another aspect treated in the paper is related to the tensile effort that may occur in the geosynthetics from the landfill bottom system, as a result of the foundation soil settlement. The settlement calculations were performed according to the Romanian technical norms: "Technical norm for foundation of buildings on moisture – sensitive, collapsible soils, indicative NP 125: 2010" and "Technical norm regarding the determination of characteristic and calculation values of geotechnical parameters, indicative NP 122: 2010", which are correlated to the Eurocode 7.

1 INTRODUCTION

In Romania, collapsible soils cover about 19% of the country's territory (approximately 40.000 km^2) and it is common in the eastern part of the country.

Moisture-sensitive or collapsible soils are unsaturated macroporous cohesive soils that, upon saturation with water, undergo sudden and irreversible changes of the internal structure, reflected by additional settlements with collapsing character and decreases in the values of geotechnical parameters of mechanical behavior (NP 125: 2010).

The design of a municipal solid waste landfill on a collapsible soil is a particular situation due to the fact that several technical regulations that impose certain restrictions must be respected.

On the one hand, the "Technical norm regarding the storage of waste", approved by OMMGA 757/2004 imposes a slope along the drains of at least 1%, drains that collect the leachate both at the time of opening the landfill, as well as after filling it and consuming the settlement of the foundation soil under the load transmitted by the deposited waste.

Figure 1.   Collapsible soil spreading in Romania (NP 125:2010).

On the other hand, NP 125:2010 "Technical norm for foundation of buildings on moisture – sensitive, collapsible soils" contains two provisions from this point of view: the water supply networks must have a double protection and the calculation of settlement must be performed also in the hypothesis of the flooding of the foundation soil.

2   THE SETTLEMENT EVALUATION FOR COLLAPSIBLE SOILS

In the case of normal consolidated soils, the settlement is evaluated by accepting a linear relationship between stress and deformation (Hooke's law) and is a function of the deformation modulus and the vertical stress due to overload (σ_z). In the case of collapsible soils, the vertical effort due to its weight (in natural conditions and in saturated state) and the total effort due to the construction, respectively the sum between the geological load and the effort due to overload, is evaluated. The settlement is obtained as a difference of the settlements generated by the initial (geological load under natural conditions) and final effort (after flooding the foundation soil and completing of the construction).

Annex 5 from the NP 125: 2010 shows how to calculate the additional settlement caused by saturation by wetting the collapsible soil divided into: additional wetting under geological stress (I_{mg}) and additional wetting by saturation under the load transmitted by the foundation (I_{mp}). Following the calculation steps from the technical norm, it is simulated the flooding of the soil and evaluated its response (I_{mg}) and later the construction on the saturated soil and the evaluation of the total settlement ($I_{mg} + I_{mp}$). The NP 125: 2010 does not present the assessment of the probable settlement after the construction was carried out, in the hypothesis of maintaining the natural moisture content of the foundation soil (s), an extremely important component in choosing the foundation solution.

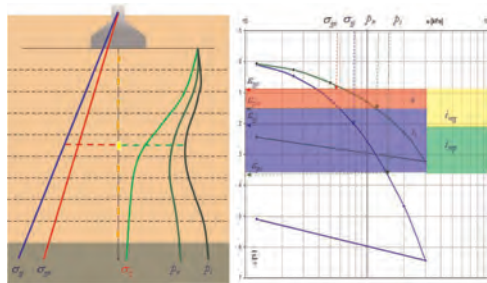
Figure 2 is a schematic diagram for calculation of the settlement of the collapsible soil, and highlights the efforts of vertical loads required for calculation, while the specific strain is


Figure 2.   Scheme for the calculation of the foundation soil settlement for a collapsible soil layer. σ_{gi} - geological stress in saturated conditions, σ_{gn} - geological stress at natural moisture content, σ_z – vertical stress due to surcharge, $p_n = \sigma_z + \sigma_{gn}$ – total vertical stress at natural moisture content, $p_i = \sigma_z + \sigma_{gi}$ – total vertical stress in saturated conditions, ε – specific strain, s – specific settlement at natural moisture conent, s_i – supplementary specific settlement in saturated conditions.

obtained directly from the stress-strain curves, from the tests of compressibility in oedometer of the samples at natural moisture content and the initially saturated samples.

3 CASE STUDY

3.1 *Geotechnical investigation*

For the construction of a municipal solid waste landfill were carried out geotechnical field and laboratory investigations. The size of the landfill is approximately 250×300 m.

According to the geotechnical investigations, it was found that the foundation soil is composed, under a layer of top soil with a thickness of about 70 cm, from a layer of loessoid soil intercepted up to the depth of 13.70 m, followed by a layer of clayey silt – silty clay in a plastic state: medium-soft to stiff. The groundwater was intercepted at a depth of 21 m.

On undisturbed samples from the loess layer, 44 compressibility tests were performed in the oedometer, 27 at natural moisture content and 17 on initially saturated samples, in order to determine the additional settlement caused by the wetting, the structural strength (σ_0) and the behavior of the material under the applied loads.

As a result of the graphic representation of the additional settlement caused by saturation at 300 kPa, depending on the depth (Figure 3), it has been noticed that at the surface, the material records very high values for i_{m300}, which reach even 8 ... 10%, while for depths of 7 to 13 m, this value decreases to 2 ... 5%. As a result, the loess package was divided into 3 layers. Layer 4 is identical from a granulometric point of view but, due to the high natural moisture content, the material has lost its sensitivity to wetting ($i_{m300} = 0 ... 0.5\%$).

For each calculation layer, the characteristic values of the geotechnical parameters necessary for the settlement calculation were determined. Based on the compressibility tests in oedometer, the characteristic values of the specific settlements were determined under the applied loading steps ($\varepsilon_{k\ inf}$, $\varepsilon_{k\ sup}$). For the overestimation of the settlement, only the values $\varepsilon_{k\ sup}$ were selected and the characteristic compression-settlement curves were drawn, for which a function was searched to approximate it.

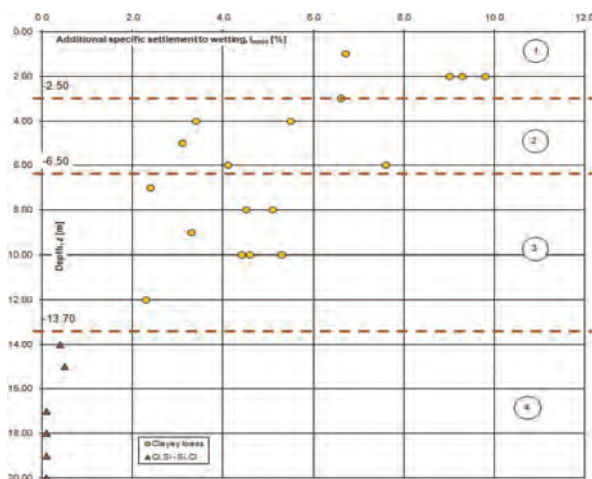
Figures 4 and 5 shows the upper characteristic curves obtained on natural samples and on initially saturated samples. Also, the functions that approximate the characteristic values of


Figure 3. The variation of the additional settlement caused by saturation, im300, depending on the depth.
Figure 4. Compression – settlement curves on natural samples from layer 1.
Figure 5. Compression – settlement curves on initially saturated samples from layer 1.

the specific settlement are indicated. These characteristics were determined for each layer but, for example, the values determined for layer 1 are presented graphically.

3.2 *The settlement calculation of the foundation soil*

The settlement of the foundation soil was calculated vertically for 27 points distributed evenly throughout the landfill but also in its vicinity. The load transmitted by the waste was assimilated with two triangular loads (the marginal sections) and a rectangular one (the central section).

The settlement calculations were done iteratively, proposing in an initial phase a slope of 1 % for the landfill base. Figure 6 shows the results of the settlement calculation. Starting from the natural ground level, the designed ground level was calculated to ensure the initial slope of 1% by calculating the settlements, the shape of the base of the landfill was determined after consuming the settlements in case of maintaining the moisture conditions, but also in the hypothesis of saturation of the foundation soil.
Figure 6.   The settlement calculations with a slope of 1% for the landfill base.

From the calculations performed, we noticed, first of all, the very high values of the settlements in the center of the landfill: 1.3 m in case of maintaining the moisture content of the natural soil and 2.3 m in case of its saturation. It should be mentioned that these values were obtained for a pressure of 360 kPa resulting from the storage height of 30 m and the specific weight of the waste of 12 kN / m^3, evenly distributed over a very large surface (250 × 300 m).

In this initial hypothesis, after the consumption of the settlements, the drain that takes the leachate from the landfill will have for the downstream area a slope of less than 1% and even counter slope in both calculation hypotheses. It turns out that, between sections 13 and 22 of the calculation of the settlement, the slope of the landscaped land will have to be reshaped so that the slope after consuming the settlement is greater than 1%. It turns out that, between sections 13 and 22 of the settlement calculation, the slope of the designed ground level will have to be reshaped, so that the slope after consuming the settlement is higher than 1%.

Figure 7 shows the initial profile of the designed ground level and is imposed, in all sections, a slope higher than 1%, after consuming the settlements. Basically, changes were made between sections 13 and 23. Accepting initially the same settlements of the foundation soil, the slope of the designed ground level was calculated, which varies between 1.6 and 3%, which is why it was modulated in two sectors with slopes of 2 and 3 %.

By reshaping the base of the landfill, excavations of up to 2 m will be carried out, through which the 1st layer of loess will be exceeded, layer which has a high sensitivity to moisture. For this reason, the settlement calculations were remade and the results are presented in Figure 7. It is noted that, by shaping the ground level with slopes of 1, 2 and 3%, during the entire period of operation of the landfill, respectively, from the moment of beggining, until the drainage of the foundation soil is consumed, the drains for taking the leachate will have slopes greater than 1%. If initially the upstream section will have a slope of 1% and the downstream sections of 2 and 3%, after consuming the settlements, the upstream section will have slopes of 2 ... 3% and the downstream sections of 1 ... 2%.
Figure 7. Reshaping the slope of the base of the landfill in order to obtain a slope >1% after consumption of the settlements.

