Construction scheduling is a complex process with a lot of considerations for successful project delivery with different and specific approaches for each scheduling constraint (Okonkwo et al., 2022). Preparing good schedules is a time-consuming process that requires a deep understanding of the construction process (Sulbaran, & Ahmed, 2017). Construction schedules serve many purposes ranging from informing owners on state of progress, establishing long-term coordination among crews and trade contractors, to specifying terms of payment (Halpin & Senior, Bolivar, 2017). The construction schedule is one of the most important planning and control tools for the construction process (Rosłon et al., 2020), frequently includes a very large number of activities (Essam et al., 2023) and it is the core of the project plan. It is used by the project management team to commit resources to the project and show the organization how the work will be performed (Magalhães-Mendes, 2011). The main goal of a construction schedule is to identify the activities needed to complete a project and sequence them in the most efficient way possible within the timeframe and resources available (Essam et al., 2023). Construction scheduling is a complex process due to the interdependence and contradiction of project activities (Essam et al., 2023). Construction schedule practices rely heavily on manually elaborated descriptions of construction means and methods (Amer & Golparvar-Fard, 2019). The preparation of a construction schedule including the number of activities, the names of the activities, the duration of those activities, and the relationship between the activities which heavily relies on the judgment and expertise of the project management team.

The names of the construction activities are the only unstructured data attribute in the construction schedules (Hong et al., 2021). Construction activities are described using Natural Language expressions with little or no standardization, grammatical errors, abbreviations, project and construction-specific terms (Heigermoser et al., 2019). Construction activities have been widely discussed in the construction literature (Amer & Golparvar-Fard, 2019) as they are critical in construction schedules. The activity names are devised to communicate between stakeholders, however, they are often written using inconsistent terminologies with omitted contextual information

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Tulio Sulbaran, *Evaluating the Comprehension of Construction Schedules of an Artificial Intelligence,* pp. 545-552,
DOI 10.36253/979-12-215-0289-3.53

(Hong et al., 2021). The inconsistency and omissions are due in part because construction schedules are prepared by project management teams' using their tacit knowledge. The tacit knowledge is the common knowledge on the process of conformance checking that is applied by domain experts (Yurchyshyna & Zarli, 2009). This inconsistency in the activity names is further aggravated by the variety of construction means and methods to perform construction activities and the differences in practice between different construction companies (Amer & Golparvar-Fard, 2019). It is also the case that in most instances, historic information including scheduling decision reasoning is not documented and disseminated for use in other future projects (Hong et al., 2022). Although construction companies might establish procedures to propagate their construction scheduling knowledge between different projects and teams (Amer & Golparvar-Fard, 2019), it is ultimately the project management team that prepares the construction schedule. This current scheduling practice leads to activities written in an inconsistent format with inconsistent terminologies (Hong et al., 2021) which makes it extremely challenging for both humans and machines to understand the meaning and scope of the activities.

The problem addressed by this paper is the challenge faced by machines to comprehend the activities of a construction schedule. Thus, the objective of this paper is to evaluate the ability of an Artificial Intelligence (AI) implementation to comprehend activities of a construction schedule. The AI's ability to comprehend construction activities is critical to further advance the AI competence to assist project management team in the preparation of construction schedules or perhaps prepare drafts of the construction schedules for them to review and fine tune.

Artificial intelligence (AI) is poised to rapidly transform businesses particularly the construction industry. Although, AI is still a new technology in the construction industry, it has the potential to have a major impact particularly in construction schedules. AI powered scheduling tools could help the project management teams create more accurate and efficient schedules, which could lead to significant cost savings and time savings. Optimized schedules are expected to yield significant cost savings over the actual schedules employed (Kettunen & Kwak, 2018).

Artificial Intelligence has many branches and sub-branches as shown in Figure 1. Artificial Intelligence is the capability of a device to perform functions that are normally associated with human intelligence, such as reasoning and optimization through experience (Grewal, 2014). Artificial intelligence brings into being machines that respond to stimulation consistent with traditional responses from humans, given the human capacity for contemplation, judgment and intention (Grewal, 2014).

A subset of Artificial Intelligence (AI) is Machine Learning (ML) in which intelligence is provided to a system so that it can act automatically make decisions depending on the past experiences (Tiwari, 2022). Machine learning focuses on the development of algorithms that can learn from data without being explicitly programmed. ML algorithms are typically trained on large datasets of labeled data, and they can then be used to make predictions or decisions on new data. One of the types of machine learning is unsupervised learning in which the algorithm is not given any labeled data. Instead, the algorithm is given unlabeled data and it must find patterns in the data on its own. Unsupervised learning algorithms try to infer a function to find hidden relations between data points (Tiwari, 2022).

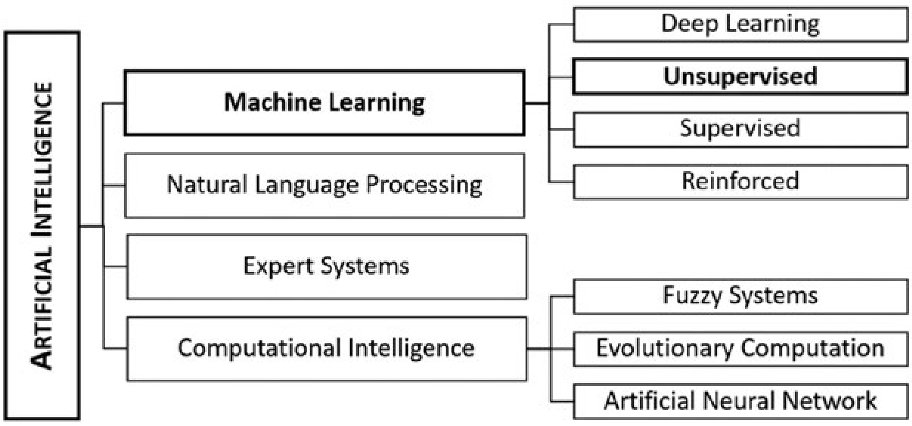

Fig. 1: Sample Areas of Artificial Intelligence

2. RESEARCH METHODOLOGY

A mixed research method was used in this research. The mixed research method draws largely on quantitative and qualitative research (Leedy et al., 2019). Despite its advantages in comparison to mono methods, mixed methods research had been underutilized in the management sciences (Molina-Azorin & Cameron, 2010). However today, mixed methods research is increasingly being used in many disciplines (Bentahar & Cameron, 2015). The use of mixed research method has increased so much that a specialized journal is devoted specifically to mixed methods research - The Journal of Mixed Methods Research, published by Sage (Bentahar & Cameron, 2015). The mixed method was used in this research because both non-numerical and numerical data were needed to evaluate the ability of an AI implementation to comprehend activities of construction schedules. The implementation of the mixed research method was done in four stages: data collection, AI training and preparation, activity interpretation, and analysis as shown in Figure 2.

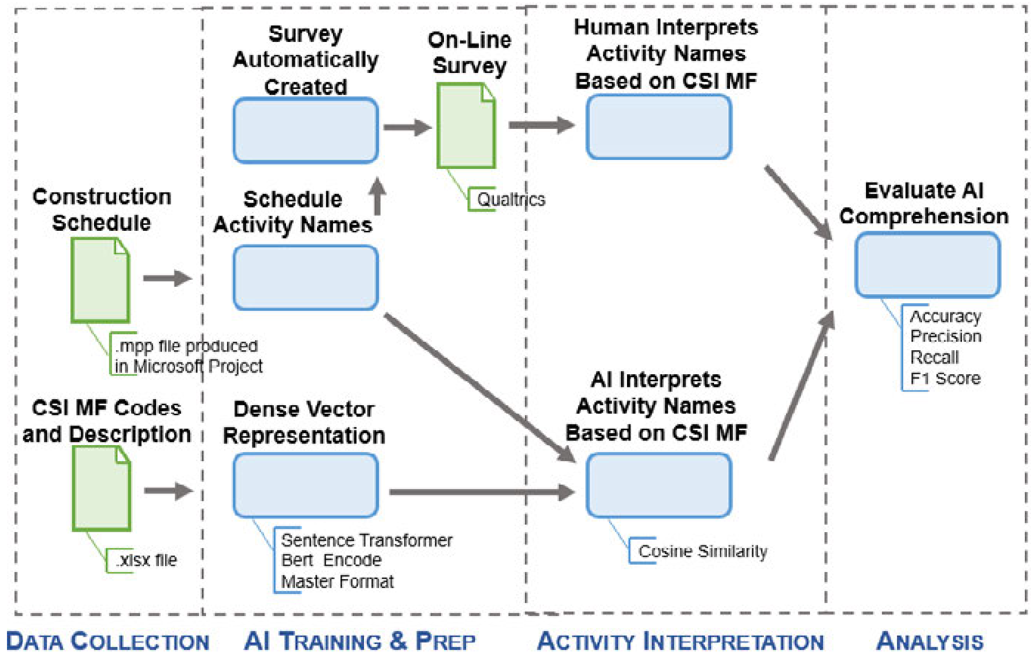

Figure 2: Research Stages

- *Data Collection:* data of a construction schedule as well as data regarding the Construction Specifications Institute (CSI) Master Format (MF) 50 divisions activity codes and descriptions were gathered.

- *Artificial Intelligence Training and Preparation:* the CSI MF 50 divisions activity codes and descriptions were used to train the machine using sentence transformer with a BERT encoder. During the stage also the activities from the construction schedule were extracted and used to automatically create the question of a survey to be deployed on-line through Qualtrics.

- *Activity Interpretation:* the activities of the schedule were provided to a group of humans and an AI. They both were asked to interpret the activities in accordance to the CSI MF 50 divisions. The humans completed the tasks through the online-survey in Qualtrics while the AI completed using the cosine similarity metric.

- *Analysis:* confusion matrix was used to evaluate the AI comprehension of activities in the construction schedule including four metrics – accuracy, precision, recall, and F1 scores to provide a complete picture of the AI performance.

3. RESULTS

3.1 Data Collection

The construction schedule gathered for this research project was composed of 94 activities from notice to proceed to final completion. The project was a 6,500 SF, single story, steel frame, metal stud, gypsum partitions with loadbearing brick and block. The project was a court house in a city in the United States with an approximate cost of $300/SF and a total estimated cost of approximately 2 million dollars.

The Construction Specifications Institute (CSI) Master Format (MF) 50 divisions activity codes and descriptions gathered for this project were composed 7533 individual activities grouped in 35 divisions currently activity from Division 00 – Procurement and Contracting Requirements to Division 48 – Electrical Power Generation.

3.2 Artificial Intelligence Training and Preparation

The training of Artificial Intelligence (AI) was done in Jupyter Notebook which is a free, open-source, interactive web tool known as a computational notebook (Perkel, 2018). Jupyter Notebook was used because it has emerged as a de facto standard for data scientists (Perkel, 2018). The programming code in Jupyter Notebook was done using Python taking advantage of the Sentence Transformers framework to compute semantic similarity and develop the embedding model (Devika et al., 2021). An embedding model is a type of machine learning model that is used to represent words or other discrete entities as real-valued vectors. The real-valued vectors were created using the Bidirectional Encoder Representation Transformers (BERT) Natural Language Inference (NLI) which maps sentences & paragraphs to a 768-dimensional dense vector space and can be used for tasks like clustering or semantic search (Devika et al., 2021). The BERT-NLI models was provided the list of the Construction Specifications Institute (CSI) Master Format (MF) 50 divisions activity codes and returned the corresponding vector for each of the 50 divisions.

The preparation of the survey was done by uploading the construction schedule into a Jupyter Notebook. The Jupyter Notebook extracted the 94 activities from the construction schedule and automatically prepared the 94 questions using the template shown in the Table 1a. Additionally, the questions were grouped into four quartiles according to the cosine of similarity values between the activity and the CSI MF 50 Divisions per the AI Interpretation of the Activities as shown in Table 1b. The four group of questions were uploaded into Qualtrics. In Qualtrics, randomized sub-set of questions to be shown to each participant from each quartile were entered as shown Table 2.

Table 1: Template, Quartiles, and Number of Questions

a. Questions Template
Activity Description: <Activity from Construction Schedule Here> Select from the pulldown below the CSI Master Format Division for which the activity description above (in bold) belongs to. If the activity does NOT belong to any of the CSI Master Format select "None of the Above".

b. Quartile and Number of Questions

Quartiles	**Cos Similarity Values**	**Number of Activities**
Top 25%	More than 0.875	24
Second 25%	0.875 to 0.831	23
Third 25%	0.830 to 0.779	23
Bottom 25	Less than 0.779	24

3.3 Schedule Activity Interpretation

The first part of the construction schedule activity interpretation was done by humans. To ensure that the participating humans could answer the questions within 15 minutes, only the randomized sub-set of questions were provided to each participating human. The sub-sets were composed of 18 of the 94 questions. In the 18 questions, there were three questions from the top two quartiles and six questions from the bottom two quartiles as shown in Table 2. This decision of having more questions from the bottom two quartiles was done because it was anticipated that there was going to be a lower percentage of AI construction activity interpretation that were going to match the interpretation from the participants. Additionally, none of the questions were mandatory, so the participants could skip some of the questions resulting in a total of 316 answers from the participants. The second part of the construction schedule activity interpretation was done by AI using the BERT-NLI model. The AI was given the same construction schedule activities with the same questions given to the human.

Table 2: Questions Template and Number

Quartiles	Questions Per participant	Total Questions Answered
Top 25%	3	51
Second 25%	3	53
Third 25%	6	105
Bottom 25%	6	107
Total	18	316

3.4 Artificial Intelligence Schedule Activity Analysis

The task of interpreting the activities of a construction schedule according to the 50 Divisions of the CSI Master Format was completed first by eighteen human participants. The participants' demographic was as follows: 77.8% Hispanics, 61.1% between 20 and 24 years old, 77.8% males, and 55.6% with 1 to 5 years work experience. The responses of the participants were grouped in the same four quartiles of questions as shown in Table 1 then the answers of the AI were also grouped in according to the four quartiles. If the answer of the AI matched the answer of the humans, the answer was considered a match if not it was considered a no match. The AI identification of the activities match the human answer on average 50% for the first the three quartiles which correspond to the quartiles that the AI was expected to match the human answer. Likewise, the AI identified activities did not match the human answer in the bottom quartile 75% of the times as expected.

Table 3. Questions Template and Number

Quartiles	Number of Activities	Number and % of Match	Number and % of No match	Number and % of Match	Number and % of No match
Top 25%	24	14 (58.3%)	10 (41.7%)	35 (50.0%)	35 (50.0%)
Second 25%	23	10 (43.5%)	13 (56.5%)		
Third 25%	23	11 (47.8%)	12 (52.2%)		
Bottom 25%	24	6 (25.0%)	18 (75.0%)	6 (25.0%)	18 (75.0%)

Furthermore, the Artificial Intelligence (AI) comprehension of the scheduling activities was also done using a confusion matrix. A confusion matrix represents the prediction summary in matrix form (Tiwari, 2022). It is a tool to determine the performance of the AI useful to identify areas where the AI may need improvement. The confusion matrix is useful because shows how many predictions are correct (true) and incorrect (false) per class (Tiwari, 2022). The two classes used in this research were that the AI was either expected to identify (top three quartile) or no identify (bottom quartile) the activities in the construction schedule.

The values used in the confusion matrix for the AI Activity interpretation correspond to the first top three quartiles for identified and the bottom quartile for the not identified. Also, for the actual activity identified corresponds to the match while the not identified correspond to the no match. As shown in Figure 3, the confusion matrix has two rows and two columns with four possible outcomes (true positive, false negative, false positive, and true negative). The top left quadrant shows the number of true positives, which are cases where the AI implementation correctly identified the activity. The bottom left quadrant shows the number of false negatives (also known as type II error), which are cases where the AI implementation was not expected to identify the activity but was in fact able to identify the activity. The top right quadrant shows the number of false positives (also known as type I error), which are cases where the AI implementation was expected to identify the activity, but provided the wrong activity interpretation. The bottom right quadrant shows the number of true negatives, which are cases where the AI implementation was not expected to identify the activity and in fact was not able to identify the activity.

AI Activity Interpretation	Actual Activity: Identified	Actual Activity: Not Identified
Identified	True (1) Positive (TP) 35	False (2) Positive (FP) 35
Not Identified	False (3) Negative (FN) 6	True (1) Negatives (TN) 18

Legend:

AI was expected to identify activities

TP = True Positive = AI correctly identified activity (as expected)

FP = False Positive = AI did not identify activity

AI was not expected to identify activities

FN = False Negative = AI correctly identify activity (although it was not expected to identify the activity)

TN = True Negatives = AI did not identify activity (as expected)

(1) Correct predictions

(2) Type I Error

(3) Type II Error

Figure 3: AI Interpretation of Construction Activities Confusion Matrix

The confusion matrix information was used to calculate four metrics – accuracy, precision, recall, and F1 scores to provide a complete picture of the AI performance in comprehending the activities in the construction schedule.

- *Accuracy:* is used to find the portion of correctly interpreted activities. In other words, measures how often the AI is correct. The value ranges from 1 for 100% accurate to 0 for 0% accurate. The equation used to calculate accuracy is presented in Equation 1 resulting in the AI having an accuracy to identify activities of 0.56.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} = \frac{35+18}{35+18+35+6} = 0.56 \qquad \text{Equation 1}$$

- *Precision:* is used to calculate the AI's ability to interpret positive values correctly (True). In other words, measures how often the AI correctly identified the activity when it was expected to do so. Precision is equal to the ratio of the number of construction activities correctly interpreted to the total number of construction activities predicted. The value ranges from 1 for 100% precise to 0 for 0% precision. The equation used to calculate precision is presented in Equation 2 resulting in the AI having a precision to identify activities of 0.50. This result is consistent with literature as fully AI automated approach is still immature to be used in the industry where the best model scored 0.511 precision (Amer et al., 2021)

$$Precision = \frac{TP}{TP+FP} = \frac{35}{35+35} = 0.50 \qquad \text{Equation 2}$$

- *Recall:* (also called sensitivity) is used to calculate the AI's ability to interpret activities among all the activities. In other words, measures how often do the AI correctly identified the activities weather or not is expected to do so. Recall is the ratio of the number of construction activities correctly interpreted to the total number of construction activities interpreted. The value ranges from 1 for 100% recall to 0 for 0% recall. The equation used to calculate precision is presented in Equation 3 resulting in the AI having a recall to identify activities of 0.85.

$$Recall = \frac{TP}{TP+FN} = \frac{35}{35+6} = 0.85 \qquad \text{Equation 3}$$

-*F1-Score:* is the harmonic mean of Recall and Precision. In other words, it is useful when a balance between Precision and Recall needs to be taken into account.

$$F1\ Score = \frac{2*Precision*Recall}{Precision+Recall} = \frac{2*0.50*0.85}{0.50+0.85} = 0.63 \qquad \text{Equation 4}$$

4. SUMMARY

The construction schedule activity names are of particular interest as they are the critical core unit to create the schedule. Unfortunately, there is no standard naming conversion for those activities and they vary from project to project as well as from project management team to project management team. This inconsistency of the activity name makes it extremely challenging for both humans and machines to understand the meaning and scope of the activities. Therefore, the objective of this paper was to evaluate the ability of an Artificial Intelligence (AI) implementation to comprehend activities in a construction schedule. Following a mixed method in this research, the AI was implemented using the Bidirectional Encoder Representation Transformers (BERT) Natural Language Inference (NLI) with the list of the Construction Specifications Institute (CSI) Master Format (MF) 50 divisions activity codes. The result was that the AI has 0.56 accuracy, 0.50 precision, 0.85 recall and, 0.64 F1 Score.

5. FUTURE WORK

Despite the AI not being 100% accurate, this paper opens a wide variety of future research opportunities grounded on the mixed method used in this research with the four stages (Data Collection, AI Training and Preparation, Activity Interpretation, and Analysis). Some of those future research opportunities include: 1- Used other method to evaluate the NLP such as the Area Under the Curve (AUC) of the Receiver Operating Characteristic (ROC) curve, 2- Evaluating other NLP Encoder, 3- Comparing Performance among multiple NLP Encoders, 4- Implement a mixture of unsupervised and supervise NLP, and 5- Expand the number and type of schedule activities to be implemented just to mention a few. Upon achieving a higher level of comprehension future research could be directed towards using AI to assist humans in the preparation of construction schedules or perhaps prepare drafts of the construction schedules for the human to review.

MULTI-ROBOT FEDERATED EDGE LEARNING FRAMEWORK FOR EFFICIENT COORDINATION AND INFORMATION MANAGEMENT IN SMART CONSTRUCTION

Xinqi Liu, Jihua Wang, Ruopan Huang & Wei Pan

The University of Hong Kong, Hong Kong SAR

ABSTRACT: *Smart construction involves a growing array of devices that generate extensive data, capable of enhancing construction efficiency and productivity. Nonetheless, the handling of this diverse and abundant information, along with the geographical spread of construction sites, poses challenges to effective communication and information processing within the management system. Multi-robot systems, as a new type of Internet of Things device, have the potential ability to coordinate workers to complete their work while serving as an edge node for information storage and processing. This paper presents a multi-robot federated edge learning framework that facilitates construction information management and communication. The work demonstrates the role of distributed databases in processing information during project execution, in contrast to centralized information systems. To address the intricacies of construction sites and the wide array of equipment involved, unmanned aerial vehicles and quadruped robots are employed as edge nodes. The formation of a federated edge learning framework ensures the real-time processing of massive data and data privacy issues. The Federated Multi-Robot (FedMR) framework is a global sharing model focused on preserving differential privacy protection. This framework is distributed to multiple edge robots in each round, enabling local real-time processing of robot tasks. The system can accomplish target detection and tracking of workers based on computer vision. Additionally, we collect MiC energy consumption data during the construction process and predict carbon emissions. Based on the implementation and testing of the system, it has been shown to provide structured and reliable information, fast local transmission, and the ability to process information in real-time. The system's ability to coordinate workers and process information makes it a valuable tool in smart construction.*

1. INTRODUCTION

The increasing development of the construction industry towards being smart and the concern about management informatics stimulate a higher requirement for adopting construction technology. Internet of Things (IoT), blockchain smart contracts, and AI in construction are emerging as the next wave in smart construction, with examples such as detecting the presence of objects in the construction environment to improve safety (Fang et al., 2018). The management of complex projects will be efficient, automated, and intelligent with computer vision technology (Xu et al., 2021). Prefabrication involves the use of different components from different manufacturers. This makes it difficult to standardize data sharing across the industry, leading to a lack of consistency in the data that is shared. And Prefabricated buildings, spearheaded by modular integrated construction (MiC) as a future trend in the construction industry, can lead to poor data sharing and communication resulting in the uniqueness of their supply chain (Wuni et al., 2022). The construction process is different from traditional construction methods. Prefabricated buildings are constructed off-site in a factory-controlled environment, where the materials and labor are streamlined and optimized for efficiency. This requires a unique supply chain that is focused on the procurement and delivery of materials to the factory, as well as the transportation and installation of the finished product to the construction site. Construction usually requires the cooperation of many stakeholders, which can be divided into four categories according to their functions: client, manufacturer, logistics company, and contractor. The process of modular construction involves various aspects of design, engineering, manufacturing, logistics, installation, and project management. Each stakeholder brings a unique set of skills and expertise to the project, including architects, engineers, contractors, manufacturers, transportation specialists, and project managers. And these multidisciplinary stakeholders have different expectations, interests, and motivations, and the plethora of participants in a construction project leads to low information transparency, inefficient transactions, and even frauds. (Luo et al., 2019) Today's construction is operating in highly dynamic environments, which requires the information facilities to be able to provide stable network services and adequate computing sources in interaction with the environment on site. For example, verifying the statuses of the modules can monitor the construction progress . At the same time, the high level of privacy and the large amount of information generated during the

Xinqi Liu, Jihua Wang, Ruopan Huang, Wei Pan, *Multi-Robot Federated Edge Learning Framework for Efficient Coordination and Information Management in Smart Construction,* pp. 553-563, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.54

project management process leads to a decrease in efficiency. In order to effectively tackle the challenges posed by inadequate infrastructure and privacy concerns during the construction process, it is imperative to implement a robust on-site system architecture that facilitates mobile crowdsensing, shared storage, and processing of information from computational sources while ensuring data privacy. This technology is critical for the advancement of Construction 4.0, and can only be accomplished with ample computing resources and a reliable network. By bringing information technology to this traditional yet modern field, we can revolutionize the construction industry. The system can improve information transparency, reduce information asymmetry and facilitate collaborative work throughout the construction project lifecycle. Managers can keep track of the project's construction progress in real-time, identify problems and solve them in time to avoid causing construction problems such as deliveries delay, the absence of workers, machinery breakdowns, etc. Effective information sharing can also coordinate tasks between managers and workers, improve communication efficiency and optimize the construction process (Jiang et al., 2021).

The limitations of information technology, such as data transmission, make communication and data visualization in construction less efficient (Niu et al., 2015). This has a significant impact on the design of low-energy buildings, which require real-time monitoring of the environment and control. Niu et al. proposed A virtual reality integrated design approach to improving occupancy information integrity for closing the building energy performance gap (Niu et al., 2016). But this approach also generates a lot of private data due to the fact that the attitude of companies such as manufacturers towards new technologies depends on the environmental and organizational context (Pan & Pan, 2019). Building organizations can have concerns about the use of technologies that contain similar issues. In turn, this data cannot be fully utilized in a shared manner. A framework that can break through the efficiency of data transfer and address data privacy is necessary for the construction process.

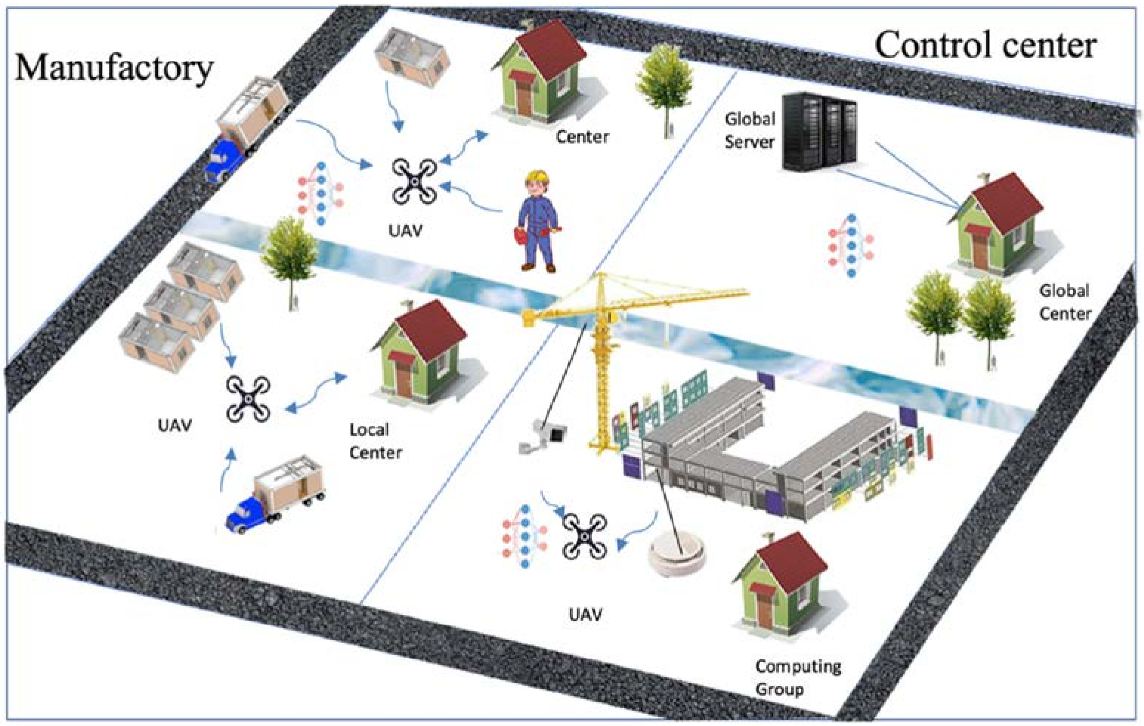

Fig. 1. An example of construction information management by federated learning

Fig. 1 Illustrates the multi-robot horizontal federated edge learning framework for construction information Management. The framework enables robots to gather information from workers and vehicles and transmit it in real-time through sensors to the robots. The robots then sample the information and process their query on the device. For instance, if one frame includes a vehicle, the robot will detect and send back the data to the user while another section of the sampled frame will be forwarded to the edge server for object detection, specifically the detection of the vehicle. Throughout the video analysis query processing lifecycle, the edge device and edge server collaborate to provide the user with detection results. By utilizing this framework, the system can effectively manage construction information by collecting and analyzing data from various sources, ultimately improving project efficiency, and reducing errors.

The increasing development of smart construction and the concern about the application of the IoT in construction stimulate a higher requirement for information exchange and communication quality. There are privacy issues in the transmission, storage, and analysis of data. These data relate to confidential industry information, such as the operations and costs of the companies involved. Institutional restrictions hinder information sharing between clients and contractors. Strict regulations undermine the efficiency of information sharing between clients and contractors. As factories, shipping companies, and contractors are independent. They cannot share data between them, which makes it difficult for project management as a third-party company to organize and coordinate the entire construction process. Site coordination requires the exchange of information between different contractors and sharing raw data between different contractors may compromise privacy and lead to problems such as communication barriers. The lack of information sharing between construction companies and suppliers is a significant barrier (Ojo et al., 2014) . Smart Construction is a method of construction that requires coordination in construction duration. A highly coordinated construction program of plant, transport, and construction is required. However, if clients and contractors do not accept relational matters as a long-term strategy, they will refuse to share implicit information (Yan, 2014).

Insufficient computing power equipment on site due to the complex environment of the construction site and the lack of well-established power and communication system. The raw data collected on the edge devices need to be uploaded to a cloud server for processing, which requires a lot of data transfer and processing time. For the construction of security systems, functions such as path planning and target recognition require real-time computing capabilities. While the majority of devices currently possess at least one image sensor and the ability to record and play high-resolution videos, they are deficient in the processing power required to execute intricate real-time computer vision algorithms. They are still unable to perform high-intensity performance computer vision tasks in real-time, with high frame rates and low latency (Honegger et al., 2014).

Star topology is widely used when the intelligence of the network is concentrated on the central node. However, the star topology has many disadvantages (Bisht & Singh, 2015). The star topology has many redundant links to ensure high connectivity, which results in high installation and maintenance costs and poor resource-sharing capabilities. Also, the communication lines are only used by the central and edge nodes on the line, which lead to communication lines being poorly utilized. Nevertheless, the central node demands frequent attention, and if it malfunctions, the entire network will come to a standstill. As computing evolves from centralized mainframe systems to many powerful microcomputers and workstations, the use of the traditional star topology will be reduced.

The purpose of this study is to introduce a multi-robot federated edge learning framework that can facilitate communication and information management in smart construction. The paper highlights the challenges posed by the large amount and wide variation of information involved in construction and the spatial dispersion of construction sites to the information management system (Akinosho et al., 2020). The paper propose the use of unmanned aerial vehicles and quadruped robots as edge nodes to process information during project execution. The framework is a worldwide sharing model founded on the principles of differential privacy protection. It gets distributed to numerous edge robots during each round, enabling local real-time processing of robot tasks. The system can accomplish target detection and tracking of workers based on computer vision, and predict carbon emissions. The authors demonstrate that the system can provide structured and reliable information, fast local transmission, and the ability to process information in real-time, making it a valuable tool in smart construction.

This section below sets the scene by giving an overview of the existing initiatives and status concerning construction information systems. The rest of the paper is structured as follows: Section 2 reviews the literature of federated learning, federated learning in construction, and distributed ledger technology. Section 3 discusses the research methodology and object selection. Section 4 presents the system architectures and federated edge learning. Section 5 discusses the applications to the construction industry and performance evaluation of the federated edge learning framework. Finally, Section 6 draws the conclusions and suggests future research.

2. LITERATURE REVIEW

2.1 Federated learning

Federated learning (FL) is a distributed machine learning scheme based on parallel computing that can overcome the challenges of data sensibility and data silos through the collaborative and decentralized neural network structure. FL has a high correlation with distributed learning, while it focuses on providing a collaborative model without privacy leakage (Li et al., 2020) At present, the FL has two mainstream open-source frameworks. Google

(Google, 2019) proposed a TensorFlow Federated (TFF) framework for meeting the demands of deep learning services in decentralized data. Webank (“Webank (2019a),” n.d.) presents the first industrial-level framework, Federated AI Technology Enabler (FATE) serves for cross-organizational architecture. Furthermore, Ramaswamy et al. (Ramaswamy et al., 2019) proposed the prediction of emoji in mobile keyboards, which is a successful application for model improvement and Secure Aggregation for the concern of stakeholder privacy. And Yang et al. (Yang et al., 2019) divide FL frameworks into three categories: vertical FL, horizontal FL, and federated transfer learning. In the case of vertical Fl, data is partitioned in the vertical direction by the feature dimension. Horizontal FL is suitable for cases in which data are multiple in sample space and a set number of overlaps among the feature of data storage in various nodes. Upon most occasions, data shares are quite distinct from sample space and feature space. Therefore, federated transfer learning can solve the problem in this setting is poor data quality without data labels (Li et al., 2020).

2.2 Construction information management

Having access to data at the right time for construction managers can assist project construction in assessing the construction performance of the corporation and subcontractors (Carrillo et al., 2013). When implementing construction information management, accurate data recording and comprehensive data analysis help to establish the credibility of stakeholders (Yang et al., 2019). Construction is a complex, one-off manufacturing process that involves many businesses, including design, manufacture, and transport. To assess the risks linked to each stakeholder, unprocessed data is necessary. Forecasting stems from data mining, a result of the methodical management of construction data. In addition, based on the data simulations, the manager can predict the potential problem area and plan for them (Arayici et al., 2012). With the completion of the first phase, the requirement for additional equipment and material in the second phase is identified. The analysis also provides construction stakeholders with visual information on project progress (Doloi, 2013). With the better access to and updating of the management system, the raw data should not be recorded with simple storage. It also provides data analysis servers. The potential for innovative algorithms based on artificial intelligence to support efficient construction processes (Pan et al., 2022). Data analytics and IoT are useful for the analysis of construction impact on parameters. In construction, construction information management is as important as construction, as information affects all construction-related activities (Kim et al., 2013).

3. METHODOLOGY

3.1 Problem definition

The primary focus of this present research is on information processing, analysis, and collation in construction scenarios. To achieve the study aim, construction robots have been designed as computational nodes, each corresponding to a construction safety monitoring device. These monitoring devices include cameras such as RGB, RGB-D, and LIDAR. Construction robots can be integrated as computational nodes, and can assist in the construction process while also collecting data and training models locally. This local processing ensures that data safety functions can be achieved while analyzing data on-site. In the context of construction safety monitoring, construction robots equipped with safety monitoring devices can help ensure safety compliance in construction sites. Additionally, they can help identify potential safety hazards, such as structural instability or unsafe working conditions. Furthermore, the collected data can be processed and analyzed locally, without the need to transfer sensitive information to external servers, ensuring data safety and privacy. By doing so, data can be analyzed in real-time, enabling quick decisions and actions to be taken to prevent accidents or hazards.

By utilizing the FedMR approach, data sharing is minimized, and data privacy is protected while effectively predicting the facial fatigue status of workers in real-time. This approach can aid in improving construction safety by enabling prompt interventions, when necessary, ultimately reducing accidents and improving the overall safety of workers and equipment vehicles in the construction scene.

3.2 Construction information framework overview

Construction is a complex process that generates a vast amount of information, as depicted in Fig. 2. The construction information is created from the design phase at the start of the project, and all project-related data is stored in a distributed manner on the construction site. This includes the management of approvals and material information, installation and transportation processes, and the information can be collaboratively managed. Through federated learning, all resources can be integrated securely, and machine learning can be used to efficiently integrate resources and make plans. Construction projects are complex endeavors that involve a multitude of stakeholders, including architects, engineers, contractors, and subcontractors.

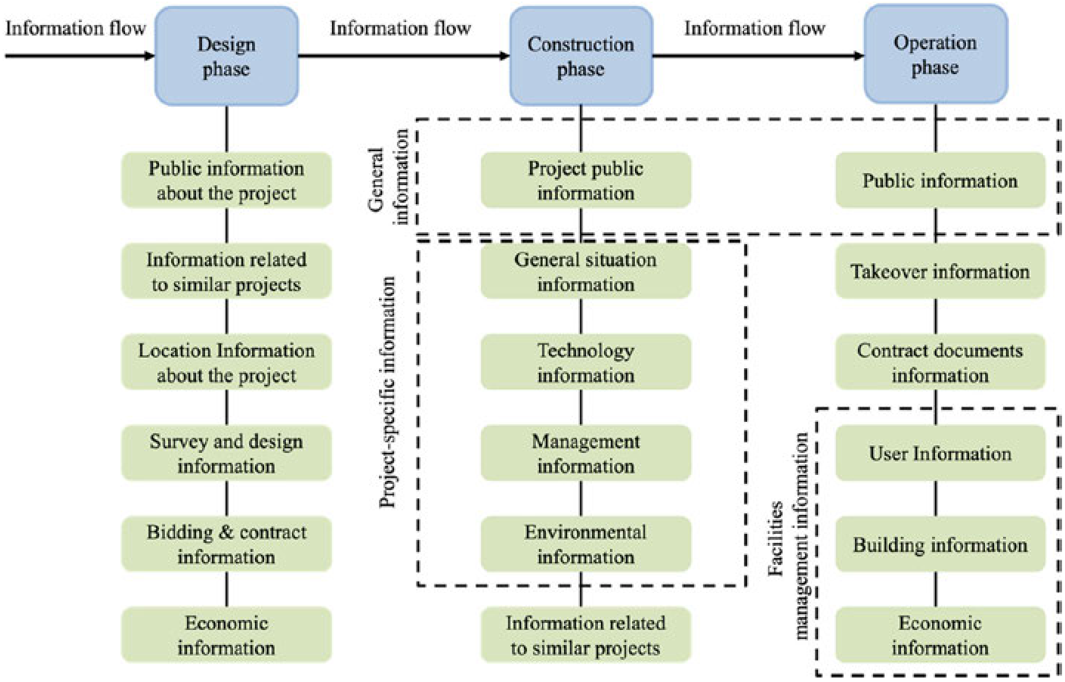

Fig. 2. Construction information on the different phase

Coordinating the information flow among these entities can be challenging, especially given the extensive data that requires sharing and processing. Federated learning presents a promising remedy, providing a secure and efficient approach for construction information management. It enhances efficiency and accuracy without compromising data privacy and security, as multiple parties collaboratively train a model without sharing raw data. When well-implemented, federated learning aids stakeholders in early problem identification and informed decision-making, ensuring project success.

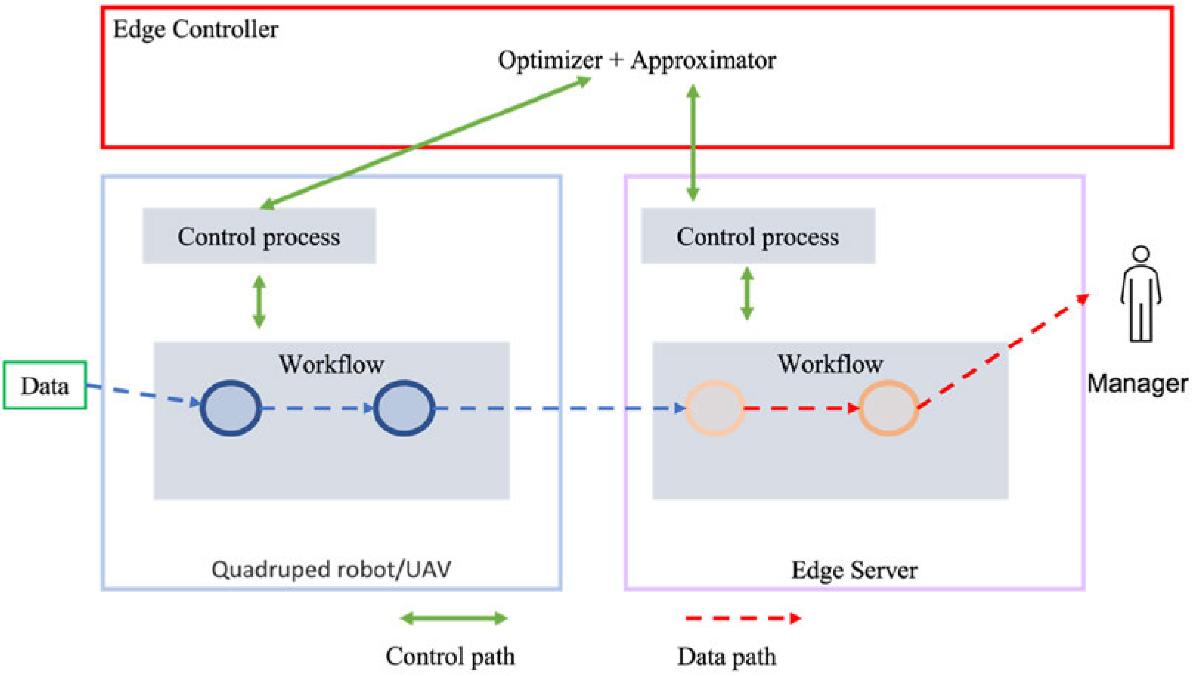

Fig. 3. FedMR system framework overview

The Federated Multi-Robot (FedMR) framework consists of an edge controller, a series of multi-robot systems, and servers, as illustrated in Fig. 3. The data flow involves two routes: the data path and the control path. A user's query traverses through the robots and servers in the workflow, which consists of a series of functions. In the data path, construction takes place sequentially from the first function to the last one in the workflow. Following data processing through this workflow, the resulting outputs are then delivered back to the user.

By employing the FedMR framework, construction information can be managed efficiently and securely, enabling prompt interventions when necessary and improving the overall safety of workers and equipment vehicles on the construction site.

4. APPLICABILITY OF THE FEDMR SYSTEM

To validate the viability of the approach, experiments were conducted to detect targets in images using a quadruped robot that captured local video data. The system carried out target recognition at the robot's side when the edge server retrieved images of vehicles. The training dataset for detecting moving objects in construction sites (MOCS) was preloaded into the robot.

In essence, the system's target detection capabilities were put to the test using real-world scenarios. By setting up video data collected by the quadruped robot, the system was able to accurately identify and classify targets within the images. The edge server, which received images of vehicles, promptly recognized the target objects, thanks to the training dataset preloaded in the robot. The MOCS dataset proved invaluable in training the system to detect moving objects in construction sites. By integrating the dataset into the robot, the system was able to recognize and classify objects in real-time, even in complex construction environments. This approach demonstrates the effectiveness of preloading training datasets into robots, enabling them to perform target recognition efficiently and accurately.

4.1 Environment setting for image test

The experiment, depicted in Fig. 4, employs YOLOv8 on Pytorch 1.8.1. The NVIDIA RTX3090 GPU serves as the platform for training and testing the model. Due to the rough road surfaces present in the construction site, a quadrupedal robot was selected as the ideal load-carrying system, as a typical wheeled chassis would have struggled to navigate the build environment with ease.The industrial camera used in the experiment is DF100-1080P (JIERUIWEITONG), while Unitree Go1 and DJI M200 function as edge devices. During the training phase, the new model incorporates parts of the pre-trained model from YOLOv8x. Since YOLOv8 and YOLOv8x share most of the backbone (block 0*8) and some of the head, it is possible to transfer a wide range of weights from YOLOv8x. Leveraging these weights during training can save significant time and computational resources. Overall, the use of YOLOv8 on Pytorch 1.8.1, combined with the powerful NVIDIA RTX3090 GPU, enables the model to train and test efficiently. Additionally, the use of industrial cameras, as well as the Unitree Go1 and DJI M200 edge devices, further enhances the experiment's reliability and accuracy. By incorporating pre-trained models and weights, the experiment provides a practical approach to target detection that can be easily adapted to a wide range of scenarios.

Fig. 4. Quadruped robot-based edge devices

4.2 Object detection in federated edge learning

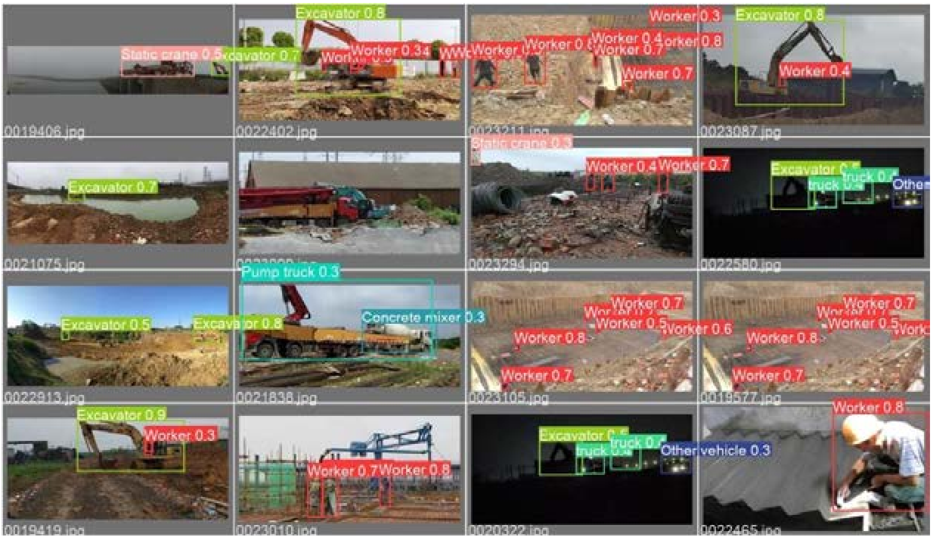

Fig. 5. Results of a target recognition system based on the FedMR framework

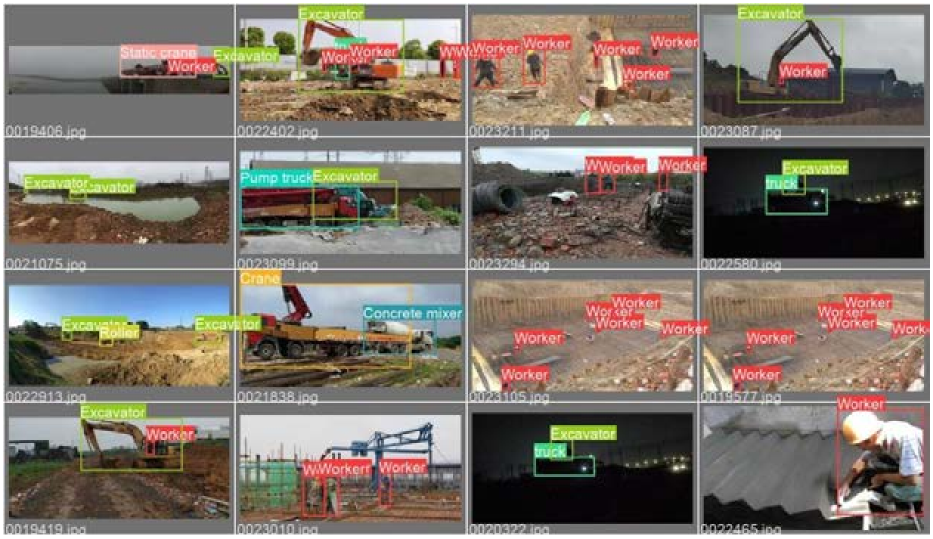

Fig. 6. Validated datasets with labels.

As illustrated in Fig. 5 and Fig. 6, the model trained on the local data training set achieved impressive results in target recognition. All targets were recognized compared to the labelled images. However, some of the worker targets had smaller IoU values when they were smaller in size. On the other hand, large vehicles were well recognized if they were presented as a whole. The best results were obtained for excavators.

When the edge server makes a query for a relevant target, the query image can be transferred back to the corresponding server. This enables the data to be trained and queried under local conditions, facilitating the management of information for construction while maintaining data security. By utilizing this method, administrators can access the information they need for security, management, etc., without having to access data from other departments.

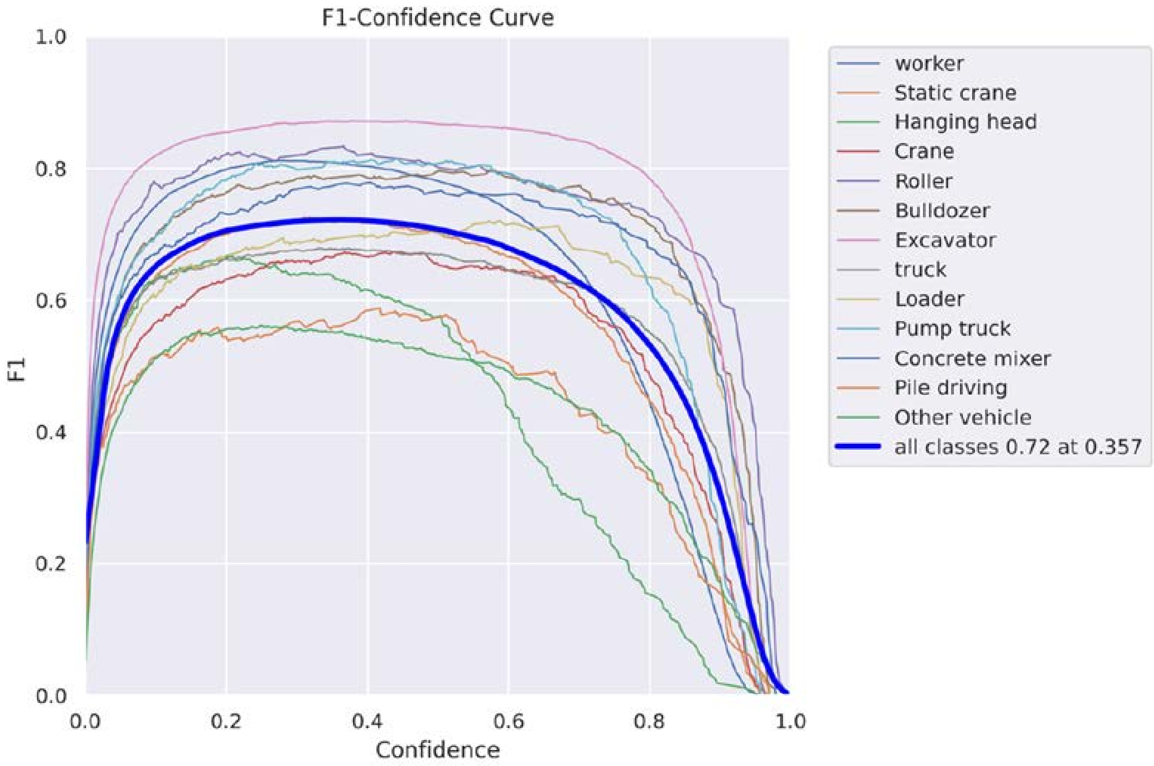

Fig. 7. The result of F1-scores

As shown in Fig. 7, the F1(H-mean) score is a combined evaluation indicator of recall and accuracy. The F1 value represents the division of the arithmetic mean by the geometric mean, with a higher value indicating better performance. Analyzing the Precision and Recall formulas in the context of this reveals that when the F1 value is low, there's a relative increase in True Positives and a decrease in False Positives, leading to a relative increase in both Precision and Recall. Essentially, F1 is a weighted measure that considers both Precision and Recall.

$$F1 = \frac{2}{\frac{1}{P} + \frac{1}{R}} = \frac{2 * P * R}{P + R}$$

The P is the precision of the YOLOv8 based on FedMR , and R is the recall of algorithm.

The worker and crane identification had the best F1 score. The confidence of all categories was 0.72 at F1=0.357, which is a significant improvement compared to the YOLOv8 standard of 0.65. This indicates that confidence is also guaranteed to be very good at higher recall. This data proves that edge nodes can provide good data processing capabilities, and the local model can process the data collected in the field in real-time. With a confidence level of 0.35 at 0.70 in comparison to YOLOv8 utilizing a non-FedMR framework, it is evident that the FedMR framework significantly enhances information processing capabilities. This improvement leads to better performance, even when data processing is restricted to a localized environment.

The FedMR have adapted the original FederatedAveraging (FedAvg) algorithm to our framework as shown in **Algorithm 1**. This aim is to investigate the impact of various data divisions and federated learning settings. To achieve this, the framework have modified the FedAvg algorithm to a FedMR algorithm by replacing the server-client communication framework, such as SocketIO, with a method that saves and restores checkpoints on hard-devices. This simplifies the model aggregation process. However, our implementation can also be effortlessly transferred to FedAvg.

Algorithm 1 FedMR

Input: N client parties$\{C_k\}_{k=1..N}$,total rounds T , and Server side S;

Output: Aggregated Model ω

S initializes federated model parameters, and saves as checkpoint. Client parties $\{C_k\}_{k=1..N}$, load the checkpoints.

for $t = 1, ..., T$ do

for k= $1, ..., T$ do

$\omega_k = \omega^{(t)}$

each client $\{C_k\}$ do local training:

for $i = 0, 1, ..., M_k$ do

(M_k is the number of data batches b in the client C_k)

client $\{C_k\}$ computes gradients $\nabla\ell(\omega_k, b_i)$

update with $\omega_k = \omega_k - \eta\nabla\ell(\omega_k, b_i)$

end for

save ω_k results to checkpoints.

end for

S loads checkpoints and get averaged model with $\omega^{(t)} = \frac{1}{N}\sum_{k=1}^{N}\omega_k$

end for

Return $\omega^{(T)}$

5. CONCLUSIONS

FedMR has demonstrated its versatility as a comprehensive model for handling information, optimizing processes, and monitoring isolated data. This empowers robots to offer insights, predictions, and warnings tailored for individual distributed construction workers prior to task execution at the work package level. However, existing machine learning approaches for modeling, optimization, and monitoring in construction information management necessitate data sharing or aggregation from each company, posing privacy risks and failing to deliver personalized monitoring of construction site conditions.

Therefore, this paper has proposed a horizontal federal learning framework, FedMR, to aggregate cryptographic information data parameters from different building stakeholders without compromising privacy and personalize the model differently based on the jobs each robot is responsible for. The model is improved based on the Fedvision model, utilizing the multi-robot as the edge device. The testing process is experimentally validated through the retrieval of image information by managers, using a target detection approach by training and testing locally. After experimental verification, the efficiency of YOLO algorithm can be improved in FedMR framework can be improved by 1.5% under the premise of user privacy F1 can be improved. The evaluation results show that the proposed FedMR can achieve mainstream YOLO recognition performance, and privacy is well protected. However, there is still room for improvement in terms of model performance and scalability. Future research should focus on exploring the potential of incorporating more advanced machine learning techniques such as the Large language model. Additionally, as the use of robots in construction becomes more prevalent, it is important to continue to prioritize the development of secure and personalized monitoring solutions to ensure the safety and efficiency of construction processes.

6. ACKNOWLEDGE

The work described in this paper was supported by the Research Impact Fund of the Hong Kong Research Grants Council (Project No.: HKU R7027-18) and the 43rd Round University Research Committee PDF/RAP Scheme of The University of Hong Kong.

ROBOTIC ASSEMBLY AND REUSE OF MODULAR ELEMENTS IN THE SUPPLY CHAIN OF A LEARNING FACTORY FOR CONSTRUCTION AND IN THE CONTEXT OF CIRCULAR ECONOMY

Jochen Teizer, Kepeng Hong, Asger D. Larsen & Marcus B. Nilsen
Department of Civil and Mechanical Engineering, Technical University of Denmark, Denmark

ABSTRACT: *Although robotic solutions have been making significant contributions to fabrication environments, implementations in the construction are rare. It seems a disconnect between the industries exists where in construction the high number of non-uniform work tasks, the wide assortment of types and shapes of building materials and elements, and the presence of human workers creating safety hazards make the deployment of rather rigid robotic manipulators on construction sites much more complex than in production-like work environments. To advance construction with robotic solutions, it could prove beneficial to make each sector aware of the barriers that exist, and likewise, introduce a physical space for joint experimentation with state-of-the-art technologies from both fields. One way of alleviating this issue is to connect the sectors by providing hands-on education and research experiences, defined hereby as Learning Factory for Construction (LFC). This paper presents a scaled-down version of a LFC that has a robotic manipulator perform fully-automated and precise assembly, deconstruction, and reuse tasks of modular construction elements, whereas the elements are tracked with fiducial markers according to a known building information model and schedule. Furthermore, the FLC continuously gathers and analyzes data for performance, measures successful completions, assembly times, and potential quality defects. This project involved Masters level students with domain expertise from architectural, civil, and mechanical engineering in a cross-disciplinary and collaborative learning exercise of building a working prototype within a semester-long study project. Beyond the core tasks of the digital design and robotic application, the group developed theoretical concepts and limitations for more holistic views on circular economy, lean production, on- and off-site logistics, modularization, and construction safety, just as expected from a LFC. It is anticipated that the next generation of professionals working in the built environment and intending to solve some of the larger and more complex societal problems will require both the technical and communication skills that a LFC can stimulate. Therefore, LFC is expected to become an important component of active learning environments.*

1. INTRODUCTION

For the past decades there has been an increased interest in robotic technology in construction applications. Economic projections foresee a prospering field and actual widespread usage in practice, requiring new policies and rules across the impacted industries (EC, 2022). However, many challenges still present themselves regarding robots in construction. Simple tasks that prove easy to execute for humans, prove extremely difficult for robotic manipulators due to a lack of perception and cognitive abilities. The size and weight of robots in industrial work environments, often tackling singular and highly repetitive tasks, does not fit the challenging, complex, and highly dynamic work environment that exists in construction sites. Yet, finding the necessary functionality and usability are a few of the additional barriers that exist and prevent robots from mainstream implementation. Despite some recent and rather serious interest from the industry, robotic applications in construction have stayed limited to niche research or exploration projects. Automated and robotic brick laying machines (Usmanov et al., 2017; Ravi et al. 2021) and additive manufacturing are some examples (Teizer et al., 2016).

To enable the use of robotics, suitable methods to assist the robots are necessary to consider. Yet, they are difficult to develop as construction touches a multi-disciplinary field that makes it challenging to find acceptable solutions. A few somewhat isolated disciplines (and stakeholders) are: design (architects/planners), construction (civil engineers), machinery (mechanical engineers), and systems and processes (industrial engineers). While innovation in any field, like in construction, calls for lifting the boundaries between these domains, a further major aspect to consider before introducing robotic applications in construction is to maintain a high level of trust, productivity, and safety in new technologies (EC, 2022).

Change to fabrication environments came over decades, with fully-automated solutions replacing isolated and

Jochen Teizer, Kepeng Hong, Asger D. Larsen, Marcus B. Nilsen, *Robotic Assembly and Reuse of Modular Elements in the Supply Chain of a Learning Factory for Construction and in the Context of Circular Economy,* pp. 564-573, DOI 10.36253/979-12-215-0289-3.55

highly repetitive work tasks humans would not endure. The typical construction work environments yet may demand a similar time frame and even more. For example, active human-robot collaborations are supposed to solve the sector's rather complex and interconnected work tasks. The involvement of multi-trades' expertise and the manifold types of product or material specifications constitute a few of the other but plentiful technical challenges that semi- or fully-automated robotic solutions are envisioned to solve before decision-makers would buy into them for final field use (Slaughter, E.S., 1998; Goodrum & Haas, 2016)

Yet, the effects that a transition to robotic labor would have on construction can include improvements to construction industry-wide problems, including but not limited to achieving higher productivity and better safety and health performances. As such, prioritization of human time and purpose of life and health, and ease of system installation and maintenance, to name only two criteria, reflect the current construction industry's efforts towards digitalization, automation and robotization (Yamamoto, 2020).

The concept of a Learning Factory (LF) is not new, and yet they hardly exist for construction purposes. Teizer and Chronopoulos (2022) expressed that a Learning Factory for Construction (LFC) can provide a useful active collaborative working environment for engineers that are interested in exploring prototypical solutions that have the potential to solve known industry problems. In their articulated vision, a LFC provides the explorative collaboration space to (a) detect the organizational barriers that prevent innovation, (b) allow objective and scope definitions by understanding the technical limitations in existing work processes, and (c) create prototypical hard- and software solutions that can be tested on small but at realistic scale and with little risk of losing large investments. Gaining knowledge in a LFC first is required to later adapt solutions to a larger workspace and with increased autonomy. And yet, students that participate in a LFC should have fun, like Teizer et al. (2020) and Wolf et al. (2022) found out when observing construction apprentices that played serious games for construction safety.

As the widespread application of robotics in manufacturing industries has significantly improved productivity and efficiency, there has been significant research interest in construction robotics. Besides reducing project delivery delay, construction robotics can benefit the workers by assisting them with non-ergonomic tasks (e.g., lifting weights) and taking over dangerous activities (e.g., demolition). However, the implementation of construction robotics heavily relies on manual input from task to task due to the complicated nature of construction activities. For instance, the difference between as-built and as-designed models during the construction stage can be challenging for preprogrammed construction robots to understand the changing environment at the construction site. Only in combination with a higher level of digitalization construction robotics can it be effectively implemented for automated or semi-automated construction. Emergent methods and technologies, such as BIM and vision-based object recognition, collaborate with construction robotics to complete the workflow of automated construction. Such collaboration requires various fields of engineering to understand all involved technology and the interplays between these technologies. Figure 1 integrates many of the currently existing digital technologies and how they relate to each other. Highlighted in grey background color are those that are part of this LFC.

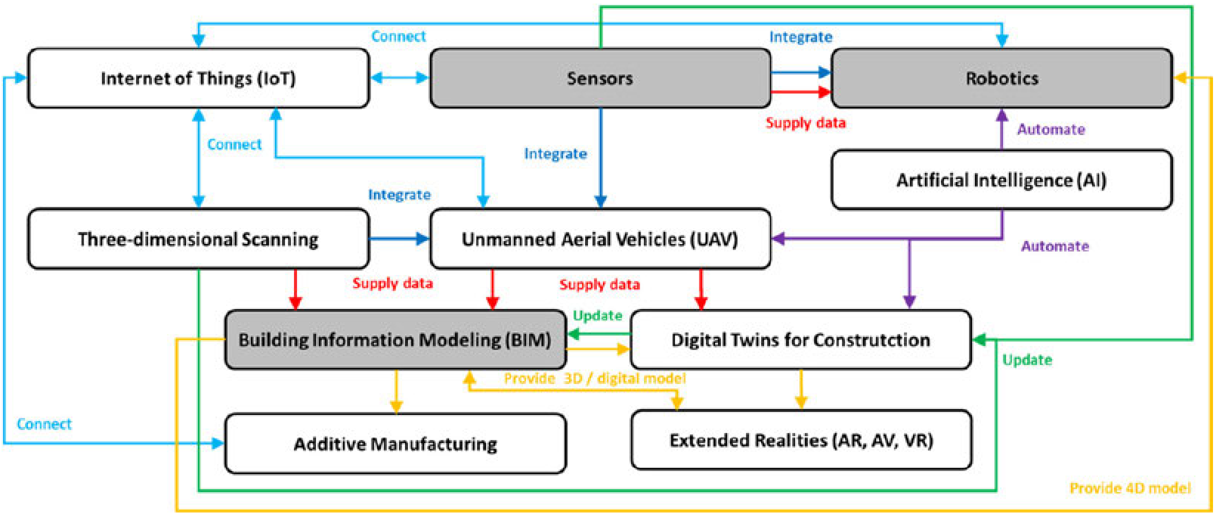

Fig. 1: Overview of relation between digital technologies; modified, originally from EC (2021),

The goal of this paper is to demonstrate the viability of the integration of a robotic manipulator into a LFC, displaying the advantages of using modular components in the context of autonomous construction in a circular economy. The following sections first review the background, then introduce the developed LFC, a scaled-down version of a building construction site, and finally demonstrate its capabilities in a case study where a robotic manipulator handles modular elements for building assembly and reuse under some of the typical real constraints that exist in the construction supply chain and in a circular economy.

2. BACKGROUND

Several existing cases have shown that assembly processes using robotic manipulators are favorable. Wang et al. (2020a) stated that robotic construction was both faster and more accurate compared to conventional manual methods by construction workers alone. However, it was stated that robotic solutions were limited to being either conducted in non-complex work environments or limited to handling specified objects. In other words, robotic solutions still required some aspects of human labor to complete complex activities. These limitations pose some of the biggest challenges to overcome.

The recently-completed research project HEPHAESTUS proved successful in installing curtain wall modules using a large-scale cable-driven robot alongside a robotic manipulator, but many improvements were left to be implemented (Iturralde et al., 2020).

Using robotic manipulators for construction has shown to be easier executed when introducing the modular and parametric design in assemblies of complex constructions. Research on modular design for robotic construction showed that it is possible, using modular components, to verify the design and construction process through simulations (Sun et al., 2022).

Using timber panels, which are identified by computer vision and machine-readable QR codes, has proved to make it possible for a robot arm to do insertions of panels to create simple assemblies (Rogeau et al., 2020). In addition, a robot arm using standardized timber was able to construct complicated structures with high precision. Results from Leng et al. (2020) showed the benefits and possibilities of utilizing standardized materials, with precise parameters being a key factor. A similar research with timber addressed the issues of wood being a natural and imprecise material which complicates handling, highlighting the issues of production tolerances (Hasan et al., 2019).

The notion of having robots build from a digital model has been investigated in several papers, with a focus on exporting Building Information Modeling (BIM) to a robot from an as-designed model or importing the physical as-built model for guidance purposes. Likewise, using a Digital Twin for Construction (Sacks et al., 2020), the process of having a robot build from a BIM and updating the as-built model using sensor data was validated (Wang et al., 2020b). At the moment, software packages are being developed to help link BIM-based design with robot control which could ease the process of future digital-to-physical model building (Yang et al., 2019). Slebicka et al. (2021) placed an important vision for Fabrication Information Modeling (FIM) that intends to close the gap between BIM and Digital Fabrication that, at some point in time, will heavily depend on automation and robotics.

While only a small amount of the above-mentioned research addresses the interaction between autonomous robots and human workers, human-robot interaction proves to be detrimental when considering on-site safety (Wu et al. 2020). With the prospect of robots in construction, it is recommended to also investigate their social impact since the potential changes to workplaces will require workers to acquire additional skills, competencies and responsibilities (Karl et al., 2018). A proposed method of tackling safety is to introduce the concept of an LF, which emphasizes hands-on experience. LFs offer a high potential to improve education, training, and research in a controlled environment (Abele et al., 2017).

Gharbia et al. (2019) concluded that rapid prototyping assisted in the creation of robotic solutions. In this context, introducing a robot manipulator into a LFC would educate on, and increase the awareness of the capabilities of autonomous robots in a construction work environment and help involved project stakeholders (engineers and workers) adapt increasingly advanced technologies to a construction site.

Related to this effort, robots of different sorts have already been introduced to various Learning Factories in relation to Industry 4.0. Several researchers have included robotic arms in their own specialized Learning Factories, albeit with a focus on manufacturing and assembly (Matt et al., 2014; Kaménzy et al., 2018; Nardello et al., 2017).

As with Industry 4.0, the recent technological advances will gradually replace the roles of humans in construction, in what is coined Construction 4.0 (Sawhney et al., 2020). However, the challenge of integrating a robot into a LFC environment with the purpose of improving construction processes is yet to be investigated.

3. ROBOTIC MANIPULATOR IN A LEARNING FACTORY FOR CONSTRUCTION

The first part of this section briefly explains the relevant backgrounds of the research methods employed in this work of Masters-level students in a semester-long study project that utilizes the LFC at the Technical University of Denmark. Next, the hard- and software components of the LFC are introduced. Experiments and results follow with a discussion summarizing the lessons learned at the end.

3.1 Introduction to components

3.1.1 Learning factory for construction

LF has proven to be an effective way to provide active hands-on learning (Abele et al., 2017). LF typically reproduces or simulates a production environment, allowing participants to gain practical knowledge and skills in a controlled setting. In addition, LF also provides a platform for researchers to investigate and improve processes and workflows. In this case, our LFC is meant for university students but can also involve apprentices or full-time professionals, like workers, technicians, and engineers from the construction industry. The purpose of our LFC is to provide the physical space that facilitates education and research on automation and robotics in construction.

3.1.2 Robotic manipulator

A robotic manipulator performs tasks as a human arm (Matt et al., 2014). In our case, the robot mimics a mobile or tower crane on a construction site. Our LFC consists of multiple modules that include robotic elements, of which only the robotic manipulator UR5e, its mounted camera and gripper, and a computer will be explained in the further text. Details of the other existing components of our LFC can be found in Teizer and Chronopoulos (2022). While these eventually will be connected to each other, this paper introduces the part of the LFC that simulates the process of three steps in automated modular construction: automated assembly, disassembly, and reuse according to a BIM-based building design. The UR5e is made of several interconnected segments, has joints, and one end-effector, allowing it to make rotary and linear movements. The end-effector performs assigned tasks at any position within the spatial coordinates of the robotic arm. The learning factory uses UR5e as the robotic arm and mounted gripper as the end-effector so that it can grab, lift and place any given components at the assigned positions. It has six degrees of freedom (x, y, z, roll, pitch, yaw), whose value can be changed so that the gripper mounted at the end of the arm can be moved to desired position and orientation. There exist three types of movements, *moveJ* (the robot moves each joint independently), *moveL* (the robot moves in a straight line), and *moveP* (the robot moves following the designed path).

3.1.3 Building information model and construction schedule

BIM is a comprehensive and collaborative method across the whole building life cycle (Oraee et al., 2017). Yet, it has less been used in combination with automation and robotics than other applications. Our LFC uses commercially-available BIM software for the manual design of a fictive modular building project and, likewise, is the sequence of constructing the modular elements planned digitally. While this may imply a detailed construction schedule comprised of the precise timing and dependencies of the construction tasks, only the Work Breakdown Structure (WBS) is needed. The BIM software is also used for visualization purposes. Otherwise, the IFC format contains geometry and position information for each of the modular elements and the task sequence.

3.1.4 Building materials

The building is constructed with standardized physical models using the UR5e. The pieces are made from lightweight plastic and come in several shapes.

3.1.5 Object detection

In order for the robot to handle the modular elements, object detection and recognition with final localization is required. Object detection is made possible by computer vision that identifies and localizes the modular elements of next interest within the video frame capture. There exist two main approaches for object detection, traditional (e.g., rule-based, handcrafted features) and deep learning-based approaches. Out LFC integrates traditional object detection algorithms for construction sites and modular component detection.

3.1.6 Human-robot interaction

Human-robot interaction happens only twice in this part of the LFC: first, to place new modular elements in the arrival area to the simulated construction site that is within range of the robot arm, and second, when the building owner makes a choice of selecting a building design and floorplan. Otherwise, the developed module of the LFC operates fully autonomously, as explained in the following.

3.2 Methods

The framework of the LFC is shown in Figure 2. It comprises two parts. The first part is a remote control, where students in the role of an architect or civil engineer upload their IFC file to the computer. Note that the modular building designs of the students allow some variation but still follow the material specifications and parameters that were given to them beforehand. The computer extracts the geometry and position information of each modular building component and determines the construction sequence. The spatial and temporal information of construction is translated into robot commands and then sent to the robot for controlled execution. The manipulator first scans the entire site to locate and map the coordinates of the material pick-up, the temporary depot, and the construction zones. When ready, the robot finally receives the building commands to start the construction process.

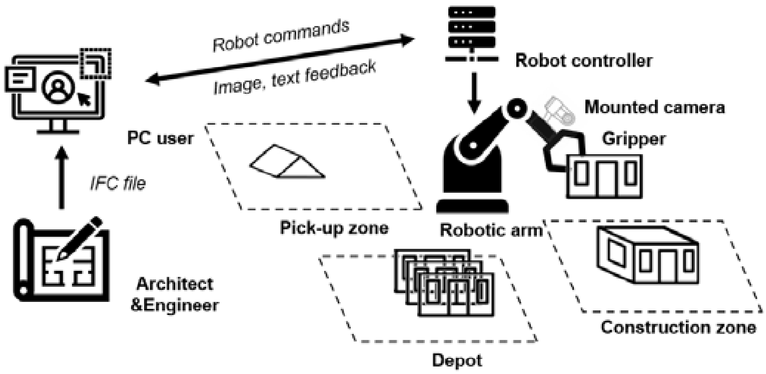

Fig. 2: Learning Factory for Construction (LFC) at the Technical University of Denmark: Construction site module.

The hardware and software requirements and descriptions for the learning factory are listed in Tables 1 and 2. The BIM translation and robotic remote control are implemented in a Python environment due to its simplicity and extensive library support.

Table 1: Hardware in the construction site module of DTU's LFC.

Equipment	Description
Robotic manipulator	UR5e for grabbing, lifting, and placing building components
Camera on end-effector	OnRobot RGBD camera for object detection and as-performed data collection
Computer	Processing BIM files, translating commands, receiving and processing data, control

Table 2: Libraries and software for the learning factory

Library and applications	Version	Description
URX	2.0.1	UR5e remote control and program execution
IfcOpenShell	1.6.1	IFC file translation and querying
OpenCV	20.10.22	Visual detection ad recognition
BlenderIFC		IFC file editing and viewing

For reliable object detection, the camera uses fiducial marks attached to the construction site and building components to recognize the different objects, as shown in Figure 3.

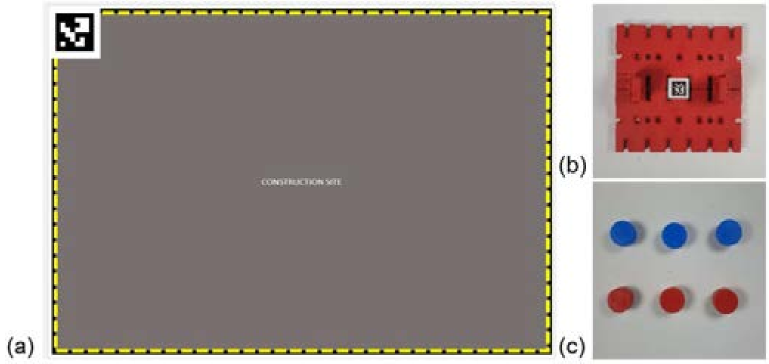

Fig. 3: Examples of (a) a zone and (a) modular building elements, all marked with different fiducial marks for object recognition. Note. The elements are further detected by shape and color.

3.3 Implementation and preliminary results

The preliminary implementation of this component of DTU's LFC is shown in Figure 4. The layout and setup follow the concept mentioned earlier. For a simplified demonstration, a basic two-story building consisting of 5 IFC elements is designed, shown in Figure 5. The five components are positioned at distinct heights so that the algorithm can easily sort the order of construction. Figure 6 shows the simplified modular building elements to which each unique fiducial markers are attached. Existing computational algorithms later detect and recognize the fiducial marker when it is within the field-of-view of the mounted camera on the end-effector.

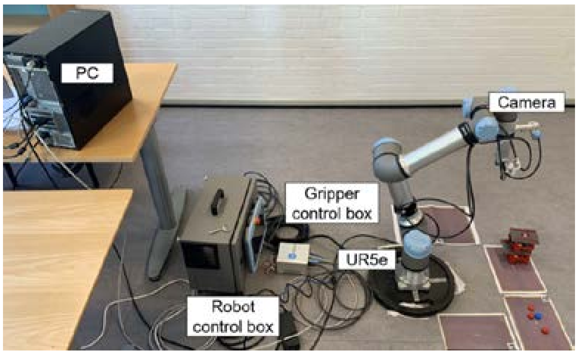

Fig. 4: Experimental setup of LFC.

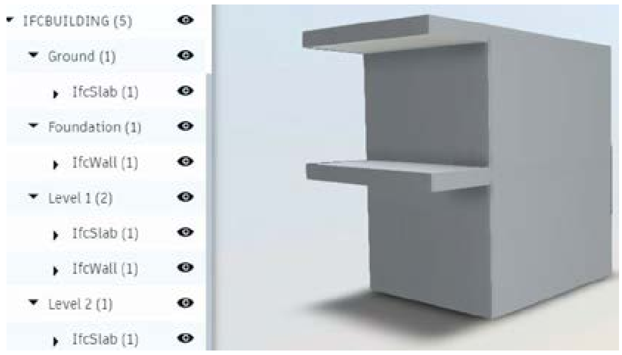

Fig. 5: IFC model of the 2-story modular building project

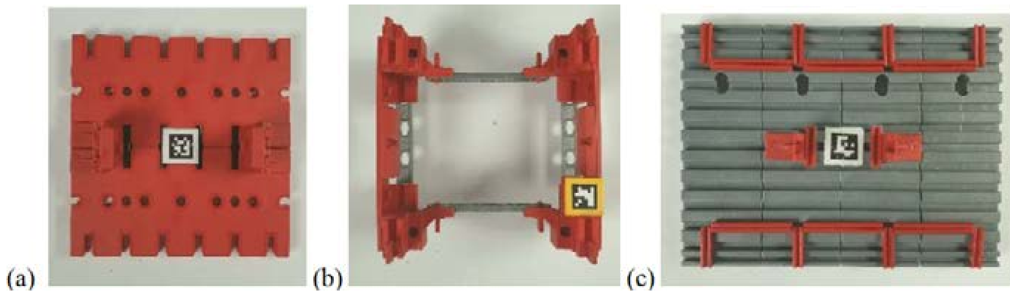

Fig. 6: Modular components: (a) foundation, (b) wall, and (c) floor.

Figure 7 illustrates the construction process. After the students load their IFC file, the computer extracts the spatial information of building components and determines the construction sequence. The corresponding list of the modular elements and the building sequence is shown in Table 3. The robot registers the coordinate of the construction sites by using the mounted camera to detect the fiducial markers of the zones. After the coordinate system is registered, the robots start to detect, grab, lift, and place the modular construction elements iteratively until the last component is assembled onto the building. Reversely, the disassembly process can also be achieved. All modular elements are taken apart and placed in a temporary storage zone (called depot). Next, human interference is needed if the next phase of the building lifecycle is of interest to the student. The student can choose to select an alternative building design, upload it, and the new building process can start again. Note, whenever possible, the robot reuses parts of the modular building elements lying in the depot. Once the second building is completed, typically, the LFC experience stops.

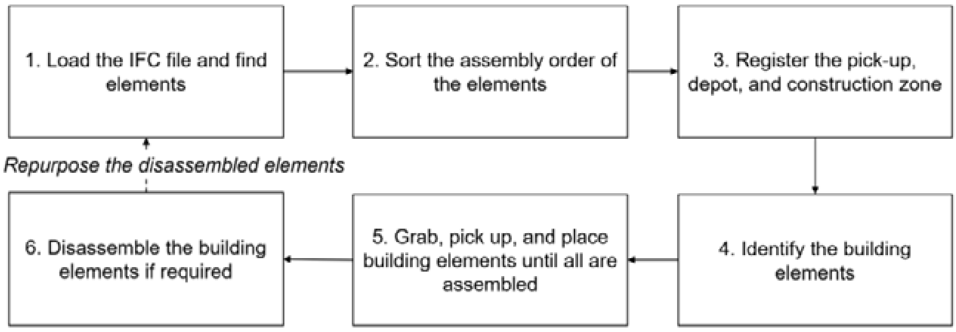

Fig. 7: LFC-workflow of the robotic manipulator module: First the design, then the robotic assembly and disassembly, optional: re-design and -use.

Table 3: List of the modular building elements and example of a building sequence by the ascending z coordinate

Number	Elements	Coordinates	Sequence
1	'Foundation:297060'	(x1,y1,z1)	1
2	'Floor:301328'	(x2,y2,z2)	3
3	'Floor:301575'	(x3,y3,z3)	5
4	'Wall:304810'	(x4,y4,z4)	2
5	'Wall:305546'	(x5,y5,z5)	4

As the algorithm is sorting the construction sequence by a bottom-up approach, it may only be viable for modular building elements with simplistic spatial relations. The construction order can be determined using a predefined construction schedule in 4D BIM. For each IfcElement, IfcTask and IfcRelAssignsToControl are attributed so that the algorithm can understand the predecessor of each step and validate the correct order during the construction stage.

While, iterative occurred during the system's development, demonstrating that the entire workflow was tested 5 times in front of a small audience from industry and academia. Although no strict scientific verification and validation methods were ready at the end of the semester project, the students were able to run the system two times successfully from start to end. Twice the students assisted by snapping an element (one floor and one wall element, in separate tests) into place with a very slight push of an index finger. Once the robot stopped after assembly the first design. The reason is still unknown. Yet, runtime data from the system was recorded during all test runs and is being processed at this time (and will be implemented in the final version of this paper).

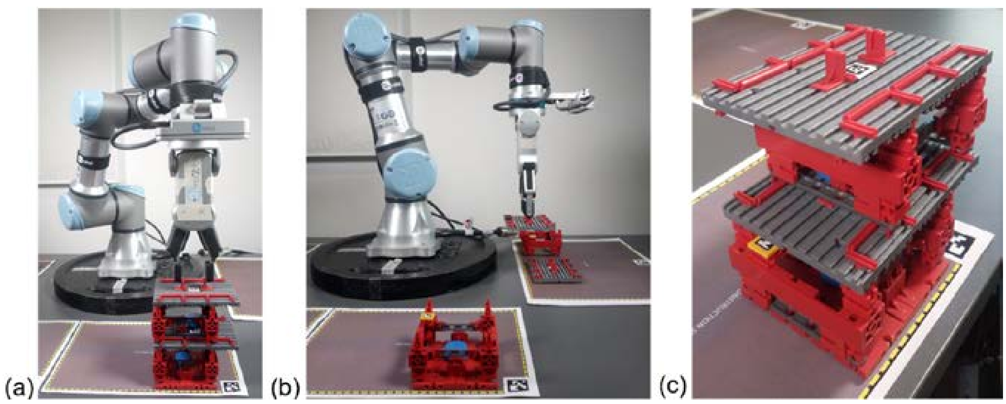

Fig. 8: Impressions from final demonstration exercises: Robot manipulator completing the fully-automated (a) assembly of the first modular building design, (b) disassembly and temporary storage, and (c) re-use of modular elements for assembly of second building design (manual selection, after disassemble).