The base of the landfill, shaped with the slopes of 1, 2 and 3% creates a convex surface with a length of 234.82 m. After the consumtion of settlements in natural moisutre content conditions, the profile transforms into a concave surface with a length of 234.84 m and, it the foundation soil becomes saturated, after the consumption of the additiona settlement to wetting, the length of the profile becomes 234.81 m. Therefore, no tensile forces will appear in the geosynthetics from the landfill bottom lining and drainage system due to the initially shape of a convex surface that becomes concave after the consumption of settlements.

4 CONCLUSIONS

By reshaping the designed ground level according to the method described above, the minimum slope of 1% of the drains is ensured for both hypothesis of maintaining the moisture conditions of the foundation soil and in the hypothesis of his saturation.

The maximum settlement of 2.3 m in the central section of the landfill site will not lead to a significant elongation of the geosynthetic materials from the base of the deposit and will not subject them to further tensile efforts.

Multiple use of geosynthetics in a hazardous waste landfill

M. Bianchi
SCL Ambient, Milan, Italy

HUESKER Srl, Trieste, Italy

ABSTRACT: Bulera's landfill is one of the few authorized landfills for hazardous waste in Italy. In the year 2016 an expansion was decided adding additional volume above the old waste body temporarily covered, for total expected further quantity of 640,500 m^3. The project involved many challenging problems which have been efficiently solved with the use of geo-synthetics. Very restrictive requirements had to be respected for the intermediate barrier system and capping, both from hydraulic and static point of view. To ensure the overall stability of the landfill body reinforced embankments were adopted. Furthermore, road base reinforcements were used to support the traffic of heavy vehicles on soft soils. Erosion control mats were also implemented to protect the slopes of the entire area. The paper illustrates the problems faced and the criteria adopted for the choice of the different solutions with geosynthetics.

1 GENERAL CONTEXT

In 2016 it was decided to expand the Bulera landfill located in the province of Pisa (Italy), intended for the storage of hazardous waste. The expansion consisted in adding a further 640,500 m^3 to be stored on the waste body of the old landfill.

Figure 1. Overview of Bulera's landfill.

To achieve this goal, it was necessary to address many problems which were effectively resolved using geosynthetics. The most important problems faced were the followings:

– The inclined intermediate barrier was, at the same time, the capping of the old waste body and the bottom of the new one. It was necessary to study a multilayer system with geo-synthetics capable to fulfill hydraulic (impermeabilization and drainage), mechanical (protection) and static requirements. With analogous approach also the final capping was designed.

– Since the landfill develops along the side of a hill, different stability problems were analyzed, either global, compound, internal and sliding stability scenarios. From these analyzes it was necessary to implement a steep reinforced slope at the foot of the landfill with the use of high strength geogrids, in order to assure the stability of the additional volume of waste.
– A new reinforced concrete tank for leachate treatment was built and founded on the old waste body saturated with leachate. A geotechnical reclamation of the bottom was therefore studied to assure its stability.
– Due to the presence of soft soils in the entire area, it was necessary to reinforce the base of internal roads with proper reinforcing geocomposites to allow the traffic of heavy vehicles.
– Erosion control mats have been foreseen to protect the slopes of the road embankments and the inclined soil layer above the capping.

2 TECHNICAL PROBLEMS AND SOLUTIONS ACHIEVED WITH GEOSYNTHETICS

2.1 *Geotechnical reclamation of tank foundation*

Before building the new reinforced concrete tank, it was necessary to remove over 10,000 m^3 of existing waste. The excavation, remained open for a long time, was subjected to the action of rains that caused the accumulation of water on the subgrade, which became muddy and difficult for the access of construction vehicles. So, it has been necessary study a geotechnical reclamation of the bottom, keeping the total thickness of the project. The reclamation was characterized by the following phases (Figures 2 and 4):

– Removal of the first ten centimeters of ground material
– Laying of a heavy nonwoven geotextile (1200 gr/m^2) with puncturing resistance $\geq$ 13,000 N.
– Installation of two layers of PET geogrids 80 kN/m overlaid orthogonally only under the base of the tank
– Installation of 40 cm of aggregate layer (size 40 – 70 mm)
– Installation of a second layer of nonwoven geotextile to protect the subsequent barrier system composed by a double layer of a rough bentonite geocomposite, an HDPE rough liner 1.5 mm thick, protected by a further nonwoven geotextile 1200 gr/m^2.

Figure 2. Installation phases of the base reclamation (left to right): 1. Nonwoven and geogrid, 2-3. Aggregate layer, 4-5. Rough bentonite geocomposite, 6. Rough HDPE geomembrane.

2.2 *Reinforced embankment*

To counteract the pressure of the new waste mass acting at the foot of the landfill side, it was necessary to build a reinforced embankment 8 meters high, 250 m long with front inclination of 60°, founded on the existing waste (Figure 3).

The structural design of the embankment was performed according with the Ultimate Limit State method taking in consideration different scenarios: it was analyzed the stability of the overall landfill body, as well as the stability of the new waste mass applied on the intermediate

barrier which represent a potential sliding plane. A critical leachate level was assumed in the calculation model. Internal, compound and global stability analysis were performed under static and seismic conditions. Circular and polygonal sliding surfaces (according with Bishop and Janbu method respectively) were investigated considering different specific scenarios.
Figure 3.   Typical section and view of the treatment tank and reinforced embankment.

For load combinations and factor of safety the Italian standard NTC 2018 was adopted while, due to the lack of specific Italian regulations for geosynthetic reinforcements, the British Standard BS 8006-1 2020 was used to determine the long term ultimate tensile strength T_D (1) of the geogrids, according with the following formula:

$$T_D = \frac{T_{char}}{RF_{CR} \cdot RF_{ID} \cdot RF_W \cdot RF_{CH} \cdot f_s} \tag{1}$$

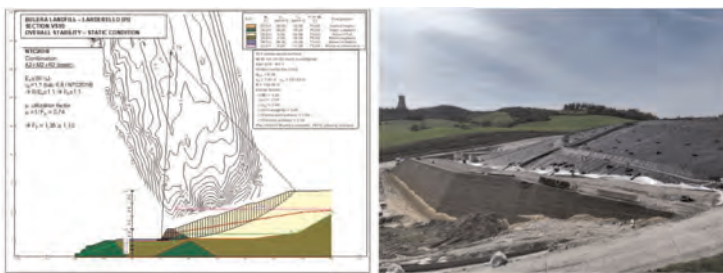
The design strength T_D is calculated reducing the short-term characteristic tensile strength (obtained according EN ISO 10319) by reductions factors which take into account the creep (RF_{CR}), the installation damages (RF_{ID}), the weathering (RF_W), the chemical and environmental effects (RF_{CH}) and the extrapolation of data (f_s). As filling soil for the embankment was used clay with permeability $K = 10^{-9}$ m/s, and the geotechnical parameters adopted were: internal friction angle $\phi = 27°$; Cohesion c = 20 kPa; unit weight $\gamma =18.5$ kN/m^3. As reinforcing elements Fortrac T polyester geogrids were used which long term design strengths T_D were obtained using the reduction factors certified by Hapas Certificate 13/H197. As result of the stability calculations geogrids with short term resistance of 600 kN/m (at the base); 80 kN/m and 35 kN/m were adopted, disposed with different anchoring length in layers 60 cm thick (Figure 4).


Figure 4.   Stability analysis of one studied scenario and reinforced embankment during construction.

2.3   Reinforcement internal roads

The road subgrade is composed by 1 m. of clay and, below, by old waste deposits. The internal unpaved roads had to be able to allow the continuous passage of heavy vehicles. According to the general project, a total foundation thickness of 50 cm had to be adopted but, due to the poor geotechnical characteristics of the lower layers, it was necessary to implement a base reinforcement in order to keep the road base thickness assuring a proper bearing capacity and to prevent the formation of deep ruts.

To calculate the required strenght of the geosynthetic reinforcement it was considered the load of heavy trucks (50 tons) and, for the underlying layers, the following parameters were adopted:

− For the subgrade it has been adopted an undrained cohesion C_u = 70 kPa.
− For the road sub-base course a sandy gravel 40 cm thick plus a layer of 10 cm of stabilized material was adopted.

The semi-empirical method of Jaecklin & Floss has been used for calculation purposes, obtaining a minimum tensile strength of 26.18 KN/m. For a service life of 20 years, the composite geogrid Basetrac Duo C 65 B15 in polyester (short term strength 65 KN/m) assembled with a polypropylene nonwoven was adopted.(Figure 5).

Figure 5.   Construction phases of internal roads with the use of base geocomposite reinforcement.

2.4 *Bottom barrier system*

The landfill's expansion has been designed adding additional volume above the old waste body temporarily covered. The Tuscan region imposed the construction of an intermediate barrier between the waste of the old landfill and the new ones belonging to the extension. This barrier was to act, at the same time, as a capping for the old landfill and as a bottom of the new one, in accordance with Italian regulation 36/2003 (in force that time) that required, for hazardous waste landfills, a mineral clay layer with permeability $K \leq 10^{-9}$ cm/s and a thickness of minimum 5 m. Due to technical, environmental, and financial issues a 5 m thick barrier was not practicable. The regional authorities allowed the designer to find alternative solutions that could have analogous performance. To overcome this problem, an equivalent mineral barrier system was studied, consisting in one meter layer of clay combined with a special bentonite geocomposite (GCL).