4. CONCLUSIONS AND OUTLOOK

This work is the result of a semester-long study project that exposed four Masters-level students, one in architectural, one in civil, and two in mechanical engineering, to backgrounds that they had not learned before. For example, both the architectural and civil engineering student had no previous experiences with the field of automation and robotics, and likewise had mechanical engineering students neither a background in design or planning with 4D BIM nor any expertise in modular construction. The developed concept of a LFC has been partially validated, as the robot manipulator was able to follow a digital design and sequence to erect, disassemble, and rebuild a small-scale building while applying constraints that exist in a circular economy, for example, making as much use as possible of reusing building material. However, as observed, the limited project time that was given to the students restricted their curiosity in exploring additional research domains, for example, planning for alternatives, generative costing, digital twinning, and testing usability. In the future, a focus on qualitative and quantitative assessment methods must be set to evaluate both the students' and LFC's performances. Yet, the students' claimed new knowledge by applying their own expertise and discovering other fields. Furthermore, the experienced hands-on experiences with respect to realistic and still basic implementations of information modeling, computational coding, automation, and robotics, strengthened their learning. It is envisioned that the construction industry will benefit from students with such skill sets that a LFC is able to develop, share, or enhance. Yet, scaling up the developed concept of a LFC could yield future insights how digital building design can guide real-life automation and robotic applications in construction.

IDENTIFYING AND DEVELOPING PREREQUISITES FOR TAKT PLANNING IN A BIM-BASED CONSTRUCTION PROCESS

Efraim Ljung
Skanska Sverige AB

Mikael Viklund Tallgren, Mattias Roupé & Mikael Johansson
Chalmers University of Technology, Sweden

ABSTRACT: *The construction industry is undergoing a significant shift in how design and production are conducted. Building Information Modeling (BIM) has emerged as a key tool for coordinating information from all involved disciplines and providing a more holistic view of the construction process. However, effective coordination and communication between different professions remain major challenges that require new approaches to project management. Takt planning has gained increasing attention as a potential solution to improve traditional planning methods. Despite this, there is a lack of real-world studies exploring BIM and takt planning where information is structured according to takt planning. A takt planning structure for all BIM-models would bring a more holistic understanding of what is to be done, controlled, and reported back. To address this gap, this paper presents findings from a three-stage research process. Firstly, form a focus group of disciplines to find a shared structure to present the execution in a common way for design and construction in a lab environment at a conceptual level, secondly implementing it to the detailed design information for real -world case project in workshops and group meetings with the focus group and then thirdly, evaluate it in the case project with the site staff involved. The findings highlight the importance of a shared denominator to get a holistic approach to project management and enabling takt planning throughout all phases of construction, providing insights into its practical application and benefits for the construction industry.*

KEYWORDS: *WBS; Building information modeling (BIM); Project Management; Takt planning.*

1. INTRODUCTION

The construction industry is undergoing a significant shift in how design and production are conducted, this also affects how projects are documented and handed over once finished. This shift can be seen as a digital transformation, with a strong focus on technologies (e.g. Howard et al., 2002; Samuelson & Björk, 2014). A key in this transformation is the emergence of Building Information Modeling (BIM) for coordinating information from all involved disciplines and providing a more holistic view of the construction process (Azhar, 2011; Sacks et al., 2018). BIM can also alleviate information loss that occurs in conventional non-digital workflows (Borrmann et al., 2018, Chapter 1; Sacks et al., 2018). Thus, BIM is seen as a major contributor to the digital transformation of the industry (Samuelson & Stehn, 2023). While there are some projects moving from drawings towards a model-based construction and process (Disney et al., 2021; Gaunt, 2017), there is still a reluctance to fully adopt BIM and thus slowing change.

One factor identified as barrier to change is the fragmentation and high specialization of the construction industry, where a disconnect between design and construction phases contributes to the fragmentation (Cerezo-Narváez et al., 2020; Mohd Nawi et al., 2014), and the prevailing project conditions preserves roles, processes, value chains and working methods within individual companies and prevents change (Samuelson & Stehn, 2023). Traditionally, construction projects mostly follow a waterfall principle where information in each phase is adjusted and modified for respective phase (Leicht et al., 2020). Furthermore, the high fragmentation and specialization amongst subcontractors is identified as potential factor for projects overshot budgets and schedule overruns occur (Nepal & Staub-French, 2016). Work Breakdown Structure (WBS) can help in defining and structure the project (Makarfi Ibrahim et al., 2009). Cerezo-Narváez et al. (2020) stresses that by using a well-developed Work Breakdown Structure (WBS), that integrates the Cost Breakdown Structure (CBS), a more representative project schedule and budget can be produced, as well as project roles and responsibilities can be assigned to subcontractors more easily. Furthermore, Cerezo-Narváez et al. (2020) also emphases that there is a lack in alignment between WBS and CBS and that a more structured work management is essential, especially in the digital management of projects. Thus, a standardization of classifications could enable integration of the WBS and CBS and ensure a connected information flow. Jung and Kang (2007) notes that standardization of the WBS could contribute to a wide set of project control systems, such as scheduling, cost control, materials management amongst other construction business functions, this confirms similar conclusions shown in Garcıá-Fornieles et al. (2003), which also adds

Efraim Ljung, Mikael Viklund Tallgren, Mattias Roupe, Mikael Johansson, *Identifying and Developing Prerequisites for Takt Planning in a BIM-Based Construction Process,* pp. 574-584, DOI 10.36253/979-12-215-0289-3.56

responsibility assignment and information management to the list. Therefore, there is a need to find shared information and classification structure to enable a flow of information from design to production and all the way to operations and maintenance (O&M). There is a lack of structuring of this in BIM data between different disciplines such as planning, scheduling and cost control (Cerezo-Narváez et al., 2020; Makarfi Ibrahim et al., 2009). Makarfi Ibrahim et al. (2009), concludes that a standardized WBS structure is missing and proceeds to develop and present a structure fitted to the UK construction sector, they also note limited possibilities for generalization of this structure worldwide and that WBS structures should be developed contextualized to respective market.

With regards to planning and control, standardized processes have been proven to be beneficial (Haghsheno et al., 2016), along with a BIM-model, the project can be divided into identifiable repetitions where Takt planning can aid in the communication and implementation of the schedule (Viklund Tallgren et al., 2022). With the rise of the use of BIM-models, research points towards a possibility to improve information flow between design and construction phases as well as improved communication and collaboration within phases, especially during planning and scheduling (Crowther & Ajayi, 2019; Nepal & Staub-French, 2016; Viklund Tallgren et al., 2021). However, there is a need for a more systematic approach to the coding of models to be able to use them throughout design and construction phases.

Thus, there is a need to support processes spanning over both design and construction, and through to O&M. Both internationally and nationally there are numerous examples on standards to address increased digitalization in construction, such as CoClass which is supposed to replace the older BSAB in Sweden, Cuneco Classification System in Dennark, Uniclass in the UK and the North American Architectural, Engineering and Construction industry system OmniClass for example (Cerezo-Narváez et al., 2020; Eckerberg et al., 2016). CoClass was developed to carry information about classes, properties and activities connected to different construction related processes. A sub-set of information created in one such process is a model view definition (MVD), governed by the information delivery manual (IDM).

Thus, the aim of this research is to investigate what information is needed for production control and management to integrate from the design phase to the construction phase and how this information should be structured to help understand the project and its challenges better. This paper proceeds with this question, and addresses the general question through the following research questions:

1. Which stakeholders need to be involved from design and construction phases to find a shared common information and coding structure?
2. What are the challenges with a shared information and coding structure for design and construction phases?
3. How are the developed shared information and coding structures utilized in an actual construction project?

This paper is structured as follows; a review of related works connected to WBS, classifications and planning is shortly presented, followed by an account of the results with regards to the research questions. As a result, from the focus groups a shared coding structure was identified that extends current classification. The discussion shows that the addition of deliverables and construction scope could be used throughout the phases of the project and was found to help communication between disciplines and construction phases. The findings highlight that this type of structured information enables the prerequisites needed to increase digitalization and integration between disciplines, enabling for example a more holistic Takt planning.

2. METHODS

This research uses a qualitative approach to explore the three research questions. A combination of methods has been used to gather data. A brief overview of these methods is followed by a more in-depth description later in this section. The research was instigated through an identification of the critical stakeholders to bridge the design phase and the construction phase. These stakeholders formed a focus group. The focus group combined workshops with focus group meetings to capture context and initial requirements for the information structure. These initial meetings informed the research and development process, and two additional stages were decided to be added. The second stage concentrated on implementing and evaluating information that formed the structure. The third stage expanded the group and focused on the effects of the proposed structure. The aim of the research was to investigate what information was needed for production control during the stages from design to construction and how this information should be structured to help understand the project and its challenges better.

The focus group meetings were documented with meeting minutes and field notes. Throughout the research one single project, Hovås Tak, was used as a case.

Fig. 1: The Hovås tak apartment project (Hovås tak, Nordr, 2022)

2.1 Case Study – Hovås Tak – An Apartment building

The project used in the research was an ongoing construction of an apartment building, located in southern Gothenburg, Sweden. The house is an apartment building with two co-joined tower-blocks forming a single body, se Fig. 1. Each stairwell has four apartments on each floor with a total of 59 apartments. The building has a total gross area of 5170 m^2 with a framing of precast walls and slabs, with light steel infill walls and a non-load bearing brick façade.

2.2 The three research stages

2.2.1 Stage 1: Identifying a Coding Structure and Required Information

There are a lot of people involved in a construction project, but not everyone has the same degree of influence on how the information is structured. In the case project, Hovås Tak project, the disciplines that account for the most decisive and or governing amount of information for the design and construction management were analyzed, and a focus group was formed with these disciplines to try to find a shared structure for the information.

The focus group of ten people was represented by following disciplines:

- Client – controls the vision, the purpose of the project and what is to be built. Control the names and designations of the different parts of the building as well as documents related to the project.
- Design manager and BIM coordinator – controls the information and information structure from the designers.
- Cost manager – advises over the content of the calculation and how it is structured.
- Scheduler – controls the structure of the schedule, the content is developed together with the site management.
- Site management (Project Manager, Site Manager, Site Engineer) – advises over construction planning, logistics, purchasing, site layout plan. (i.e., the overall structure of how the project will be executed, in the more detailed planning those involved in the module will be involved)

Through workshops, the focus group tried to find ways to group and or sort the information in a way that would primarily facilitate construction planning and scheduling. The workshops were used to define coding structure and the definition of the designations *"deliverables"* and *"construction scope"* used in the case project, Hovås Tak.

2.2.2 Stage 2: Implementing and Evaluating the Coding Structure and Information

The participants in the focus group were also active in the development of the detailed design documents. This took place in parallel with the second stage of the focus group workshops. The workshops also served the purpose to create consensus of the boundaries between the deliverables and the construction scope. The designations were documented continuously to create a uniform project language.

2.2.3 Stage 3: Effects of Using the Coding Structure

The construction documents were completed in Q1 2023, and construction started in early 2023. The focus group then begun to evaluate the effects of the developed shared information structure. The group also studied how the structure affected the understanding of the project documents and how the structure was used for the more detailed construction scheduling and documentation. An expanded focus group that also involved the main contractor, Skanska's entire site organization in the case project, Hovås Tak, was established, and in a workshop the group identified the changes brought about with the newly introduced coding structure.

3. RESULTS

The workshops and focus group meetings showed that the waterfall principle was used where the information structure is adapted to each discipline on the way downstream. Upstream traceability was secondary as the focus were identifying functional requirements and compiling the cost and steering towards the set budget. During this process, it was recognized that each discipline's description of the construction work was optimized for its discipline. The information was statically presented in the form of reports, drawings, and 3D models. The site management's planning during this stage was mostly highlighting, extracting relevant amounts of information to describe the step-by-step execution of the building via a detailed job planning description and assembly drawings.

The pre-manufacturing elements were manufactured from documents based on geometries and functional requirements that existed as construction documents. A disconnect were thus created between the created construction documents and the original design documents. Traceability backwards was secondary, and this made lessons learned more difficult to document. In comparison, digitization and model-based construction made the information less static, and the information could dynamically be presented/sorted in different ways to describe different purposes.

3.1 Stage one – Identifying Coding Structure and Required Information

During the workshops, the focus group began by clarifying the vision with the information, creating an aim and purpose for the information structure. Here, the client clarified the project vision for the case project, Hovås Tak. The client stressed that it should be a "*carefully planned and well-thought-out apartment building*". This influenced all the project communication and work processes.

The next workshop challenge was to find a consensus in the project designations. In the absence of clearly communicated names of the different parts of the building, prior projects have been shown that the different disciplines create their own designations to orient themselves. For the case project, a document was created to handle the project designations, and any revisions were logged in a similar way to a building document. The marketing team was represented by the client to ensure that a clear consensus was created in the designations towards end customers, facilities management, and O&M.

3.1.1 The disciplines different information structures in the case project

During the workshop it was identified that the model structure of the designers and the structure for material take-off both are linked to building parts and functional quantities. For the case project, Hovås Tak, the main contractor, Skanska's cost calculation structure and process is based on BSAB83 (Swedish classification system from 1983), and the BIM-model's structure is based on BSAB96 (Swedish classification system from 1996). The workshops concluded that the BSAB structure worked well for technically describing building components and functional quantities. Furthermore, the various contracts that were procured was based on similar groupings of functional requirements, so documentation for purchasing was relatively easy to filter out from the BIM.

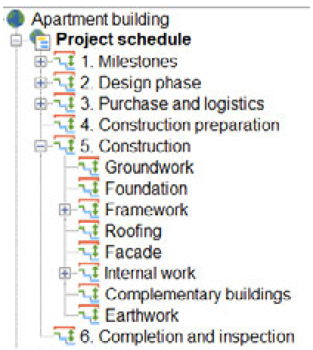

Fig 2: The schedule and time planning are based on the illustrated information structure.

The client's information structure was partly tailored for marketing to end customers and partly for O&M. The marketing material used the project designations when describing the final design of the building and the design and content of the different apartment types. The marketing language and information structure were adapted to attract the identified target customer group. O&M information was structured based on how the management of the property was planned. The client had a specific company-adapted structure for the facility management information which resembles a general BSAB structure.

The information structure of the scheduling is based on Skanska's basic scheduling template for housing projects see Fig. 2, which has been developed over the years and enables a rough comparison between projects. The site management together with a scheduler bases the schedule on this template structure and then details the phases to the specific project in accordance with the site management precious experience from similar projects.

Fig. 3: When having the same WBS and coding, it is possible to analyze projects KPI's against each other to find outliers.

For a number of years now, all housing projects at Skanska extract Key Performance Indicators (KPI) for cost and time according to crucial milestones – essentially a schedule plan analysis. The general phase schedule which is used as input for the analysis is shown in Fig. 3 (left), together with the project completion date KPIs plotted for a number of individual projects (right). By using the same general structure in all projects, it is thus possible to compare KPI metrics between different apartment building projects and identify outliers or projects that must be optimized when it comes to productivity. The case project, Hovås Tak, was analyzed using this specific structure to predict and forecast performance. As seen in Fig. 3 (right) the schedule analysis places Hovås Tak at the lower end of construction time, and at the mid-range for cost when compared to similar projects (i.e., as illustrated by the lower-left rectangle).

The Construction planning was then based on an execution structure (a step-by-step completion structure), for the project. The execution structure was based on Site layout plans for the general construction phases, the master schedule, logistics and delivery schedules and purchasing schedule.

3.1.2 Shared information structure

The information of each discipline was structured to describe their vital information in an effective way. A common denominator was identified as missing by the focus group. The denominator should enable grouping of information in a similar way regardless of discipline to coordinate a shared sequential execution The focus group decided to refine the basic schedule template and the schedule analysis together with the phases in the construction planning to create deliverables that group the information in a similar way for all disciplines.

A methodology for finding the shared information structure was developed. Through an iterative process where the first loop created the first overall names and a first overall division of the deliverables of the construction phases and its geographical division were adapted to the project's conditions and scope. A side effect of this work was that as more information was generated in the project, the focus group continually helped coordinate and structure the information to create consensus in project designations and construction phases, see Fig. 4.

CoClass was identified as a possible shared coding structure. However, suitable properties were missing to get a shared structure used by all disciplines.

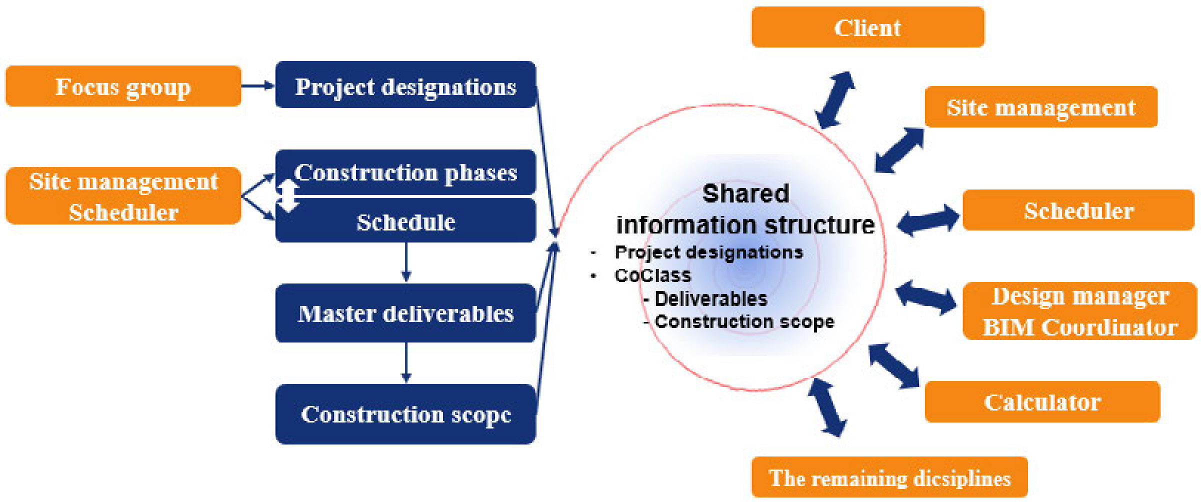

Fig 4: Illustration showing how a shared information structure for the construction project could support all the disciplines with CoClass coding of Deliverables and Construction scope.

In dialogue with Svensk Byggtjänst and the development team of CoClass, a contribution to the classification was made in the form of two new properties:

- Deliverables, "TPPR Produktions etapp" in Swedish, which is defined as a temporal object property indicating production phase.
- Construction scope, named "PRWT Produktionsdel", which can be defined as production property that specifies the spatial division of work.

By adding these two properties, the CoClass structure enables a shared structure to describe the project execution as well as the technical description for all disciplines. The case project, Hovås Tak, did not use CoClass to its full extents because existing coding structures were too tightly tied to the existing planning and cost management systems and their information structures, but the new properties were added to existing systems.

3.2 Stage two – Implementing and Evaluating Coding Structure and Information

By using storyboard form like film and sketching out a sequence of events for each construction phase, the focus group could agree on a more project-adopted division of the deliverables. The content of each deliverable was analyzed to ensure that the deliverables reflected and supported the actual execution. In particular, the focus group needed to discuss the transitions between the different deliverables for the information to be delimited in a similar way for all disciplines. The structure of the deliverables was then arranged in a hierarchy with a more comprehensive structure broken down into more detailed levels for certain deliverables where there was a need to describe the execution more clearly, see example in Fig. 5.

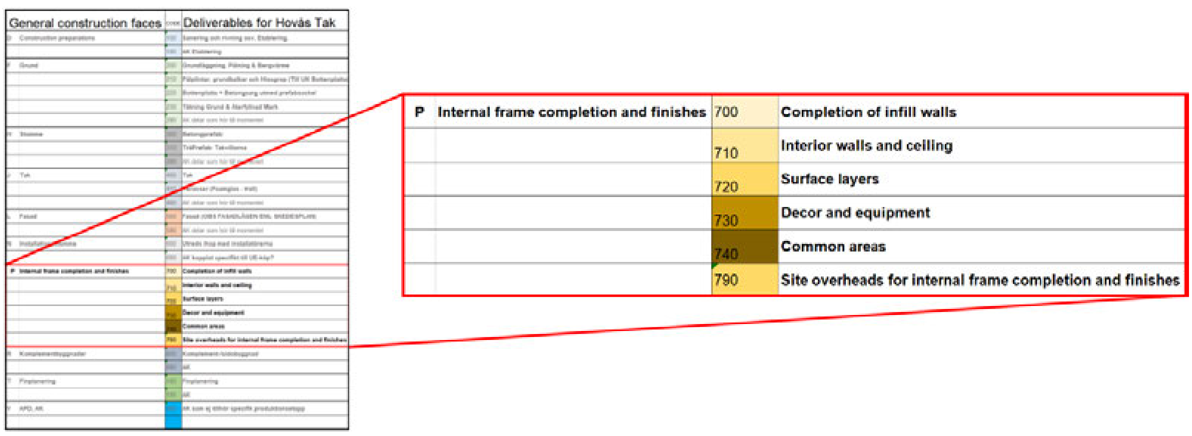

Fig. 3: Left part shows the general phases side by side with deliverables.

When the boundaries of the deliverables began to become clearer, the geographical distribution was analyzed to find a suitable material and workflow for each construction scope. This also had the effect that other disciplines could provide timely input to each other.

The construction scope was created to reflect the material flow to the specific location, the gradual execution of tasks within the scope, and provide structured information from construction for use during the O&M. Furthermore, digitization and model-based construction and takt-planning made the information less static and enabled filtering and sorting in different ways to describe different purposes.

3.2.1 Challenges

Both during design and cost management of the project the new coding structure posed challenges. In each phase it was found that the supporting systems did not easily allow mirroring of the execution process into deliverables. As a solution some composite model objects created from the classifications in the system were decomposed in more detailed functional parts to fit with the deliverables. A typical example is found in exterior walls for the case project. The design and cost management uses composite object to represent functional object of the exterior wall, meanwhile the schedule and the site management represents and complete the exterior wall in four different deliverables:

1. Construction framework,
2. Façade (external finishes),
3. Internal frame completion and
4. (internal) finishes.

While changing the systems for cost management and design was not a viable solution, a workaround was needed. This created extra administration in each discipline both in working with these WBS codes and filling them out and to work and ensure the quality of each discipline's own information.

3.3 Stage three – Effects of Using the Coding Structure

The first and foremost effect identified was the reduced language confusion in dialogue between the disciplines and how information was consumed between them. The disciplines experienced a reduced need to process and re-fit information in later stages of the construction process when the information was coded with deliverables and construction scope. By gathering construction results using this shared coding structure, a more holistic understanding of the project was formed by each discipline. Information that used to be found in different systems, sorted by different coding structures was now found more easily through the shared code structure. Additionally, disciplines could use the shared coding and information structure to ensure that they talked about the same deliverables and objects. Thus, communication between the design manager, BIM-manager, cost managers, the scheduler and site management could flow more easily.

Following are some distinct examples of how the shared coding structure simplified communication and where the combined information created more value than each piece of information on its own.

3.3.1 Schedule – presented in 3D model.

By connecting the deliverables of the models and the schedule and its construction scope, a visualization of the schedule was created directly using the BIM module in Powerproject. The visualization of the scope and content to be scheduled increased the understanding for the disciplines involved, and reconciliation of work completed became easier to review.

3.3.2 Upload quantity takeoff and easier cost control

Since the quantity takeoff from the model was already coded with deliverables and construction scope, time for the cost manager to structure the costing data was shortened. Changes in quantities were easier to identify by the focus group and updating the cost control was faster because a smaller amount of information had to be compared within a clearly defined area using the construction scope coding.

Since the cost estimate was able to be sorted based on how the case project, Hovås Tak, was to be executed, deliverables were faster reviewed and understood, and each sequence clearly visualized by the model using deliverables. The cost management could thus be linked to the degree of completion of each deliverable. Performance-based payment plans could also be linked to the work completed in each deliverable.

3.3.3 Quality work and inspection plan

The quality controls continued during the execution and ensured that the requirements were met in the finished product. With the help of the deliverables, quality risks for each deliverable could be identified. The monitoring of the inspection plan and self-inspections also became more clearly structured. The review of the inspection plan by the inspection manager together with the site organization and the various contractors was also greatly facilitated.

3.3.4 Work environment and safety risks

During the design phase, the principal designer is tasked with identifying work environment risks and as far as possible, eliminating them. The identification of work environment risks was facilitated by the simulation of the coordination of all discipline's BIM-models and construction phase schedules, gaining valuable insights into work environment risks needed to be considered in each deliverable.

3.3.5 Basis for takt planning

The sequential breakdown of the information, simulating the execution of the construction works were identified to be fully in line with the structure of the takt planning. One or more deliverables formed the basis from which work packages were created. The work packages could then be broken down into takt zones consisting of one or more construction scopes. This breakdown formed teams of disciplines that performed the work in each takt. The sequence of work in each takt zone formed a takt-train. All BIM-models follow this hierarchy and the addition of information and review of status of the BIM-model could be done continuously via each takt-wagon. By connecting the takt-planning with the model it was possible to dynamically filter and visualize the takt zones and takt-wagons for the different subcontractors.

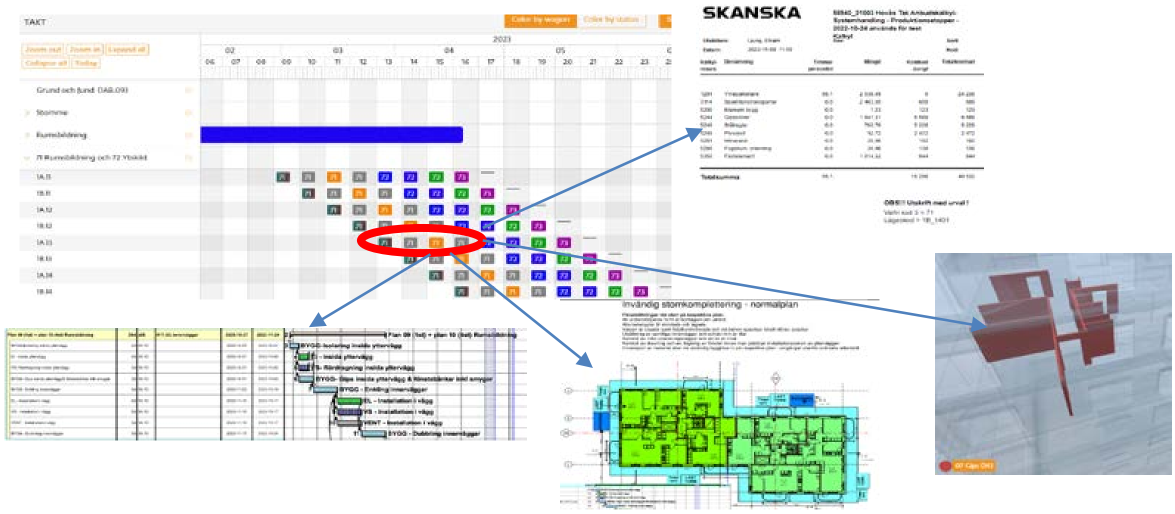

Fig. 4: By structuring of information in the project and BIM into shared code and information structure that supported and reflects how work progresses on-site, it was possible to connect the construction schedule, the cost control plan and takt schedule.

4. DISCUSSION AND ANALYSIS

The main insight during the focus group meetings were that a shared WBS and coding structure was lacking in the execution planning, similar insights has previously been presented but limitations in generalizability has been stressed (Cerezo-Narváez et al., 2020; Makarfi Ibrahim et al., 2009). Since the main contracting company recently has taken a more of a coordinating responsibility in new projects results show there is a great need to improve communication and coordination, similar conclusions are stressed in related studies (e.g., Crowther & Ajayi, 2019; Nepal & Staub-French, 2016; Viklund Tallgren et al., 2021). Thus, communication and coordination of subcontractors and designers, cost managers, schedulers and other stakeholders is as important for the project as it is for the site management.

The documentation of common language and designations eased communication process throughout the project. However, it could be argued that it is not necessary to replace the existing WBS and code structures that are well established for each discipline. The key is to bridge organization, process, technology, and information and through dialogue find common project denominators that enable the WBS and information to be grouped in shared way by different disciplines. This is supported by the conclusions and like the structure presented in Makarfi Ibrahim et al al., (2009), but customized and developed for the Swedish context. Deliverables and construction scope groups the project in ways that reflect how work progresses on-site and complements the traditional description of the construction results emphasized by existing coding structures and existing WBS systems.

The traditional segmentation of work in contracts, disciplines or functions will still be needed since each area has their own needs and demands on how to ensure quality of their information and optimize their work in their systems. The traditional division works well enough for optimizing purchases and clarifying responsibilities between contracts and disciplines. The added coding of deliverables enables a more pro-active and fine-grained analysis than previously was possible. Furthermore, a common WBS and information structure enables new possibilities to the development of schedule analysis and the KPI's on the master schedule critical path. This can give a deeper insight and understanding of how different projects progress and find outliers or inefficient projects. But this data could also be used in the future for machine learning and artificial intelligence during the bidding phase or planning of new construction projects.

Another outcome from the study was that the implementation by the focus group also improved the overall work processes, where the team came together and a closer bond was formed between design, cost management and site management, lowering the threshold for communication amongst them, in line with precious research (Crowther & Ajayi, 2019; Nepal & Staub-French, 2016; Viklund Tallgren et al., 2021). One of the main insights during the implementation of the developed WBS and coding structure was that the dialogue in the focus group was especially important to ensure that information from each discipline was coded in the right way. The presentation of the visualized sequencing through the BIM-model and the deliverables created a necessary foundation for the following dialogue between design, cost management and site management. This was seen in more open discussions between disciplines, enabled through the better understanding of the holistic view of the construction scope which is in line with previous research (Azhar, 2011; Sacks et al., 2018). The extra administration the respective disciplines experienced in the coding and its structure, is thus mitigated.

By moving from static information to a digital information structure enabled information to dynamically be sorted and grouped in new ways to better suit the needs of different stakeholders. Through this common WBS and information structure, a common ground was created adding flexibility to each stakeholders' specific needs, without affecting their basic needs. Thus, it could be argued that the process gave a better understanding how different parts and resources should work together to reach a better result in the project.

Since the production of the case project, Hovås Tak, started in January 2023, the production planning and implementation of the first production stages has been conducted and evaluated. An initial reflection is that even though the information more closely followed how the construction was conducted, it was difficult for the site management and workers to absorb the information in this new way, especially in the BIM system used. With everyone used to read static drawings and descriptions; new working processes and tools had to be introduced on site. A first step to implement the common WBS structure in the site organization could be to visualize the information in each deliverable in a workshop form and discuss on how to use the information from each discipline. This enables an identification of affected stakeholders and make them understand the scope of the project while together developing the detailed job planning and construction schedule. Thus, utilizing the benefits of involving the right stakeholders in the planning and scheduling, as seen in Viklund Tallgren et al. (2021).

The sequential division in different deliverables enables the construction team to focus on one thing at a time, thus ensuring that each deliverable reaches each respective goal, quality wise as well as budget wise and schedule wise. As the information is coded and structured in a way that easier enables the site management to sort and review information regardless of discipline, the site management is enabled to:

- Clarify the coordination of material flows and logistics for each deliverable.
- Clarify responsibilities connected to the project's execution as well as coordination of sequencing of the project in general as well as during takt zones.
- Clarify cost flows and performance-based payment plans sorted by deliverables.
- Create a good basis for quality control within each deliverable.
- Create a good basis for inspection rounds and follow-up of work done for deliverable.
- Create good structure for all types of implementation statistics such as work environment, deviations from initial project scope and schedule.
- Get a good structure for the collection of operation and maintenance data and a basis for as-built documentation.

Furthermore, the deliverables enable a standardization and identification of repetitions that also can form the basis for the takt planning, as highlighted in Haghsheno et al. (2016). In the case project, the deliverables were analyzed to build effective teams that work together to reach the common goal of the finished deliverable and where the construction scope was analyzed to create optimal takt trains. The common WBS structural hierarchy in deliverables and construction scope means that the information generated in the execution can be easily linked with the information sources (construction document, production estimates, schedules, and production planning such as purchasing and logistics). In a way the coding structure standardizes information expressed as missing in prior research (Cerezo-Narváez et al., 2020; Makarfi Ibrahim et al., 2009). Furthermore, the information gap between project stages indicated in Borrmann (2018) can be avoided in with the use of shared coding structures as brought forward in this research. Project documentation, facility management documentation and O&M instructions that normally tend to be based on how it was planned to be built and function, can now reflect as built.

Knowledge transfer with regards to finance, quality, productivity, becomes administratively simpler when all information is sorted with a shared structure and coordinated to get a better overall picture. The risk of some area being prioritized and the rest being suboptimized is then avoided.

Also, by using a common WBS and BIM-model in this way enables data-driven pro-active decisions throughout a project. This could in the future assist the construction industry with meeting climate objectives, where informed data-driven decisions reduce waste and lower the overall climate impact in the projects. Implementing WBS through BIM, with the support of other digital technologies can improve circularity assessments, increase material recycling and reuse, and more accurately track environmental data throughout a building's lifecycle all the way to decommissioning and dismantling of building.

Furthermore, this study and the developed WBS and information structure has contributed with input to the continued development of the Swedish classification system CoClass.

5. CONCLUSIONS

This paper presents a study of the design, development, and validation of a WBS and coding structure for supporting BIM and takt-planning in the context of a real construction project, Hovås Tak (case project). The aim has been to establish a shared information structure for all disciplines and investigate; what structure is needed for production control and management from design to construction and how this structure could help project management to understand the project execution and its challenges better. By structuring the WBS and its information in the BIM it was possible to support and mirror how work progress on-site. In this context, it was possible to connect the construction schedule, site management planning, the cost management, and the model of the project to a better holistic understanding. BIM enables the visualization of the step-by-step progression of the construction. Digitization and BIM enables detailed multidimensional WBS and coding, a shared code does not have to be governing, but a shared coding with lower common denominator can provide new interoperability opportunities between disciplines. Digitization, model-based construction makes the information less static and enables filtering and sorting BIM in different ways to describe different purposes. Furthermore, the common WBS and information structure is also an important base for a pro-active construction management and could be a base when it comes to takt-planning of the construction site and to gather information to the digital twin.

6. ACKNOWLEDGEMENT

This work is part of the Digital Twin Cities Centre and funded and supported by Sweden's Innovation Agency Vinnova under Grant No. 2019–00041 and by SBUF Grant No. 14237 (Development Fund of the Swedish Construction Industry) and CMB (Centre for Management of the Built Environment).

ABSTRACT: *In pursuit of a sustainable built environment, BIM plays a crucial role in the project's performance and has egressed as a powerful technology in the construction industry, impacting the outcome and the project delivery workflows. Numerous dynamic and interdependent factors influence BIM performance. However, Existing literature prominently focuses on exploring the influencing factors for BIM performance, ignoring the impact and strength of the interplay of these factors on one another, therefore offering an inadequate picture of optimizing BIM performance. The evolving nature and degree of complexity of construction projects necessitate the identification and comprehensive understanding of the interdependencies between factors contributing to BIM performance in the sustainable built environment. A Fuzzy Cognitive Map (FCM) is a modeling method that represents and analyses the interplay between the factors in a complex system. So, this study proposes an FCM-enabled approach to investigate the interdependencies of factors contributing to BIM performance and conduct what-if scenarios, including predictive analysis. The developed FCM model can help reveal the hidden cause-effect relationships among a complex system of BIM performance factors, enabling stakeholders to develop more informed strategies and proactively plan to optimize BIM Performance.*

KEYWORDS: *BIM performance, Fuzzy Cognitive Map (FCM), Built environment*

1. INTRODUCTION

Sustainable development has become the crucial state that all sectors aim to achieve, and the built environment is no exception. Sustainable development implies balancing human socioeconomic activities and the natural environment's capacity to provide resources and absorb waste on a global scale. In pursuing sustainable development, delivering construction projects with improved performance to achieve sustainable goals shall play a significant role. Studies in the literature have shown several factors influencing project performance. Chang et al. (2017) explored the factors that influence project performance and highlighted the technological aspects that significantly affect project performance, pushing stakeholders towards adopting the technology in the built environment. Building Information Modeling (BIM) has emerged as a promising digital technology in the AEC sector, enabling the ability to enhance performance in areas including design, procurement, prefabrication, construction, and post-construction(Wang et al., 2022). Although the BIM concept dates back to the 1970s, the adoption of the BIM was seen as significantly increasing since 2000 (Caglayan & Ozorhon, 2023). Effective adoption and continuous performance improvement of BIM requires maximizing the benefits and high exploitation of the capabilities of BIM, further pushing stakeholders to gain a holistic approach and a deep understanding of the dynamics of the influencing factors. Several studies have been conducted on BIM adoption and assessing its performance in various project phases, including design and construction. However, BIM performance is not an isolated aspect. Moreover, inefficiencies are caused by the influence exerted not by discrete factors but by the amalgamate impact of the combination of dynamically connected factors in construction projects. Therefore, identifying the causes of inefficiencies also becomes crucial (Zhang et al., 2021) to improve BIM performance. While existing studies have made momentous strides in identifying factors that influence BIM performance, there is a noticeable gap in understanding the dynamics between the factors whose influence propagates throughout the system of the construction project and eventually impacts the BIM performance. This study attempts to address this noticeable gap by proposing a Fuzzy Cognitive Map (FCM) model to explore the intricate mechanism of dynamic interconnections among the factors that influence BIM performance. The study aims to identify the factors (individually or in combination) causing inefficient BIM performance and provides a dynamic model that can be used to simulate the propagation of influence caused by policy modification through FCM theory.

2. LITERATURE REVIEW

2.1 BIM Influencing Factors

BIM has been extensively studied in the research community, attributed to its positive impact on project

performance. Several studies have been looking into the factors that impact BIM adoption and its performance. These factors are often called critical success factors, or risk factors, or key performance indicators (Caglayan & Ozorhon, 2023). Rogers et al. (2015) investigated the factors driving BIM adoption for engineering consulting services (ECS) in the Malaysian construction industry. Inadequacies of BIM experts, guidance, and government support were found to be hurdles for the ECS. Lee et al. (2018) Propose an innovative trust-centric contracting model to enhance BIM performance within Engineering, procurement, and construction (EPC) projects and explain trust's positive influence on BIM performance. Caglayan & Ozorhon (2023) propose a framework to determine BIM effectiveness and identify the project, industry, and company-based factors influencing BIM effectiveness. Project and company-based factors were identified to govern the BIM effectiveness. Badrinath et al. (2018) propose an empirical methodology to explore the factors for successful BIM projects and identifies highly governing factors groups such as the BIM technology, stakeholder skills, and competencies. Several studies have examined BIM performance and attempted to explore the influencing factors to exploit the full potential of BIM. However, the studies in the literature rarely considered the system complexity and dynamics of the interactions among the factors, ignoring the causal propagation of impacts of any discrepancies of influencing factors. Furthermore, inefficiencies are caused by various degrees of influence by factors. Hence, identifying and eradicating those causes are significant in preventing inefficiencies (Zhang et al., 2021). This necessitates analyzing the dynamic relationships among factors influencing BIM performance. Luo et al. (2022) highlighted several static methods available to study the influencing factors, such as the Fuzzy analytical hierarchy process (FAHP) and Fuzzy analytic network process(FANP), However, these methods pay little to no attention to the dynamic interaction and complexity of the system. Hence, this study employs the FCM method to investigate the dynamic interactions among BIM performance factors and aims to identify factors causing inefficiencies in BIM performance.

2.2 FCM Approach

FCM was introduced by Kosko (1986) to model and simulate dynamics systems. FCM helps mimic a complex system by considering the causal relationships between the concepts (Poczeta et al., 2020). It is a powerful method that can simulate the interaction of factors. FCM enables the systematic propagation of causal relationships between the factors, hence a suitable and systematic decision approach for analyzing and deriving insights into complex system performance (Zhang et al., 2021). Luo et al. (2022) used FCM to explore the dynamic relationship between influencing factors and prefabricated building cost, further, employed FCM to identify the root causes and sensitivity of factors to conclude that the scale effect has the greatest effect on the prefabricated cost. Zhang et al. (2021) employed the FCM method to measure the Tunnel Boring Machine (TBM) performance and conduct root-cause analysis and what-if scenario to explore the dynamic relationship between the factors that influence the TBM performance. Case et al. (2018) examine the application of FCM in modeling construction management problems and project complexities and details the construction of FCM models for construction management problems. Luo et al., (2020) propose a novel hybrid approach that combines the structural equations model (SEM) and FCM to examine the impacts of discrepancy in project complexity on the project's success. Luo et al. (2022) compared the four typical methods that are used for the simulation of the interaction between the factors.

3. METHODOLOGY

The methodology of this research involve FCM-enabled predictive analysis for BIM performance and consist of identifying concepts, determinination of relationships, and FCM computation and analyzing, as described in the following subsections.

3.1 FCM Development and Computation

3.1.1 Identification of Concepts

Identification of the concepts provides the basic structure for the FCM. FCM consists of several concepts, often called nodes or factors, referring to variables, elements, or attributes mimicking the various aspects of the system. Zhang et al. (2021) highlight the sources for identifying concepts such as accepted knowledge from the domain, empirical knowledge, and domain experts. Figure 1 illustrates a simple FCM model. These concepts (C_i) are connected by directed arcs, often called connections or edges, to represent the causal linkage between the concepts. Every concept in the FCM model bears a value ranging from 0 to 1 (Poczeta et al., 2020).