It should be emphasized that the study of barrier systems always involves an accurate analysis of both the hydraulic and static aspects. Both have been taken into consideration with absolute attention in this project. Applying the equivalent criteria it was approved an intermediate multilayer as follow (from bottom to top):

− Old waste
− PP nonwoven geotextile 300 gr/m^2 as separator layer.
− 100 cm of clay with $K \leq 10^{-8}$ m/s
− Bentonite geocomposite with rough surfaces (high internal and external shear strength)
− HDPE rough liner, thickness 2.5 mm
− PP nonwoven geotextile 1200 gr/m^2 as protection layer on the horizontal surfaces
− Drainage composite as drainage and protection layer on slopes
− 50 cm of aggregates as drainage layer on horizontal surfaces
− New waste

So, the mineral barrier system was completed with HDPE liner 2.5 mm, drainage geocomposite and protective geotextiles nonwovens. The equivalence has been demonstrated with two methods (comparison between "flow rates" and application of "Koerner's formula") considering three water heads (H_1 = 0.3 m, H_2 = 0.5 m, H_3 = 1.0 m) so as to be able to identify the minimum technical characteristics required for the geosynthetic clay liner (GCL) adopted. The flow index (q) as well as the other parameters (permeability and thickness after expansion) relating to the bentonite geocomposite (GCL) were determined according to UNI EN 16416. The equivalence calculation criteria between the mineral layer and the geocomposite was based on two methodologies:

− Equivalence of the flow index: expressed in m^3/m^2/s; represents the water flow per unit of surface and time that passes through the layer. This is the closest method to reality because it refers to a physical parameter that can be directly measured in laboratory.

Considering the mineral clay layer 5 m thick and K $\leq 10^{-9}$ m/s, the flow index that was not to be exceeded by the equivalent layer was 1.06 10^{-9} m³/m²/s for H_1 = 0.3 m, 1.1 10^{-9} m³/m²/s for H_2 = 0.5 m and 1.25 10^{-9} m³/m²/s for H_3 = 1.0 m.

- Equivalence through Koerner's method: the input characteristic parameters of the method were used, that is, the permeability and the thickness of the saturated geocomposite after controlled expansion. This value, used in the Koerner method, is obtained from laboratory tests in accordance with UNI EN 16416. According to the Darcy's formula, the permeability needed for the bentonite gecomposite was calculated varying the hydraulic water head, from 0.3 m to 1.0 m, and the GCL thickness after a controlled expansion from, 9 mm to 13 mm.

During the design phase, several materials were examined to evaluate their equivalences as a function of the increasing hydraulic heads, both using the flow rate index and the Koerner method. The equivalence has been proven on all products for H = 0.30 meters while, considering higher water heads levels, the market choice was limited. The final selected material was the GCL Nabento RL-N 5500 F (WB) having the following characteristics: unit weight of sodic bentonite 5500 g/m², minimum thickness before controlled expansion of 9 mm and maximum permeability of K$\leq$ 1.25x10^{-11} m/s for water head of 1 m. Another important performance characteristic of this GCL is its high internal and external shear strength, due to the rough surfaces and the assembly process. These mechanical parameters are relevant since they were considered in the stability analysis of the new waste mass above the inclined intermediate barrier. The barrier system was completed with an HDPE rough liner 2.5 mm thick protected above horizontal surfaces by geotextiles nonwoven of 1200 gr/m² with static puncturing resistance $\geq$ 13,000 N and, along the internal slopes, with a drainage geocomposite (Figure 6). Externally, the 4-meter-high slopes have been protected with the erosion control coconut Bionet HC/40.

Figure 6. Slopes covered, from left to right, with the rough GCL, the HDP liner, drainage geocomposite (slopes) and nonwoven geotextile (bottom).

2.5 *Drainage geocomposites*

The entire design of the landfill expansion comprises the construction of the intermediate barrier and the final capping. No production of biogas is expected so the adopted drainage layers have been foreseen foreseen in two different levels and with two different functions:

- On the intermediate barrier a drainage geocomposite was adopted to be laid only along the slopes of the external and internal embankments (which act as internal cell separators).
- On the capping, over the impermeable barrier, to drain the rain water infiltrated through the covering soil layer.

The drainage geocomposite for the intermediate barrier has two functions: speed up the drainage of the leachate towards the horizontal drainage layer made with 50 cm of aggregates and protect the HDPE geomembrane. At this level, the material is subjected to a pressure of about 320 kPa, corresponding to the pressure of a column of waste up to 20 m thick. For this reason, the drainage geocomposite Pozidrain 6S 500 D, with HDPE cuspated, core was selected since can work effectively with long-term pressures up to 500 kPa.

For the capping, in which the acting pressure is in the order of 20 kPa, was chosen a particular and more economic drainage geocomposite, the Pozidrain G type, which consists of a cuspated HDPE drainage lattice embedded between two layers of non-woven filter/protection geotextile. The draining lattice members provide equal drainage capacity through the longitudinal and

cross ribs. An evaluation of the allowable drainage capacity of the product was done compared with 50 cm of gravel as required by the Italian regulation. The composite also provides protection and, thanks to its irregular structure with windows, the interface friction angle with the cover soil is high, that makes the material suitable to be used on inclined cappings.

2.6 *Final capping*

At present the capping has not been done yet and the design was done with analogous approach of the intermediate barrier. As mentioned above, a specific drainage geocomposite was chosen considering the acting pressure and the inclination of the capping. While, regarding the bentonite geocomposite, a less performing model from a hydraulic point of view was chosen because it was sufficient to comply with regulatory requirements. The characteristic of rough surfaces and high internal and external shear strength was maintained for stability reasons. On the barrier, due to the inclination of the slopes and the interface friction angles between layers, it was necessary to add a tridimensional reinforcement geogrid (Fortrac 3D 120 of 120 kN/m) to assure the veneer stability and prevent the sliding of covering soil layer. For the stability analysis the method developed by Russo (2008) was used. The capping, starting from the waste is as follow:

- Nonwoven weight 300 gr/m^2 to separate the waste.
- 30 cm of clay, K $\leq 10^{-8}$ m/s
- Bentonite geocomposite with K $\leq 5.0\ 10^{-11}$ m/s; 7 mm thick
- HDPE rough liner; 1.5 mm thick
- Drainage geocomposite for rainwater with lattice structure
- Antisliding tridimensional reinforcement geogrid (nominal strength 120 kN/m)
- Topsoil, 1 m thick.
- Bionet for erosion control in coconut fiber to be used only on lateral slopes
- Hydroseeding and bushes.

3 CONCLUSIONS

The design of the extension of Bulera's landfill involved the solution of many challenging problems of diverse nature that have been successfully solved using different types of geosynthetics. The paper describes the most important problems faced and the criteria adopted for the choice of every solution. Each application has been designed and calculated considering the specificity of the context. In this project, a barrier system with 5 m of mineral clay layer was not feasible, so, thanks to the use of geosynthetics, it was possible build a thinner barrier and carry out the work. Product test reports and certificates were essential for the adoption of input reliable data used for design. The versatility and reliability that characterizes geotechnical designs with geosynthetics allowed to find cost effective and sustainable solutions compared with the conventional ones.

Multi-linear drainage geocomposite for sub-slab depressurization and radon mitigation

E. Vial & M. Vanhée
Afitexinov, Champhol, France

S. Fourmont
Afitex-Texel, Ste Marie, Quebec, Canada

ABSTRACT: Sub-slab Depressurization (SSD) aims to reduce building occupants' exposure to toxic gases from the soil. These gases can either be generated from contaminated soils (like Volatile Organic Compounds or Landfill Gas) or naturally present in the soil (like Radon). The SSD system is composed from the bottom to the top of a separator geotextile, a drainage layer, and a vapor barrier. One or more gas pits are located according to the gas concentration in the area and to the geometry of the building. Because most of the SSD systems are constructed in high-density population areas (e.g., new construction in old industrial zones), the truck traffic and the noise resulting from the excavation works, and the transportation of granular material is a nuisance for residents. It also damages the local road network that is not designed to handle heavy vehicles traffic. This paper presents the sizing and the use of multi-linear drainage geocomposite as part of the SSD system providing separation and gas collection functions. The geocomposite is composed of non-woven geotextile layers incorporating perforated mini-pipes regularly spaced and running the roll length. It is connected to a collector pipe and to the gas pit. It collects the soil gas and reduces the head losses thanks to the high-density network of perforated mini-pipes within the product and the specific fittings used to connect the product to the main collector pipe. The sizing of the geocomposite is done using laboratory tests and software to characterize the flow capacity and the head losses of the system. Multi-linear drainage geocomposites have been found to be efficient for both passive and active SSD systems.

1 INTRODUCTION

The reclamation of industrial brownfield sites or former waste deposit sites for new developments is already common practice in various parts of the world. The infiltration of underground gases poses a serious threat to the safety of the occupants of these reclaimed sites. Gases generated by both waste products (biogas) and contaminated soils (such as volatile organic compounds VOC), and even natural gases like radon produced by the natural decay of uranium and other naturally occurring elements are commonly detected in affected areas. Sub-slab gas collection systems, using a natural permeable layer such as crushed stones paired with draining pipes and vents, are frequently used to prevent gas infiltration into new developments. However, geosynthetic products such as multi-linear drainage geocomposites present an excellent alternative for both passive and active sub-slab gas collection systems.

This technical paper aims to present a comprehensive overview of the installation and performance of such systems, while demonstrating their benefits over conventional approaches to underground gas collection.

2 SUB-SLAB DEPRESSURIZATION SYSTEM

2.1 General description

Sub-slab depressurization (SSD) aims to reduce building occupants' exposure to toxic gases from the soil. A gas collection network is installed under the entire slab and connected to an exhaust pipe, typically 100 mm minimum diameter, installed vertically from below the floor to the roof.

In order to prevent subsurface vapors from entering homes and other buildings, mitigation solutions can be achieved by passive or active SSD. In a passive SSD system, the gas is collected from under the slab by the drainage system to a collector pipe connected to one or several vents, which extracts the gas from the building by natural draft. An active SSD system is created by adding a fan to the drain vent of a passive system to increase the negative pressure applied to the system.

2.2 Gas venting layer

The gas venting layer is constructed using the Draintube multi-linear drainage geocomposite (terminology as per ASTM D4439). It is composed of non-woven geotextiles that are needle-punched together with perforated, corrugated Polypropylene (PP) mini-pipes regularly spaced inside and running the length of the roll. The mini-pipes have two perforations per corrugation at 180° and alternating at 90°. The geocomposite provides the filtration/separation, gas collection and mechanical protection functions with a single product and a single installation.

The mini-pipe components of the geocomposite have a diameter of 25 mm and are typically spaced at 2 m on-center. With this configuration, it exhibits a long-term transmissivity superior or equal to 1×10^{-3} m²/s. This value is measured as per ASTM D4716 or ISO 12958-2 standards, for a hydraulic gradient of 0.02, confined in soil under a normal load of 2400 kPa and a seating time of 1000 hours.

The main characteristic of Draintube multi-linear drainage geocomposites is that they maintain their drainage capacity over time, even under high load (Figure 1). They are not sensitive to creep in compression, nor geotextile intrusion (Blond *et al.* 2010).

Unlike other planar geocomposites, the load transfer mechanism between the overlying and underlying material is only a fraction of the normal load. The mini-pipe component of multi-linear drainage geocomposite is confined by the surrounding soil, thus loads are
Figure 1. Geocomposite transmissivity under 2400 kPa for 1000 hours (ASTM D4716 / GRI GC15).

calculated using traditional flexible pipe design methodologies. The soil arching effect that applies to other flexible pipes also applies to this type of geocomposite.

2.3 *Gas suction pit*

The number and location of gas suction pits are determined according to the position of the header pipe, the gas concentration and the geometry of the building. Using an active SSD system with a venting layer under the overall surface of the building will decrease the number gas suction pits riequiered.

2.4 *Vapor barrier*

A membrane is typically placed under the concrete slab. It prevents contamination of the underlying layers when the concrete is cast and limits the gas migration through the floor. The performance of the membrane layer is dependent on the composition and thickness of the material, but also on its installation (joints between panels, connection to the walls, etc.).

   The vapor barrier can be installed directly on top of the multi-linear drainage geo-composite. Thanks to its geotextiles layers, the geocomposite mechanically protects the membrane from puncture of the underlying soil. The installation of a protective geotextile may also be required on the vapor barrier to prevent puncture by the overlying layers.

   Multi-layers true gas barrier membranes with an ethylene vinyl alcohol (EVOH) core co-extruded between polyethylene (PE) layers are recommended, especially in presence of VOCs. These types of membrane exhibit much lower gas permeability characteristics by an order of magnitude of 10^3 compared to high density polyethylene (HDPE) membranes (Kelsey 2014).

   Membranes are efficient to prevent gas migration, but should not be used without the depressurization system underneath. Indeed, they exhibit a thickness generally lower than 1.0 mm and they are sensitive to puncture, especially during installation. Moreover, junctions between membrane rolls, and connections to the perimeter walls and any interior slab penetrations, such as columns, etc. are weak points and potential causes of leaks. It is crutial to keep the soil underneath the concrete slab at a pressure lower than inside the building with a gas venting layer like multi-linear drainage geocomposite. In case of leaks, the gas migration will then go from inside to ouside of the building where it is harmlessly vented to the atmosphere.

3 INSTALLATION

3.1 *Gas venting layer*

The installation of the gas venting layer is achieved by unrolling the multi-linear drainage geocomposite on the subgrade such that the mini-pipe components are oriented with the intended flow direction and perpendicular to the main header pipe (Figure 2). Rolls are connected along the side with a minimum overlap of 100 mm and secured using seams, welds, or additional overlap. The connection at the terminating edge of the roll is overlapped such that the upper geotextile layer can be rolled back 150 mm and the end of the next roll inserted into the opening. Mini-pipes are connected using snap coupler fitting.

   In the case of columns or other interior slab penetrations, mini-pipes are diverted along the side of the penetration. If diversion is not possible, additional mini-pipe is positioned to redirect the flow to the next closest mini-pipe. Interior walls are addressed using drainage channels for the mini-pipes.

Figure 2.   Installation of the geocomposite on the subgrade.

3.2   *Connection to the header pipe*

The gas venting layer is connected to one or more header pipes. This is a function of the geometry of the building, and the number of exhausts. These connections are achieved using quick connect connectors that allow the geocomposite mini-pipes to be mechanically attached to the header pipe. These quick connects prevent displacement of the mini-pipes during the installation of the upper layers and reduce the head losses at the connection between the venting layer and the exhaust pipe. This mechanical connection allows for single or double connections of the geocomposite to the header pipe.

Depending on the cross section of the SSD (with or without granular fill), the header pipe may need to be placed in a trench (Figure 3) to prevent intrusion into the thickness of the concrete slab.

Figure 3.   Connection to the header pipe.

1445

3.3 *Vapor barrier*

The vapor barrier is generally delivered in rolls that are unrolled and connected with a 300 mm overlap. Joints between rolls, around penetrations and against the walls are sealed to prevent unwanted gas migration. (Figure 4).

Figure 4. Vapor barrier and geotextile installation.

4 DESIGN AND PERFORMANCE

The aim of the gas venting layer is to migrate the gases to the header pipes and then outside of the building using the exhaust pipes. This exhaust system prevents the accumulation of gas under the slab that could eventually infiltrate into the building. The multi-linear drainage geocomposite is compatible with passive and active SSD.

4.1 *Design software*

A software for the hydraulic design of drainage geocomposite and granular drainage layers , named Lymphea, has been developed by LIRIGM (Laboratoire Interdisciplinaire de Recherche Impliquant la Géologie et la Mécanique) at the University of Grenoble (France) in collaboration with Afitex Group and validated by large scale tests (Faure *et al*. 1995). It has been updated and improved with the contribution of the SAGEOS, CTT Group in Quebec, the CEGEP of Saint-Hyacinthe in Quebec, and the University of Saskatchewan in Alberta (Fourmont *et al*. 2023). The calculation module for gas collection using a multi-linear drainage geocomposite is based on the following flow conditions:

– Gas supply with a homogeneous flow distribution perpendicularly to the geocomposite,
– Horizontal or non-horizontal position of the drainage layer with the flow condition down or reverse to the slope α,

The fluid inside the drainage layer is assumed to flow perpendicular to the perforated mini-pipes. This hypothesis is conservative and reasonably good as the distance between the mini-pipes is 2 m maximum, provided the length of the mini-pipes is generally more than 10 m. The flow per unit area collected by the multi-linear drainage geocomposite is calculated with the software as a function of:

– distance between mini-pipes,
– transmissivity of the geotextile drainage layer itself,

1446

– slope (if any),
– length of drainage (distance to the main collector),
– type of gas (density, dynamic viscosity),
– vacuum (negative pressure) applied to the system.

The software allows for SSD design in passive or active conditions. In passive conditions, the determination of the negative pressure applied to the system is based on the Barometric formula, which is a function of the height of the exhaust pipe.

4.2 *Performance of the geocomposite venting layer*

Figure 5 gives the collected flow rate per unit area as a function of the negative pressure applied, for several lengths of drainage, for a multi-linear drainage geocomposite with the mini-pipe components 25 mm diameter spaced at 2 m centers into the product. Calculations have been conducted using air but can also be done for other gas like methane, radon, or any gas mix. The length of drainage is the maximum drainage length to the header pipe, or the half distance between two header pipes in case the geocomposite is connected at both ends.

As an example, in the case of a passive SSD system under a two-storey building, the applied vacuum into the system is 0.070 kPa (6 m height exhaust pipe) and the multi-linear drainage geocomposite will collect a flow per unit area of 7×10^{-6} m³/s/m² over a maximum length of 25 m to the header pipe. The collected flow is then 1.75×10^{-4} m³/s per linear meter of header pipe.
Figure 5. Collected flow per unit area.

As a function of the expected flow of gas to collect, and the vacuum applied into the system, additional header pipes can be installed (to reduce the maximum length of drainage) or the use of a multi-linear drainage geocomposite with a higher density of mini-pipes inside, e.g. mini-pipes on 1 m centers instead of 2 m. The Lymphea software yields the size of the geocomposite based on the project's characteristics.

5 CONCLUSIONS

Draintube multi-linear drainage geocomposite is an effective solution as a gas venting layer in the SSD system. Its dense network of perforated mini-pipes and its mechanical connection

to the header pipe provides a uniform negative pressure under the overall slab of the building. Compared to granular drainage material, the installation of the geocomposite is simple, requiring less excavation works and readily available labor without specialized skills. Additionally, in terms of greenhouse gas emission, social acceptability and economic competitiveness, the system has more positive assets than its conventional counterpart. Multi-linear drainage geocomposites can be used for passive or active sub-slab depressurization systems. A dedicated software is available to calculate the collected flow per unit area as a function of the negative pressure applied, the type of gas and the specific geometry of each project.

In replacement of a granular drainage layer and separation geotextiles, multi-linear drainage geocomposites aim to reduce the Green House Gas emissions while maintaining the same level of effectiveness. Geocomposites save up to 85% of CO_2 equivalent emissions, mostly due to less excavation being needed during installation compared to a granular drainage layer and lighter equipment used in evacuating soil and transporting gravel (Durkheim *et al.* 2010). The geocomposite solution reduces drastically the related costs because there is no soil excavation needed compared to a gravel layer and so no fees for disposal of the excavated polluted soil in a waste facility. It also avoids any problem of supply of granular materials and preserves these natural resources which are not renewable. Because SSD systems are most often required in high-density population areas (e.g. new construction in old industrial zones), the use of a multi-linear drainage geocomposite reduces the social impact on neighboring populations by limiting construction traffic and reducing the duration of the works.

A medical-triage approach to mitigating risk of geomembrane uplift in high wind events during construction

A.K. Maskal & S.L. Maskal
Solmax Geosynthetics

ABSTRACT: Construction and testing sequences at large facilities can require multiple hectares of geomembrane to remain exposed for some time between installation and placement of cover materials. Winds create uplift pressure that can lift an unballasted geomembrane, creating risks ranging from moving the membrane out of place to complete destruction of an installed geomembrane.

The sloped ridge/valley topography used for drainage and stability in landfill cells often resembles an airfoil shape that creates uplift pressure that enhances risk of uplifting an exposed geomembrane to damage.