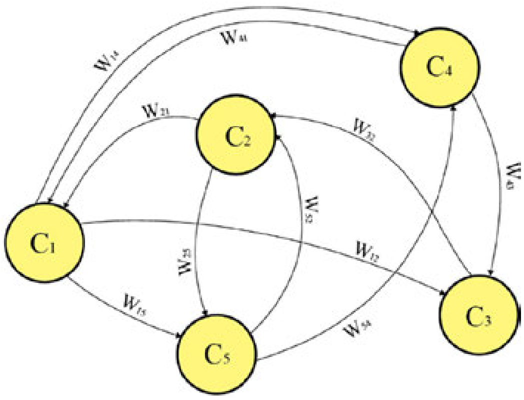

Fig.1. Illustration of simple FCM

In this study, BIM performance influencing concepts are derived through a literature review and further reduced and added after a brainstorming session with experts. Finally, 18 BIM performance controlling concepts are finalized. Concepts include BIM knowledge of the project participants (C_1), BIM training (C_2), BIM motivation (C_3), Consistent views on BIM between stakeholders (C_4), Top management support/BIM leadership (C_5), Project delivery methods encouraging collaboration (C_6), Collaboration and communication (C_7), Change management (C_8), Project complexity (C_9), Availability of BIM guidelines/protocol (C_{10}), Provisions in contracts on data security (C_{11}), Provisions in contracts on liability & risk (C_{12}), Provisions of agreed standard of rules to protect the BIM employees (C_{13}), BIM execution plan (C_{14}), Hardware and software infrastructure (C_{15}), The capability of hardware and software infrastructure (C_{16}), Information Quality (C_{17}), BIM experience of the stakeholder's company (C_{18}) and BIM Performance (C_T). The descriptions of concepts are described in Table 1.

Table 1. Concept identification for BIM Performance.

ID	Concept	Description	Reference
C_1	BIM knowledge of the project participants	Competence of project participants in using BIM tools and methodologies.	(Caglayan & Ozorhon, 2023)
C_2	BIM training	Training programs to develop BIM-related skills and knowledge among project participants.	(Einur Azrin Baharuddin et al., 2019)
C_3	BIM motivation	Incentives and drivers for project participants to adopt and implement BIM.	Suggested by expert
C_4	Consistent views on BIM between stakeholders	Alignment and agreement among stakeholders on the goals and benefits of implementing BIM.	(Al-Mohammad et al., 2023)
C_5	Top management support/BIM leadership	Endorsement and active support from top-level management for successful BIM implementation.	(Caglayan & Ozorhon, 2023)
C_6	Project delivery methods encouraging collaboration	Project delivery method facilitating better collaboration among stakeholders (for example, integrated project delivery).	(Salim & Mahjoob, 2020)
C_7	Collaboration and communication	Effective collaboration and communication processes among project participants using BIM.	(Oraee et al., 2019)
C_8	Change management	A systematic approach to managing and implementing changes associated with BIM adoption.	Suggested by expert
C_9	Project complexity	Level of complexity and size of the construction project.	(Jiang et al., 2021a)

C_{10}	Availability of BIM guidelines/protocol	Internal guidelines/protocols for consistent BIM implementation in the project.	(Al-Mohammad et al., 2023)
C_{11}	Provisions in contracts on data security	Provisions in contracts addressing data security, privacy, and confidentiality in BIM projects.	(Al-Mohammad et al., 2023)
C_{12}	Provisions in contracts on liability & risk	Provisions in contracts addressing liability and risk allocation for stakeholders in relation to BIM implementation.	(Al-Mohammad et al., 2023)
C_{13}	Provisions of agreed standard of rules to protect the BIM employees	Agreed standards of rules protecting the rights and liabilities of individuals involved in BIM projects.	(Al-Mohammad et al., 2023)
C_{14}	BIM execution plan	A comprehensive plan outlining BIM implementation strategy, processes, and deliverables.	(Franz & Messner, 2019a)
C_{15}	Hardware and software infrastructure	Adequate hardware and software resources for BIM implementation.	(Al-Mohammad et al., 2023)
C_{16}	The capability of hardware and software infrastructure	BIM software capability to meet project requirements, handle complex geometries, and more. (interoperability)	(Al-Mohammad et al., 2023)
C_{17}	Information quality	Accuracy, completeness, and reliability of information within BIM models and datasets.	(Song et al., 2017)
C_{18}	BIM experience of the stakeholder's company	Level of experience and familiarity with BIM technologies and processes within the company.	(Caglayan & Ozorhon, 2023)
C_T	BIM Performance	Effectiveness of BIM adoption and utilization in a project, aiming to maximize efficiency, return on investment, and harness the full potential of BIM across all project phases.	(Caglayan & Ozorhon, 2023)

3.1.2 Identification of causal relationship and computation

The concepts are linked by causal relationships. The direction of the causal relationship is represented by the connections or arcs describing the degree of influence between the concept C_i and C_j, often referred to as weights (W_{ij}) (S. Lee et al., 2004) that can be positive or negative, with values ranging from -1 and +1. In the complex system, in the case of any variation in the state of C_i results in a variation in the state of C_j, the arc is used to represent the causal relationship between C_i and C_j. $W_{ij} > 0$ represents the increase or decrease in the C_i leads to an increase or decrease in C_j, respectively, while $W_{ij} < 0$ represents an increase or decrease in C_i leads to a decrease or increase in C_j, respectively. Furthermore, if the W_{ij} equals zero, it indicates the absence of a causal relationship(Maitra & Banerjee, 2014). Identification of the causal relationship is the key component of building a FCM. Luo et al. (2022) highlight the two approaches to determine the degree of causal influence between the concepts, such as the learning method, which demands a large number of historical data, and the expert method. This study employs expert methods and uses fuzzy semantics to describe the degree of causality among concepts using nine levels of fuzzy semantics such as negatively very strong, negatively strong, negatively moderate, negatively weak, neutral, positively weak, positively moderate, positively strong, positively very strong with membership vales as -1, -0.75, -0.50, -0.25, 0, 0.25, 0.50, 0.75 and 1 respectively.

Causal interconnections of the FCM are mathematically presented by the n x n matrix(Zhang et al., 2021), and the state value of concept C_i at the time t+1 can be obtained through the following equation (Stylios & Groumpos, 2004)

$$A(t+1) = f\left(A_i(t) + \sum_{j=1, j\neq i}^{n}\left(W_{ji} \times A_j(t)\right)\right) \quad (1)$$

where $A_i(t+1)$ represents the state value of the concept of C_i at time t +1 as $A_i(t)$ and $A_j(t)$ represents the state value of concept C_i and C_j at time t, respectively.

Two types of threshold functions are employed in the FCM framework, i.e., sigmoid and hyperbolic tangent functions.

$$f(x)=(1/(1+e^{-cx})) \quad (2)$$

$$f(x)=\tanh(x)=((e^{x}-e^{-x})/(e^{x}+e^{-x})) \quad (3)$$

Eq. (2) is employed to map values between 0 and 1, whereas Eq. (3) is employed to map the values between -1 and +1 (Zhang et al., 2021). In dynamic FCM models, usually, the connection values range from -1 and 1(Barbrook-Johnson & Penn, 2022). In this study, experts' responses on causal relationships are taken in the range of -1 and 1 to understand the dynamic interaction between the influencing BIM factors. Hence we choose the hyperbolic tangent function [Eq. (3)]

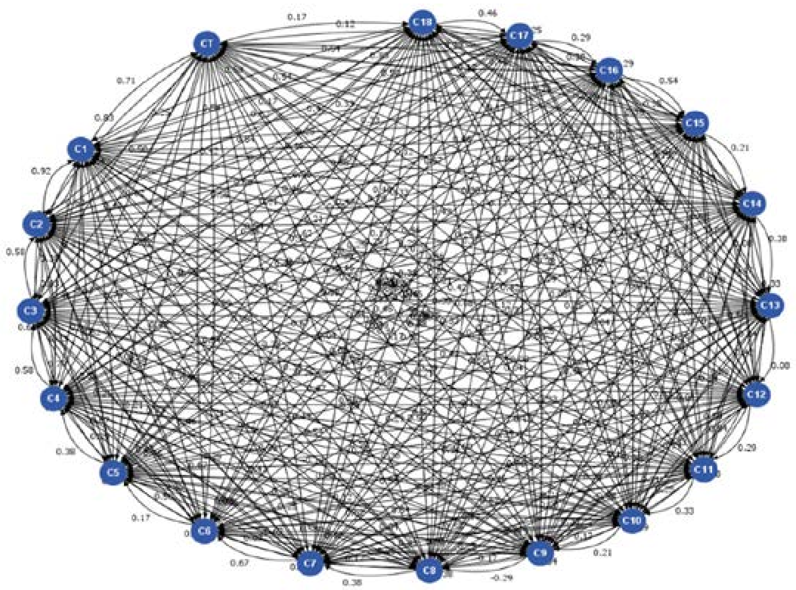

Fig. 2. Fuzzy Cognitive Map of BIM Performance

The responses of a totally 6 experts from India and Taiwan were received for the questionnaire and respondent background is shown in Table 2. The answers from the experts are further complied to calculate the weight for each concept by the center of gravity (COG) method. For example, W_{1T} is aggregated to be 0.71 as three experts rated positively strong, two experts rated positively moderate, and another rated positively very strong.

Table 2. Expert's background

Respondent	Professional background	Educational background
Expert 1	BIM Manager	Master
Expert 2	Researcher	Doctor
Expert 3	BIM Manager	Master
Expert 4	BIM Engineer	Bachelor
Expert 5	BIM Manager	Master
Expert 6	BIM Strategist	Doctor

There are several tools to facilitate the development of the FCM model. Nápoles et al. (2018) identified and compared several FCM tools and proposed a tool called FCM Expert, which facilitates adequate graphical support and higher experimental options. In this study, FCM Expert tool is employed, considering its advantages of FCM Expert over other tools. Creating the concepts and assigning aggregated weights to the concepts, results in the FCM model of BIM performance that is graphically presented in Fig. 2. FCM facilitates to simulate the behavior of systems and enables the what-if experiments (Papageorgiou & Salmeron, 2013). In order to identify the concepts influencing BIM performance, considering the dynamic interplay among the concepts, FCM, once modeled, allows the predictive analysis.

3.2 Predictive Analysis and Discussion

FCM-enabled predictive analysis facilitates the forecast of the outcome or impact of a cause when information or evidence of the cause is available (Zhang et al., 2021). It allows to curate the experiments involving simulation of impacts of the target variable (C_T) when evidence of change is available in the influencing variables (Luo et al., 2022). To address the uncertain nature of the concepts, a five-point linguistic scale: very favorable, favorable, neutral, unfavorable, and very unfavorable, with numerical values as 1, 0.5, 0, -0.5, and -1, respectively. The dynamic propagation of the effect of change in nature (very favorable, favorable, neutral, unfavorable, and very unfavorable) of influencing concepts (C_1 to C_{18}) on CT in a system of network simulated and the effect of the target variable (C_T), i.e., BIM Performance is observed. For example, the initial nature of all the concepts is set to neutral except C_9, whose nature is assumed to be very favorable, favorable, unfavorable, or very unfavorable, to observe the effect on BIM Performance (C_T) until it stabilizes. Table 3. Presents the stable values of CT after a set of iterations in different values (1,0.5, -0.5,1) of C_1 to C_{18}. For example, the stable value of C_T when C_1 is very favorable (=1) is 0.948, implying a positive correlation between C_T and C_1. All the concepts except C_9 tend to have a positive correlation with the target variable, i.e., BIM Performance. The stable value of C_T when C_9 is very unfavorable (=-1) is 0.951, implying the negative correlation between them. Fig.3 illustrates the impact of the concepts C_1 and C_9 on C_T. Predictive analysis results showed that concepts C_1 (BIM knowledge of the project participants), C_2 (BIM training), C_9 (Project complexity), and C_{14} (BIM execution plan) have a high influence on BIM performance. Similar results are demonstrated by other studies, such as Caglayan & Ozorhon, (2023) demonstrate that project-based factors such as BIM training and BIM knowledge of the individuals on the BIM project have a direct impact and great influence on the effectiveness of the BIM. Project complexity (C_9) has a significant impact on BIM performance. The negative correlation here implies poor BIM performance resulting from the combination of the influence of BIM knowledge and training. Jiang et al. (2021b) study BIM performance, project complexity, and user satisfaction and highlight project complexity as the key factor for BIM performance and user satisfaction. Furthermore, Franz & Messner, (2019b) shows the positive impact of the BIM execution plan, not only on participating members but also the performance. Similarly, the results of predictive analysis tend to show the positive influence of the BIM execution plan (C_{14}) on BIM performance. The predictive analysis aids the deeper understanding in enhancing the effectiveness of BIM adoption and aiming to use the full potential of BIM.

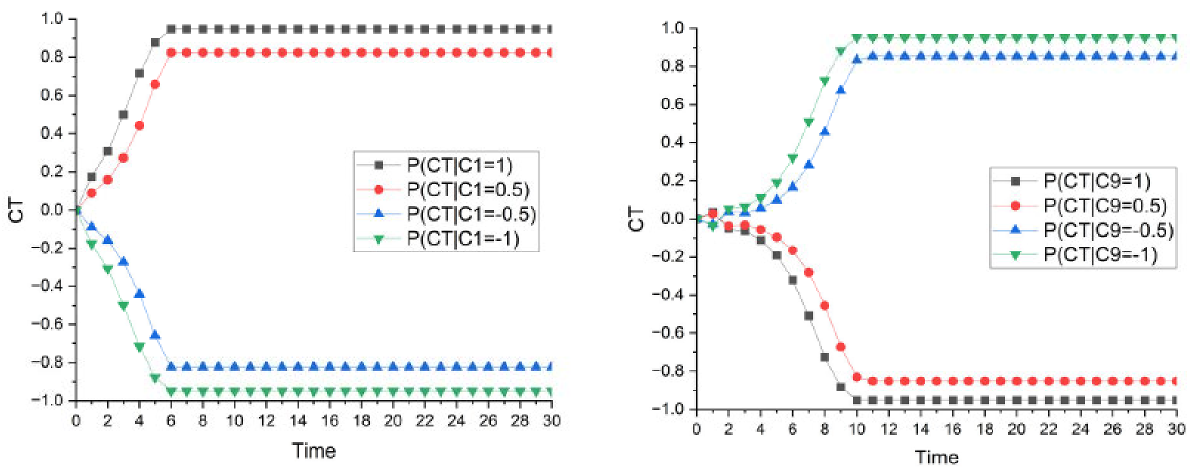

Fig.3. Impact of concepts C_1 (BIM knowledge of the project participants), C_9 (Project complexity) on C_T (BIM Performance)

Table 3. Stable values of C_T under different scenarios

Concept ID	$Ci = 1$	$Ci = 0.5$	$Ci = -0.5$	$Ci = -1$
C_1	0.948	0.823	-0.823	-0.948
C_2	0.942	0.839	-0.839	-0.942
C_3	0.811	0.621	-0.621	-0.811
C_4	0.830	0.682	-0.682	-0.830
C_5	0.835	0.689	-0.689	-0.835
C_6	0.890	0.747	-0.747	-0.890
C_7	0.911	0.793	-0.793	-0.911
C_8	0.942	0.808	-0.808	-0.942
C_9	-0.951	-0.832	0.832	0.951
C_{10}	0.892	0.763	-0.763	-0.892
C_{11}	0.780	0.611	-0.611	-0.780
C_{12}	0.690	0.609	-0.609	-0.690
C_{13}	0.780	0.619	-0.619	-0.780
C_{14}	0.979	0.900	-0.900	-0.979
C_{15}	0.849	0.721	-0.721	-0.849
C_{16}	0.908	0.790	-0.790	-0.908
C_{17}	0.940	0.807	-0.807	-0.940
C_{18}	0.903	0.788	-0.788	-0.903

4. CONCLUSION

BIM adoption and enhancing its performance in construction projects is a complex system where several factors influence its effectiveness in exploiting the high potential of BIM. It is crucial to pinpoint the factors causing the strong influence on BIM performance, considering the dynamic relationship among them. FCM models are better suited to explore and reflect the cause-effect relationship among the concepts (Luo et al., 2022). FCM's approach to understanding the dynamic relationship between factors that influence BIM performance is suitable due to its dynamic complexity. Furthermore, it allows predictive analysis to forecast the behavior of the network of the system. The concepts for the BIM performance were identified from the literature and further filtered through brainstorming sessions with experts to finalize 18 concepts. Relationships between the concepts were captured through a survey, and FCM was developed to enable predictive analysis. The results showed a high positive influence from the concepts: BIM knowledge of the project participants (C_1), BIM training (C_2), and BIM execution plan (C_{14}) have a big influence on BIM performance, whereas Project complexity (C_9) tend to show the negative correlation implying the special precautions to be taken by stakeholders to enhance the effectiveness of the BIM adoption to leverage the full potential of BIM in high complexity in the construction project.

In the course of this study, highlighting encountered limitations shall aid the improvement in future studies. The factors identified for the study are pivotal for exploring the dynamic interaction among the BIM performance influencing factors and are not extensive. Additionally, the reliability of the FCM employed could be strengthened with high responses and the widespread input of experts.

The exploration of the relationships among the factors is enabled through several methods, as mentioned before. However, understanding the dynamic relationship among them and the propagation of ripple effects among the network system is better understood through adopting less static models like FAEM and FMEA. In order to capture the dynamic complexity, the systems thinking approach can be used to understand the behavior of the system of BIM and assess BIM's performance with higher experts' involvement. To date, several construction activities are highly dependent on the experience of the experts; the FCM can be used to capture crucial human knowledge in the context of effective BIM adoption to aid better decision-making for the stakeholders involved.

ABSTRACT: *Currently, industrial robot arms are trending in prefabricated building construction; however, a notable gap exists in established automated processes and related research specifically for the insertion of batt thermal insulation. The current method for accomplishing this task relies on manual insertion, which is labour-intensive for the workers and poses long-term health and safety concerns. This research presents an ongoing research project aimed at developing a feasible robotic process for the automated insertion of batt thermal insulation into prefabricated light-frame wood wall frames. This research focuses on the utilization of a single 6-degree-of-freedom robot arm for the insertion process, complimented by the design of a custom-built end-effector. The proposed robotic insertion process, named GLITPP, comprises of six major steps: (1) Grasp, (2) Lift, (3) Insert, (4) Tilt, (5) Push, and (6) Press. The GLITPP insertion process, along with the custom-built end-effector effectively mitigates the influence of the insulation's nonlinear mechanical properties, while also taking collision avoidance into consideration. This ensures a tight-fitting insulation within the frame cavity, without visible gaps and deficiencies. The necessary physical operating parameters for the insertion process, such as angles, offset, and force requirements, are identified to ensure the precision, efficiency, and repeatability of insertion. A prototype of the designed end-effector is used to demonstrate and validate the robotic method, achieved a high success rate of 93.3%. The development of this research will further advance the complete automation of light-frame wood wall panel prefabrication, offering the industry a wider range of options for selecting thermal insulation for their processes.*

KEYWORDS: *Robotic Building Prefabrication; Robotic Insertion; Light-frame Wood Construction; Robotic End-effector; Automation in Construction; Thermal Insulation*

1. INTRODUCTION

Industrial robot arm technology is increasingly being demonstrated and utilized in building construction processes due to its cost effectiveness, ease of programmability, high accuracy, and capacity (Chai et al., 2022; Koerner-Al-Rawi, Park, Phillips, Pickoff, & Tortorici, 2020; Leung, Apolinarska, Tanadini, Gramazio, & Kohler, 2021). Robot arms support mass production due to their high efficiency in performing repetitive tasks and their scalability, making them particularly suitable for the construction of prefabricated modular light-frame wood wall panels. These panels are prefabricated offsite, incorporating essential building elements such as framing, insulation, and sheathing. The use of robotic arms for cutting, assembling, and nailing timber for framing and sheathing is already well established and utilized (Stricot-Tarboton, 2019).

Various insulating materials are available on the market for timber framed structures, but the common types include blow-in insulation, spray foam insulation, and batt thermal insulation, made from fiberglass or mineral wool. Among these, batt thermal insulation holds a dominant market position due to their low cost to effective thermal performance ratio (Latif, Bevan, & Woolley, 2019). Currently, the automated insulation installation solution used to support the construction of modular light-frame wood wall panels are blow-in insulation (Orlowski, 2020) and spray-foam ("SprayWorks Equipment" n.d.; "Spray-R" n.d.), due to their loose form and ability to easily conform to voids. However, batt thermal insulation still needs to be manually installed by workers in the light-frame wood wall panel construction process (Stricot-Tarboton, 2019), which hinders achieving a fully automated construction process using this type of insulation.

The mechanical behaviors of batt insulation made of either mineral wool or fiberglass are classified as semi-rigid and non-rigid, respectively. In terms of mechanical properties, both these insulations are considered anisotropic deformable materials due to random fiber orientation. The result is that the rigid body assumption cannot be employed. In addition, predicting deformation and deflection of insulation using classical approaches is insufficient. Furthermore, the relationship between stress and strain is nonlinear thus complicating the modelling

Xiao Han, Cheng-Hsuan Yang, Yuxiang Chen, Alejandra Hernandez Sanchez, *A Robotic Method to Insert Batt Insulation into Light-Frame Wood Wall for Panel Prefabrications,* pp. 594-604, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.58

process which has downstream effects on simulation and analysis. To the best of our knowledge, there has been no formal study or research on the robotic process of inserting anisotropic deformable material into a shallow cavity for a tight-fit. Manipulating deformable objects presents challenges as classical analytical force relationships are no longer applicable. Consequently, predicting and controlling material behavior during manipulation requires complex contact analysis and modeling of nonlinear material behavior (Arriola-Rios et al., 2020; Zaidi, Corrales, Bouzgarrou, Mezouar, & Sabourin, 2017).

The successful development of this research will allow for direct integration into existing prefabricated modular light-frame wood wall panels construction processes to realize full automation or prefabricated construction using batt thermal insulation. The implementation of this automated process offers several benefits, including the elimination of risks to workers from developing chronic respiratory diseases due to exposure to airborne dust and fibers, as well as reducing their exposure to carcinogens and volatile organic compounds. Additionally, it will decrease the ergonomic risk arising from repetitive movements during manual insulation installation. (BREUM, SCHNEIDER, JØRGENSEN, VALDBJØRN RASMUSSEN, & SKIBSTRUP ERIKSEN, 2003; Kupczewska-Dobecka, Konieczko, & Czerczak, 2020; Li, Han, Gül, & Al-Hussein, 2019).

This paper is structured into six sections. Section 2 introduces the research objectives. In section 3, the design concept of the robotic end-effector and robotic insertion process are explained. Section 4 covers the implementation and parameters identification. Following that, Section 5 presents the outcomes of the conducted experiments, providing an in-depth analysis of the results. Lastly, Section 6 presents our conclusions and outlines potential avenues for future research and development.

2. RESEARCH OBJECTIVES

This research aims to develop a robotic method to automatically insert batt thermal insulation into a light-frame wood wall frame. Studies have been conducted to explore the process of utilizing industrial robot arms to insulate wall panels through blow-in insulation and spray foam insulation methods. However, the utilization of robotic methods for inserting batt insulation has been rarely discussed. When implementing the robot arm for batt insulation insertion, the most critical challenges are effectively manipulating deformable materials, along with ensuring collision-free trajectories for the robot arm. To achieve the goal of automatically inserting batt thermal insulation using robotic methods, the objectives of this research will focus on the following:

1. Designing a robotic end-effector capable of proficiently manipulating batt thermal insulation, while considering its geometrical properties and deformable material behaviors.
2. Developing a robotic process for inserting batt thermal insulation into light-frame cavities using the proposed robotic end-effector to mitigate the influence of the deformation uncertainties and nonlinear mechanical properties.
3. Identifying variable parameters (e.g., angles, location, forces, etc.) of the developed robotic process to ensure the integrity and success of insertion and to minimize potential collisions.

3. ROBOTIC END-EFFECTOR & INSERTION PROCESS DESIGN

The developed robotic method contains two major parts: the robotic end-effector and the robotic insertion process. First, to facilitate the pickup and manipulate batt insulation to correct positions, a dedicated robotic end-effector was designed. Then, a robotic insertion process with six major steps was developed to effectively insert the batt insulation into the light-frame.

3.1 Assumptions

The developed robotic insertion process is based on the following three assumptions:

1. The light-frame wood wall is a typical straight wall without any piping or wires within the cavity.
2. The wood stud utilized in the frame is in a favorable condition, with negligible warping.
3. The working platform features a smooth surface, and the friction between the insulation and the working platform is considered negligible.

3.2 Robotic End-effector Design

Illustrated in Figure 1, the end-effector comprises four components: a two-finger gripper, a force-torque sensor, an adaptor, and a pair of gripping jaws. The two-finger gripper with linear stroke is an off-the-shelf product. For standard batt insulation, its width is larger than the width of the cavity to achieve a tight-fit once inserted. These dimensional differences require the robot arm to apply compressive force to insert the batt insulation into the cavity. Therefore, a force-torque sensor that allows control of the applied force is mounted atop of the two-finger gripper. The gripping jaw adaptors are designed to connect the off-the-shelf gripper to the gripping jaws. The adaptors are CNC-machined L-shaped steel braces. The last component of the end-effector is the custom-built gripping jaws. The surface inside the jaw is textured to increase friction, with all else being equal reduces the grasping force, between the jaw and the insulation. The sizing of the jaw should be determined considering the dimensions and weight of the insulation, as well as its degree of elasticity. The jaw dimension is crucial to minimize the permanent deformation during manipulation.

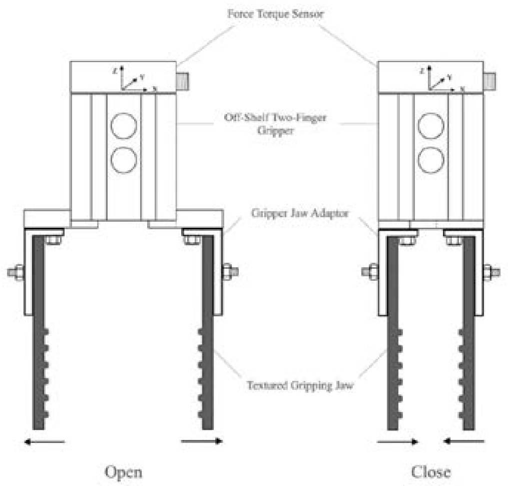

Figure 1. The proposed robotic end-effector.

3.3 Robotic Insertion Process Design

The proposed process for inserting batt insulation in this section is inspired by both the manual insertion process and the research conducted by Kim & Seo (2019). The research focused on the insertion of rigid objects into shallow cavities, incorporating primitive operations such as grasping, tilting, and tucking. In the context of batt insulation insertion, the proposed robotic insertion process, coined as GLITPP, contains six major steps: (1) Grasp, (2) Lift, (3) Insert, (4) Tilt, (5) Push, and (6) Press (as illustrated in Figure 2).

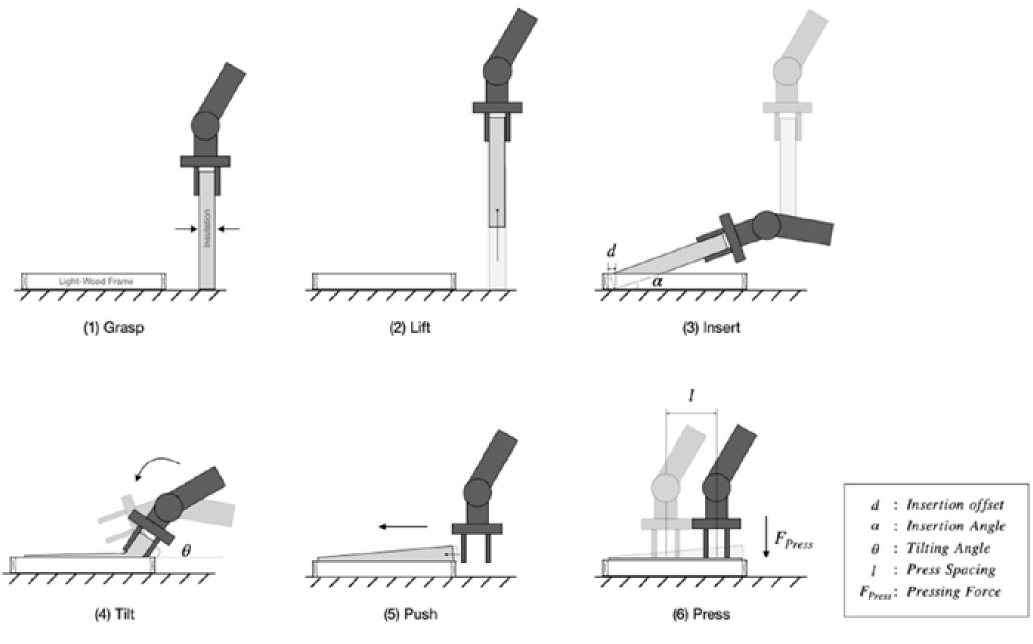

Figure 2. The GLITPP insertion process.

The initial step is to grasp the insulation from an initialized position. The robot arm moves to the top of the insulation using a point-to-point motion (PTP motion). Subsequently, the robot arm descends linearly (LIN motion) until the gripper reaches the insulation's top edge. Upon reaching the edge, the gripper closes to securely grasp the insulation. The second step is lifting. After grasping the insulation, a LIN motion is utilized to lift the insulation linearly. This is followed by a PTP motion to position the insulation in proximity of the frame cavity. In the third step, a combination of PTP and LIN motions is programmed to insert one edge of the insulation into the frame cavity with consideration of an insertion angle (α) and offset (d). For the fourth step, the end-effector is tilted. This ensures that when the grippers open, they avoid collisions with the frame and release the insulation without shearing it. Achieving this involves a PTP motion, tilting the end-effector to a specific angle (θ), and then releasing the insulation. To align the insulation accurately with the frame, pushing operations are employed along the uninserted edges. The robot arm utilizes LIN motions to enable the gripping jaws to gently push the insulation until it aligns flush with the cavity. For the final step, the gripping jaws are employed to press the uninserted edges of the insulation into the frame cavity, using defined press spacing (l) and pressing force (F_{Press}) parameters. The pressing pattern initiates from the corners of the inserted edge and proceeds along the edges perpendicular to the inserted edge and then finally along the parallel uninserted edge. The task description and associated robot motions outlined above are summarized in Table 1.

Table 1. Six steps of the GLITPP insertion process.

Steps	Task Description	Related robot motions
Grasp	From the initial position, the insulation is securely grasped by robotic gripper for pick up and manipulating.	1. PTP motion to the top of the insulation. 2. LIN motion down till the gripper reaches the insulation's edge. 3. Close the gripper.
Lift	The robot arm picks up the insulation and moves it close to the frame cavity.	1. LIN motion to lift the insulation. 2. PTP motion to move the insulation close the frame cavity.
Insert	The robot arm inserts the insulation into the cavity with an insertion angle (α) and offset (d).	1. PTP motion to rotate the insulation. 2. LIN motion to insert the insulation into the cavity.
Tilt	The robot arm tilts the insulation to a tilting angle (θ).	1. PTP motion to tilt the insulation
Push	The robot arm uses its gripping jaw to push the insulation along the uninserted edges of the insulation until it is flushed with the cavity.	1. LIN motion down till tip of the gripping jaw reaches the bottom of the insulation. 2. LIN motions parallel to the frame's direction to push the insulation into the cavity.
Press	The robot arm uses its gripping jaws to press the insulation into the frame cavity.	1. PTP motion to the pressing location. 2. LIN motions descend till the force reaches the pressing force. 3. LIN motion up. 4. LIN motion to the section pressing location 5. Repeat step 2 to 4 until the insulation is inserted.

4. IMPLEMENTATION & PARAMETER INDETIFICATIONS

4.1 Prototype of the End-effector

For the implementation, this research developed a prototype of the robotic end-effector (Figure 3). Detailed specifications of the end-effector components are listed in Table 2. The Robotiq FT 300-S Force Torque sensor, capable of measuring forces up to ±300 N and offering a data output of 100 Hz was utilized. Additionally, the Robotiq Hand-e gripper, with a maximum stroke length of 2 inches, was selected to serve as the parallel gripper. The custom adaptor was designed, in accordance with the Hand-e gripper specifications, to incorporate M3 screws for attachment onto the gripper's tracks. The gripping jaws, with dimensions of 4 inches by 4.5 inches and a thickness of 3/16 inch, were 3D printed with a textured interior surface at the lower section. The final assembly of the end-effector provides a clearance of 3.75 inches when the gripper is open and reduces to 1.75 inches when closed.

Figure 3. The prototyped robotic end-effector at Fully open position (left) and at fully closed position (right).

Table 2. Specifications for the prototyped end-effector.

Part	Manufacturer	Model	Specifications
Force torque sensor	Robotiq	FT 300-S	• Measuring range: ±300 N • Data output rate:100 Hz
Two-finger gripper	Robotiq	Hand-e	• Stroke: 2 in • Form-fit grip payload: 11 lbs • Friction grip payload: 8.8 lbs • Weight: 2 lbs • Gripping force: 20 to 185N
Adaptor	Custom-built	-	• Material: CNC machined steel
Gripping jaws	Custom-built	-	• Material: 3D printed PLA • Size: 4-inch (W) × 4.5-inch (L) × 3/16-inch (T)

4.2 In-lab Robotic Cell Setup

The in-lab robotic cell setup is illustrated in Figure 4. A Universal Robot UR5e was utilized as the robotic manipulator. The UR5e is a robot arm with 6 degree-of-freedoms. Its operational capacity is 11 lbs for payloads and accompanied by a maximum reach span of 33.5 inches. The robot arm was mounted on 46 inches by 34 inches table platform. The platform's upper surface is constructed from plastic, providing a smooth texture that minimizes friction effects between the insulation and the surface. Ultimately, the prototyped end-effector was affixed to the 6th axis of UR5e.

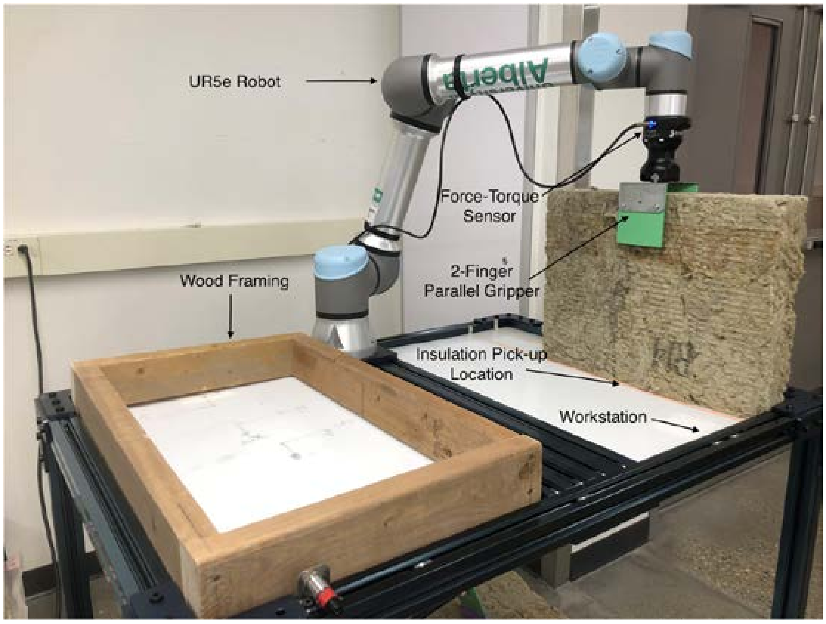

Figure 4. The in-lab robotic cell setup.

The light-frame wood wall utilized in this research is constructed using four 2 inches by 4 inches SPF Dimensional Lumbers. This lumber dimension is representative of a common type of light-frame wood wall used in building construction. The spacing between wood studs is set at 16 inches on-center, a standard stud spacing commonly employed in building construction, which results in a cavity width of 14.5 inches. Due to hardware constraints, specifically the reach of the robotic arm, the height of the wall cavity has been scaled to 26 inches, instead of the typical 8-foot wall. The overall dimensions of the wood cavity are 14.5 inches in width, 26 inches in height, and 3.5 inches in depth.

4.3 Parameters Identification

The GLITPP insertion process involves five key parameters: insertion angle (α), insertion offset (d), tilt angle (θ), press spacing (l) and pressing force (F_{Press}). These parameter values are determined through a series of individual robotic trials. All the trials are tested on 26 inches of mineral wool insulation. Once a set of feasible parameter values are ascertained, they are integrated to illustrate and formalize the entire robotic insertion process, the results of which will be presented in Section 5.

4.3.1 Insertion angle & Insertion offset & Tilt angle

There exists an interdependency among the insertion angle (α), insertion offset (d), and tilt angle (θ). Changes in the values of one parameter affect the other, as demonstrated by Eq.1. This equation represents an affine function that defines all points (x, y) on the outer surface of the fully opened gripper jaw in its tilted position. Notably, the parameter values must satisfy the condition that the affine function (hyperplane) is positioned to the left of the boundary point (P). This arrangement ensures collisions-free between the frame and the gripper. Figure 5 illustrates the variables used in Eq.1: L represents the distance from the tool center point (TCP) to the end of the insulation, H is the wood stud width, which is equal to the insulation thickness, W denotes the frame cavity width, E stands for the distance from the TCP to end of the gripper, G represents the distance between the center line and the outer surface of the gripper jaw in its fully open position, and P corresponds to the inner edge of the wood stud, serving as the boundary point.

$$y = (2x * \sin(\theta) - 2L * \sin(\theta - \alpha) + H * \cos(\theta - \alpha) - 2 * d * \sin(\theta) - 2G)/(2\cos(\theta)) \quad (1)$$

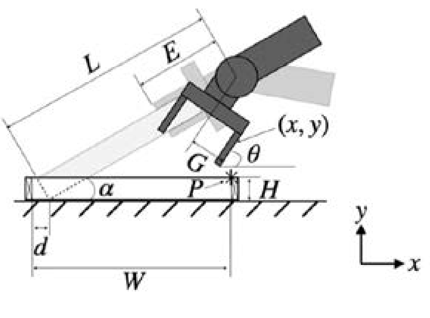

Figure 5. Illustration of the variables in Eq.1.

Due to the texturing on the gripper, a tilt operation is employed to facilitate the release of insulation from the gripper jaws after insertion into the frame cavity. This approach reduces disruptions to the insulation's intended position, prevents damage to its fibers by eliminating shearing, and allows for maintaining a minimal insertion angle. Thus, obtaining the minimum tilt angle is essential for achieving the effective release of insulation. The determination of this minimum tilt angle then allows for the calculation of the insertion angle and offset. Moreover, tilting indirectly contributes to the insertion process by pressing more edges of the insulation into the frame cavity. The minimum tilt angle is determined to be 55°, factoring in the insulation's weight and frictional forces. A list of trialed tilt angles and their corresponding outcomes are presented in Table 3.

Table 3. A list of trialed tilt angles with success rate.

θ (°)	Success Rate	Failure Mode
30	0/5	Insulations were pulled out of the frame cavity.
45	0/5	Insulations were first pulled, followed by shearing of the insulation fibers.
55	5/5	N/A

The insertion offset is the distance between the insulation and the frame's edge. When the offset is either too small or too large, the risk of collision increases during the insertion or pressing steps, respectively. This necessitates finding a balance between within the feasible range of offsets. Regarding the insertion angle, a smaller angle results in a longer edge of the insulation being inserted into the frame cavity. This minimizes the likelihood for the insulation edges to catch or snag during the subsequent titling and pressing steps, thus, ensuring proper seating of the insulation within the frame cavity. The lower limit of the insertion angle depends on the tilt angle in order to prevent collisions after titling when the grippers open to release the insulation. The insertion angle for a specific insertion offset, utilizing the minimum tilt angle obtained earlier, can be determined from Figure 6. This figure is generated by computing the solution pairs that satisfy Eq.1. Three combinations were selected for testing and the results are presented in Table 4. The tested minimum feasible combination of insertion angle and insertion offset is achieved at 30° with an offset of 0.75 inches.

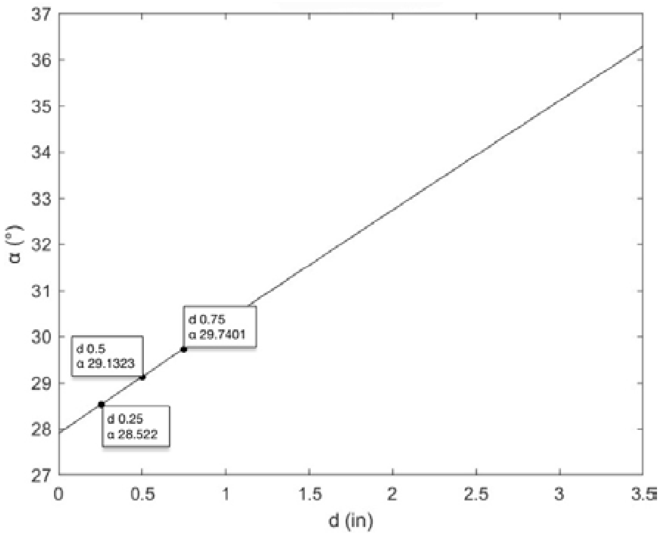

Figure 6. Combination of insertion angle and insertion offset.

Table 4. A list of trialed combination of insertion angle and insertion offset with success rate.

α (°)	d (in)	Success Rate	Failure Mode
29	0.25	0/5	Collision warning during insertion due to excessive compression of insulation.
29.5	0.5	0/5	Collision warning during insertion due to excessive compression of insulation.
30	0.75	5/5	N/A

4.3.2 Press spacing

The press spacing signifies the positions where the gripper will apply pressure along the uninserted edge of the insulation, facilitating its complete insertion into the frame cavity while ensuring no insulation edges remain exposed. While there are no explicit limitations on the quantity of presses, minimizing press count contributes to time efficiency. In the conducted trials, the center-to-center distance of the press spacing varies from 15 inches to 5 inches, with the initial press initiated from a corner. The outcomes of the trials are compiled in Table 5. It was noted that a 5-inch press spacing effectively accomplishes the insulation's insertion into the frame cavity, without any conspicuous convexity.

Table 5. A list of trialed press spacing with success rate.

l (in)	Success Rate	Failure Mode
15	0/5	Evident convexity noticeable between each press point.
10	3/5	Evident convexity noticeable between certain press points.
5	5/5	N/A

4.3.3 Pressing force

Once the press spacing is determined, it becomes crucial to apply the minimum amount of force necessary to press the insulation into the frame cavity. This approach ensures that the insulation avoids permanent deformation, which could lead to a loss of effective R-value. The lower and upper bounds for the pressing force are 80N and 120N, respectively. The results of the trials are listed in Table 6. It was determined that a pressing force of 100N fully and reliably presses the insulation into the frame cavity each time.

Table 6. A list of trialed pressing force with success rate.

F_{Press} (N)	Success Rate	Failure Mode
80	2/5	There were instances that the insulation was not fully pressed in.
100	5/5	N/A
120	4/5	There was an instance where the insulation had permanent deformation.

5. VALIDATION

The designed GLITPP insertion process, using the parameters obtained above as shown in Table 7, was tested with mineral wool and fiberglass batt insulations in two distinct scenarios that represent the actual configurations of insulation installation in construction: (1) a single piece of insulation filing the entire frame cavity, and (2) two pieces of insulation planed in tandem within the frame cavity. In Scenario 2, the process involved two steps: first inserting the 20-inch piece and then 6-inch piece to fill the entire frame cavity. During the insertion of the 6-inch piece, an additional 1-inch offset was applied between the two insulations to avoid the interaction of large frictional forces between the mating surfaces. For Scenario 1, ten tests were conducted for each insulation type. For Scenario 2, ten tests were conducted for each step and each insulation type. Each test was performed using new insulation to simulate the actual application in construction.

Table 7. Summarized selected parameter values obtained from Section 4.3.

Parameter	Value
Tilt Angle (θ)	55°
Insertion Angle (α)	30°
Insertion Offset (d)	0.75 in
Press Spacing (l)	5 in
Pressing Force (F_{Press})	100 N

5.1 Results and Discussion

Table 8 summarizes the experiment results using the selected parameters obtained in Section 4.3. Fig. 8 shows the progress of all the experiments and final insertion completion with the front and back of the insulation. The success of the entire GLITPP insertion process is defined by the insulation fitting tightly within the frame cavity, the absence of visible voids and gaps between the insulation and wood frame, and the insulation having no shearing or permanent deformation. The overall success rate stands at 93.3%.

Table 8. Experiment results for entire GLITPP insertion process.

Scenario	Insulation Length (in)	Batt Insulation Type	Success Rate
1	26	Mineral Wool	9/10
1	26	Fiberglass	10/10
2.1	20	Mineral Wool	10/10
2.1	20	Fiberglass	9/10
2.2	6	Mineral Wool	8/10
2.2	6	Fiberglass	10/10

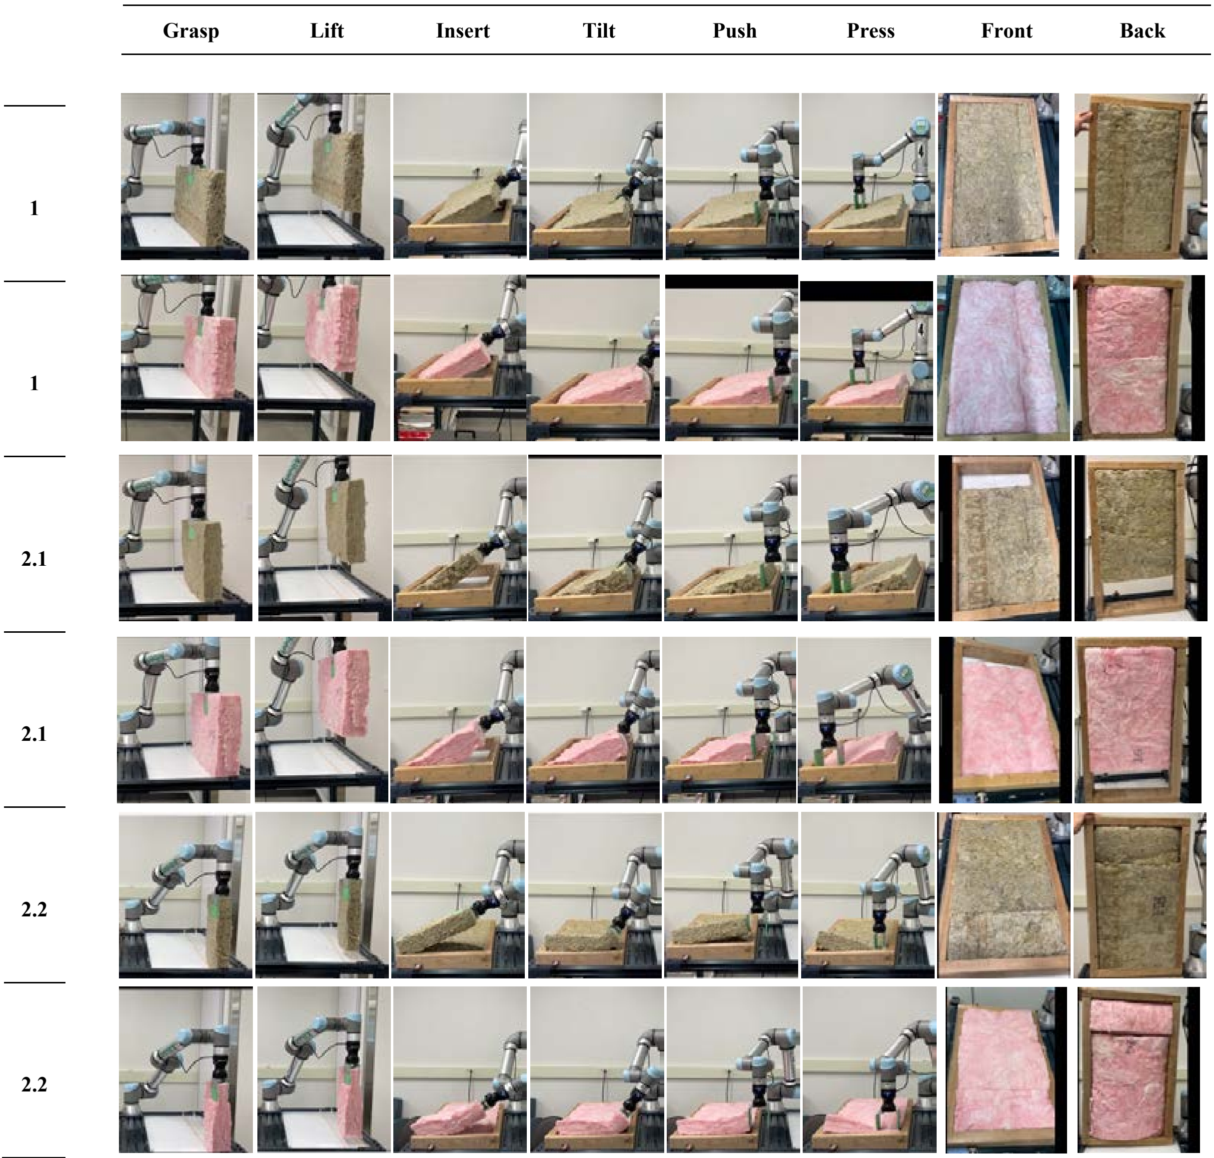

Figure 8. Experiment progress. Each row is the scenario associated with the corresponding rows of the Table 7.

The high success rates, as showed in Table 8, were achieved by mitigating the negative effects of deformation and uncertainties in mechanical properties through the GLITPP insertion process. The integration of individual parameter identification into a single continuous process, facilitated by custom-built grippers, is seamless and repeatable. The results substantiate that the manipulation of deformable insulation using the designed grasping, lifting, and inserting steps yields high accuracy in achieving target positions. The tilting step reduces the risk of shearing of the insulation during release, while the pushing step offers guidance that minimizes uncertainties and random disturbances before pressing. Ultimately, the pressing step ensures a tight-fitted insulation within the frame cavity, without any discernible gaps and deficiencies. A notable feature of the GLITPP process is that it can be extended to full-scaled 2x4 light-frame wood wall panels and light-frame wood wall panels with varying wood stud sizes, achieved by employing different sizes/numbers of grippers and tuning of parameters.

There were four instances in which the GLITPP process did not succeed. In scenario 2.1, the failure was an outlier, as no defects were observed in the insulation. For scenarios 1 and 2.2, the lack of success resulted from pre-existing creases and pockets of low-density in the insulation. Notably, the insulations used in validation were all chosen randomly from the packaging without any rejection of unideal pieces of insulation. Incorporating insulation pre-inspection, selection, and rejection would raise the success rate.

6. CONCLUSION

This research introduces a robotic method to insert batt thermal insulation into light-frame wood wall frame. The method comprises two major components: a custom-built end-effector and a corresponding robotic insertion process. The design of the robotic end-effector integrates seamlessly with an off-the-shelf two-finger gripper. The end-effector is constructed of a force-torque sensor, a two-finger gripper, an adaptor, and a pair of gripping jaws. The proposed robotic insertion process, named GLITPP, encompasses a sequence of six major steps: Grasp, Lift, Insert, Tilt, Push, and Press. To identify the variable parameters within the GLITPP insertion process, an in-lab robotic cell equipped with a prototyped end-effector was utilized. Through a series of individual robotic trials and iterative refinements, these parameter values were determined. The effectiveness and feasibility of the proposed robotic method were evaluated using two common batt thermal insulations: mineral wool and fiberglass. Test scenarios encompassed both a single insulation piece filling the entire frame cavity and the tandem placement of two insulation pieces within the cavity. The results exhibited a remarkable 93.3% success rate for the GLITPP insertion process. To ensure the broader applicability of the proposed method, future works will involve testing the GLITPP insertion process on a larger capacity robot arm with full-scaled panels. Additionally, the integration of an insulation condition identifying sensor is envisioned, enhancing adaptability by combining it with our robotic insertion process.

THE IMPACTS OF DIGITAL FABRICATION ON THE CONSTRUCTION INDUSTRY: A SYSTEMATIC REVIEW

Mehdi Keshtkar, Emmanuel Daniel & Louis Gyoh
School of Architecture and Built Environment, University of Wolverhampton, United Kingdom

ABSTRACT: *The building industry is a major consumer of natural resources and a large contributor to environmental degradation, leading to a need to rethink current building practices. Digital fabrication (Dfab) technologies, which transform design and engineering data into physical products, are gaining traction in the Architecture, Engineering and Construction (AEC) industry. This study aimed to evaluate the implications of digital fabrication in the construction industry, by identifying the current Dfab applications and the hindrances that are limiting its implementation. The research questions addressed were why Dfab is essential in the construction sector, the current state-of-the-art of Dfab in the construction industry, and how Dfab is improving the construction industry. Through a systematic literature review, the findings proposed that Dfab can revolutionize the construction sector, enabling freeform architecture, reducing construction costs, cutting material waste, and increasing worker safety. Nevertheless, further research is needed to overcome obstacles such as high costs and the lack of digital skills in the construction industry.*

KEYWORDS: *Digital fabrication, Construction industry, Project management, Digital technology, Systematic review.*

1. INTRODUCTION

The building industry is recognized as a large consumer of natural resources and a significant contributor to environmental impacts and is considered an inefficient manufacturing process (Wu, Wang and Wang, 2016). It is still working to improve the situation and boost overall productivity, but there are obstacles to overcome (García de Soto *et al.,* 2018). To address environmental challenges, there is a need to rethink conventional building models and techniques due to the predicted increase in global population in the coming decades (Naboni, Breseghello and Kaunic, 2019). To promote sustainability, the architectural profession needs to develop fully automated production forms and processes (Tuvayanond and Prasittisopin, 2023).

The ability to create objects directly from design information is causing a transformation in many fields of design and production (Agustí-Juan and Habert, 2017). The key to fostering high-quality industry growth is creating and applying digital transformation (Yuan *et al.,* 2022). The use of digital fabrication (Dfab) technologies is rapidly increasing in the Architecture, Engineering and Construction (AEC) industry (Graser, Kahlert and Hall, 2021). The "third industrial revolution," also known as digital fabrication, is anticipated to revolutionize the construction sector by allowing freeform architecture, lowering construction costs, reducing material waste, and raising worker safety (Wangler *et al.,* 2016). Dfab refers to a construction process that utilizes digital code to control manufacturing devices and processes, allowing for the seamless conversion of design and engineering data into physical products (Graser, Kahlert and Hall, 2021). Dfab is an automated fabrication method that uses data to enhance efficiency and productivity (Ng and Hall, 2021).The technology began developing more than 25 years ago, but its rapid development started later (Žujović *et al.,* 2022). The use of Digital design and fabrication technologies have created methods and processes for producing more complex and customised architectural solutions while still utilising standard building materials over the last two decades (Carvalho and Sousa, 2014). Integrating design and construction is essential for new technologies such as digital fabrication, and a specialised design management strategy is required to overcome integration barriers (Ng, Graser and Hall, 2023). Digital technology allows for better control, increased construction efficiency, the removal of the need for conventional formwork, and the ability to customise building materials during the construction process compared to traditional methods (Yuan *et al.,* 2022). The use of computational design and robotic fabrication together has the potential to bring about significant advancements in the form and structure of architecture (Agustí-Juan and Habert, 2017).

Digital fabrication necessitates a redesign of the design process. Thus, there is a need for a better understanding of digital systems in areas such as technical development, technological systems, organisational contexts, contractual provisions, and business models (Ng *et al.,* 2022). However, the use of additive Dfab in large-scale construction is still in its early stages and requires overcoming challenges in changing traditional construction processes and roles of those involved in the project (García de Soto *et al.,* 2018).

FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Mehdi Keshtkar, Emmanuel Daniel, Louis Gyoh, *The Impacts of Digital Fabrication on the Construction Industry: A Systematic Review,* pp. 605-615,

A BIM platform is not essential for Dfab design in small-scale projects, as long as there is integration of process, information, and organisation (Ng, Graser and Hall, 2023). BIM is a cutting-edge digital system that promotes innovation and enhances project values through information integration in construction projects, which also involves changes in design management and overall best practices (Ng, Graser and Hall, 2023). Different non-destructive methodologies to capture complex shapes have been developed through the use of photographs, video-recording, laser sensors and LED light projections, demonstrating the significant advantages in speed and accuracy that these digital methods can offer compared to conventional analogue processes (Lorenzo and Mimendi, 2020). Many countries have plans to increase the proportion of construction activities carried out off-site (Kim, Cuong and Shim, 2022). However, the effectiveness of DFAB is determined by the inclusion of fabrication information and organization in the design process, which can be challenging to achieve in traditional delivery models such as Design-Bid-Build (Ng and Hall, 2021).

Project management and delivery models have shifted fundamentally due to the digitization of project information (Hall, Whyte and Lessing, 2020). The uniqueness of each construction work is due to its immobility, customization of both construction works and processes, and interdisciplinarity (Bischof, Mata-Falcón and Kaufmann, 2022). DFAB techniques combine automated subtractive, formative, or additive building methods with computational design approaches (García de Soto *et al.,* 2018). An alternative to costly and inefficient manufacturing practices was proposed through automation in construction and architecture (Tuvayanond and Prasittisopin, 2023). The limits of architectural design and production may be expanded by digital fabrication techniques (Agustí-Juan and Habert, 2017). Dfab adoption faces not only technical challenges, but also organizational and process barriers, as it involves multiple research disciplines and professions such as architects, materials scientists, roboticists, structural engineers, manufacturers, and trade contractors (Graser, Kahlert and Hall, 2021). However, there is a desire to investigate alternative methods of creating formworks using digital fabrication technology (Carvalho and Sousa, 2014).

In recent years, the intersection between digital fabrication techniques and cementitious materials has become significant (Wangler *et al.,* 2016). Digital fabrication with concrete is a newly developed and wide-ranging field that can potentially reduce environmental impact and promote industrialization in construction while meeting various construction requirements (Bischof, Mata-Falcón, & Kaufmann, 2022). Modern product creation has shifted to rely heavily on 3D printing (Agustí-Juan & Habert, 2017). Digital fabrication has been applied to the production of formworks using concrete, a significant application of this technology (Wangler *et al.,* 2016). However, in free-form, digital fabrication using concrete, accurately predicting the material's mechanical properties in its fresh state is crucial to ensure control over element deformations and overall stability during the printing process (Esposito *et al.,* 2021). Bucklin et al. (2023) describe a new construction method called the Mono-Material Wood Wall (MMWW), which employs subtractive manufacturing with digital control to enhance the functionality of wood and eliminate the need for other materials, thereby improving sustainability compared to traditional construction techniques. The impact of the fast-growing demand and regeneration rate of renewable building materials on the environment in the long term is yet to be determined despite the industry's shift towards them (Bitting *et al.,* 2022). However, using non-traditional renewable materials and developing suitable design and construction processes will be necessary for large-scale construction (Lorenzo & Mimendi, 2020).

According to Graser, Kahlert, & Hall (2021), it is crucial to reduce the time it takes to introduce new Dfab technologies to the market to speed up adoption, but this has been challenging. To successfully implement digital fabrication in the construction industry, better integration of fabrication-related information and organization into the design process is needed despite its growing emergence (Ng & Hall, 2021). Correspondingly, an increasing number of studies investigate the industry needs and strategies for adopting digital fabrication (Ng *et al.,* 2022). It is essential to research the environmental advantages of digital fabrication in architecture and construction, as it is still a developing technology, to make necessary adjustments in the early stages (Agustí-Juan and Habert, 2017). Despite extensive literature outlining its challenges, limited attention has been given to strategies employed in projects to successfully implement Dfab. The construction industry is currently focusing its research efforts on robotic fabrication, collaborative work between humans and robots, and prefabricated technologies as part of smart construction (Yuan *et al.,* 2022).

Given this, the current study determines the impact of digital fabrication on the construction industry. The study seeks to answer the following research questions:

1. Why is digital fabrication important in construction industry?
2. What is the state-of-the-art of digital fabrication related to construction industry?

3. How is digital fabrication improving the construction industry?

2. RESEARCH DESIGN AND METHODOLOGY

The analysis performed in this study identified the main research themes and categorized them based on the impacts of digital fabrication (Dfab) in the construction industry. The results may benefit other researchers as they summarise recent advancements, patterns, and potential research and innovation opportunities in the AEC sector. Based on the selected research philosophy, this study adopts a qualitative research strategy with an inductive approach. In qualitative research papers, the methods section emphasizes transparency of the methods used, such as the reasons, processes, and individuals involved in their implementation, to provide a deeper understanding and facilitate discussion of how they may have affected material's mechanical properties (Busetto, Wick and Gumbinger, 2020).

This study used the systematic literature review (SLR) method, that minimizes bias by exhaustively searching relevant studies through a systematic, transparent, and reproducible process (Chung, Lee and Kim, 2021). This study utilized the keyword search method and the snowball method to gather relevant information. In order to gather more information and discover papers that may have been overlooked, the keyword search and the snowballing technique were combined. To initiate the development of this study, the primary task was to identify the relevant keyword for retrieving research articles from academic databases. The following summary provides an outline of the process involved in this stage.

Researchers utilized the Scopus database, benefiting from its advanced search features, including filters for authors, affiliations, publication years, and document types, facilitating the discovery of pertinent and up-to-date research in specific fields. In the initial search for relevant literature, researchers employed the keyword string "[digital AND fabrication AND construction AND industry]" and obtained 300 documents. Subsequently, they applied specific restrictions, including open access availability, subject area in engineering, English language, and exact keywords "Digital Fabrication" or "Construction Industry," resulting in the retrieval of 47 documents directly related to their research topic.

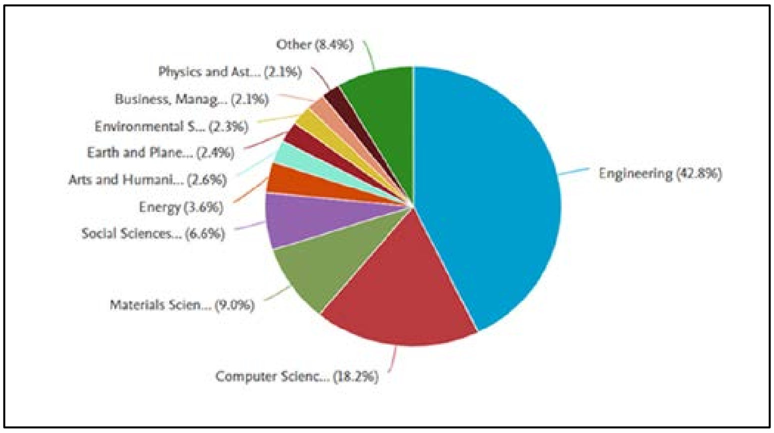

Figure 1: The distribution of documents by subject area before applying any restrictions to the search results in Scopus

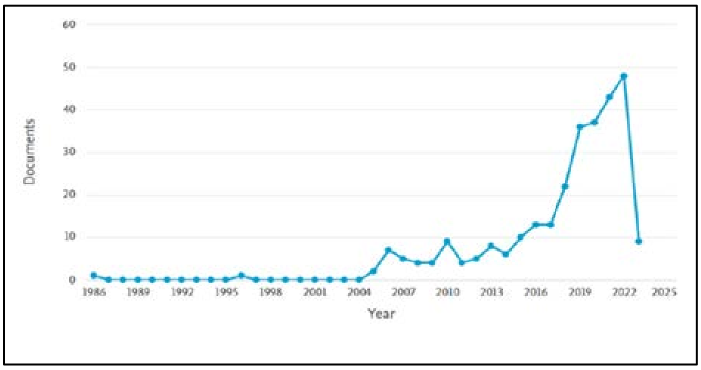

Figure 2: The distribution of documents by year before applying any restrictions to the search results in Scopus

The main objective of this section was to evaluate the appropriateness of the selected resources rather than the procedure itself. To determine eligibility, the study utilized an inclusion and exclusion approach, ensuring that only publications directly related to emerging digital fabrication in the construction industry were included. A benefit of these resources is that they contain highly relevant information pertaining to the study's topic. The researchers based their document selection on criteria that focused on the relevance of content to "Data Analysis and Management" in the most recent publications within the "Construction" field, specifically related to the use of "Digital Fabrication" in construction. Through an examination of titles, abstracts, and full texts, irrelevant documents were excluded, resulting in the selection of 27 articles that met these criteria.

The chosen resources were subject to content analysis, with most being journal articles providing comprehensive insights into digital fabrication in construction. While some sources were not directly construction-related, they still contributed to understanding the emerging digital technology. The selected studies utilized diverse qualitative or quantitative research methods, ensuring varied findings that enhance the credibility of this study concerning the research questions. Finally, the last step involved identifying the primary themes associated with the research questions.

3. DATA ANALYSIS AND MANAGEMENT

These documents' titles, abstracts, and full texts were examined to remove any irrelevant ones, resulting in 27 newly selected articles that are relevant to the study as shown in table1.

Table1: 27 newly selected articles that are relevant to the study

4. RESULT AND DISCUSSIONS

4.1 Qualitative Analysis and Discussion

The study aim to present an overview of the impacts of digital fabrication in the construction industry.

4.1.1 Importance of digital fabrication in the construction industry

Due to industry fragmentation, the AEC sector adopts new technologies more slowly than other sectors, but the emergence of Digital Fabrication (DFAB) offers a systematic innovation that can help with this problem (Ng, Graser and Hall, 2023). Recent studies have focused on the impact of new digital technologies like Building Information Modelling (BIM) on design management (Ng, Graser and Hall, 2023). Although a complete consolidation that outlines the factors contributing to the design process for digital fabrication is currently unavailable (Ng *et al.,* 2022). However, research on Dfab is still in its early stages. It lacks well-developed mechanisms allowing full-scale project adoption in the sector (Ng and Hall, 2019).

According to Ng et al. (2022), igital Fabrication is becoming increasingly common due to its potential to improve project efficiency by connecting design and construction processes, and it can be categorized into five groups: technological systems, organizational framework, contractual terms, and business models. Two possible approaches for dfab management are provided by lean construction management and design for manufacture and assembly (DfMA) (Ng and Hall, 2019). Adopting DFAB has many advantages, such as increased productivity and resource efficiency, reduced waste in the building industry, and increased worker safety (Graser, Kahlert and Hall, 2021).

Projects offer a distinct opportunity to investigate and add to the emerging understanding of Dfab in AEC due to their capacity to integrate complex knowledge (Graser, Kahlert and Hall, 2021). The adoption of Dfab in AEC faces significant challenges due to the industry's fragmentation, weak coordination between contractors, and high participant turnover between project phases, making the organizational and social context as important for industry adoption as technological feasibility (Graser, Kahlert and Hall, 2021). To minimize environmental impacts, structural complexity should result from material reduction strategies such as structural optimization or multi-functionality (Agustí-Juan, Jipa and Habert, 2019).

According to Agustí-Juan, Jipa and Habert (2019), Digital fabrication techniques that achieve multi-functionality lead to a construction process that is efficient in its use of materials and has significant environmental benefits during production. The on-site mass production of complex, customised structures is made possible by digital fabrication in building (Agustí-Juan and Habert, 2017). With the projected increase in global population, it is necessary to rethink traditional building methods and establish new techniques to reduce the environmental impact of the construction sector. Digital fabrication can aid in this effort by reducing material usage and overall environmental impact (Naboni, Breseghello and Kunic, 2019).

However, to make a positive change in the built environment, this mode of digital architecture is expected to work towards fully automated production forms and processes that promote equality, sustainability, democracy, diversity, and inclusiveness (Žujović *et al.,* 2022). Collaboration between structural engineers, roboticists, builders, and material scientists will be crucial for digitally fabricating concrete (Wangler *et al.,* 2016).

4.1.2 The state-of-the-art of Digital Fabrication related to the construction industry

Academic and industrial applications have explored various additive technologies in different scales and contexts, from thermoplastics to clay, gantry 3D printers to robotic arms and drones (Naboni, Breseghello and Kunic, 2019). Many researchers are looking into robotic 3D printing, a new digital fabrication technique, to address the problem of traditional building methods' declining productivity (Yuan *et al.,* 2022).

On-site digital fabrication, which aims to bring additive fabrication processes to construction sites, is divided into three main categories: large-scale robotic structures, mobile robotic arms, and flying robotic vehicles (García de Soto *et al.,* 2018). Scholarship explores the use of digital systems, such as BIM platforms that can help stakeholders coordinate the management data, including 3D models and algorithms that link to digital fabrication (Ng *et al.,* 2022).

The data from the researched case study by Graser, Kahlert and Hall (2021) indicates that implementing DFAB projects can increase its acceptance as a legitimate practice in AEC. However, for DFAB adoption to be successful, it needs to be accepted not just within the project organization but also outside it. Large-scale AM machines are being used to construct recent architectural projects globally, which has sparked a growing interest in implementing and expanding the technology within the construction industry and architecture (Tuvayanond and Prasittisopin, 2023). A study by Bitting et al. (2022) provides an overview of the current state of research and applications of mycelium-based materials, emphasizing digital fabrication, production, and design and discussing issues such as low mechanical properties and the absence of standardized production methods. The use of digital design information to drive production processes, such as 3D extrusion printing, CNC machines, and robotic assembly, is known as digital fabrication, and it is an essential component of modern construction processes (Ng *et al.,* 2022).

Wu, Wang and Wang (2016) explored the significance of component design about 3D printing capabilities and raw material performance and the potential benefits of using BIM to support design variations and improve performance, while also reducing the time and costs associated with design changes and reprinting.

Despite the potential advantages of automation, there have been few cases of robots being used to automate construction in recent years (Relefors *et al.,* 2019). The prefabricated bridge construction process has used DfMA, a design method commonly used in manufacturing manufacturing (Kim, Cuong and Shim, 2022). Digital fabrication techniques can be categorized into subtractive methods such as milling and cutting, and additive methods such as 3D printing, which has become increasingly popular and accessible for home use (Agustí-Juan and Habert, 2017).

Bischof, Mata-Falcón and Kaufmann (2022) assert that widespread adoption of digital fabrication in the construction industry is critical to making a meaningful impact on improving its environmental impact, but currently, it has not yet reached the mass market. Chung, Lee and Kim (2021) point out that despite the rapid expansion of research and market for 3D concrete printing (3DCP), there is a lack of a widely accepted technical specification framework for comparing 3DCPs with various characteristics. Despite automation initiatives in both research and industry, such as Built Robotics and MX3D, the construction industry has not yet demonstrated a shift towards automation (Relefors *et al.,* 2019).

4.1.3 How Digital Fabrication improves the construction industry

Digital fabrication has the potential to bring about extensive positive impacts, such as improved material efficiency and waste avoidance, reuse of materials, workplace health and safety, integrative work design, and productivity (Graser, Kahlert and Hall, 2021). The integration of digital and manual tasks was crucial for the project, and there was a need for better collaboration processes with digital machinery (Graser, Kahlert and Hall, 2021). The productivity rate for robotic construction is constant, which means it doesn't depend on the complexity level of the construction (García de Soto *et al.,* 2018). Concrete 3D printing reduces waste production by 60%, construction time by 50-70%, and labour costs by 50-80%, potentially decreasing construction costs by up to 35% while improving the industry's sustainability (Senthilnathan and Raphael, 2022).

To promote sustainable development opportunities through the use of digital systems, design modeling with parametric modeling capacity can be utilized to minimize rework and waste by testing the feasibility and soundness of integrated digital twin models through physical mockups prior to tendering (Ng *et al.,* 2022). Despite being promoted in various countries, there is a lack of consistency and diversity in stakeholder perspectives and research advancements regarding the implementation of digital fabrication, with interdependencies between industry needs creating complexities for stakeholders to adopt such projects, further hindering their adoption on a larger scale, highlighting the need for a better understanding of industry practitioners' needs and how they are related to one another (Ng *et al.,* 2022).

According to the research by Ng and Hall (2021), Target Value Design (TVD) implementation can help manage and optimize DFAB processes to meet time, cost, profit, and aesthetic requirements in less time while maintaining the needs of stakeholders. The conventional Design-Bid-Build model's separate processes can impede the implementation of digital fabrication techniques by making it difficult for stakeholders to manage project costs (Ng and Hall, 2021). Digital fabrication is anticipated to result in a more sustainable construction industry by enabling more efficient structural design that uses materials only where necessary and by reducing waste generation through more efficient construction techniques, particularly about formwork (Wangler *et al.,* 2016).

5. RECOMMENDATIONS AND DIRECTIONS FOR FUTURE RESEARCH

The impacts of digital fabrication in the construction industry are still an area that requires further research. Several recommendations and directions for future research can be made based on the reviewed literature. One area that requires investigation is the potential economic benefits of digital fabrication in construction projects. Future studies could conduct a cost-benefit analysis to provide a clearer understanding of the potential economic benefits that could be achieved by implementing digital fabrication in the construction industry. Another area that requires exploration is the potential environmental benefits of digital fabrication in the construction industry. Future studies could focus on the potential environmental benefits that could be achieved through digital fabrication in the construction industry, such as reducing waste and carbon emissions. In addition, future research could investigate the best strategies for implementing digital fabrication in the construction industry. This could include examining the barriers to adoption, identifying practical training and education programs, and exploring the potential role of government policies and incentives. The reviewed studies provide valuable insights into the impacts of digital fabrication in the construction industry. They are applicable in various areas within the field, including but not limited to construction management, architecture, and engineering. For example, the studies provide insights into the potential benefits of digital fabrication in terms of cost, time, and quality management in construction projects. They also provide insights into the potential for digital fabrication to revolutionize the design and construction of buildings and other structures, as well as improve the efficiency and effectiveness of engineering processes in the construction industry.

One potential research question that could be addressed in future studies is: What are the best strategies for overcoming the barriers to adoption of digital fabrication in the construction industry? This question would be designed to address the identified need for research on implementation strategies and could help to provide insights into how digital fabrication can be successfully integrated into the construction industry.

6. CONCLUSION

The research on the impacts of digital fabrication in the construction industry highlights the potential benefits and challenges associated with adopting this technology. Through a systematic literature review, the study explores the current state of digital fabrication (Dfab) in construction, its significance, and its potential to improve the sector.

The study's extensive research has provided valuable insights into how digital fabrication could bring about a revolution in the construction sector. Firstly, Dfab enables the creation of intricate and customized structures that were previously impossible using conventional methods, thus offering new possibilities for innovative and sustainable designs that can shape the industry's future. Secondly, Dfab has the capacity to substantially lower construction costs and minimize material waste, thereby boosting efficiency and contributing to resource conservation, a crucial factor for environmental sustainability. Additionally, the adoption of Dfab could enhance worker safety by automating hazardous tasks and reducing the necessity for manual labor in risky conditions. Despite the intriguing benefits, the study has brought to light the difficulties that prevent Dfab from being widely used in the building industry. To effectively utilise the promise of digital fabrication, significant barriers such as high starting prices and a lack of digital expertise in the market must be overcome. Also, there are organisational and operational challenges when incorporating Dfab into conventional building processes and delivery models, which emphasises the necessity of communication and cooperation across many disciplines.

The qualitative analysis conducted in this study highlights the importance of seamless integration and collaboration among various stakeholders, such as architects, engineers, roboticists, and material scientists, for the successful deployment of Dfab technologies in the construction industry. Furthermore, the adoption of digital fabrication calls for a comprehensive redesign of the design process, considering technical development, organizational contexts, contractual provisions, and business models.

This study was limited to academic journals, articles, and conference proceedings found in the listed scientific sources. Following an inductive methodology that only used secondary data, the qualitative analysis and discussion were conducted. Primary data, however, might have provided a more in-depth and analytical grasp of the subject.

The study recommends further research to investigate the economic and environmental benefits of implementing Dfab in construction projects. Additionally, it emphasizes the need to identify effective strategies for overcoming barriers to adoption to ensure successful integration.

ABSTRACT: *Video-based fire detection is a crucial object detection problem that relies on accurate and reliable data to detect fires. However, collecting and labeling fire-related data can be time-consuming and expensive, making it difficult to obtain sufficient data for training machine learning models. To address this challenge, uncertainty-based active learning techniques can be used to iteratively select the most informative samples for labeling. This can reduce the amount of labeled data needed to achieve high model performance and has the potential to even prune the training data with fewer informative samples. The traditional sampling-based uncertainty estimation methods are computationally expensive. Hence, an efficient prior network-based ensemble distillation State-of-the-Art approach is evaluated on an internal dataset which still requires relatively higher overhead computation making it difficult for production deployment. A biased softmax differencing-based uncertainty approach and a feature-based hard data mining approach are proposed and compared with the distillation approach. The novel approaches are found to have a very low overhead uncertainty estimation time compared to the ensemble distillation approach and traditional sampling techniques. The methods are evaluated in the context of curating the unlabeled pool data and improving the training data. For completeness, the experiments are performed on three different data sizes, and overall, the frame-wise selection strategy is proved to be better than the sequence-wise querying strategy. The Principal Component Analysis (PCA)-based hard data mining outperformed other methods and improved the model performance by 16.33% with* $AUC_{2\%}$ *metric when compared with the random selection of data. The approach even outperformed the main network trained on full data by 7.33%, henceforth improving the training data by using informative 26.39% data. The results indicate that novel data mining provides efficient training and pool data curation.*

1. INTRODUCTION

Traditional smoke detectors require a volume of smoke to reach the detector location and hence generally have a high detection time. Thermal cameras (Sousa, et al. 2020) on the contrary are quite expensive and work in the infrared spectrum resulting in fire detection only when there is significant heat produced. There is no visual confirmation of the fire when using thermal cameras. Hence, deep learning-based video detection can be the solution to decrease the detection time and detect fires based on patterns in the video rather than heat produced. However, for an industrial Deep Learning (DL) application of Fire Detection (FD), the speed and the reliability of the predictions are of major concern. The non-reliability can lead to high economic losses and even human endangerment. Late detection can cause heavy economic and even human losses. Speaking about statistics in the industrial setting in the USA, 1.2 Billion $ in economic loss along with 16 deaths and 273 injuries occur annually (Campbell, 2018) indicating the importance of reliable video-based fire detection. However, in order to have a reliable DL model for detecting fire, the data selected for the model training should be of high quality.

The research takes inspiration from Peter Norvig's quote: "*More data beats clever algorithms, but better data beats more data*". The traditional thinking of improving a DL model by increasing the quantity of the data in object detection does not answer why the new data is being added to the training data. Nevertheless, even if large amounts of data is readily available, in object detection problem, the requirement of labeled data raises the cost of annotation massively. In order to improve the performance of the model and simultaneously decrease the cost of labeling, the most informative data have to be sampled.

The aim of decreasing the annotation costs can be achieved by answering two questions: which data has to be selected and why? The passive learning models which receive the data randomly or by humans do not consider the informativeness associated with the data. However, the information is associated with uncertainty related to the data. With the help of uncertain information linked with the data, using Active Learning (AL), the informative data can be sampled iteratively. Sampling informative data using AL requires the estimation of uncertainty. The uncertainty can be referred to as a negative reliability score while a higher uncertainty score means low reliability. The uncertainty can help increase the reliability of the DL models by sampling informative uncertain data from the large dataset, thereby using AL to decrease the cost of the annotation. The concept of AL can assist in the data selection process or autonomously select data, which can subsequently be reviewed and labeled by a human annotator for subsequent training sessions.

The major contributions of our work can be summarized as follows:

- We propose two different methods for estimating uncertainty. One of the methods focuses on estimating uncertainty using feature space and the other approach uses softmax differences for uncertainty estimation.
- We compare different methods based on the time required for uncertainty estimation and the performance when implemented in an iterative AL setting.
- We experimentally show that our novel approach is efficient w.r.t time for uncertainty estimation. The approach even outperforms the State-of-the-Art (SOTA) approach on the AUC metric in an active learning setting.
- We evaluate the performance of different methods w.r.t improving the full training data set by decreasing the data using AL.

2. RELATED WORK

Uncertainty estimation can be used as an additional component for the DL model to increase the trust and robustness of the SOTA architectures. DL models are often black box models, with often limited or no interpretability of the results. With the predictions of the DL model, uncertainty estimates can be incorporated to increase the reliability of the results from the black box models. Gal and Ghahramani (Gal & Ghahramani, 2016) introduced a Monte Carlo Dropout-based (MCD) uncertainty quantification method that has a very low overhead computation cost. The drop block-based uncertainty estimation (Deepshikha, *et al*. 2021) was proposed using Monte-Carlo DropBlock (MCDB). Deep ensembles (DeepEns) (Lakshminarayanan, *et al*. 2017) was used to estimate the predictive uncertainty using model re-training. The Test-Time-data Augmentation (TTA) (Manivannan, 2020) was compared with MCD, MCDB, and DeepEns in the context of uncertainty estimation. The research in the domain of uncertainty quantification is usually done in the fields of model and data uncertainty separately. However, one of the first methods combining the effects of both epistemic and aleatoric uncertainty was proposed in (Kendall & Gal, 2017). The loss function to estimate both uncertainties was suggested for the depth regression and segmentation tasks. Malinin and Gales proposed to estimate the predictive uncertainty of the deep learning model using Prior Networks (Malinin & Gales, 2018) which incorporated explicit modeling of distributional uncertainty. This approach parameterized the Dirichlet network over the categorical distribution to maintain the distribution extraction capability from the student model after the knowledge distillation (Malinin, *et al*. 2019). The Bosch internal research method of a low overhead FACER (Schorn & Gauerhof, 2020) based prior network (FacerDir) uncertainty quantification method will be used in the thesis as one of the SOTA methods for benchmarking. However, due to the high uncertainty estimation computation time, we propose novel approaches with both lower estimation time and more reliable uncertainty estimates.

With the need for better-performing object detection methods, the requirement of the data for training the SOTA architectures has also increased. In order to prioritize the labeling of the data and data curation, a lot of research has been done in the field of Active Learning. A comparison of various acquisition functions for computing uncertainty was done in the setup of AL (Nguyen, *et al*. 2022). Choi et al. (Choi, *et al*. 2021) proposed a probabilistic approach to estimate both the model and data uncertainty in a single pass and later performed Active Learning. The scalability and transferability were tested over the probabilistic Active Learning approach. An adaptive framework for active learning was developed and proposed in (Desai, *et al*. 2019) which performed adaptive switching between strong and weak supervision.