Previous efforts have defined the mechanics of wind uplift for exposed geomembranes in smaller pond configurations where geomembranes can remain exposed during their service life. However testing and cover aggregate availability often prevent covering a geomembrane during construction, leaving it at risk of being uplifted, displaced, damaged, or even destroyed in sudden high winds.

This paper re-examines wind uplift mechanics for exposed geomembranes and proposes a potential risk/time-weighted procedure for different topographies to minimize the risk of geomembrane damage and loss due to sudden and extreme wind events that occur during construction.

1 INTRODUCTION

Uplift pressures resulting from wind blowing over surfaces lined with geomembranes have been widely studied, and there are a variety of ballasting and anchoring approaches for exposed geomembranes in widespread successful use throughout the world. The uplift pressure in wind events increases proportionally with the square of wind velocity, leading to uplift pressures in high winds that can far exceed what might be expected by an inexperienced observer. In certain topographies for example, uplift pressures can require on the order of 120 kg/m^2 to resist uplift in 160 km/hr winds (25 lb/ft^2 in 100 mph winds). In properly designed and installed ballasting systems, various combinations of soil ballast and mechanical attachments are routinely used to provide downforce that exceeds the uplift, distributed in such a way that the forces mobilized do not damage the geomembrane.

The performance benefit of installation quality control has also been well established, leading to regulatory requirements for specific tests to be performed and accepted. It is therefore common in many parts of the world to have geomembranes that will ultimately be overlain by cover soil remain uncovered for extended periods while testing is performed. Repairs for failed construction quality assurance tests are typically the responsibility of the geosynthetics installer if a geomembrane is still exposed. However, with the vast majority of geomembrane damage caused by cover soil placement activities, the responsibility for repairs is not so clear if testing is not completed on a completed geomembrane installation prior to placing cover soil.

Standard design practice, experience, and common sense all lead one to observe that high wind speeds occur less frequently than more typical slower wind speeds (for example, at a given site, a 5 m/s wind may be likely to occur several times daily while a 50 m/s wind occurs once in several years). The cost and time needed to place and remove temporary ballast create the need for some amount of judgement of cost vs. risk to determine the amount of temporary ballast needed to resist uplift created by winds that will occur during the relatively short periods that geomembranes remain exposed waiting for testing. For relatively short periods wherein a geomembrane is to remain exposed for testing, it is typically appropriate to use much less ballast than will be needed to anchor a geomembrane to withstand all wind events during its lifetime.

Unfortunately, extreme wind events can happen with little warning. Such wind events occasionally happen during the relatively short periods that sections of geomembranes that remain exposed with only temporary ballast. And on rare occasions, there may not be enough time to place enough ballast to resist the resulting extreme uplift pressures in sudden storms. Large sections of geomembranes can and have been lost to wind damage during such "perfect storms."

2 PREVIOUS WORK

Several methods have been proposed for designing ballast systems based on the work of wind tunnel testing by Dedrick (1973, 1974a, 1974b, 1975), development of practical guidance by Giroud, Pelte, and Bahurst (1995) and several subsequent refinements covering different anchoring approaches and topography details.

3 FIELD OBSERVATIONS DURING CONSTRUCTION

There are several applications where large and relatively flat surfaces are lined with geomembranes such as mine heap leach pads and coal combustion residual landfills. In settings where topography is relatively flat, it is common to grade a larger area into a series of alternating upward and downward slopes separated by alternating parallel ridges and drainage swales (similar to common grading in a flat parking lot). The geomembrane is ultimately covered with drainage geocomposites and/or granular materials. Geomembranes with such topography are nearly universally covered with soil prior to service, so there has been little need for research into wind uplift resistance designs for such cell topographies. However, in these large installations – often in remote areas – installed portions of the geomembrane can remain exposed for extended periods awaiting seam test results, geoelectric leak detection surveys using water-based test methods, and cover soil placement within a larger construction sequence.

One of the authors was called to a facility with this type of cell topography following a major unexpected wind event that included wind speeds in excess of 160 km/hr (100 mi/hr) that led to the loss of approximately 50,000 m^2 (500,000 ft^2) of geomembrane that was awaiting test results in a remote area in the southwestern U.S.

A section of geomembrane covering three pairs of ridges and swales remained uncovered for testing with sandbags in place to resist typical seasonal winds. A strong storm changed direction, blowing over the site with very limited preparation time. The specification prohibited heavy equipment from driving directly on the geomembrane, limiting the amount of ballast that could be placed in the short amount of time before the storm.

The contractor and facility owner reported the direction of the strongest winds perpendicular to the ridges and swales. The geomembrane behaved consistently in the wind direction, generally repeating at each of the three exposed ridge/swale structures – remaining

largely in place on the windward slope, rupturing along each ridge line, sliding downwind on the leeward slope leeward slope, and accumulating as wrinkles in each swale.

Although the slopes were relatively flat (on the order of 5%), the repeated pattern created the opportunity for multiple observations of the effects of downforce and uplift on the type of topography used in large flat landfill settings. These observations included:

- Uplift pressures appeared to have been small enough (and/or downforce adequate) to largely keep the geomembrane in place on the windward slopes, effectively anchoring the windward side of the geomembrane along each ridge;
- Rupturing along the ridgelines implies tensile loading in the leeward direction with maximum magnitude at the ridgeline;
- Some combination of uplift pressure and possibly wind below the geomembrane allowed sliding down the gentle leeward slope;
- Effective anchoring of the entire windward slope "trapped" the geomembrane, causing material that slid downslope to accumulate as large (up to approximately 1m tall) wrinkles and creases at each low swale area.

4   KEY QUESTION

In this case, it was impossible to ballast adequately to save all of the geomembrane, making the loss of some portion of the geomembrane inevitable. However, one might wonder how to use some smaller amount of ballast to most benefit – in other words, how much geomembrane could be saved if a limited amount of ballast were placed optimally. This can be thought of as being analogous to the "triage" prioritization of limited medical resources in an emergency situation. The goal being to save as many lives as possible, which requires (1) having a working understanding of resource capacity and (2) very quickly deciding which patients can be saved using the limited resources. In extreme circumstances, these decisions would involve leaving some patient(s) to die while patients that can be saved are treated.

5   ANALYSIS

The windward slope largely remained in place, so for the purposes of this exercise, it is assumed that the entire leeward slope can be saved without additional ballast. Thus, any available ballast should be used on other areas.

The windward geomembrane was effectively anchored at the ridge, and tensile loads resulting from uplift were clearly greatest at the leeward side of each ridge, so placing additional ballast at the ridge would not likely provide any benefit.

This leaves the leeward slope to be anchored with whatever amount of ballast can be deployed. The remaining question is whether deploying a limited amount of ballast to anchor the upper or lower section of the leeward slope would save more geomembrane. For this, a calculation was performed for an example slope measuring 100m long × 400m wide to determine the amount of geomembrane that can be kept in place with a given amount of ballast. 44 m/s wind speed and 1,600 kg/m^3 cover soil density were used as typical values.

Reference uplift pressure was calculated using the Bernoulli equation:

$$P = 1/2\rho v^2 * C_l \tag{1}$$

where P = uplift pressure; ρ = density of air (1.225 kg/m^3); v = wind velocity (44 m/s), and C_l = coefficient of lift.

It was assumed that coefficient of lift, C_l varies linearly from 0.4 at the bottom of the slope (swale) and 1.0 at the top of the slope (peak), as is typical for calculating slopes in reservoirs

(Giroud 1995). The slope was divided into segments with uplift coefficient changing in this manner. The pressure distribution was calculated for each location up the slope. The amount of ballast mass required to resist the uplift was calculated by dividing the uplift pressure by the acceleration of gravity. The results starting at the top of slope (peak) were calculated as were the results starting at the bottom of the slope (swale), so that the two directions could be compared. A graph of percentage of slope length that can be covered vs amount of ballast was prepared. The results of the calculations are presented as Tables 1, 2, and 3. Results are presented graphically as Figure 1.

Figure 1. Percentage of slope that can be ballasted using less than half of the ballast needed to secure the entire leeward surface.

6   RESULTS AND CONCLUSIONS

In the example, as much as 60% more surface area can be ballasted using the same amount of soil if ballasting operations start from the bottom of the slope. The additional amount of surface area that can be ballasted with a given amount of soil decreases higher on the slope, but remains higher at all points when starting from the bottom of slope.

It is therefore recommended that when soil quantities and/or time limit the amount of ballast that can be placed before a sudden high wind event and the windspeed and direction can be estimated with some confidence, fill quantity needed for forecasted wind speeds can be calculated using the Bernoulli equation, and ballasting should start at the low and downwind end of each area. The entire exposed geomembrane may not be saved in an extreme wind event, but using this approach will maximize the amount of geomembrane that remains undamaged by developing a ballasting plan with this very quick method. The ballasting quantities need not be calculated in both directions (as they are the same in opposite order). All of the pressures can be calculated in a table, and fill can proceed quickly starting at the bottom of each slope, proceeding up-slope as far as time, resources, and safety allow.

Yet another excellent reason for locating exposed geomembrane electrical leaks prior to carrying out dipole surveys

C. Charpentier & T. Jacquelin
Groupe Alphard

ABSTRACT: Geomembranes are now part of most designs when dealing with leachates. Good practices suggest performing an electrical leak location survey to ensure imperviousness, or to lower leakage risks to the lower level. Several methods are available for exposed and covered tests, and the relevancy of exposed methods is often questioned: Won't all leaks be found during the covered survey? Tiny leaks such as defects in extrusion seams may be found during dipole survey with ideal conditions but can be hard or even impossible to locate precisely. This scenario has been witnessed in an industrial waste treatment pond as well as in a compost pad leachate pond where a leak area was identified. The protection and drainage layer had been removed, but leak was too small to be noticeable to the naked eye and equipment was inappropriate to investigate any further. This led to a waste of time and uncertainty on all parties regarding the physical and financial responsibility of the defect, whereas a common Water Puddle Leak Location Survey would have located those leaks and they would have been repaired long before the installation of the drainage layer.