The present research in the fields of uncertainty estimation and AL will serve as the inspiration for the proposed paper, which aims to incorporate various techniques into the internal architecture of the Video-based Smoke Detection (VSD) model.

3. METHODOLOGY

An overview of the AL framework using different uncertainty estimation strategies using a business chart is depicted in Fig. 1. The chart illustrates the brief methodology of the approaches in an AL setting.

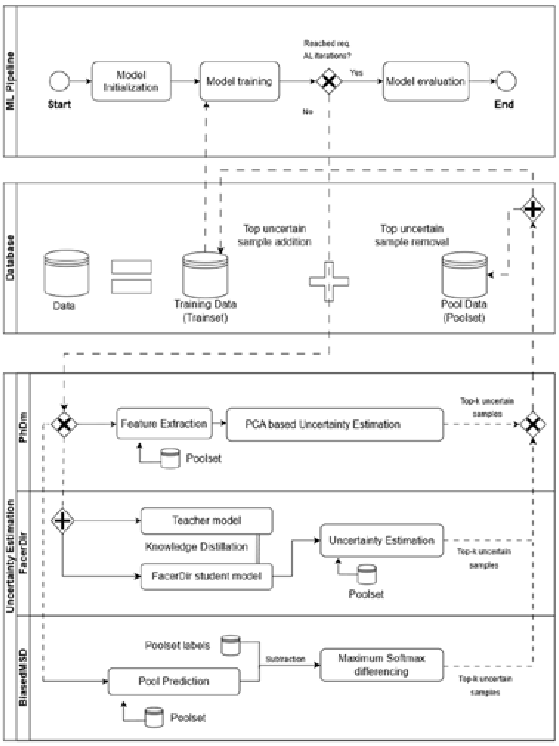

Fig. 1 Thesis methodology which describes the active learning framework implementation using various uncertainty estimation techniques.

3.1 Dataset

The dataset used in the thesis was developed by the engineering team at Bosch. As this dataset is a Bosch internal dataset, it is not available to the public. The dataset comprises Smoke and Non-smoke, “Negative” videos.

The dataset includes video sequences shot over 100 different locations. The locations can be classified into three major scenarios, viz. indoor, outdoor, and semi-outdoor. The scenarios which are shot in an indoor setting ranging from a parking lot to an industry are considered Indoor scenario. The outdoor scenario is a scenario shot in an open environment. The semi-outdoor scenario is on the contrary a setting in which there is a ceiling but lacks enclosure from all sides, resulting in a partially open space. Wind may be present in the outdoor setting and this changes the behavior of the smoke significantly.

3.2 Uncertainty Estimation

3.2.1 PCA-based Hard Data Mining (PhDm)

This approach is a novel method that is based on Principal Component Analysis (PCA) (Jolliffe & Cadima, 2016) for detecting hard samples from the pool data. PCA is a dimensionality reduction approach used to project the data to a low-dimension space and provide interpretability to the data. The PCA is applied to the feature vector space and reduced to the dimension of two. For every image sample, only the feature vector of the maximum prediction is used for dimensionality reduction as shown in Fig. 2.

The outliers found in the PCA plot were investigated and they were found to be often either hard or out-of-distribution examples. Hence, a density-based outlier detection method has been implemented to extract outliers from the PCA plot. Local Outlier Factor (LOF) (Breunig, *et al*. 2000) was used for detecting outliers in the plot which looks at the local density for each point. To query top outlier samples from the plot, a distance-based ranking is performed which ranks each outlier point based on the distance from the nearest inlier point.

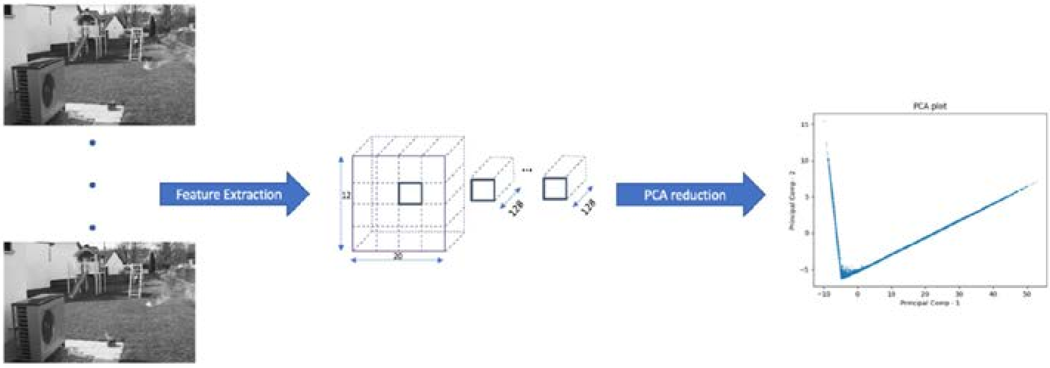

Fig. 2 Feature vector dimensionality reduction. The features (middle) are extracted through the model for the input images (left) and later PCA-based dimensionality reduction is performed. The bold patch represents the patch with maximum softmax prediction whose feature vector is used for dimensionality reduction.

3.2.2 Biased Maximum Softmax Difference (BiasedMSD)

Typically, the final layer of a deep learning classification model is the softmax layer, which produces predictions for a given input. Ideally, the model should accurately replicate the ground truth of the input sample. However, in practice, an entirely perfect or ideal model is unattainable, and a prediction close to the expected ground truth is typically observed.

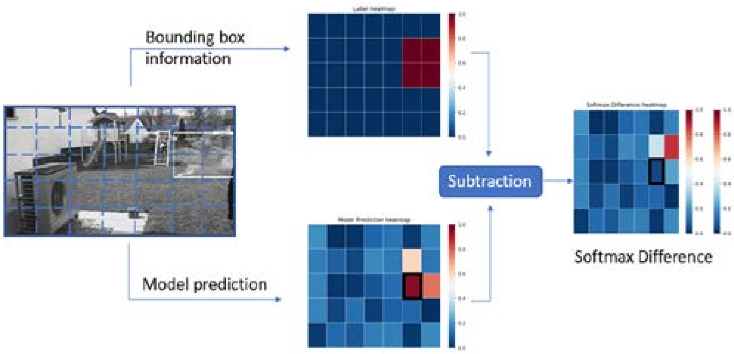

Fig. 3 Illustration of BiasedMSD approach. The difference between the model prediction (mid-bottom) and the ground truths (mid-top) is performed and termed as softmax difference (Bold patch is the patch with maximum prediction and it's softmax difference is used for the whole frame).

The Biased Maximum Softmax Difference is another novel approach that is quite simple and easy to implement. The definition of uncertainty that is adopted in this approach is the distance between the ground truth and reality. For the patch-wise classification problem, as the prediction obtained is patch-wise, the softmax difference is also obtained patch-wise for individual frames.

The drawback of the approach is that one needs the labels beforehand to estimate uncertainty. Due to this shortcoming and the requirements of the labels beforehand, the method is called **B**iased **M**aximum **S**oftmax **D**ifference (BiasedMSD), while the bias of requiring ground truth is present for estimating the uncertainty. The visual representation of the working of the BiasedMSD is illustrated in Fig. 3. The inherent bias to require labels for uncertainty estimation suggests that the method may only be used for curating labeled data.

3.3 Active Learning

The final step of the methodology in the scenario of Active Learning (AL) encompasses the implementation of all previously described efficient methods. AL initiates with random sequences in the training dataset, while the remaining data is stored in the pool set. The central concept of AL involves adding a budget (k) of samples or videos to the training set iteratively and removing samples from the pool set. As a result, the iterative process leads to an increase in the size of the training set and a decrease in the size of the pool set. The training of the model is performed on a set of training data, and the methods for estimating uncertainty are utilized to compute scores of uncertainty. The top-k selection for video-based data can be performed using two distinct approaches.

3.3.1 Sequence-wise selection

The **s**equence-**w**ise (SW) selection method involves selecting the whole video or sequence. Since uncertainty estimation is performed on individual frames, a sampling strategy is employed to aggregate the frame-wise uncertainty estimates into sequence-wise estimates. These sequence-wise uncertainty estimates are then ranked, and the top k sequences are selected. However, this approach may be influenced by a limited number of uncertain frame samples within a video, leading to a bias towards those samples.

3.3.2 Frame-wise selection

The **f**rame-**w**ise selection (FW) method directly ranks the frame-wise uncertainty estimates, and the top-k frame samples are selected. This approach eliminates the need for a sampling strategy, as the frame-wise uncertainty estimates are directly considered.

After the top-k selection, the samples or videos selected from the pool set are added to the training set and removed from the pool set as illustrated in Fig. 1. This whole process is repeated in an iterative manner.

4. EXPERIMENTATION

We conduct different experiments to evaluate and compare the performance of various uncertainty estimation methods in the context of Active Learning. Inception-v1 (Szegedy, *et al.* 2014) was used as a model backbone architecture and the input video was resized into the shape of (640, 360) grayscale images. We use Adam optimizer while training the model.

4.1 Evaluation Metric

In general, object detection algorithms are evaluated using mean Average Precision (mAP) which requires the computation of Intersection over Union (IoU) over the bounding boxes. But the model implemented in the research does not provide bounding box information as an output of the model, but rather a patch-wise classification. Hence, the Receiver Operating Characteristic (ROC) (Streiner & Cairney, 2007) curve has been adopted for performing the model evaluation. ROC curve is computed by evaluating the predictions of the model over different thresholds, and plotting True Positive Rate (TPR) and False Positive Rate (FPR) for each threshold in a curve. As in realistic applications, the FPR should be very low in order to avoid a large number of false alarms. Hence, the Area Under the ROC Curve value under the threshold of 2% FPR ($AUC_{2\%}$) is evaluated and used as a metric to evaluate different methods.

4.2 Uncertainty Estimation Comparison

We performed an analysis of the cost comparison for uncertainty estimation for videos ranging from 1 to 2000. As depicted in Fig. 4, the initial cost of deep ensembles is substantially greater than that of other methods. The State-of-the-Art FacerDir method exhibits a slightly greater initial cost relative to the conventional MCD, MCDB, and TTA approaches. However, for a higher number of video estimations, the method proved to be substantially more efficient.

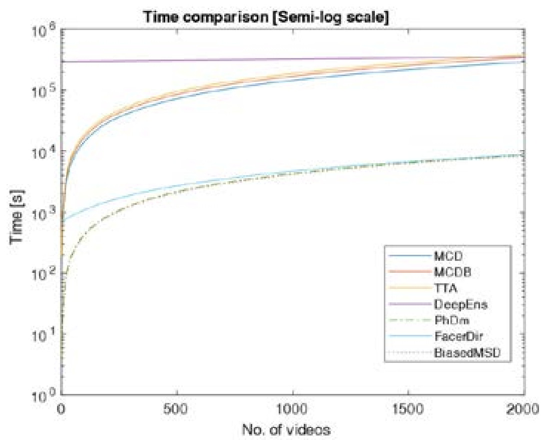

Fig. 4 Time comparison for uncertainty estimation for different methods. The plot represents the time required to estimate uncertainty using different methods over 2000 cumulative videos.

The novel proposed PhDm and BiasedMSD-based uncertainty estimation methods exhibit the least overhead time overall. The FacerDir, PhDm, and BiasedMSD-based uncertainty estimation methods exhibit considerably low overhead costs, indicating a promising opportunity to advance toward the subsequent phase of incorporating an active learning for data curation.

4.3 Baselines for Data Curation

Active learning is performed iteratively till the quarter of the informative/uncertain dataset is sampled. The model is later trained on the sampled informative training data and the following baselines are used for comparing the model performance:

4.3.1 Baseline for pool data curation

Pool data curation is one of the main purposes of active learning, while the most informative data is curated for annotation using a sampling strategy. The function *a(x)* is defined as a draw from a uniform distribution over the interval [0, 1] using the function (Gal, *et al.* 2017). This criterion ensures that the selection strategy for acquiring annotated data is superior to a random selection approach and is used in majority of scientific studies.

4.3.2 Baseline for train data curation

Active learning is seldom used in the literature to curate the training data as it is always seen as a method to curate the unknown pool data. In our research, an active learning approach was utilized to curate the training dataset with the objective of mitigating potential implicit biases that may exist within the data. The assessment and comparison of various approaches are based on the performance of the primary network, which is trained on the complete dataset utilized for active learning experimentation. In the event that the active learning technique produces a subset of the training dataset that surpasses the primary network's performance, it can be utilized for training data curation in a general context.

4.4 Active Learning for Data Curation

We conduct a series of experiments on three different data filter sizes viz. 15, 30, and 60 randomly filtered **f**rames **p**er **s**equence (fpseq). It is in-feasible to perform the experiments on the full internal dataset and hence, for research experimentation three different data filter sizes were randomly developed. It is important to note that the comparison of the metric over different data sizes internally is not possible as the data was randomly selected.

The uncertainty estimation was performed using PhDm, BiasedMSD, and FacerDir. The uncertainty estimation was iteratively used in an AL setting to sample top uncertain samples. The uncertain samples were iteratively added and removed from the training and pool dataset, respectively. The uncertainty sampling for PhDm and FacerDir-based approaches were done using **S**equence-**w**ise (SW) and **F**rame-**w**ise (FW) querying strategies. Fig. 5 represents the comparison of the performance of different experiments over various data sizes.

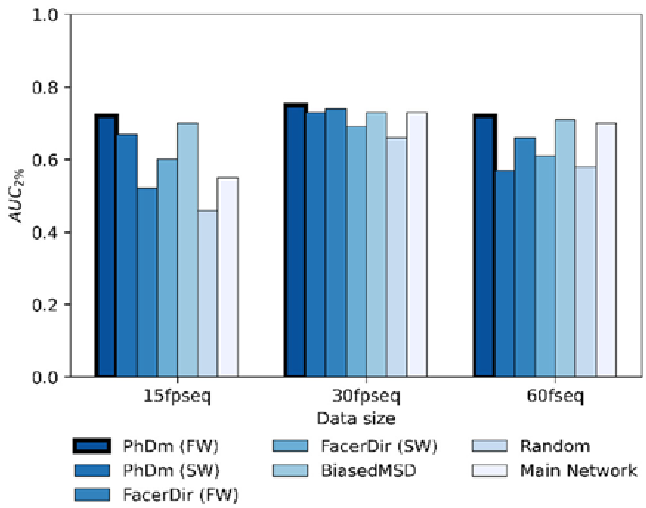

Fig. 5: AL method performance comparison for different methods applied over various filtered data sizes (bold bar represents best performing method). FW and SW represent Frame-wise and Sequence-wise querying strategies.

5. DISCUSSION

Fig. 4 illustrates the overhead cost associated with uncertainty quantification. It can be observed that the utilization of PCA and biased differencing-based techniques resulted in relatively shorter estimation times. This observation suggests that the proposed novel methods in the paper exhibit significantly lower overhead uncertainty estimation costs in comparison to the conventional and State-of-the-Art distillation approaches.

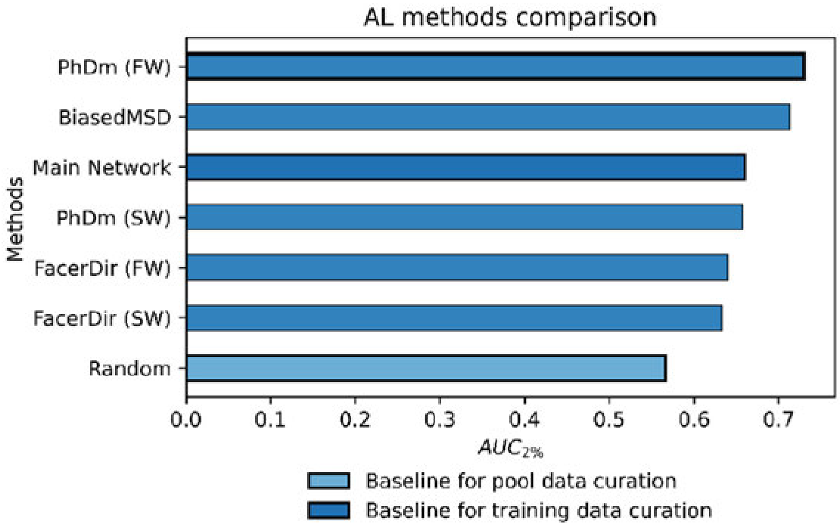

Fig. 6 Performance comparison of different AL methods. The random network is the baseline for pool data curation and the main network is the baseline for training data curation. The novel PhDm approach performance outperformed the random and main network baseline.

It is evident from Fig. 6 that the novel PCA-based method outperformed other AL approaches in the context of training and pool data curation. The overall comparison of different AL approaches is illustrated in Fig. 6 . It is evident from the figure that the frame-wise selection approach was generally better than the sequence-wise querying strategy. The frame-wise selection of images from the videos proved to perform efficiently compared to selecting the whole sequence at a time using a sequence-wise selection strategy. The frame-wise querying strategy improved the performance of the PCA-based active learning method by 7.33% and the FacerDir approach by 0.67%. This finding can be utilized to crop informative frames from different excessively long videos, which is an intriguing application of the active learning strategy. In general, every method outperformed the Random baseline. This indicated that every method performed well in the context of pool data curation and annotating the pool data using uncertainty quantification.

In every experiment conducted using varying data sizes, the novel PhDm approach outperformed the main network, despite utilizing only 26.39% of the available data for model training. The approach improved the performance of the model architecture compared to the random baseline with 16.33% of $AUC_{2\%}$ evaluation metric. The approach even improved the main network performance by 7.33% and outperformed other approaches. These findings suggest that the PhDm approach can achieve superior performance with significantly fewer training data as compared to the main network and is an approach with a very low overhead uncertainty quantification cost.

BiasedMSD selects challenging data instances that the model struggles to comprehend as uncertain samples. Therefore, this approach is expected to yield superior uncertainty estimation results and excel in AL scenarios. By including image samples that the model has identified as false positives, the approach can effectively enhance data quality. The BiasedMSD approach improved main network performance by 5.66%, however, the improvement was not as evident as seen in the PhDm approach. The performance of FacerDir-based active learning was found to improve the network by 7.33% than the random baseline compared to a significant 16.33% improvement using the novel PCA-based hard data mining approach.

Recapitulating the results observed in the experiments, the feature-based novel approach outperformed other approaches in the context of curating pool and training data using AL. This is attributable to the fact that the feature-based approach captured more information about the samples than sampling a probability distribution over several forward passes.

6. CONCLUSION

This paper focuses on the various uncertainty estimation techniques for the object detection-based fire detection problem with an aim to curate the data. We proposed two novel approaches for curating the data using active learning. The novel PhDm and BiasedMSD approaches performed uncertainty estimation efficiently compared to the sampling-based methods and the State-of-the-Art FacerDir. The novel approaches were also found to outperform other benchmark methods in the task of curating the unlabeled data. PhDm was found to be the most efficient method for curating and improving the training data by decreasing the size of the training.

Finally, we put forward potential avenues for future research exploration. Different uncertainty and active learning experiments were performed in the setting of binary classification. The experimentation on multi-class classification problems can be done using the novel approaches stated in the literature. The novel AL techniques can be further evaluated on various publicly available datasets.

ABSTRACT: *The use of closed-circuit television (CCTV) for safety monitoring is crucial for reducing accidents in construction sites. However, the majority of currently proposed approaches utilize single detection models without considering the context of CCTV video inputs. In this study, a multimodal detection, and depth map estimation algorithm utilizing deep learning is proposed. In addition, the point cloud of the test site is acquired using a terrestrial laser scanning scanner, and the detected object's coordinates are projected into global coordinates using a homography matrix. Consequently, the effectiveness of the proposed monitoring system is enhanced by the visualization of the entire monitored scene. In addition, to validate our proposed method, a synthetic dataset of construction site accidents is simulated with Twinmotion. These scenarios are then evaluated with the proposed method to determine its precision and speed of inference. Lastly, the actual construction site, equipped with multiple CCTV cameras, is utilized for system deployment and visualization. As a result, the proposed method demonstrated its robustness in detecting potential hazards on a construction site, as well as its real-time detection speed.*

KEYWORDS*: deep learning, multimodal, multiCCTV, synthetic data, pointcloud*

1. INTRODUCTION

Construction sites are dynamic and complex environments that pose significant safety risks, resulting in an high rate of accidents and fatalities worldwide (Abdelhamid & Everett, 2000). Consequently, implementing effective safety monitoring measures is vital for reducing such incidents. The use of closed-circuit television (CCTV) cameras for safety monitoring on construction sites has played a crucial role in mitigating risks. Despite this, the full potential of CCTV data is often underutilized, primarily due to the majority of existing approaches employing single detection models without considering the full context of CCTV video inputs (Park et al., 2022, 2023; Tran et al., 2020). In response to this issue, this study proposes a novel and robust system that incorporates a multimodal detection and depth map estimation algorithm, utilizing the power of deep learning. The distinctiveness of our approach lies in the context-aware analysis, providing a more comprehensive understanding of the potential hazards present within the dynamic environments of construction sites. Furthermore, our proposed method goes a step further by leveraging terrestrial laser scanning technology to acquire the point cloud of the test site and utilizing a homography matrix to project the detected object's coordinates into global coordinates. This step enhances the overall monitoring system's effectiveness by visualizing the entire monitored scene, thus providing a bird eye view of the potential hazards. A crucial aspect of any newly proposed system is rigorous validation. For our method, we have created a synthetic dataset of construction site accidents using Twinmotion, a high-powered graphic software. This dataset provides a range of simulated scenarios to test the precision and inference speed of our proposed method, ensuring its reliability and robustness in varied contexts.

Finally, we further validate our method by deploying it on an actual construction site equipped with multiple CCTV cameras, moving beyond simulations to a real-world setting. This on-site implementation allowed us to assess the practicality of our system and its ability to function optimally in an uncontrolled, real-world environment. The results from both simulation and real-world deployment demonstrate our proposed method's

robustness in detecting potential hazards on a construction site. This paper aims to highlight the potential of multimodal detection approaches in enhancing construction site safety measures, moving towards a future where such hazards can be preemptively detected and effectively mitigated. In the following sections, we will provide a detailed explanation of our proposed method, its development, and the validation process. We will also present the results and implications of this study, demonstrating how a deep learning-based multimodal approach can be used for safety monitoring in the construction industry.

2. BACKGROUND

This section provides the necessary background on the key aspects of our methodology, namely object detection, depth estimation, and multimodal synchronization. These three components collectively constitute the core of our proposed method and are fundamental in understanding the context-aware safety monitoring approach.

2.1.Object Detection

Object detection, as a fundamental component of computer vision, has undergone significant developments over the past decade, thanks to the advancements in deep learning and convolutional neural networks (CNNs) (Li et al., 2021). This involves identifying and locating objects within images or video feeds. In construction sites, object detection can identify critical elements such as workers, machinery, tools, and other potential hazards, thereby playing a vital role in safety monitoring. However, traditional object detection models typically operate independently, failing to incorporate the broader context of a scene (Jeon et al., 2023; Tran et al., 2022). These models often struggle with complex environments like construction sites, where multiple objects interact dynamically, and understanding these interactions is crucial for effective hazard detection. This limitation forms the motivation for our study, aiming to integrate a higher level of contextual understanding into object detection models using deep learning algorithms. In this research, two state of the art object detection models are utilized: Yolov8 (Redmon et al., 2016) and RTMDet (Lyu et al., 2022). These two object detectors are trained and validated in actual CCTV images and utilized for incorporation with other models.

2.2.Depth Estimation

For understanding context of input image, spatial information is crucial, therefore, a depth estimation model MiDAS (Ranftl et al., 2020) is utilized. Depth estimation refers to the task of determining the relative distance of objects within a scene from the viewpoint of the camera. It is a crucial component in understanding three-dimensional spaces from two-dimensional images or video feeds, providing invaluable information about the positioning and interaction of objects within a scene. In construction sites, depth estimation can enhance the understanding of spatial relations among various elements, such as the proximity of a worker to a moving machine, thereby aiding in detecting potentially hazardous situations. This paper incorporates depth estimation into our proposed multimodal approach, further improving the context-awareness of the system.

2.3.Multimodal Synchronization

Incorporating multimodal synchronization into safety monitoring has the potential to significantly enhance the effectiveness of hazard detection. For example, a hazard that is not visible from one camera angle may be clearly observable from another. Similarly, certain hazardous situations may only be identifiable when considering multiple factors, such as the positioning and motion of various objects, which could be obtained from different data sources. In our proposed method, we aim to utilize multimodal synchronization to integrate object detection and depth estimation data, along with point cloud data obtained through terrestrial laser scanning. This synchronization allows for the projection of detected objects into global coordinates, enhancing the visualization of the entire monitored scene and thus the system's overall effectiveness. In the subsequent sections, we will elaborate on the implementation of these components in our proposed method and demonstrate their effectiveness in enhancing construction site safety monitoring.

3. PROSED APPROACH

3.1.Proposed approach

Figure 1 depicts the proposed method as follows: First, the input image is predicted using object detectors that have been pretrained. In this study, an object detector that can infer six classes is described in detail, along with the training procedure and training dataset. In addition, the MiDAS model is used to estimate the depth map using a previously trained depth estimation model. The Euclidean distance between objects is then estimated and visualized with the given depth and bounding box coordinates, after which each object's depth map is extracted. This research considers the distance between construction machines and employees, as well as the module to estimate whether or not a worker is in the danger zone. In addition, work-related personal protective apparatus is trained and implied.

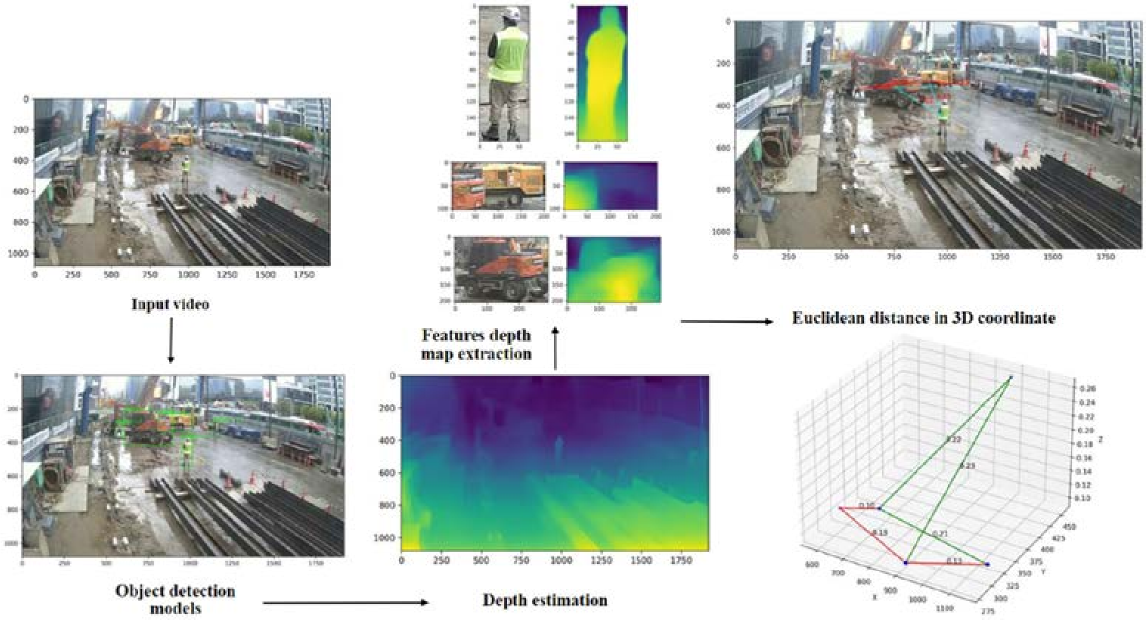

Figure 1. Proposed Approach

3.2.Dataset Acquisition

The training dataset contains bounding boxes objects from 6 classes: *normal worker, signalman, harness, hardhat, mixer truck and excavator*. As visualized in Figure 2, each object is labeled in detail from actual CCTV footage. Figure 3 presented a training and testing dataset classes distribution.

Figure 2. Dataset visualization

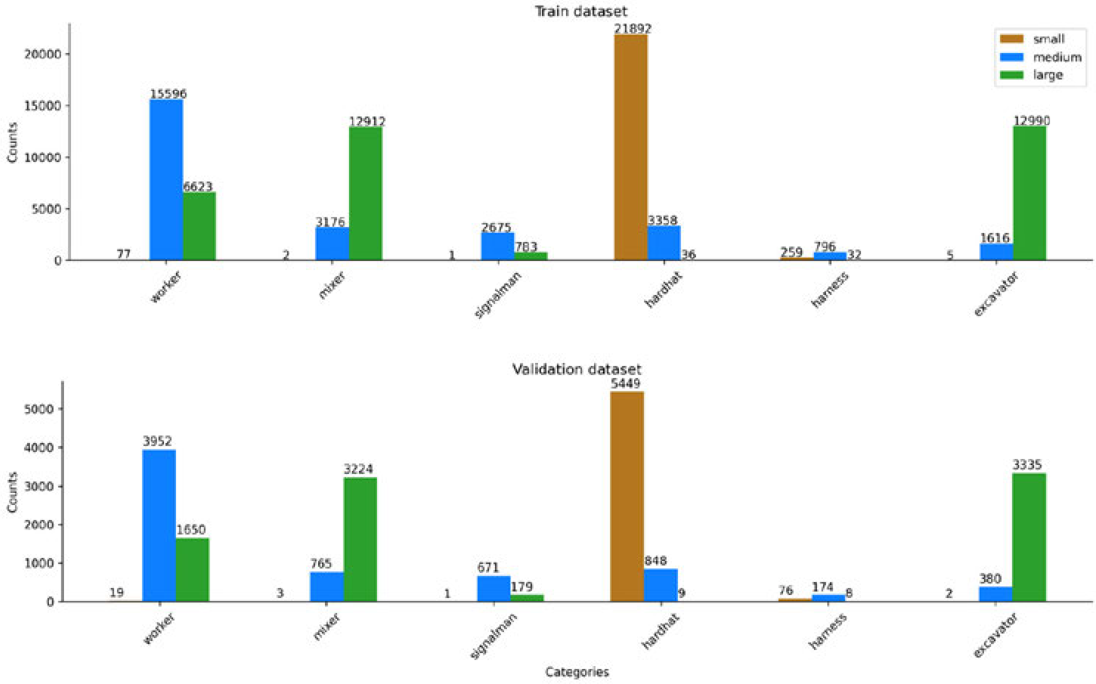

Figure 3. Training and testing dataset distribution. The y-axis depicts the total of each class in training and testing datasets. The x-axis lists the distinct class names or labels in dataset. In our case, these are: “worker”, “mixer”, “signalman”, “hardhat”, “harness”, and “excavator”.

For evaluate model performance, the detected objects are categorized into 3 types: "small", "medium", and "large" follows a specific definition based on the number of pixels occupied by an object in an image. Specifically, objects are categorized as follows:

- "Small": Objects occupying 0 to 1024 pixels, which translates to dimensions up to 32 × 32 pixels.
- "Medium": Objects occupying between 1024 and 9216 pixels, which corresponds to dimensions between 32 × 32 and 96 × 96 pixels.
- "Large": Objects occupying more than 9216 pixels, equating to dimensions of 96 × 96 pixels or larger.

With these categorizations, our dataset reflects an essential aspect of object detection tasks: dealing with objects of varying sizes. The balance or imbalance of different categories may significantly affect the predictive performance of an object detection model. In our dataset, categories such as "mixer" and "excavator" contain a substantial number of "medium" and "large" objects. Conversely, the "hardhat" category is predominantly composed of "small" objects. This imbalance suggests that an object detection model trained on this data might develop a bias toward detecting "medium" or "large" objects and underperform on "small" objects.

4. Experimental

4.1.Quantitative

Table 1. Object detectors performance.

	mAP	**mAP_50**	**mAP_75**	**mAP_s**	**mAP_m**	**mAP_l**	**Flops**
YOLOv8X	0.689	0.831	0.741	0.123	0.733	0.811	0.129T
RTMDet	0.628	0.776	0.688	0.059	0.641	0.756	79.964G

In order to quantify the results, the mean average precision (mAP) is employed as an evaluation metric. The mAP is a widely recognized indicator used to quantitatively assess the performance of object identification models. The research provides a comprehensive explanation of the mAP (Zhao et al., 2019). As presented in Table 1, YOLOv8X and RTMDet, with regard to their performance metrics, a notable variance in their effectiveness becomes clear. The YOLOv8X model exhibits superior precision with a mAP score of 0.689, which considerably exceeds the 0.628 mAP score of the RTMDet model. This indicates an overall higher rate of accurate detections by the YOLOv8X model. Further disparity can be observed at varying Intersection over Union (IoU) thresholds. The mAP_50 and mAP_75 scores, which represent the mAP values computed at IoU thresholds of 0.50 and 0.75 respectively, demonstrate a superior adaptability of the YOLOv8X model to changes in detection difficulty levels. When checking the mAP values across different object sizes, denoted by mAP_s (small), mAP_m (medium), and mAP_l (large), the YOLOv8X model continues to display superior performance. The model's proficiency in detecting small objects is particularly noteworthy, with a score of 0.123 compared to the RTMDet's score of 0.059. Nevertheless, it is crucial to consider the computational complexity of the models. RTMDet has a significant advantage in this regard, with a computational demand of 79.964G Flops, markedly lower than the YOLOv8X's 0.129T (or 129,000G) Flops. This positions RTMDet as a more feasible option for applications with limited computational resources, despite its inferior mAP performance. While the YOLOv8X model outperforms RTMDet in terms of object detection performance across various metrics, the latter's significantly lower computational demand may make it a more suitable candidate for resource-constrained applications. The selection between these two models, therefore, necessitates careful consideration of the balance between performance efficiency and resource utilization, contingent on the specific requirements of the application.

4.2.Qualitative

As mentioned in previous sections, after detecting objects, the depth map is estimated and calculating the distance between worker and construction vehicles. As can be seen from Figure 4, by utilizing spatial information, the distance can be estimated and from that, the necessary warning can be conducted.

Figure 4. Distance estimation using depth estimation and object detection.

Figure 5 showed another application of the proposed approach by identifying which workers are in the danger area. The danger area is defined by the safety officer, and when detected worker violate that area, the number of violated cases will be shown and reported directly to safety manager. Along with detecting worker, a PPE detection models also consider to utilized, as can be seen from Figure 6, both hardhat and harness is detected for checking. To reduce the false positive, we remove detected PPE outside of the worker detected area, as can be seen in Algorithm 1.

Algorithm 1. Detecting PPE

Figure 5. Detect workers in the danger area

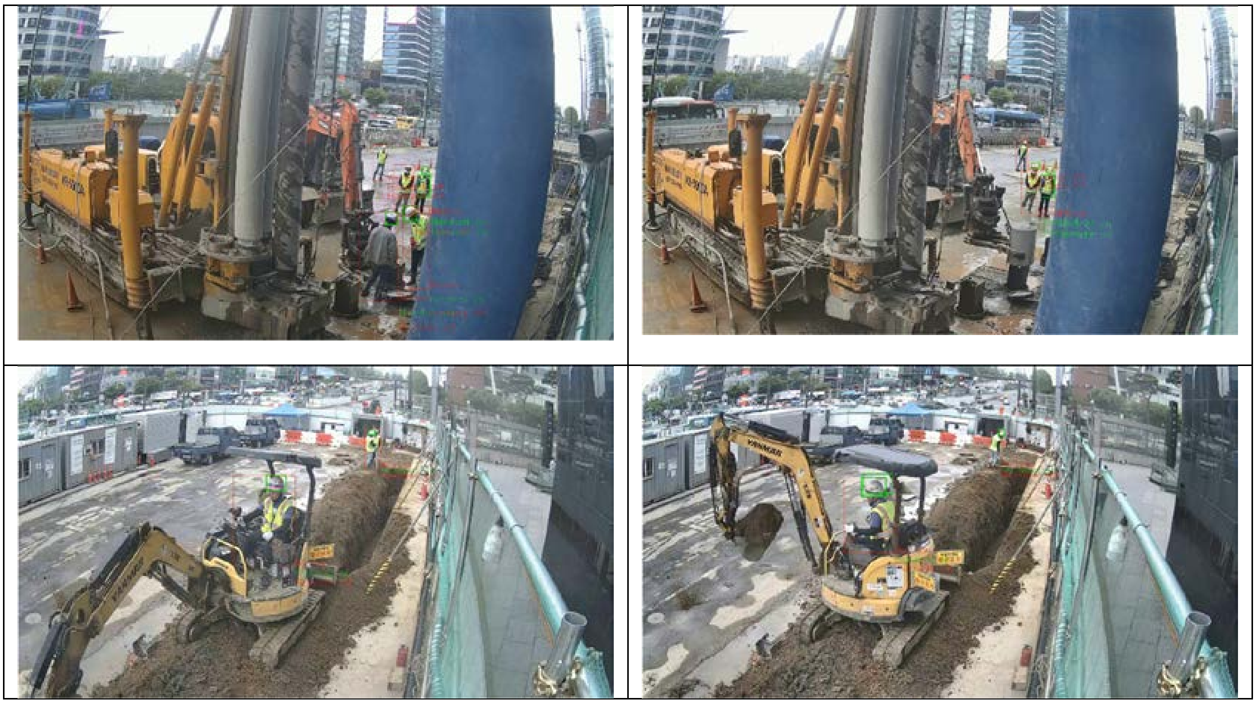

Figure 6. PPE detection

Finally, for developing multi-CCTV and bird eye view (BEV) synchronization. Two cases of examples are conducted as follows: first, by utilizing TwinMotion, the 4 CCTV channel is developed and used as an input for detection models, with homography matrix, the BEV is shown in Figure 7.

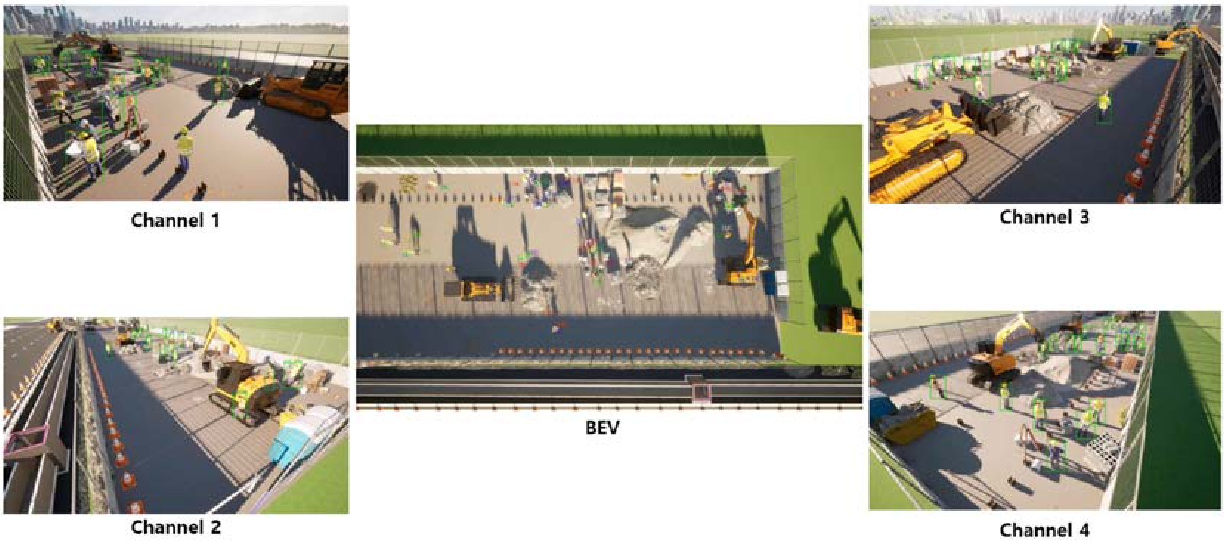

Figure 7. Multi CCTV with BEV in Twinmotion

Similarly with above example, but in actual construction site, it difficult to obtain BEV image, that why TLS is utilized for scanning and from that BEV can be estimated as shown in Figure 8 and 9. However, by only projecting all detected object into BEV, the exact ID of objects vary channels to channels. Therefore, the application of multi object detection and tracking can be used for future research. The expected output is given multi-channel CCTV, the output is the BEV with exact number and ID of detected objects. This study mostly emphasizes qualitative experiments. In order to obtain quantitative results, the forthcoming experiment will be undertaken by establishing an indoor environment and thereafter measuring the error projection using a meter.

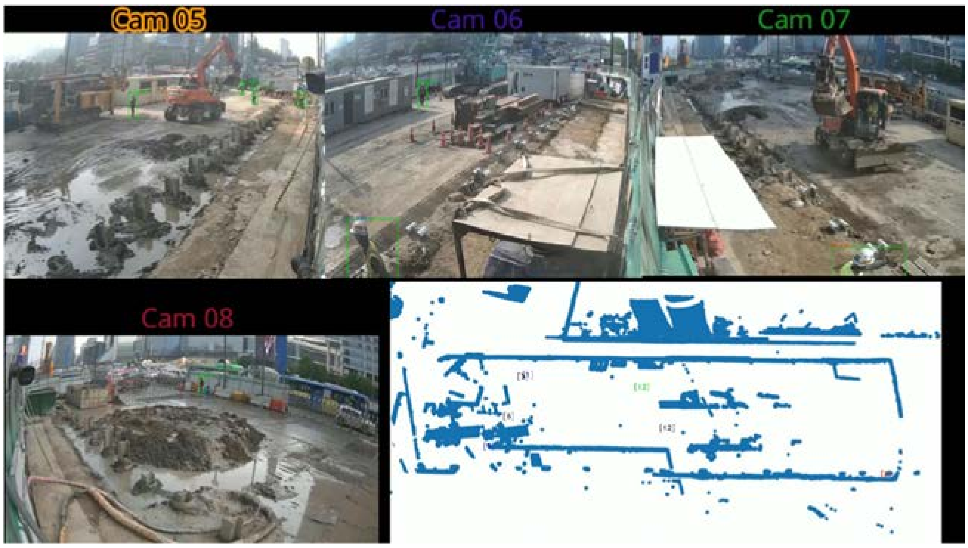

Figure 8. Multi CCTV with BEV in actual construction site

Figure 9. Multi CCTV with BEV in actual construction site

5. CONCLUSION

By adopting a multimodal detection approach, the study proposes a depth map estimation algorithm designed to enhance the contextual understanding of video inputs from CCTV. The proposed method uses terrestrial laser scanning to generate a point cloud of the test site and leverages a homography matrix to project detected objects into global coordinates. With object detection models used in the proposed method, a detailed analysis of YOLOv8X and RTMDet was conducted. YOLOv8X exhibited superior precision across various measures, including overall mAP, mAP at varying IoU thresholds, and mAP across different object sizes. However, the RTMDet model was identified as more resource-efficient, demanding significantly fewer computational resources despite its lower mAP performance. This research also presented some use cases of multimodel detections, it proves that context-aware approach in safety monitoring is important and should be considered for further research.

ABSTRACT: *Fall from height (FFH) is one of the major causes of injury and fatalities in construction industry. Deep learning-based computer vision for safety monitoring has gained attention due to its relatively lower initial cost compared to traditional sensing technologies. However, a single detection model that has been used in many related studies cannot consider various contexts at the construction site. In this paper, we propose a deep learning-based pose estimation approach for identifying potential fall hazards of construction workers. This approach can relatively increase the accuracy of estimating the distance between the worker and the fall hazard area compared to the existing methods from the experimental results. Our proposed approach can improve the robustness of worker location estimation compared to existing methods in complex construction site environments with obstacles that can obstruct the worker's position. Also, it is possible to provide information on whether a worker is aware of a potential fall risk area. Our approach can contribute to preventing FFH by providing access information to fall risk areas such as construction site openings and inducing workers to recognize the risk area even in Inattentional blindness (IB) situations.*

KEYWORDS: *deep learning, keypoint detection, pose estimation, computer vision, construction site safe*

1. INTRODUCTION

Due to numerous hazards and safety challenges, the construction industry stands out as highly dangerous, characterized by elevated rates of accidents and injuries. Among these, falls from heights (FFH) emerge as a particularly frequent and urgent concern, often leading to severe injuries or fatal outcomes. These incidents underscore the inherent risks associated with construction activities, contributing to delays and economic setbacks (Rafindadi et al., 2022).

Despite the stringent enforcement of safety standards, comprehensive worker training, and the adoption of advanced protective equipment, FFH-related accidents persist at an alarming rate. A closer examination reveals that these mishaps frequently result from worker negligence, inadequate situational awareness, or an inability to recognize impending dangers (Golparvar-Fard et al., 2013). The dynamic and ever-evolving nature of construction sites further exacerbates these challenges, rendering many traditional safety measures ineffective.

Historically, human oversight and routine inspections have been the primary means of safety supervision in construction settings. However, these methods, being inherently subjective, often result in inconsistent safety assessments. Recognizing these limitations, there's been a shift towards leveraging emerging technologies such as computer vision and artificial intelligence (AI). While these innovations promise objective, consistent, and real-time safety evaluations, challenges remain. Specifically, detecting hazards like floor openings becomes complex due to occlusions from construction materials and scaffolding. Additionally, determining a worker's position, especially when parts of their body are obscured, remains problematic.

In light of these challenges, this study proposes a novel approach, integrating computer vision and deep learning, tailored for construction site safety evaluations. The essence of our methodology lies in the fusion of quadrilateral detection, pose estimation, and single depth estimation. Quadrilateral detection accurately captures the contours

of target objects, pose estimation provides insights into their spatial orientation, and single depth estimation refines the distance measurements. By employing quadrilateral anchors, further enhanced by the Vision Transformer, our approach aims to provide a more robust and accurate tool for hazard detection and prevention.

The structure of this paper is as follows:

- Chapter 2 delves into relevant literature, providing a thorough assessment of existing approaches, their strengths, and inherent limits.
- Chapter 3 elucidates our proposed methodology, shedding light on its unique facets and potential advantages.
- Chapter 4 includes experimental results, including quantitative assessments as well as visual representations of our findings.
- Chatpter 5 concludes the paper by summarizing the paper and suggesting future avenues for research.

2. RELATED WORK

The construction industry has long grappled with the challenge of ensuring worker safety, especially in the context of falls from heights (FFH) (Helander, M. 1980). This section delves into the existing methods and recent advancements in recognizing unsafe areas and the application of deep learning in the construction site context.

2.1. FFH-related Safety Monitoring

Traditional safety measures, such as guardrails and safety nets, have been the primary defense against FFH incidents (Zhang, M. and Fang, D. 2013). However, the dynamic and complex nature of construction sites often renders these measures insufficient. The rapidly changing environment, coupled with the diverse nature of construction tasks, necessitates more advanced and adaptive safety solutions.

Historically, the realm of automated construction safety has leaned heavily on sensor-based mechanisms. Techniques like radio frequency identification (RFID) were the go-to solutions for monitoring workers' movements into potentially hazardous zones (Costin, et al., 2012). Similarly, tools like global positioning systems (GPS) and ultra-wideband (UWB) played pivotal roles in identifying unsafe regions and pinpointing the location of workers and materials (Pradhananga, N. and Teizer, J. 2013). However, the drawback of these methods was the necessity for individual sensor installations.

The modern era has seen a surge in the exploration of computer vision combined with deep learning as potential reasonable approach in safety area (Park, et al., 2020; Jeon, et al., 2023). Recent advancements in technology are poised to significantly transform the paradigm of worker safety through the automation of risk assessments. Noteworthy progress has been achieved in the application of computer vision to identify potential hazards (Tran, et al., 2022). However, some studies exhibit limitations in their scope, especially regarding the precise localization of dangers and the evaluation of workers' proximity to such hazards. In sight of these observations, there's a clear demand for a more refined approach that not only pinpoints hazards with precision but also factors in worker proximity in real-world scenarios.

2.2. Deep Learning and Computer Vision in Construction Environments

The dynamic and cluttered nature of construction sites poses unique challenges for deep learning models. The presence of obstructions like construction materials and scaffolding often disrupts the model's ability to accurately identify target objects. A popular solution, borrowed from interdisciplinary research, is the integration of attention modules. These modules enhance the model's feature extraction capabilities, emphasizing crucial aspects of images.

Recent research has showcased the potential of attention mechanisms in improving detection accuracy, especially in environments where objects are either partially hidden or appear smaller due to perspective. For instance, several works refined the triplet attention mechanism, assigning greater significance to vital features. This refinement allowed models to zero in on specific image sections, enhancing the accuracy of worker detection, even in intricate construction settings. Their model could pinpoint a worker's approximate location, even if they were partially obscured. Another noteworthy approach is the use of distance intersection over union (DIoU) based on non-maximum suppression (NMS). This technique distinguishes between overlapping objects against the complex backdrop of construction sites.

However, these methods are not without their limitations. For instance, if a worker's lower body is entirely obscured, the detection only captures the visible sections. This makes it challenging to determine a worker's exact position based solely on bounding box coordinates.

Enter pose estimation, a more adaptable solution to traditional object detection challenges posed by occlusions. Recent advancements in the intersection of construction safety and computer vision have highlighted its promise. By leveraging pose estimation, researchers have been able to identify unsafe work postures and ensure the proper use of safety equipment.

Despite its potential, few have explored pose estimation to determine construction worker locations, especially considering obscured body parts. Moreover, basic detection methods, which don't account for distance, only identify the presence of workers and hazards without gauging the relative proximity between them. This limitation hampers their ability to issue timely warnings to workers approaching danger zones.

The Vision Transformer model, applied to depth estimation, demonstrated the capability of assessing object depths and distances with a singular camera (Ranftl, et al., 2021). However, with increasing distances, the differentiation in depth becomes less discernible, potentially limiting its utility for comprehensive construction site surveillance. In conclusion, there is a pressing need for cost-effective computer vision techniques that can not only pinpoint worker locations but also preemptively warn them about impending hazards.

3. METHODS

To address the identified challenges, we propose a comprehensive methodology that leverages advanced computer vision and deep learning techniques. Our methodology consists of two main components: detection of floor openings using a quadrilateral-anchor-based Vision Transformer, and estimation of worker positions using a pose estimation approach.

3.1 Baseline Detection Architecture

Given the urgent and real-time nature of risk management on construction sites, it is imperative to employ a model that can provide immediate and accurate monitoring. YOLOv7 is boasting high accuracy while maintaining real-time capabilities in real time detection (Wang, et al., 2023). While minor trade-offs in FPS might occur, extending YOLOv7 with additional models presents an avenue for enhancing accuracy. In view of these considerations, YOLOv7 was chosen as the foundational model for our study.

3.2 Attention Mechanism

The introduction of the attention mechanism has proven transformative in object detection tasks. By dynamically emphasizing salient image features while downplaying less informative ones, models exhibit enhanced capacity for accurate object detection and classification, all while preserving the efficiency of the detection process (Park, et al., 2022; Guo, et al., 2022). Traditional attention methods, including squeeze-and-excitation (SE) (Hu, et al., 2018) and convolutional block attention mechanism (CBAM) (Woo, et al., 2018), utilize convolutional neural networks to recalibrate feature maps, enhancing model accuracy and robustness by prioritizing meaningful information over less relevant components.

3.3 Polygon Anchor for Object Detection with Vision Transformer

The detection of floor openings is achieved through a convex quadrilateral-anchor-based Vision Transformer. This approach allows for accurate detection of floor openings, even when the camera perspective is not aligned with the floor opening as shown in Figure 1. The quadrilateral anchors allow for more flexibility in defining the bounding boxes, enabling them to closely match the actual boundaries of the floor openings. The Vision Transformer is used to extract both the global dependencies between the floor openings and other parts of the building and the local features specific to the floor openings. This combination of global and local feature extraction enhances the detection performance of the floor openings.

These two components, when combined, allow for a comprehensive, real-time monitoring of safety on construction sites. They enable not only the detection of floor openings but also the identification of unsafe zones and the real-time tracking of worker positions. This comprehensive safety monitoring can significantly enhance the safety at construction sites.

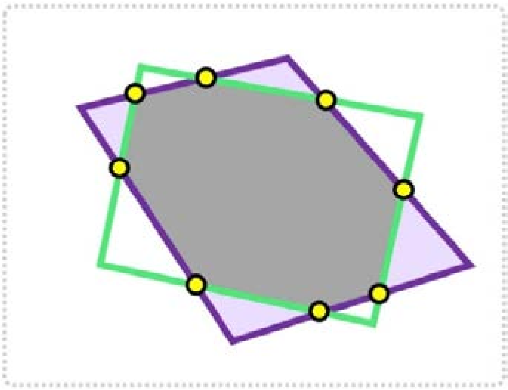

Fig. 1: Using convex quadrilateral anchors to detect floor openings. The purple boxes represent the ground truth, while the green boxes represent the predicted boxes. The overlapping area between the two boxes, indicated by yellow dots, is used to calculate the IoU (Intersection over Union).

3.4 Integrated Model for Floor-Opening Detection

we incorporate the YOLO-pose model (Maji, et al., 2022), which enhances YOLO capability to predict human poses. This model leverages pose estimation to refine object localization, offering a more comprehensive understanding of worker positions and orientations in relation to floor openings. This integration aims to amplify the focus on critical features and supply a more comprehensive contextual representation of images. This augmentation potentially heightens the efficacy and precision of our object detection model.

The envisioned integrated model aims to capture both local attributes and global interdependencies of floor openings. Local characteristics encompass attributes like shape, size, and color, facilitating nuanced comprehension and enabling their integration with other objects. Meanwhile, global interdependencies offer a holistic understanding of image constituents. For instance, floor openings often correlate with specific building elements, such as slabs, and a global outlook can encapsulate contextual information on a broader scale. This approach not only bolsters the perception of individual components but also provides insights into the overall building structure and floor opening placements.

3.5 Estimation of Relative Distances Between Workers and Danger Zone

Ensuring safety on construction sites entails assessing the proximity of workers to potential hazards, in this case, openings or drop-offs. Our method employs a combination of pose estimation and depth estimation to achieve this.

Firstly, we leverage the pose estimation of workers, specifically focusing on the leg parts, to gauge the distance, denoted as D. The rationale behind this focus is that the legs are often the closest body parts to openings or drop-offs and thus serve as critical indicators of a worker's proximity to these hazards.

Once D is determined, we then identify areas within a radius of D from detected openings as "hazard zones." Any worker located within this zone is considered at risk, warranting immediate safety interventions. Also, In the context of drop-offs, we utilize single depth estimation. When a detected individual's depth estimation result exhibits a drastic change, indicating proximity to areas with significant depth differences, they are deemed to be in a hazardous zone. Essentially, if a worker is close to an area where the depth changes abruptly, it is considered a potential fall hazard.

By integrating pose and depth estimations, our approach provides a comprehensive measure of potential risks, enabling proactive safety measures on construction sites.

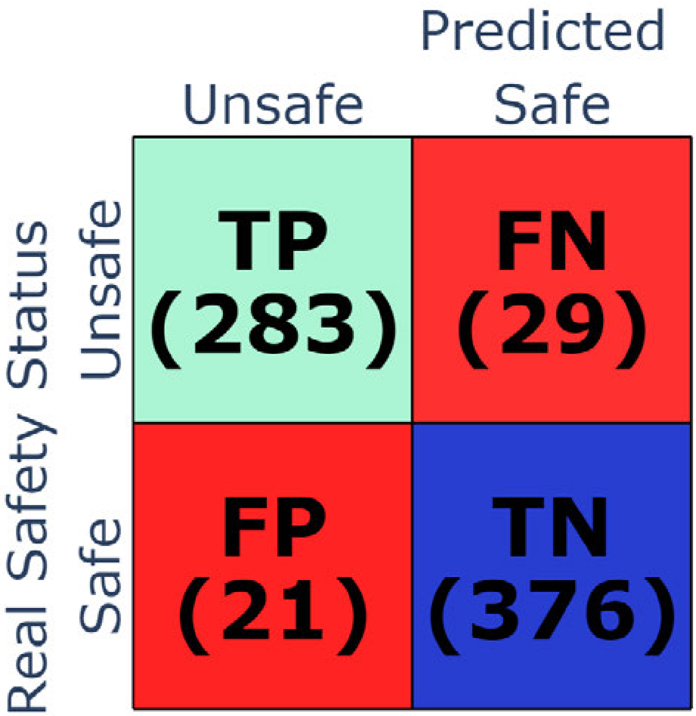

Fig. 2: The results of confusion matrix for the safe/unsafe decision making in construction site.

4. RESULTS

For our experiments, data were collected from both real construction sites and 3D simulation models. We specifically gathered images and videos of workers situated near openings and drop-offs where safety measures were not adequately implemented. In total, 3545 datasets were collected. We then employed a training-validation-test schema with a split ratio of 3:1:1, respectively, to evaluate our model's performance. The proposed method not only improves the detection of floor openings but also estimates the relative distance between the workers and the openings. The method defines unsafe zones around the openings based on this relative distance and provides real-time warnings to the workers when they enter these zones. The experiments also demonstrate the robustness of the proposed method in handling the complex and dynamic environment of construction sites.

The quantitative accuracy of the alert for FFH prevention at openings and edges from the proposed method is represented in Fig. 2, visualized using a Confusion matrix. We used a confusion matrix to assess the performance of our model in predicting whether a worker is in a hazardous zone or a safe zone. In real construction sites, due to the inherent nature of the environment, most of the samples were from safe zones, which explains the higher number of safe situation. By testing in both real and virtual environments, we ensured a comprehensive evaluation of our model's performance across diverse scenarios. Our model achieved an accuracy of approximately 93.2%, representing the proportion of total predictions that were correct. The precision of the model was 93.1%, indicating that when our model predicted a worker to be in a hazardous zone, it was correct about 93.1% of the time. The recall was valued at 90.7%, showcasing that our model correctly identified 90.7% of all actual hazardous situations. Harmonizing precision and recall, the F1-Score was found to be 91.9%. Fig. 3 visualizes the inference results of the models used in the proposed methodology. The final decision on risk/safety is automatically determined through post-processing from a combination of three algorithms.

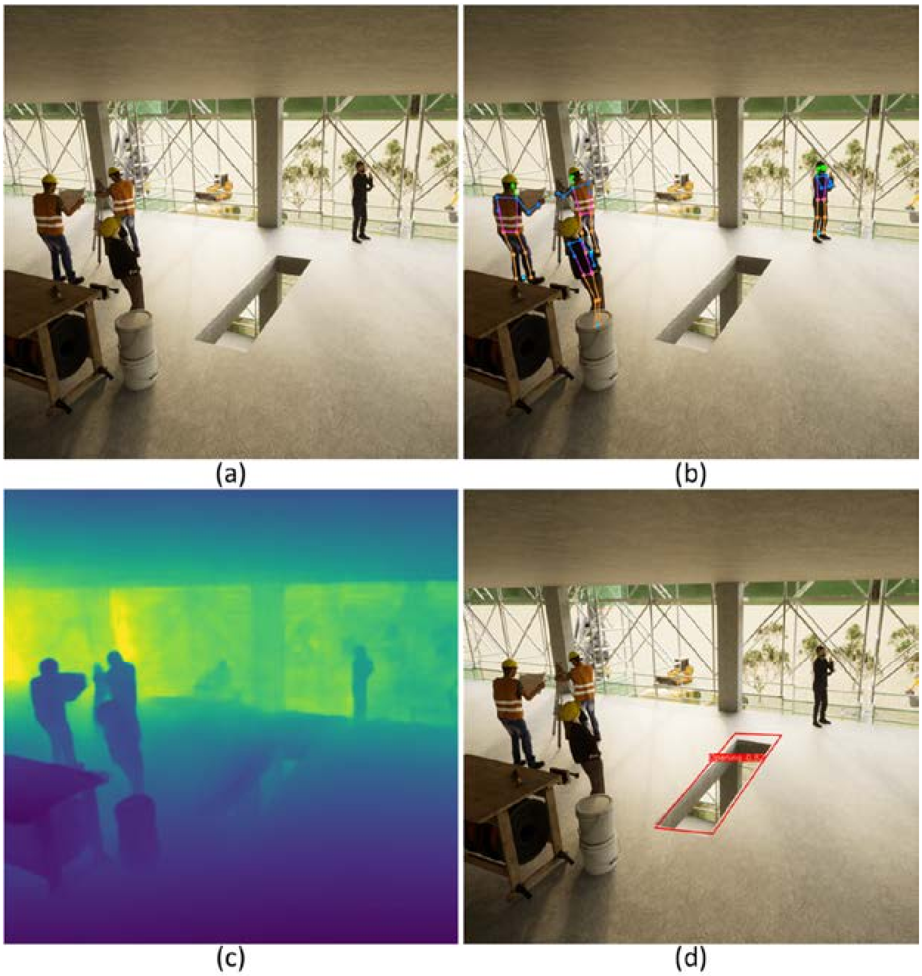

Fig. 3: Results of computer vision models in simulated hazardous situations for openings and edges using Unity. (a) Original image, (b) Pose estimation results, (c) Depth estimation results from a single camera, (d) Polygon detection results for floor openings.

5. CONCLUSIONS

This study presents a pivotal advancement in automated safety monitoring within the construction domain. By harnessing state-of-the-art computer vision and deep learning paradigms, our method adeptly detects floor openings and estimates the proximity of workers, facilitating real-time risk assessment. The potential to preempt accidents and heighten safety through this methodology is profound.

However, our study acknowledges certain limitations. Notably, while our method is primed for detecting risks, it may register false positives, especially in scenarios where floor openings function as stairs or access points, and workers are expectedly moving in and out. Conversely, false negatives can manifest when workers operate beyond a specific distance from the camera, rendering them undetectable. As per the feedback, it's crucial to clarify that we haven't explicitly stated or tested the exact distance threshold on-site, which denotes the limit beyond which workers might not be detected. These limitations point to the need for further research and improvement in our method. Future work should aim to address these issues, as well as incorporate considerations of existing safety measures on construction sites to provide more nuanced safety monitoring information.

ABSTRACT: *According to the Ministry of Manpower, falling and slipping accidents are one of the most common accidents in addition, falls from heights (FFH), including accidents during scaffolding work, are still a major cause of death in the construction industry. Regular safety checks are currently being carried out on construction sites, but scaffold-related accidents continue to occur. Sensing technology is being attempted in many industrial sites for safety monitoring, but there are still limitations in terms of the cost of sensors and object detection, which are limited to certain risks. Therefore, this paper proposes a deep learning-based pose estimation approach to identify the risk of falling during scaffolding work in the construction industry. Through analysis of the correlation between unstable behavior during scaffold work and the angle of keypoints of workers, the proposed approach demonstrates the ability to detect the risk of falling. The proposed approach can prevent falling accidents not only by detecting construction site workers, but also by detecting specific risky behaviors. In addition, in limited work environments other than scaffolding work, the information on unstable behavior can be provided to safety managers who may not be aware of the risk, thus contributing to preventing falling accidents.*

KEYWORDS: *deep learning, pose estimation, keypoint angle calculate, construction site safe monitoring, falls from heights*

1. INTRODUCTION

According to the Ministry of Manpower, falling and slipping accidents are one of the most common accidents in addition, falls from heights (FFH), including accidents during scaffolding work, are still a major cause of death in the construction industry. Working at height on construction sites is associated with a major risk of falls that must be properly managed to prevent injury and death.

Statistics from the U.S. Department of Labor in 2021 indicate that nearly one in five workplace fatalities occurred in the construction industry, with over a third of these attributed to falls, slips, and trips. The construction industry was responsible for 46.2% of all deaths from falls, slips, and trips that year(U.S. BUREAU OF LABOR STATISTICS, 2023).

Based on data from Singapore's construction sector, construction accidents have been on the rise from 2020 to 2022, accounting for 171 incidents (26% of total accidents). Of these, FFH accounted for 55 incidents (32%), while slips and trips were responsible for 27 incidents (15.8%) (MOM, 2022).

Meanwhile, in South Korea, despite the implementation of the Major Accident Act in January 2022 aimed at reducing fatalities among construction workers, there has been a 0.01% increase in such incidents as of March 2023. Specifically, in 2022, out of 539 deaths, 268 were attributed to "falls," marking the highest cause. These statistics reconfirm that the construction sector is hazardous, with a pronounced risk of fall incidents.

While various personal protective equipment and safety devices have been developed to prevent accidents, a study by (Xia et al., 2018) highlighted that one of the main causes of fall incidents is the absence or insufficiency of worker behavior supervision. Information on the posture of construction workers can serve as valuable data for evaluating safety and productivity (Xu et al., 2022). Several studies have been driven based on this perspective.

(Khan et al., 2021) researched methods to detect unsafe behaviors of workers using IMU sensors, specifically by assessing the angle of attached hooks. Enrique (Valero et al., 2016) used wearable devices based on IMU sensors to analyze movement data and detect unsafe postures. There have also been significant strides in using computer

vision for safety research. (MassirisFernández et al., 2020) proposed a method to assess work risks by analyzing joint angles of workers under limited visibility conditions.

Deep learning methodologies have also been applied to safety research. (Khan et al., 2021) utilized deep neural networks to classify and segment worker movements, detecting unsafe behaviors on moving platforms. Pinsheng (Duan et al., 2023) introduced a technique using OpenPose to detect personalized stability based on the individual characteristics and habits of workers at height.

However, a gap has been identified in safety monitoring research following the Standard Operating Procedure (SOP). This study aims to address this gap by proposing a method to monitor unsafe postures of workers during scaffolding operations based on their shoulder joint angles, in accordance with the SOP.

Furthermore, by actively incorporating such innovative technology at construction sites, it is possible to enhance worker safety and improve productivity. For instance, these posture detection systems can support workers in maintaining safe working postures and preemptively detect unsafe conditions to prevent accidents. This not only elevates safety standards in the construction industry but also enhances work efficiency while reducing fatigue and injuries during operations.

Moreover, the practical utilization of such technology in construction sites can lead to adherence to project schedules and cost savings. Real-time posture detection and analysis at the site are expected to contribute significantly to enhanced productivity and the creation of a safe working environment in the construction industry.

2. LITERATURE REVIEW

The construction industry has been a focal point of research on workplace safety, largely due to the high frequency of fall-related accidents (MOM, 2022; U.S. BUREAU OF LABOR STATISTICS, 2023). With a significant portion of accidents attributed to falls from heights (FFH), slips, and trips, it is clear that this is an area in need of targeted interventions and technological innovation.

Efforts have been made to mitigate the risk of falls in the construction industry by developing personal protective equipment and safety devices. However, studies suggest that the root cause of fall incidents often lies in inadequate supervision of worker behavior (Xia et al., 2018). Construction worker's postures are a valuable source of stability and productivity information that can be used to manage construction sites (Xu et al., 2022).

Monitoring changes in a worker's posture can provide information about whether the worker is in a safe or unsafe position. Numerous studies have been conducted to detect and analyze unsafe behaviors of workers using this approach. For instance, (Khan et al., 2021) conducted a study using IMU sensors to determine unsafe worker behavior through the angle of secured hooks. Similarly, Enrique (Valero et al., 2016) used wearable devices based on IMU sensors to measure movement data, detecting and characterizing the unsafe postures of workers. Other researchers have also leveraged computer vision to detect and analyze worker posture information. For instance, (MassirisFernández et al., 2020) evaluated job risk by inferring joint angles of workers under limited field of view conditions based on computer vision.

Deep learning has also found its applications in this context. (Khan et al., 2021) identified unsafe behaviors on mobile platforms through object correlation detection using deep neural network-based worker classification and segmentation. Also, (Duan et al., 2023) proposed a personalized stability detection technology based on high-altitude workers' body posture patterns by detecting individual physical characteristics and habits using the OpenPose method.

Amidst these technological advancements in detecting unsafe behaviors, there's a noticeable gap when considering overlapping or closely interacting workers in construction sites. Addressing this complexity, (Park et al., 2023) introduced a method for detecting small and overlapping workers at construction sites, emphasizing the intricate interactions and spatial relations of workers in crowded environments. Demonstrated significant potential in ensuring workplace safety by identifying such challenging scenarios with higher accuracy.

While these prior studies have inferred the results of unsafe worker behaviors using sensors and evaluated worker stability, they often lack in terms of monitoring safety during scaffolding work as per Standard Operating Procedure (SOP). Therefore, this study aims to monitor unsafe postures by detecting shoulder joint angles of workers during scaffolding work based on SOP, as an effort to prevent fall accidents in this context.

3. METHODS

3.1 Research framework

In the construction industry, the safety of workers holds paramount importance, especially with the rising concerns related to fall-related accidents. Traditional methodologies have primarily leaned towards sensor-based approaches to address these concerns. However, there's a growing interest in methodologies based on computer vision. In this framework, we utilize the YOLOv7 Pose algorithm to detect and assess the shoulder joint angles of construction workers to discern potential hazardous situations. As illustrated in Fig. 1 the framework to monitor the stability of construction workers working at elevated heights consists of five modules. First, data is collected from the construction site, encompassing a myriad of movements by the workers. From the collected video data, essential frames are extracted and major regions pertaining to the workers are labeled accordingly. Next, the YOLOv7 Pose algorithm is employed to detect the skeleton of the workers. Special emphasis is laid on the skeleton information around the shoulder joint to calculate the angle of the shoulder joint. Subsequently, an analysis is performed to determine if the current angle of the worker's shoulder joint poses any risk in comparison to a set standard angle. If any hazardous posture is detected, real-time alerts are displayed, urging the implementation of necessary safety measures.

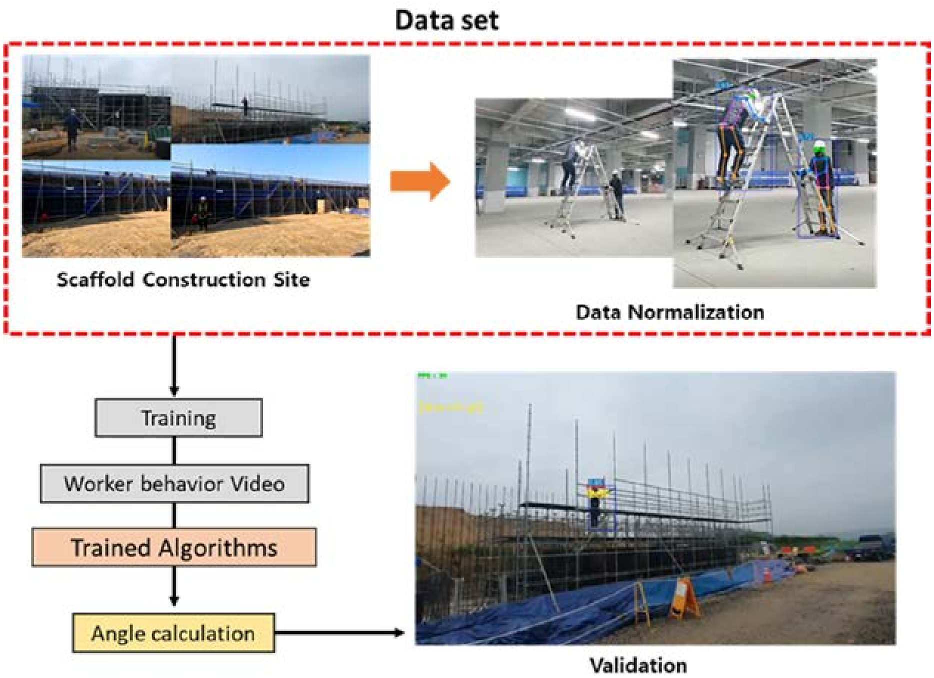

Fig. 1: Research Framework.

3.2 Identification method

Ensuring the safety of construction workers in high-risk environments, such as working at heights, has always been a top priority in the construction industry. Falls from heights are a common type of accident on construction sites, and many of these incidents occur when workers lose their balance and become unstable. In particular, scaffold work, which is frequently performed by construction workers, is associated with a high number of accidents. Therefore, in this study, the OpenPose method, which detects human postures from images and videos, was used to detect and analyze the postures and joint information of scaffold workers. The algorithm, trained using the MS COCO dataset and videos captured at construction sites, detects and represents human posture as shown in Fig. 2 It identifies a total of 17 joints, numbered from 0 to 16, as illustrated in Fig. 2, right image, and provides information about each joint. Table 1 illustrates unsafe postures that can occur during scaffold work. While various postures are possible during scaffold work, such as sitting, standing, bending, or bowing the head, there is a posture where both arms are raised simultaneously, lifting both the left and right shoulders, with a shoulder angle of less than 90 degrees. In this study, a posture involving the simultaneous elevation of both arms and shoulders with an angle less than 90 degrees is designated as an unsafe posture.

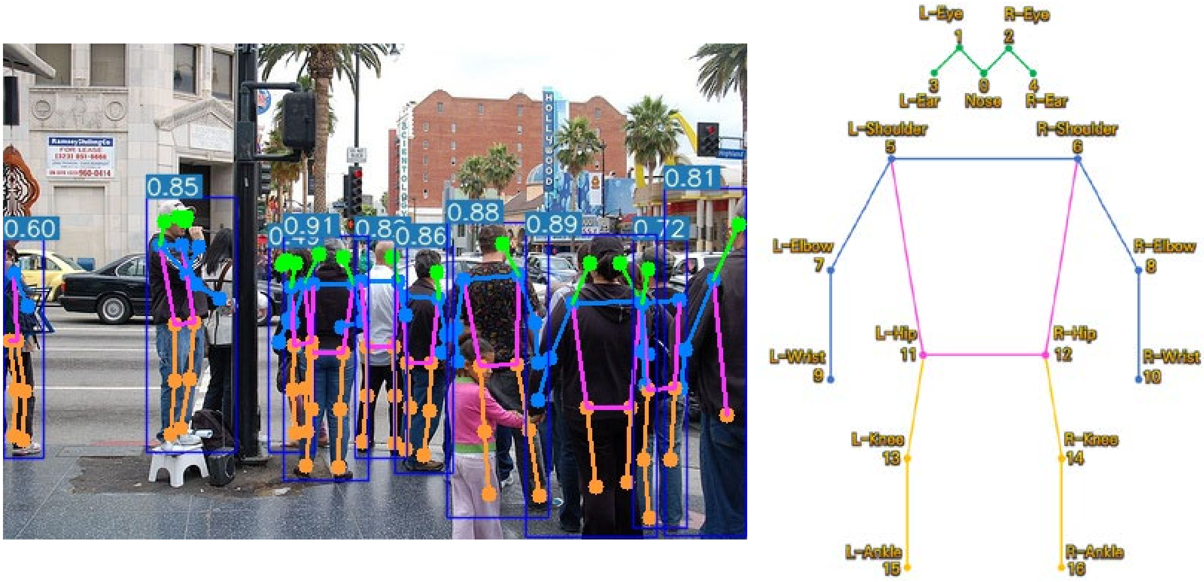

Fig. 2: Joint position information.

Table 1: Unstable behavior criteria for scaffolding operations

Unstable behavior description	Angle name	Angle numbers	Range	Threshold
Arm rasing	Left-Shoulder	∠7,5,6	0°~270°	∠LS ≤ 90°
	Right-Shoulder	∠8,6,5	0°~270°	∠RS ≤ 90°

3.3 Feature extraction

Algorithm 1 demonstrates a method for representing risk alerts based on angle calculations. This is employed to indicate stability alerts based on the angle when a worker raises their arm during operations. The algorithm consistently computes risk alerts based on shoulder angles, thereby continuously detecting workers and providing real-time notifications for risks associated with unsafe postures. It processes the input, detecting individuals in the video, and then delineates Bounding Boxes (BBox) and keypoints. Subsequently, it performs ongoing calculations for the angles of the R (Right) and L (Left) Elbows and R, L Shoulders. When the angle falls between 90 and 180 degrees, a warning notification is sent, while angles below 90 degrees trigger an Unsafe posture notification, which is visualized and transmitted.

Algorithm 1: Finding Angle between Three Points

Input: Detected Workers

Output: angle

```
Extract coordinates for p1, p2, p3 from kpts.
Calculate angle using atan2.
if angle >= 180.0 THEN label = '[safe!]', color = blue
else if 90 < angle < 180 THEN label = '[Warning!]', color = yellow
else label = '[Unsafe!]', color = red
if draw then visualize angle, label on image.
Return angle.
```

Fig. 3 demonstrates the method for detecting unsafe postures when the algorithm is applied during video recording. The YOLOv7 algorithm was utilized for its speed and capability to detect individuals while simultaneously detecting joints. The worker's joints are divided into 17 distinct points, from the head to the legs, each assigned an ID. To identify unsafe postures during scaffold work, the angles of the shoulders are crucial when the arms are raised. Therefore, angles for the joints L-Shoulder(5) and R-Shoulder(6) were detected and calculated. For angle calculation, a line connecting L-Shoulder(5) and R-Shoulder(6) was used as the baseline, and vectors were applied to the Elbow joint for angle calculation, as the calculation required angles for external rotation at each shoulder joint. Following the KOSHA GUIDELINE, when a worker raises their arm, an unsafe posture is determined based on a 90-degree threshold. The system alerts the user with three levels: over 180 degrees for safe, between 90 and 180 degrees for warning, and below 90 degrees for unsafe.

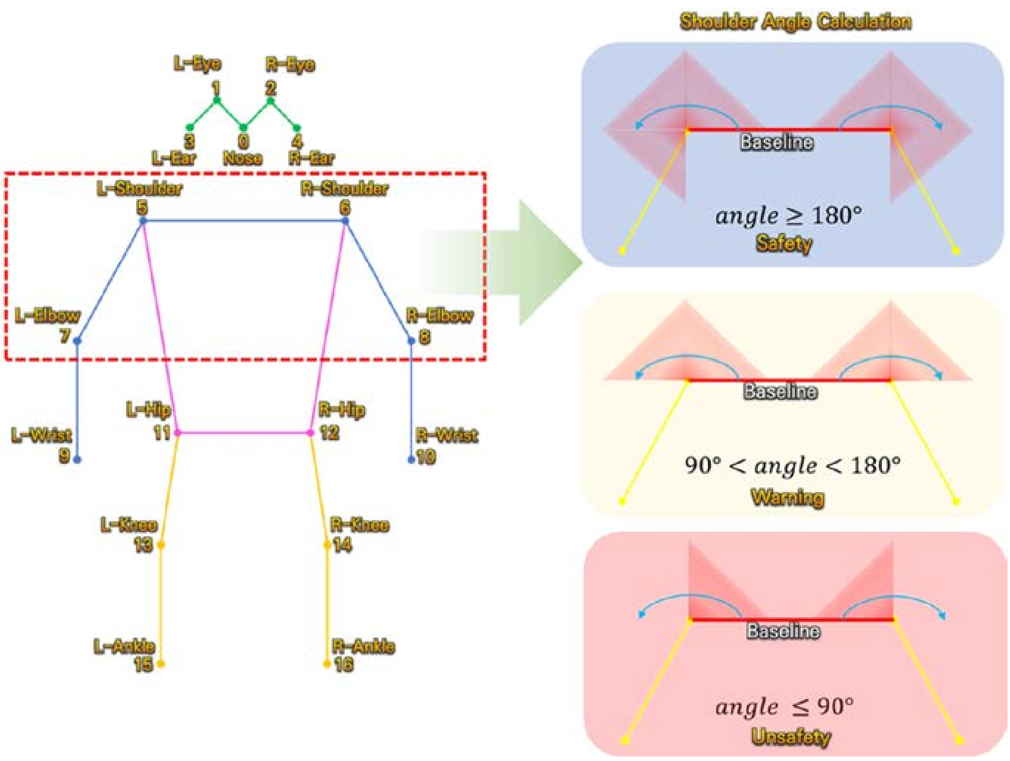

Fig. 3: Joint information and how to calculate shoulder joints

4. RESULTS

(a)

(b)

Fig. 4: Worker safety monitoring results during scaffolding operation. (a) Scaffolding installation work image taken diagonally, (b) Scaffolding installation site work image taken from the front

In Fig. 4 (a) presents the results of detecting a worker engaged in scaffold installation captured from a diagonal angle. When the worker raises their arms, the proposed angle-based criteria triggers a [Warning!] alert, indicating the detection of the worker and the activation of the alarm system. In (b), an image captured from the front showcases the construction site, not only identifying scaffold workers but also other workers engaged in different processes. As these workers are not in the arm-raised posture, no warning alerts are generated.

The proposed method for detecting unsafe postures during elevated work involves worker detection on construction sites and shoulder joint angle assessment for safety monitoring. This approach aligns with safety posture guidelines applied when workers raise their arms during elevated tasks, providing real-time warning notifications. This experiment validates the robustness of this study in facilitating easier site supervision and monitoring by administrators in complex and chaotic construction environments.

5. CONCLUSION

This study aims to contribute to the advancement of automated safety monitoring technology in the field of construction sites. The proposed method utilizes a Deep Learning-based OPENPOSE pose estimation model to estimate the postures of scaffold workers on construction sites. This estimation aims to provide real-time risk alerts to prevent falls from height (FFH) accidents. This research is expected to reduce the fatigue of construction site managers and decrease the occurrence rate of scaffold-related fall accidents.

However, during this research, limitations and areas for improvement have been identified. Due to the nature of construction sites, there are often obstacles and situations where workers are obstructed or difficult to detect due to equipment. Additionally, as objects move farther from the camera, issues were observed in joint angle calculations and false positives/negatives of worker detection. This indicates the need for further research and algorithm improvements. To address these challenges, future research aims to enhance detection accuracy based on distance and devise strategies to detect workers obstructed by obstacles. Furthermore, incorporating Multi-Camera setups is intended to calculate worker head angles.