1 INTRODUCTION

Geoelectrical Leak Location Methods have been used for decades in all sorts of projects and locations. Technological advances were made to accommodate harsh conditions (weather) and unfavorable specs (ex., double-lined ponds with no conductive layer between both geomembranes). Still, the most limiting factor for most Leak Location projects is the same: budget. The same questions are asked all the time: "why do an exposed survey and then a covered survey? Why not just do the last one?"

Our answer is quite simple: the exposed and covered methods are different, they have a different sensitivity, meaning a Water Puddle Survey will find all defects that occurred during manufacturing, transportation, storage, and installation. A Dipole Survey will find bigger defects like rock punctures, blade and bucket tears, and all big holes made by heavy machinery. Yes, in ideal conditions, a Dipole Survey can be precise enough to find pinholes, but ideal sites are scarce, and it would be unwise to guarantee that level of accuracy in the services proposal, often months before the actual field work starts.

Another great reason to request both methods is to separate responsibility. Once the geomembrane is installed and controlled internally (Quality Control), any defect found will be repaired by the installer at their cost.

From there, all subsequent risks will fall under the general contractor's responsibility such as the installation of a puncture prevention geotextile, an approved way to install the natural material layers and circulating on-site with motorized vehicles. Any additional work due to leaks found with the Dipole Method will be charged to the general contractor, and after that,

any defect and expense will be imputed to the operations department (typically the owner of the site).

On one occasion, a Dipole Survey was conducted on 600 mm of sand. A leak signal was detected, and the area was then excavated. The result was unexpected: the HDPE geomembrane was ripped and there was a sandbag underneath.

This means that the installer forgot to remove the sandbag (often used as a ballast) which resulted in a bump on the geomembrane. The general contractor's heavy machinery had its blade or bucket at approximately 200 mm off the geomembrane, which should have been safe, but in this case, ripped the geomembrane open. Again, this sandbag would have been noticed during a Water Puddle Survey, removed, and patched in no time, with no additional cost.

2 DESCRIPTION OF THE MOST COMMON METHODS

2.1 *Water puddle method (ASTM D7002)*

The Water Puddle Method (WPM) relies on the intrinsic insulation properties of geomembranes for the detection of small perforations (<1 mm^2) in the geomembrane, generally produced at the time of the installation (see following figure). A continuous DC voltage is applied into the metallic Water Puddle structure, and a grounding electrode is placed outside the limits of the geomembrane. In the presence of a leak, the current will pass from the metallic structure, through the defect, into the subgrade and to the grounding electrode, thus producing a visual and auditory signal. This technique requires only a thin film of water on the surface of the geomembrane and provides a validation of the entire exposed surface surveyed.
Figure 1. Water puddle method schematic.

2.2 *Dipole method (ASTM D7007)*

The Dipole Geoelectrical Method relies on the geomembranes' intrinsic insulation properties for the detection of perforations created during the installation of the cover material (see following figure).

This means that electrically conductive geomembranes, such as EPDM (Ethylene Propylene Diene Terpolymer), are also incompatible due to their large concentration of carbon black. Other non-plastic barriers that are impermeable but non-isolating, such as a Geocomposite Clay Liner (GCL), prevent Leak Location as well.

To perform a Dipole Survey, a current of approximately 500 V DC (direct current) is injected into the cover material (usually sand, clay, gravel, or crushed stones), and a grounding electrode is placed outside the limits of the geomembrane. Under normal circumstances electricity will flow from a different potential to a ground to discharge and reach equilibrium, however, with a non-conductive geomembrane, it is confined within the cell. If a defect is present, the current will pass through the hole to reach the ground (electrode). This will then generate a distinct electrical signature that can be identified and located by a specialized technician.
Figure 2.   Dipole method schematic.

3   TYPES OF LEAKS AND CAUSES

Most leaks have obvious causes and can easily be associated with a specific task during construction. Certain defects take the shape of a specific tool or of a power generator leg without its plastic/rubber pad. Sometimes, leaks are aligned in a pattern that can determine which machine caused it, like a faulty track on an excavator, or a pointy stone stuck on a quad tire. Other times, defects on a geomembrane have an unusual shape which really challenges the professionals in finding a cause to adjust construction and lower the risk of creating other similar defects.

Sometimes an extruder gun is put on the liner with the hot end too close to the geomembrane, making it soft, if not liquified.

Damaging effects can also appear by someone walking over waste to access a new cell and getting a piece of scrap metal stuck under their shoe, or any other loose metal on-site like staples or knife blades.

Unless an exposed geomembrane has been in operation for years and has a layer of sediments on it, or because of really bad weather during construction, any defect found should be small or else anybody would have seen and reported it. Therefore, a WPM is expected to find only small defects, faulty extrusion beads, knife cuts, and pinholes.

Our latest WPM statistics show an average of 5.38 leaks/hectare (2.47/acre), which can lead to a considerable flow through a geomembrane depending on the design. The Dipole Method aims to find a 6 mm-wide opening at any place on the site and wherever the Dipole tip lands on a predetermined grid. Site conditions cannot always grant that level of precision and smaller actual holes are not routinely found, meaning a lot of small defects and pinholes are undetected by Dipole Surveys alone.

Of course, big punctures and tears found with the Dipole Method have a far greater impact on imperviousness, it is not implied that the Dipole alone is useless, but it is important to realize not all leaks can be found with a single Dipole Survey based on ASTM D7007. Another standard practice that is used in tandem with the Dipole Method is Electrical Methods for Mapping Leaks in Installed Geomembranes (D8265). This standard has more control on site conditions and data management and implements certain best practices for testing methodology that D7007 lacks. It recognizes that a geomembrane must experience hydraulic head to create an electrically conductive path through the smallest of leaks and that multiple Leak Location Surveys may be required if significant leaks are found during the initial survey, which can reduce testing sensitivity in the same way as poor perimeter isolation. The aim of D8265 is to provide a methodology capable of locating all leaks in a lining system, both large and small.

4 HOW ACCURATE IS THE DIPOLE METHOD

Since the Dipole Method is used to pick up general contractor mistakes or bad geosynthetics leading to holes in a geomembrane, electrical signals are often strong and sharp, so it is easy for an experienced leak locator to start digging less than 500 mm away from the actual hole. That depends on many factors such as the natural material layer's thickness, homogeneity, and peripherical isolation and moisture, to name a few (Gilson-Beck *et al.* 2023). Once the power source is turned off, it is safe to excavate the area where the defect is expected, and the defect is generally easy to spot, there can be bits of torn geomembrane in the area, ripped geotextile, or other geosynthetics, and sometimes, the culprit can be a big pointy rock, a forgotten stake, or trash.

But what happens when there's a perfectly fine drainage geocomposite, a brand-new geotextile, or a geomembrane with no apparent adverse effect? The precise location of a leak relies a lot on a visual inspection of the uncovered geomembrane. If the signal was strong, the surveyor should be confident enough to have the drainage geocomposite or geotextile delicately cut open so the geomembrane can be visually inspected, but what if there is nothing apparent? The excavation might be expanded, but up to what size? If there is a geotextile, it could be watered and a Dipole Survey over it might help locate the signal's origin more precisely but remember that there is no pressure on it anymore, so a pinhole in an extrusion might not have good contact with the wet geotextile.

An installer once had a problem with a third-party Leak Location carrying out the Dipole Method because they had found a signal, excavated the sand, but couldn't locate the defect. They dug about 5 metres in diameter and finally asked the installer to do a 5 metre-wide patch in hopes that it would make the "leak signal go away".

Those small defects and pinholes would be found with Water Puddle equipment, and the repair would be quick and cheap with the installer on-site.

It is rarely the case when the general contractor adds a layer of natural material, so re-mobilizing them has a cost, even if the defect is 2 mm wide. Then, the usual "who is going to pay for that?" happens.

It is too easy to say the leak was left there before the earthworks, or say there's no proof of that, or that it's probably the heavy machinery that put stress on the geomembrane and cracked the extrusion or other tiny physical adverse effect.

5 EXAMPLES OF TINY LEAKS FOUND WITH THE DIPOLE METHOD

The most expensive Dipole Method example yet was a small leak in a toxic waste double-lined cell. As soon as rain started, the amount of water found in the "leak detection layer" was greatly over the tolerated limit.

The owner and general contractor expected a big tear somewhere and proceeded to excavate random sectors to eventually find the leakage area. Every time, a perfectly fine drainage geocomposite was found and the area was considered impervious.

This process went on for months before a Dipole Leak Location Survey was carried out, taking only two days, and a leak signal was identified close to the middle of the cell. After excavation, the drainage geocomposite was intact. A local survey was done over the wet geocomposite to precisely locate the leak, the drainage geocomposite was carefully cut open, and water was pouring out of the wedged seam, on approximately 10 mm in width. A 10 mm^2 hole doesn't sound big but having a drainage geocomposite over AND under the top geomembrane really had a constant flow from top to bottom. Fixing this solved the problem and allowed operations to use the cell.

Another Dipole Survey revealed a leak signal over a 300 mm layer of fine gravel and coarse sand. The center of the anomaly was located at the toe of a slope, which is a typical area for leaks, as bulldozers and such can hardly evaluate the exact depth of the geomembrane right where the slope starts. A tear was expected during excavation, but instead it was a HDPE pipe penetration. Extrusion seams around a small pipe (about 100 mm in diameter) can be very tricky, so the leak signal was probably coming from one point around the penetration, but where? Should the installer grind it all and redo a second layer of extrusion, just to be safe?

It is not smart to grind and weld a perfectly fine water-tight area, and we also try to limit the number of extrusions in general. Studies show that grinding and re-welding weakens the installed HDPE geomembrane (Toepfer 2015). After more observation, a drop of water was found leaking from the side of the extrusion bead. The groundwater was high at that time of the year and there was water pressure from under the geomembrane, which made the repair excessively arduous. It took the liner crew 7 extrusions before completely blocking the electrical signal.

There are many examples like those, where a leak signal is found, an excavation is done, and the geotextile or geomembrane looks intact. We have a little wand we can use that incorporates similar electronics to a Water Puddle detector, to help precisely locate the origin of a leak signature once uncovered. It requires sufficient moisture at the end and amplifies the electrical current going from the cover material (positive voltage from the power source) to a leak (technically zero volts, ground).

6 CONCLUSION

Unless site conditions are ideal (isolated, thin, and homogenous layer), small leaks will not be found.

Another way to phrase the previous sentence would be "not doing a Water Puddle Survey is knowing there are leaks and saving them for the Dipole Survey". That may be a big risk to

take considering conditions at the time of the covered survey might change (precipitations, temperature, schedules) and prevent those small leaks from being found and repaired.

Depending on the site's design, small leaks can lead to a tremendous flow through the geomembrane, and it tends to increase with time due to preferential paths and fine material washed away.

Not all impervious works are critical in terms of water tightness but doing both Leak Location Methods in projects that are critical should be planned and part of good practice. It is also worth mentioning that repairs are far easier to do on a freshly installed clean liner, as opposed to a liner after excavating sand or whatever material sits on the geomembrane, with dirt, moisture, and sometimes not enough room to work effectively (minimal excavation done by the general contractor).

As far as budget and timing go, finding as many leaks as possible during the exposed survey usually allows the installer to repair the defects in a timely manner with no additional costs. Just this point alone could represent more than the cost of a Water Puddle Survey. Our own numbers suggest that a Water Puddle Survey costs approximately 0.5% of a project's global budget. Finding leaks with the Dipole Method means excavations, waiting for the installer to send a small crew, and making repairs in non-ideal conditions. All those additional costs and delays add up quickly, making it a bigger investment than Leak Location on an exposed geomembrane.

Doing a Water Puddle Survey sometimes reveals flaws in the installer's methodology. When those leaks are found in the early stages of a project, it is possible to adjust methods and thus enhance the quality of the job as it goes, instead of having a global portrait of the geomembrane's condition at the end.

Equivalent intermediate geosynthetic barrier system in a landfill for hazardous waste

M. Bianchi
SCL Ambiente, Milan, Italy

P. Ghezzi
Getas Petrogeo, Pisa, Italy

L.E. Russo
HUESKER Srl, Trieste, Italy

ABSTRACT: Bulera's landfill, located in Larderello, Pisa, is one of the few authorized landfills for hazardous waste in Italy, for over 1 million tons. In 2016 was approved the expansion for further 640,500 m^3 but, even if the pre-existing landfill body was properly insulated, in accordance with the Italian regulations in force that time, was not possible to lay directly new waste on the old one. An intermediate barrier had to be designed which was, at the same time, the capping of the old waste body and the bottom of the new one. The equivalence between the mineral barrier required by the Italian regulations and the alternative barrier package with use of Geosynthetic Clay Liner has been demonstrated with two different methods, considering variable hydraulic heads to fulfill the required performance. The barrier system has been approved by the Tuscany Region and some cells have already been made and tested successfully.

1   GENERAL CONTEXT

In the year 2016 the expansion of the Bulera's Landfill was decided adding additional volume above the old waste body temporarily covered, for total expected further quantity of 640,500 m^3 (Figure 1).

Figure 1.   Overview of Bulera landfill.

The Tuscan region imposed the construction of an intermediate barrier between the waste of the old landfill and the new ones belonging to the extension. This barrier was to act, at the same time, as capping for the old landfill and as bottom of the new one, in accordance with Italian regulation 36/2003 in force that time (legislation superseded by the current DL n. 121-03/09/2020) that required, for hazardous waste landfills, a geological barrier (GB) with permeability $K<10^{-9}$ cm/s and a thickness of minimum 5 m. Due to technical, environmental, and financial reasons a 5 m thick clay barrier was not practicable. The regional authorities allowed the designer to find alternative solutions that could have similar performance. To overcome this obstacle, an equivalent barrier system was studied, consisting in one meter layer of compacted clay combined with special bentonite geocomposite (Geosynthetic Clay Liner - GCL). The entire barrier system was completed with a HDPE geomembrane 2.5 mm, drainage geocomposites and protective geotextiles nonwovens. The equivalence has been demonstrated with two different methods (comparison of "flow rates" and "Koerner's approach") varying the hydraulic heads to be able to identify the minimum characteristics required for the geosynthetic package adopted.

2 STRATIGRAPHIC SCHEME

According with the Italian regulation, the alternative barrier system had to be necessarily equivalent to the following:

– Geological barrier: mineral clay layer with permeability $K<10^{-9}$ m/s and minimum thickness of 5 m

   To obtain the equivalence between the two barrier systems, the flux index was considered the relevant comparison parameter to take in consideration in order to get the same streamed flow through 1 m^2 of surface per unit of time ($m^3/m^2/s$) under analogous conditions. With this purpose, the designers decided to evaluate 3 different hydraulic situations, that is, with water heads of 0.30 m, 0.50 and 1.0 m above the barrier.

   The equivalent designed barrier system proposed to carry out was (bottom up):
– 1m of a compacted clay layer with permeability $K<10^{-9}$ m/s
– bentonite geocomposites with specific performance characteristics for equivalence purposes

   With this regard sodium and calcium bentonite geocomposites have been tested.
   On top of the previous layers, the following layers had to be laid:

– HDPE liner with thickness of 2.5 mm
– protective geotextiles nonwovens with static puncturing resistance CBR $\geq$ 13,000 N

   The flow index (q) as well as the other related parameters (permeability and thickness) of the bentonite geocomposites (GCLs) have been determined according to the UNI EN 16416.

3 CALCULATION METHOD

The calculation criteria for equivalence between the mineral layer and the geocomposite layer was based on two different methodologies:

– Equivalence of the flow index. It is expressed in $m^3/m^2/s$ and represents the water flow per unit of surface that crosses a layer per unit time. This is the method closest to reality because it refers to a physical parameter that can be measured with certainty in laboratory tests.
– Equivalence through Koerner's method. This method requires the following input characteristic parameters: permeability expressed in m/s and thickness of the saturated

geocomposite after controlled expansion expressed in mm. This value is obtained from laboratory tests in accordance with ASTM D5887-09 or UNI EN 16416.

4 RESULTS

4.1 Results with the flow index method

The calculation of the flow index for the geological barrier with a thickness T_{GB} = 5 meters and hydraulic conductivity $K_{GB} = 10^{-9}$ m/s was done considering three different water head levels: a) 0.3 m; b) 0.5 m (which corresponds to the full saturation of the 50 cm thick over-lying drainage layer); c) 1.0 m (considering a more critical scenario). The results are shown in Table 1.

Table 1. Hydraulic gradient and index flux of the geological barrier under different water heads.

Water head	H_1 = 0.3 m	H_2 = 0.5 m	H_3 = 1.0 m
Hydraulic Gradient, $i_{GB} = (H+T_{GB})/T_{GB}$ [-]:	1.06	1.10	1.20
Index Flux q_{GB} [m^3/m^2/s]:	1.06 10^{-9}	1.10 10^{-9}	1.20 10^{-9}

Therefore, the equivalent barrier package must not exceed the flow index obtained for the geological barrier (GB) T_{GB} = 5 m thick, permeability $K_{GB} \leq 1 \times 10^{-9}$ m/s, under the three different water head considered, that is:

- Hydraulic head 0.3 m: maximum flow index q = 1.06 10^{-9} m^3/m^2/s
- Hydraulic head 0.5 m: maximum flow index q = 1.10 10^{-9} m^3/m^2/s
- Hydraulic head 1.0 m: maximum flow index q = 1.20 10^{-9} m^3/m^2/s

4.2 Results with Koerner's method

The essential function assigned to any barrier system is the ability to contain liquids as demanded by the specific project. The Koerner's method is linked to the previous one related to the flow index which, consequently, remains the main reference. The method, in fact, entirely refers to the concept of equivalence between the flow index and, therefore, velocities, but imposes the calculation as a function of the physical characteristics of the product, thickness and permeability, which should be considered according to the real performance values.

The values to be adopted in the calculation are those that can be obtained from certificates issued by independent laboratory tests and supplied by manufacturers to verify and assess the performance of the product: thickness after controlled expansion and actual characteristic permeability. Applying the criteria of equivalent flow rate, considered as water volume flowing through a soil layer per unit area and per unit of time, with the Darcy's formula the required minimum permeability for the GCL is:

$$k_{GCL-required} = k_{GB} \cdot \frac{T_{GCL}}{T_{GB}} \cdot \frac{(H + T_{GB})}{(H + T_{GCL})} \tag{1}$$

The maximum permeability value required for geological barrier (GB) by the Italian norm (Legislative Decree 36/03) in force that time was $k_{CCL} = 1 \times 10^{-9}$ m/s with a minimum thickness of 5 meters. As mentioned before, For Bulera's landfill it was decided to consider

three different hydraulic heads, that is, $H_1 = 0.3$ m; $H_2 = 0.50$ m and $H_3 = 1.0$ m to examine the equivalence with the GCL. Varying the thickness T_{GCL} of the bentonite geocomposite (which, according to Koerner's method, correspond to that after controlled expansion measured during permeability test), the maximum allowable permeability was obtained (see Table 2).

Table 2. Maximum allowable permeability as a function of GCL thickness after controlled expansion.

Thickness mm	max. K allowed [m/s]		
	$H_1 = 0.3$ m	$H_2 = 0.5$ m	$H_3 = 1.0$ m
9.0	3.09×10^{-11}	1.94×10^{-11}	1.07×10^{-11}
10.0	3.42×10^{-11}	2.16×10^{-11}	1.19×10^{-11}
10.5	3.58×10^{-11}	2.26×10^{-11}	1.25×10^{-11}
11.0	3.75×10^{-11}	2.37×10^{-11}	1.31×10^{-11}
11.5	3.91×10^{-11}	2.47×10^{-11}	1.36×10^{-11}
12.0	4.08×10^{-11}	2.58×10^{-11}	1.42×10^{-11}
12.5	4.24×10^{-11}	2.68×10^{-11}	1.48×10^{-11}
13.0	4.40×10^{-11}	2.79×10^{-11}	1.54×10^{-11}

5 SELECTION OF THE GEOSYNTHETIC CLAY LINER

During the selection phase, three different GCLs were investigated (Type A, B and C) on which evaluate the equivalences under different hydraulic heads, both using the flow index and the Koerner method. In Table 3 are shown the minimum performance values obtained by the manufacturer through numerous laboratory tests performed on the three types of geocomposites which allowed to obtain their thicknesses after expansion (average value - standard deviation) and the hydraulic conductivity as tested (average value + standard deviation).

Table 3. Comparative analysis of three GCLs to determine their suitability for equivalence.

GCL			Type A	Type B	Type C
Thickness [mm]	10.5	12	10.5	12.0	12.0
			max K_{GCL} [m/s] obtained from the test set		
			$K_A = 7.83$ E^{-12}	$K_B = 1.90$ E^{-11}	$K_C = 5.73$ E^{-11}
H [m]	$K_{allowed}$ [m/s]		$K_A \leq K_{all}$	$K_B \leq K_{all}$	$K_C \leq K_{all}$
0.3	3.58×10^{-11}	4.08×10^{-11}	OK	OK	NO
0.5	2.26×10^{-11}	2.58×10^{-11}	OK	OK	NO
1.0	1.25×10^{-11}	1.42×10^{-11}	OK	NO	NO

The equivalence has been determined on all products for hydraulic head of H = 0.30 meters while, for higher levels, the market choice is limited.

After carrying out a comparative analysis, the chosen material was Nabento RL-N 5500 F (WB) that fulfill all the required features: minimum unit weight 5000 g/m^2 of sodium bentonite, minimum thickness after controlled expansion of 10.5 mm and permeability values under different hydraulic heads below the maximum permissible. After this investigation, the Tuscan Region authorities decided to establish the minimum parameters that the

geocomposite had to respect in order to carry out Quality Controls of the material supplied on site, and specifically: minimum unit weight of bentonite 5.0 kg/m^2; minimum thickness before expansion T_{GCLmin} = 9 mm; maximum permeability under 1.0 m water head and $K_{max} = 1.25 \times 10^{-11}$ m/s.

Furthermore, it should be emphasized that, for design reasons related to stability issues, not only the hydraulic characteristics were considered in the choice of the GCL, as it was necessary to verify aspects related to the stability of the waste mass, up to 20 m high, placed above a sloping intermediate barrier that was a potential sliding surface. The shear strength at the interface between GCL/clay and GCL/HDPE geomembrane had to be suitable, as well as the internal long-term shear strength of the material. Thanks to the rough surfaces of the selected product and the high internal friction angle value (>36°) was possible to reach shear strengths values higher than the minimum required for every interface. All adopted values for design calculations were supported by a consistent number of laboratory tests and certificates. The stability analyzes carried out are not presented here because they are beyond the scope of this paper, but it is considered appropriate to point out the need to evaluate not only the hydraulic aspects but also the mechanical performances required of the product for the specific work when selecting a GCL.

6 BARRIER SYSTEM CONSTRUCTION

The first cells of the new landfill were constructed in the 2019. The sequence is shown in Figures 2 and 3.

The required performance was assessed trough several laboratory tests. The mineral barrier showed permeability values variable from K< 9.9×10^{-10} m/s to K< 1.2×10^{-10} m/s. The supplied geocomposites were checked through:

– Manufacturer's declaration of conformity
– Test certificates issued by independent laboratories provided by the manufacturer
– Laboratory tests performed by the manufacturer on the supplied production lots
– Laboratory tests performed on samples taken on site (results in Table 4)

Figure 2. GCL and drainage geocomposite rolls stored on flat surfaces to avoid detrimental deformations.

Figure 3. Slopes covered, from left to right, with the rough GCL, the HDP liner, drainage geocomposite (slopes) and nonwoven geotextile (bottom).

Table 4. Comparison between the minimum required values and the laboratory results obtained from 4 GCL samples taken from the site.

	Unit weight UNI EN 14169 gr/m^2	Thickness (dry condition) UNI EN ISO 9863-1 mm	Permeability (under 1 m water head) UNI EN 16416 m/s
Required	≥ 5000	≥ 9.0	$\leq 1.25\ 10^{-11}$
Sample 1	5920	9.51	$7.17\ 10^{-12}$
Sample 2	5940	9.11	$7.24\ 10^{-12}$
Sample 3	6080	9.60	$8.91\ 10^{-12}$
Sample 4	6150	9.25	$8.01\ 10^{-12}$

7 CONCLUSIONS

The construction of impermeable barrier systems in hazardous waste landfills is highly demanding. The 5 m thick layers of mineral clay layer required by law in Italy for the bottom barrier is difficult to fulfill due to technical, environmental, logistic and financial reasons.

The paper describes the possibility to construct a thinner equivalent barrier system making use of special GCLs that must fulfill specific demanding performances related to hydraulic and static issues.

In Bulera's landfill, the equivalent barrier system was designed using a particular GCL which required performance was supported by a consistent number of tests. The equivalence demonstration of the proposed solution allowed the approval by the regional authorities.

During construction, quality control assessments were done through tests made on the material supplied on site which provided positive results, confirming the validity of the adopted technical solution.

Subaqueous sediment capping with a geocomposite containing activated carbon in Sydney (Australia)

S. Niewerth
HUESKER Synthetic GmbH

G. Martins
HUESKER Australia Pty. Ltd.

ABSTRACT: At Kendall Bay in Sydney, the New South Wales Environment Protection Authority issued a sediment remediation declaration for a significantly contaminated area adjacent to a former gasworks facility. Today the disused industrial site has become a modern residential district. Therefore, not only the area on land was redeveloped but also the sediments in the bay. It was determined that remediation was required where the sediments contain total polyaromatic hydrocarbon (PAH) concentrations greater than 25 mg/kg on average and total recoverable hydrocarbon (TRH) of more than 4000 mg/kg on average. To remediate the highly contaminated sediments a subaqueous cap with an active geocomposite filled with activated carbon was built. This geotextile contaminant barrier adsorbs the organic contaminants before they can reach surface water due to diffusion and groundwater discharge. An accumulation of the pollutants in the water of the bay, the benthic and the aquatic organisms is thus prevented over several decades. In addition, the strong odor of organic contaminants is bound by the active geocomposite. The full-scale remediation work was completed from September 2019 until October 2020. In Kendall Bay, it was demonstrated that the installation process can be done quickly and in a variety of aquatic situations, including rivers, harbors, lakes, wetlands, etc.

1 INTRODUCTION

Waterways have been used as transport routes and ports as transshipment points for raw materials, fuels, and residual materials since the beginning of industrialization. In addition, the water also serves as cooling and service water. Accordingly, since the early 19th century, the processing industry and, somewhat later, power plants have settled along river courses. Until the middle of the 20th century, there were no significant requirements for water protection. As a result, contaminated subaqueous sites can be found in industrialized and emerging countries. Not only industry is a source for contamination but also waste dumps, agriculture, infrastructure, or mining. The discharge of pollutants into water bodies inevitably leads to deterioration of water quality and deposition in sediments. In order to reach water quality levels from current directives, such as Australian Water Quality Guidelines or European Water Framework Directive, these sites may need to be remediated.

Modern remediation always focuses on the entire ecosystem and considers all possible interactions resulting from the intervention in the system. Accordingly, extensive knowledge is required not only about the contaminant levels in sediments, but also experience and simulations of impact pathways from sediments to receptors, such as native plants and fish. As an example, the evolution of the pollutant concentration in fish tissue can be considered for different remediation methods. A study done by Patmont *et al.* (2014) compares three remedial options that in principle can be chosen for subaqueous remediation:

1. Monitored natural recovery/attenuation (MNR)
2. Sediment Capping (conventional and active)
3. Dredging

MNR (sometimes also called MNA) based on the principle that a variety of organic pollutants are steadily decomposed by natural processes. The degradation of the substances is continuously monitored in the water and in receptors. If a defined concentration threshold is not exceeded no further technical actions need to be done. Accordingly, this method is the one with the gentlest intervention in the ecosystem. With sediment capping the exposure pathway from the contaminated seabed to the surface water and thus to receptors is interrupted with the help of an isolation layer. Compared with dredging, the method is also gentle with regard to contaminant spills as a result of sediment raising in the water. This technique will be explained more in details in the next chapter. Dredging of contaminated sediments is probably the most common remedial option. With the help of a dredger, the sediments are removed from the seabed, dewatered ex situ and, if necessary, securely refilled, landfilled, or utilized. The advantage obviously lies in the elimination of the source of the pollutant and possibly also in the deepening of the water body. A study on the spillage of pollutants from the three named methods was carried out by Patmont *et al*. (2014). It becomes apparent that dredging work inevitably causes a strong, short-term increase in the concentration of pollutants in receptors (here fish) during and after the construction work. In the long term, the concentration in receptors reaches the same low values as with sediment capping. Next to the long-term development of contaminant concentration there are also many other factors to consider when choosing the best remedial option for a specific site (sediment management plans, functions of waterway for navigation and flood storage, etc.).

2 SEDIMENT CAPPING

2.1 *Conventional capping*

A distinction is often made between a conventional thick layer cap and an active thin layer cap. A conventional cap consists of 1 m or more of sand that is placed on top of the seabed. These clean sediments isolate the contaminated sediments, i.e. avoid a contaminant migration with the pore water in the benthic habitat layer and the surface water. As sand has no sorption capabilities a thick layer is necessary. Not only the weak chemical isolation properties of sand but also construction related uncertainties (mixing of clean and contaminated seabed, placement unevenness, etc.) and influences from the energy water environment (currents, waves, erosion, vessel traffic, etc.) lead to the high thickness, as shown in Figure 1.

Figure 1.   Design of a conventional thick layer cap (based on Reible & Eek 2017).

Thus, it must be ensured that the minimum thickness for the chemical isolation (∼30 cm) under the habitat layer (∼10 cm) is given even if all uncertainties have been realized, i.e. mixing has taken place, cap is installed uneven, and parts of the cap have eroded.

2.2 *Capping with active geocomposites*