ABSTRACT: *Construction industry has reported among the highest accident and fatality rates over the past decade. In particular, crane lifting is a notably hazardous operation on construction sites, causing fatal accidents like workers being struck by the boom or objects fallen from tower cranes. Manual monitoring by on-site safety officers is labour-intensive and error-prone, while incorporating computer vision techniques into surveillance cameras would enable more automatic and continuous monitoring of construction site operations. However, existing studies for lifting safety mainly detect the presence of individual objects (e.g. workers, crane components), while a methodology is needed to predict their potential collision more proactively before accidents happen. This paper develops a vision-based framework for predictive lifting safety monitoring, including three modules: (1) object detection and classification: targeting at hook and lifting materials to enable danger zone estimation, along with workers and their personal protective equipment; (2) worker movement tracking and prediction: analyzing the historical moving trajectory of each unique worker to foresee his/her future movement in certain period ahead; (3) multi-level safety assessment: issuing predictive warning in real-time upon any crane-worker conflict foreseen. The proposed framework is applicable to real-time site video processing and enables end-to-end lifting safety monitoring with instant alerting upon unsafe scenarios observed. Importantly, the proposed framework predicts the future movement of workers to proactively identify potential site hazard, in order to trigger earlier safety alert for more timely decision-making. With a large video dataset capturing tower crane operations, the proposed framework demonstrates competitive accuracy and computational efficiency in crane-worker conflict prediction, validating its practicality for real-time lifting safety monitoring.*

KEYWORDS*: Computer Vision; Construction Safety Monitoring; Crane-Worker Conflict Prediction; Deep Learning; Predictive Safety Assessment; Trajectory Tracking.*

1. INTRODUCTION

The construction industry has been plagued for long by a high frequency of accidents and fatalities. According to statistics from the Hong Kong Labour Department (2018), the industry accounted for 76% of occupational fatalities in 2017, making it the most dangerous sector in Hong Kong. Similarly, the U.S. Bureau of Labour Statistics (2018) reported an average rate of 2.6 deaths per day, resulting in 949 deaths for the year. With reference to an overview of the Hong Kong construction industry (Shafique & Rafiq, 2019), there were on average 3597 occupational injuries and 20 occupational fatalities per year between 2011 and 2017. The U.S.A Department of Labour (2022) indicated that the estimated cost of employers' direct compensation to construction accidents is up to US$1 billion per week. These statistics suggest the urgent need for improved construction safety measures to protect the lives of workers and mitigate the financial burden that accidents impose on employers and the economy.

To address this critical issue, governments have established safety guidelines and regulations to standardize the industrial practices of construction safety monitoring. Lifting operations using tower cranes are a crucial aspect of construction work that requires particular attention, as they involve dynamic interactions between workers and machines. Traditionally, safety monitoring relies heavily on manual inspection by on-site safety officers. However, this method is prone to errors due to human fatigue, which can result in overlooked incidents. In recent years, advancements in artificial intelligence have led to the development of computer vision (CV) methods that can automate construction safety monitoring. These methods enable real-time object identification, improving the accuracy and efficiency of safety monitoring. However, there are two research gaps: (1) Previous approaches have focused on analyzing individual objects, such as workers and machines, separately, without a more comprehensive framework that considers their spatial interaction in real-time. (2) Previous studies have primarily focused on analyzing current scenarios/activities on sites, while a more predictive mechanism is needed to proactively identify and prevent potential accidents ahead of time. Therefore, this study develops a predictive safety assessment framework that monitors potential crane-worker conflicts and enable proactive incident prevention, ultimately reducing the number of accidents and fatalities in the construction industry.

2. RELATED WORK

Collision between workers and construction equipment happens regularly in complex and distracting construction environment that is overcrowded with workers. Close contact between construction machines and workers are one of the major causes of collision event that lead to injuries and deaths. Sensors such as GPS and RFID have been explored in prior studies. With the help of sensors, real-time spatial-temporal information could be provided for proximity measurements. As a result, a spatial-temporal relationship can be detected, and an early warning can be sent out to prevent the accident from happening (Liu et al., 2021). However, to obtain enough information to safeguard the construction site, numerous sensors have to be installed. The heavy financial burden will be caused by purchasing and hiring a professional individual to install and maintain the sensors (Zhang et al., 2020).

CV-based object tracking is a superior alternative to sensors since it lowers the cost and requires fewer resources to set up, therefore, more appealing to the industry. Previous research has trained YOLOv3 deep learning model for 2D positioning various construction site entities on 2D images captured from Aerial vehicles. Several studies developed convolutional neural networks to detect personal protective equipment (PPE), such as helmet and reflective vest (Cheng et al., 2022, Fang et al. 2018, Nath et al. 2020). Besides object detection, several studies developed human tracking algorithms to analyze behavior of each person more continuously (Kim et al., 2019, Wong et al., 2021). Other studies attempted to predict the future action of construction machines like excavators, based on their historical motion patterns (Luo et al., 2021), and also semantic segmentation that fine-grains the detected objects at pixel level to allow better positioning (Jeelani et al., 2021).

While previous studies can perform real-time object detection and tracking, a more comprehensive framework beyond developing those algorithms is needed for practical construction safety monitoring. An automatic safety evaluation system shall be established to enable effective intervention mechanisms to prevent the accident from happening. Previous studies have proposed some distance-based hazard evaluation criteria (Son et al., 2019). Some researchers have taken the velocity of construction equipment and workers into consideration as there is an association between larger velocity and collision accidents (Golovina et al., 2016). A previous study has attempted to determine the dynamics direct fall zone of a crane load using a mounted tower crane camera with computer vision (Chian et al., 2022). These studies enhance construction safety monitoring with the ability to predict the direct fall zone, where workers can be proactively prevented from entering danger zones.

3. PROPOSED METHODOLOGY

To facilitate tower crane safety monitoring, a vision-based framework is developed which comprehensively supports end-to-end CCTV analytics for real-time safety assessment. The overall procedure and information flow are summarised in **Figure 1**, with three major functional modules: (1) **object detection and classification**: interested objects in each video frame are detected and classified into three categories (i.e. workers, hook and lifting materials); (2) **worker movement tracking and prediction**: analyzing the historical moving trajectory of each unique worker and predict his/her possible location in certain period ahead; (3) **multi-level safety assessment**: issuing predictive warning in real-time upon any unsafe crane-worker conflict observed.

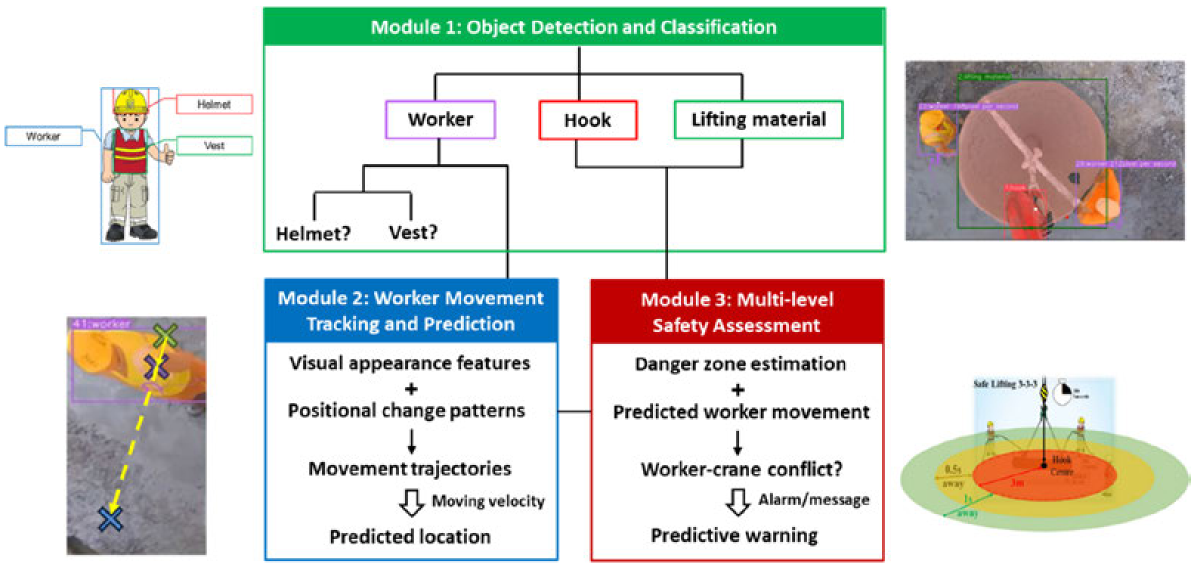

Figure 1: Overall information flow of the proposed crane safety monitoring framework

3.1 Object detection and classification

Upon receiving the raw videos from multiple cameras, the objects of interest are identified in Step 1. This is a crucial step that demands an automated process and accurately bounded objects (i.e. cropping the portion of image around each object with minimal background clutter). There have been numerous studies specialized in construction object detection (Fang et al., 2018; Luo et al., 2019; Memarzadeh et al., 2013), as well as comprehensive surveys of various state-of-the-art object detection methods (Brunetti et al., 2018; Huang et al., 2017). Hence, this paper adopts a competitive detection model for the object detection step. In particular, the YOLOv8 algorithm is used in view of its detection accuracy and inference efficiency revealed in recent studies.

More specifically, three types of construction objects are targeted, i.e. construction workers, crane hook and lifting materials during crane operations. With videos collected from construction sites, each object-of-interest is detected and cropped as a rectangular bounding box. Subsequently, a classification module outputs the corresponding class index associated with each bounding box. **Figure 2** illustrates a sample output of detection and classification (worker bounded by a purple box, hook by red and lifting material by green).

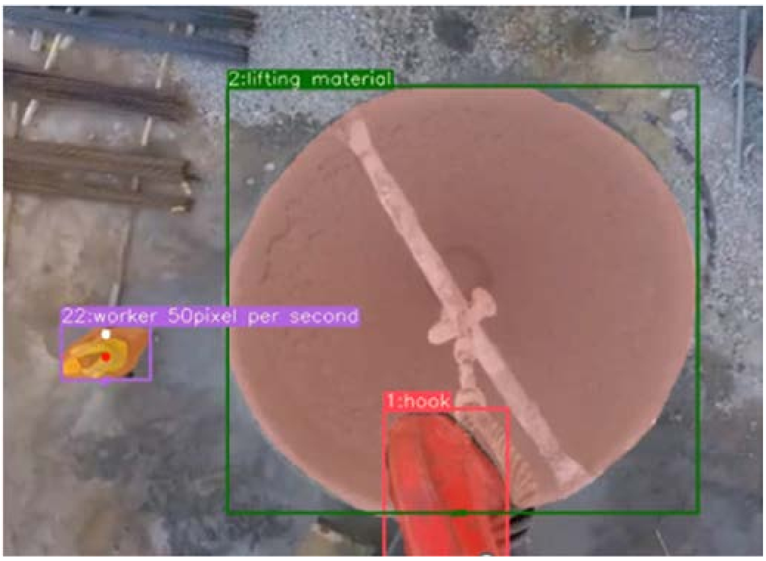

Figure 2: Illustration of object detection and classification results

For those detected boxes labeled as workers, a more fine-grained classification regime is defined to further analyze whether each worker wears necessary PPE, i.e. helmet and vest. As illustrated in **Figure 3**, two sub-categories are output by the classification model to determine the presence of helmet and vest respectively in their corresponding part of a body. To make the methodology more practical, the model is trained with both confirming and dis-confirming classes, e.g. the head part is marked even no helmet exists around there. This approach renders the PPE inspection more accurate, because it avoids improper behavior, e.g. hand-carrying a helmet without properly wearing on the head. In that case, our method can correctly report that PPE is not properly worn, while ordinary detection method only identifies the presence of PPE in hand, which indeed violates PPE compliance.

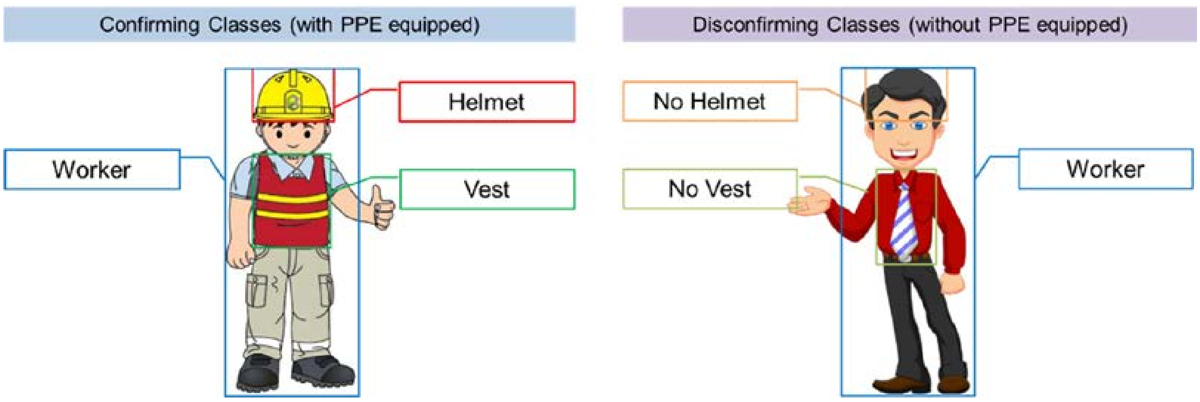

Figure 3: Definition of PPE statuses of a worker

3.2 Worker movement tracking and prediction

On top of the object detection results, worker trajectory tracking is performed to support worker behavioral analysis based on movement pattern. In this study, the method DeepSORT (Wojke et al., 2017) is utilized as a baseline to perform worker trajectory tracking over video frames, acquiring a complete trajectory of individual construction worker. The set of bounding boxes classified as ‘worker’ in Step 1 are further processed by DeepSORT, which subsequently analyzes the appearance features extracted from each worker and the positional change of the bounding boxes, in order to map unique identities to individual worker. **Figure 4** illustrates the assignment of unique identities to individual workers (22 to the left-sided worker, 29 to the right one).

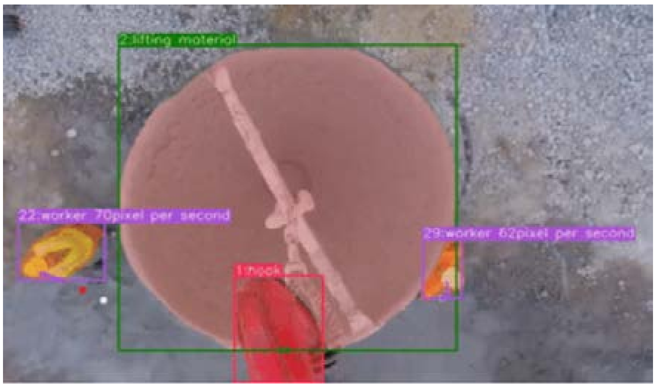

Figure 4: Illustration of worker tracking with unique identity assigned to different workers

Based on the trajectories of individual construction workers, their potential movement is then predict to foreseen whether their moving trajectories will potentially coincide with any lifting zone of the tower cranes nearby. This will allow dispatching warning signals in a more timely manner before workers actually enter the lifting zones. The prediction of future movement of each worker is defined in **Equation (1)**, which computes the image coordinates of the predicted worker location *t* timesteps later based on his/her observed velocity *v*.

$$d_2 = d_1 + v \times t \quad \textbf{(1)}$$

where,
d_1 = coordinates of the current location,
d_2 = coordinates of the predicted location,
v = velocity along corresponding direction,
t = time (measured by number of frames).

3.3 Multi-level safety assessment

By combining the output from object detection and worker movement tracking modules, spatial relationship between construction workers and lifting equipment is established. Regarding tower crane operations, the “Safe Lifting 3-3-3” Principle published by Hong Kong government (2020) is an industry standard in lifting operations. As illustrated in **Figure 5**, the 3-3-3 Principle states that workers should keep themselves 3m away from the lifting materials to ensure their safety. Yet, the 3-3-3 Principle only defines a single level of safety distance to be maintained from the lifting zone, while different degree of proximity may imply various levels of safety. Moreover, the standard only considers static behavior of workers (i.e. current location), while a more predictive safety monitoring regime is needed to consider the possible movement of each worker in certain period ahead.

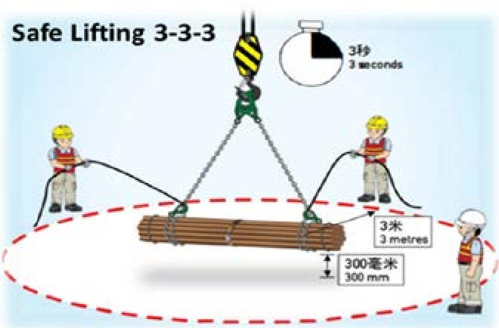

Figure 5: Definition of Safe Lifting 3-3-3 Principles

On top of the 3-3-3 Principle, the 3m operating region is defined as the danger zone around the lifting material detected by the object detection module. With the bounding box of lifting material generated, a danger zone of radius 3m around the bounding box centre is estimated. Different warning signals are then sent according to the corresponding risk scenarios and the predicted trajectory of the workers. As summarized in **Table 1**, different scenarios implies corresponding level of response. If a worker is already inside a fatal zone, 'Action' is issued to urge for immediate handling. If he/she is predicted to enter a fatal zone in 3 or 5 seconds, the responses become 'Alarm' and 'Alert' respectively which are less severe. Such a multi-level warning mechanism enables more flexible and predictive safety assessment.

Table 1: Proposed three-level mechanism of lifting safety assessment

Response	Scenario
Action	Worker inside fatal zone
Alarm	Worker will enter fatal zone in 3 seconds
Alert	Worker will enter fatal zone in 5 seconds

To alert both the workers and the residential site safety personnel to the potential safety hazards, an instant warning system is developed with a series of if-else loops, and connected with an external chatbot API. When the model detects the worker's tendency to enter the defined lifting zone, warning messages are issued to inform safety officers of the incident detected. The corresponding frames is also captured, with descriptive text about the unsafe scenario, and sent to registered stakeholders via an instant messaging platform (e.g. Telegram) for remedial actions.

4. EXPERIMENT

4.1 Experimental setup

To prepare a rich dataset for validation, CCTV videos taken in different angles were collected, including those taken by at-grade cameras and mounted-on-crane cameras. **Table 2** summarizes the attributes and sources of the videos solicited, which can be referred to in future studies for tower crane safety monitoring.

Table 2: Statistics of the image dataset collected for model evaluation

Angle	Length	Types	Sources
At-grade	2 min 50 sec	PPE wearing	https://youtu.be/zmVjnWEX_5c
At-grade	24 min 36 sec	Crane operations	https://youtu.be/Ag5yV8qZKMQ
At-grade	15 min 56 sec	Worker behavior	https://youtu.be/3AbhT6TLf60
Top-down	3 min	Crane operations	https://youtu.be/IlaEJgq0aEw
Top-down	4 min 18 sec	Crane operations	https://youtu.be/Vg6SOcPviDs
Top-down	4 min 35 sec	Crane operations	https://youtu.be/lrhQHX3r-pM
Top-down	59 sec	Crane operations	https://youtu.be/viBcyF2H_1A

A total of 5575 images were generated by extracting frames out of the collected videos, with manual inspection and sampling of high-quality frames, i.e. capturing diverse details of worker / crane operations. A detailed statistics of the dataset generated is summarized in **Table 3**.

Table 3: Statistics of the image dataset collected for model evaluation

Set	No. of images
Training	4889
Validation	458
Testing	228
Total	5575

The collected data then underwent a series of augmentations to maximize the generalization capability of the model being trained. The types of pre-processing include image resizing, rotation by EXIF orientation values and grayscale conversion. The images were also augmented by horizontal and vertical flipping, hue and saturation adjustment. Afterwards, the dataset was split into training, validation and testing sets. The training set was fed into different variants of object detection models, including YOLOv8-Large, YOLOv8-Small and YOLOv8-Nano, which consist of different degrees of model complexity in terms of neural network architecture.

As summarized in **Equations (2)-(4)**, the evaluation metrics of for object detection and classification include recall, precision and average precision (AP) score. Moreover, the accuracy of worker trajectory tracking is evaluated by multi-object tracking accuracy (MOTA), as defined in **Equation (5)**, where $IDSW$ denotes the frequency of identity switching among workers detected. In addition, the computational speed of the proposed method is also evaluated (in frame-per-second), which validates the practicality of our framework in real-time CCTV processing for construction site monitoring.

$$Recall = \frac{TP}{TP + FN} \tag{2}$$

$$Precision = \frac{TP}{TP \ + FP} \tag{3}$$

$$AP\ score = \frac{TP + TN}{TP \ + FP + TN + FN} \tag{4}$$

$$MOTA = 1 - \frac{FN + FP + IDSW}{TP + TN} \tag{5}$$

4.2 Results and discussion

Table 4 summarizes the AP scores of the object detection module of the proposed framework. Overall, a mean AP of 97.0% is achieved among all the three object classes, with 99.5% AP score for both the classes 'hook' and 'material'. A slightly lower AP score of 92.0% is obtained for 'worker', because of the significant variation of worker sizes in the images, which capture both top-down and at-grade angles from largely varying distances.

Table 4: Evaluation results of object detection

	Class	**AP score**
Class-wise	Worker	92.0%
	Crane hook	99.5%
	Lifting materials	99.5%
Overall	Recall	98.0%
	Precision	96.0%
	Mean AP	97.0%

Table 5 summarizes the AP scores of the worker PPE classification module of the proposed framework. Overall, the mean AP improves from 96.9% to 99.5% when training the PPE classification module with both confirming and dis-confirming cases. Such an approach also boosts the class-wise AP scores, from 96.7% to 99.3% ('helmet') and from 97.0% to 99.5% ('vest'). The effect of incorporating the dis-confirming cases is that the classification model has learnt more distinctive features of those PPE from the negative samples. For instance, by seeing ordinary cloths without vest, the model intrinsically learns better how a vest should look like and hence more accurately classifies whether a person is properly wearing a vest.

Table 5: Evaluation results of worker PPE classification

		Case 1 – trained with confirming classes only	**Case 2 – trained with confirming & dis-confirming classes**
Class-wise AP scores	Helmet	96.7%	99.3% ↑
	No helmet	/	99.2%
	Vest	97.0%	99.5% ↑
	No vest	/	99.6%
Overall scores	Recall	96.9%	98.8% ↑
	Precision	97.1%	98.8% ↑
	Mean AP	96.9%	99.5% ↑

Table 6 summarizes the MOTA (for worker tracking) and computational speeds when combining DeepSORT with different YOLOv8 variants. Regarding worker tracking accuracy, YOLOv8-Large outperforms the other two models with the highest MOTA of 90.1%, while having slower computational speed than the other two (2.7 frames per second). YOLOv8n-Nano shows the fastest inferencing (13.4 frames per second), while its MOTA is 81.8% which may be due to the increased chance of missing detections. Hence, YOLOv8-Small achieves the most balanced performance (85.2% MOTA and 7.9 frames per second).

Table 6: Evaluation results of worker trajectory tracking and overall computational speed

Model variant	MOTA	Computational speed (frame-per-second)
YOLOv8-Large+DeepSORT	90.1%	2.7
YOLOv8-Small+DeepSORT	85.2%	7.9
YOLOv8-Nano+DeepSORT	81.8%	13.4

Figure 6 illustrates the predictive warning mechanism of the proposed framework. The developed modules process a complete video and identifies that construction workers are working within the danger zone during lifting operations. By detecting the location of the lifting equipment and tracking the movement of individual construction workers, warning signals and recommended actions are dispatched via a Telegram chatbot upon identifying the unsafe scenarios. The spatial relationship among the equipment and workers is accurately established, which then informs on-site safety managers of the workers' risk statuses, urging for immediate actions more timely. Hence, our proposed framework enables more predictive safety monitoring of crane operations.

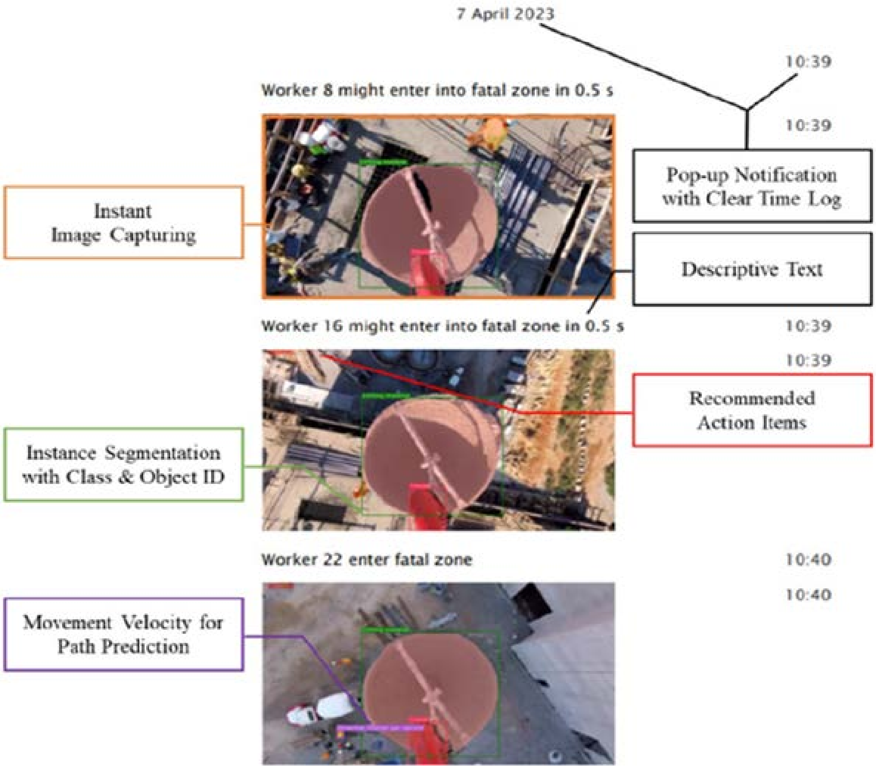

Figure 6: Demonstration of predictive warning mechanism in video processing

5. CONCLUSION AND FUTURE WORK

This paper proposes a vision-based framework for predictive lifting safety monitoring, relieving the tedious and error-prone manual inspection on sites in traditional practices. By analyzing the spatial interaction among essential objects in lifting operations (e.g. predicted movement of workers, danger zone around hook and lifting materials) more predictive incident identification is enabled for timely on-site safety assessment. The competitive accuracy and computational efficiency demonstrated in this study validates the practicality of the proposed framework. Based on the experimental findings, two research directions are suggested for future research: (1) **camera placement optimization in actual deployment**, considering various factors such as view coverage, degree of object occlusion, view angle and distance (implying video quality and hence analytical accuracy), etc. Research effort may be devoted into quantifying these factors into optimization framework formulated for camera placement, including the number of cameras, their position and orientation, etc.; (2) **multi-modal sensor integration**, extending the vision-based methodology to analyze more worker behavior such as injury/fall detection, and possibly also incorporating other kinds of sensors such as temperature sensor for heat-stroke warning monitoring and proximity sensor for worker-equipment conflict. More comprehensive research in the future will contribute to forming a systematic approach for construction safety monitoring.

LOCALIZING AND VISUALIZING THE DEGREE OF PEOPLE CROWDING WITH AN OMNIDIRECTIONAL CAMERA BY DIFFERENT TIMES

Tomu Muraoka, Satoshi Kubota & Yoshihiro Yasumuro
Kansai University, Japan

ABSTRACT: *The Corona Disaster increased the demand for information on the degree of human crowding, as it was essential to balance avoiding restricting behavior and reducing the risk of crowding. Although there are many technologies for detecting people using monitoring cameras, the number of cameras installed in a wide area is costly, and coverage is limited. In this study, we propose a method to qualitatively visualize the distribution of people by using images captured by a moving omnidirectional camera from the viewpoint of facility management during regular security patrols. Omnidirectional images are used for both 3D modeling of the target space based on SfM* (*structure from motion*) *and person detection/tracking by machine learning. The distribution of people is visualized qualitatively by obtaining the positions of the extracted people on the 3D model of the site and mapping them. The parallel software processing of visitor observation and mapping is expected to be highly cost-effective in terms of implementation and operation. On the other hand, although there are time deviations in the mapping depending on the location, the visualization and the updated time show their usefulness in understanding the distribution of congestion.*

KEYWORDS: *COVID-19, people's congestion, omnidirectional camera, SfM (Structure from Motion), machine-learning*

1. INTRODUCTION

1.1 Research background

COVID-19 infection was moved to category five infectious disease in Japan on May 8, 2023. The wearing of masks has been left to the discretion of individuals and businesses, and the condition is coming to an end. During the coronavirus outbreak, infection control measures such as wearing masks, hand sanitizers, and refraining from going to places with a high risk of becoming infected became widespread at the individual level and effectively controlled other infectious diseases. However, with the relaxation of waterfront measures and the increase in the number of foreign tourists, there is a risk that other contagious diseases may be brought into Japan, and the number of older people at high risk of serious illness is expected to increase due to the aging of society. As shown in Fig. 1, the number of influenza cases reported from medical institutions (fixed points) nationwide in 2023 showed an increasing trend, with many weeks exceeding the average number of cases reported over the previous five years (National Institute of Infectious Diseases, 2023).

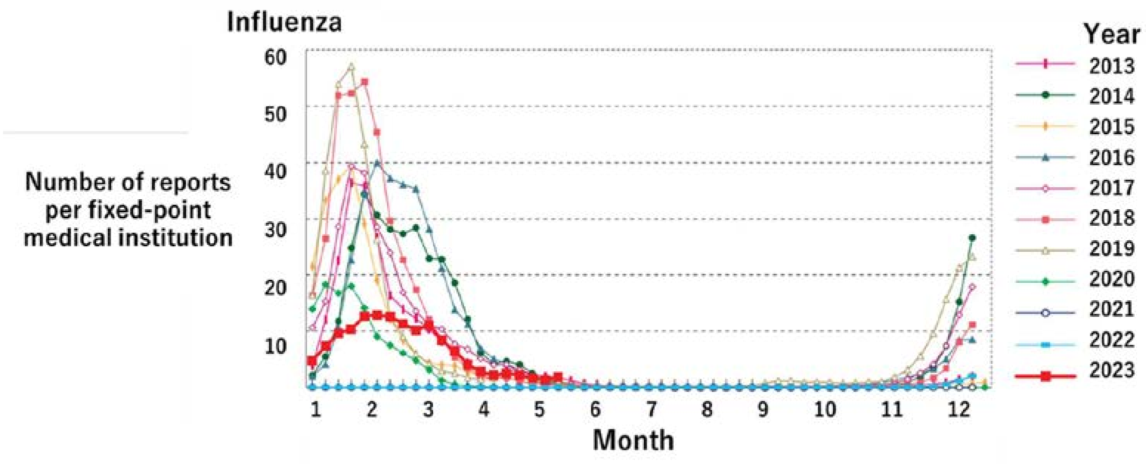

Fig. 1: Number of Influenza Infections
(National Institute of Infectious Diseases, 2023, partially modified and translated)

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)

Therefore, in the after-coronas, it is necessary to continue infection control measures for individuals such as the older generations and people with underlying medical conditions who are at high risk of serious illness.

On the other hand, consumers are restricted in their purchasing behavior by spatial interference and competition among customers in a retail environment with high customer density within a store. As a result, it has been confirmed that consumers' purchasing decisions are negatively affected, resulting in lower satisfaction (Eroglu et al., 2005). Therefore, in terms of large-scale facility management, a system to ensure social distance is still essential in tourist attractions, commercial facilities, and other places where many people usually gather, and there is a high demand for being able to check the level of congestion in an environment where people tend to gather before visiting.

1.2 Previous work

An example of a familiar means for consumers to obtain local congestion information in advance is the "Congestion Radar" published on the web by Yahoo! (Yahoo! JAPAN,2023). Fig. 2 shows an example of the "Congestion Radar" display of congestion in the vicinity of Tokyo Station (Japan). The "Congestion Radar" visualizes the degree of congestion on a heat-map-like color-coded map of Yahoo! Japan by generating statistics of user location information based on the usage of applications provided by Yahoo! As shown in Fig. 3, EXPOCITY (Japan), a large-scale commercial facility, uses existing technology to visualize the traffic volume aggregated by sensors that detect intrusion and passage in a color-coded format, allowing users to view parking lot congestion on the official homepage. These are all abstract and have the disadvantage that it is difficult to confirm the state of each part of a commercial facility and the distribution of individual people, making it difficult to visualize the state of congestion. In addition, many technologies detect and visualize people using monitor cameras inside facilities (Hitachi, Ltd, 2020, for example). However, since it is necessary to install multiple cameras in a wide area to check and compare the field of view individually, the operation of existing monitor cameras is costly in terms of the number of cameras installed, and there are also limitations in terms of the stability and comprehensiveness of the images. As a study to visualize human distribution from monocular wide-field images, the authors have conducted 3D modeling of the target space based on SfM (Structure from Motion) and human detection and tracking processing by machine learning from images captured by a 360 deg camera and mapped them onto a 3D model of the site and demonstrated its effectiveness in principle (Muraoka et al., 2022). However, this method has drawbacks in systemization regarding scalability and continuous operation since the 3D data of each site is regenerated each time it is photographed to update the information on the distribution of people. In addition, because the people's distribution is visualized on the 3D model of the site, it was not easy to grab the surrounding location relationships and thus limits readability for users as a map.

2. PROPOSED METHOD

2.1 Outline of the proposed method

To solve the above problem, this study proposes a method of displaying and updating congestion information on a floor map, as shown in Fig. 4, by moving around while taking pictures with an omnidirectional camera carried by security guards or regular base patrol officers in large commercial premises where people move in and out relatively frequently. Fig. 5 shows the processing steps of the proposed method. First, an omnidirectional camera captures images of the surroundings while moving around the target site. Using the photos from the video frames as input for the SfM process, which performs 3D reconstruction of the target scene, and a 3D coordinate system is constructed. As shown in Fig. 6, the captured video is processed for large-scale sites by dividing it into multiple areas. SfM is performed for each area to generate a 3D reconstruction and coordinate system. The video is zenith-corrected so that the vertical axis direction of the image is aligned with the vertical direction of the SfM model. Next, a coordinate transformation equation from the SfM model coordinates to the image coordinates of the floor map image of the facility is calculated by solving a point set matching problem, and the positional relationship between the SfM model and floor map for each patrol position is mapped as shown in Fig. 7. The above process is the preliminary processing performed only at the beginning.

In the person placement process, the same zenith correction processing as above is performed on video frames taken by security guards and others during their patrol duties, and the video data is stored in the cloud service. The video frames are used as input for person detection and tracking. Fig. 8 shows a person detection and tracking process for a video image V taken at a particular location. A specific detector detects multiple targets to be tracked in each video frame, and the same ID is assigned to the same target tracked from frame to frame. In a group of images obtained at regular intervals from video frames (Frame t in Fig. 8), the information on the same person in the frames is integrated to determine whether the object detected as a person in each image is new. If the person is newly detected, the image in which the person is detected is added to the set of input images for SfM. When SfM is executed again, the coordinate system that has already been generated is maintained, and the information of the added image is processed incrementally to calculate the coordinates of the shooting position of the new image. Then, the coordinates of the feet of the new person in the image are obtained, and the person's position in the SfM model is calculated based on the relationship with the camera coordinates. In this way, the distribution of persons can be additionally and successively updated in a consistent coordinate system.

The position of a person on the floor map is calculated by transforming the coordinates from the previously calculated SfM coordinates to the floor map image, and a symbol of the person's size is placed. The symbols on the floor map are then deleted each time data captured by the omnidirectional camera is input, and the map displaying the distribution of people is updated at each time based on the input timestamps. Even over a wide area, the map can be updated piecemeal, corresponding to the location relation on the floor map. SfM is performed on the video frames captured in each area. In this way, the system patrols and displays the positions of persons on the floor map, providing the user visualization of congestion in advance.

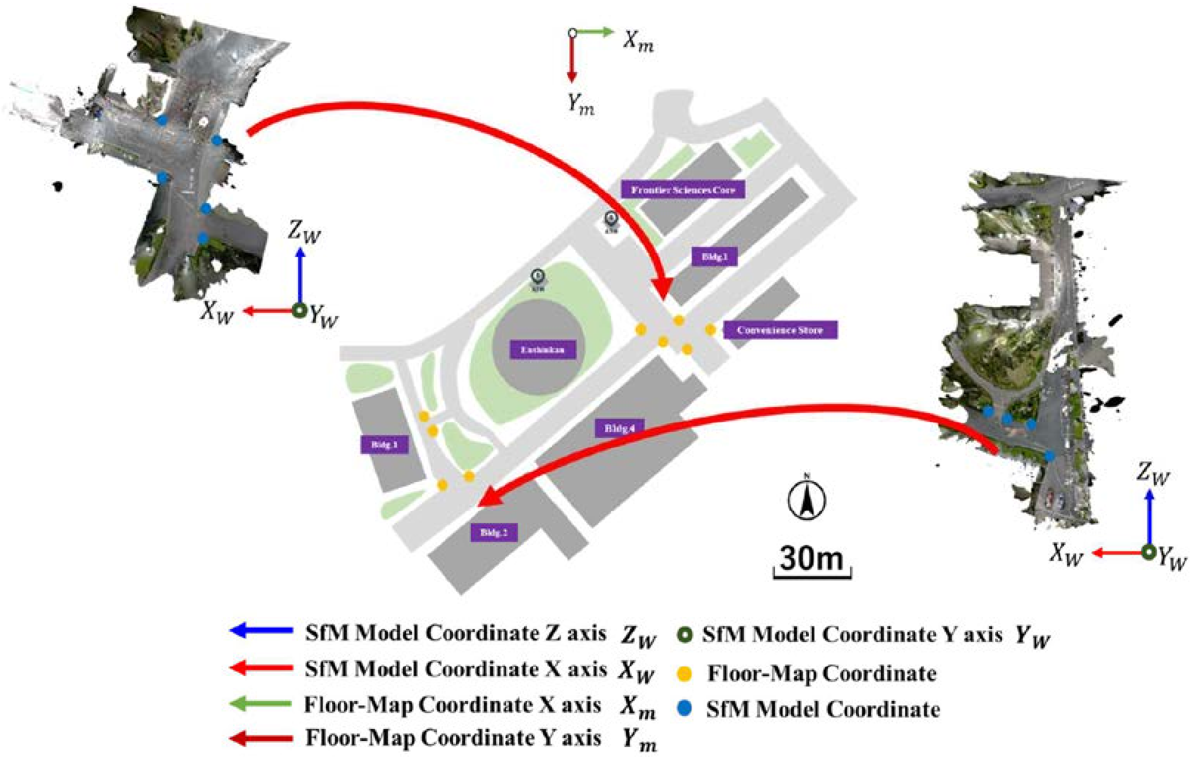

Fig. 7: Mapping examples of SfM model coordinates to the floor map coordinate

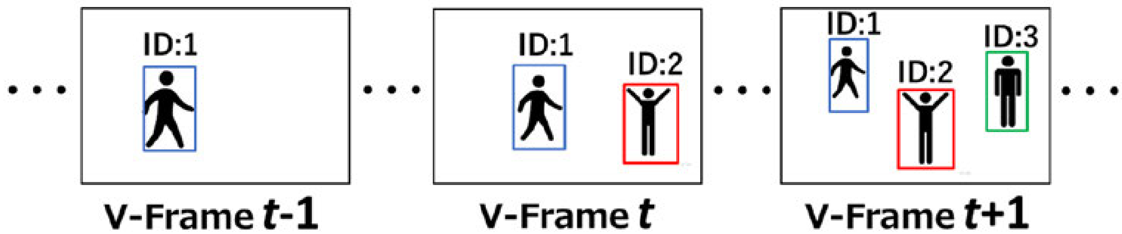

Fig. 8: Human detection and tracking through consecutive frames

2.2 Identification of the human's position

In identifying the standing position of a human on the floor map, the first step is to obtain the pixel positions (a, b) of the feet of the person in the omnidirectional image with width W px and height H px, as shown in Fig. 9. Since the height direction of the omnidirectional image corresponds to the Y_c axis of the camera coordinates through the zenith correction process, as shown in Fig. 10, let θ_1 be the angle between the vertically downward direction of the omnidirectional camera and the line-of-sight direction through the human's feet, and θ_2 be the azimuth angle of the person's feet based on the Z axis of the camera coordinates, $\theta_1 = \pi a/H$ and $\theta_2 = 2\pi b/W$ and The following is a calculation of the azimuth angle between the ground and the origin of the camera coordinates. Next, the height h from the ground to the origin of the camera coordinates is the difference between the Y_w coordinates of each camera and the Y_w coordinates of the point cloud of the ground detected by plane estimation using RANSAC (M. A. Fischler et al.,1981) on the point cloud data obtained by the 3D reconstruction process of the target site. In the X_c-Z_c plane of the camera coordinate system, if the distance from the origin to the person is d, the position of the human (X, Z) projected onto the X_c-Z_c plane is obtained by the following equation.

$$d = h \tan\theta_1 \qquad (1)$$

$$X = d \sin\theta_2 \qquad (2)$$

$$Z = d \cos\theta_2 \qquad (3)$$

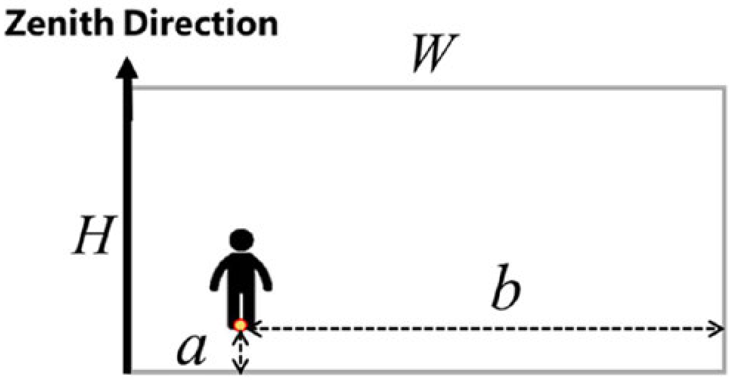

Fig. 9: Position of a person in an omnidirectional image

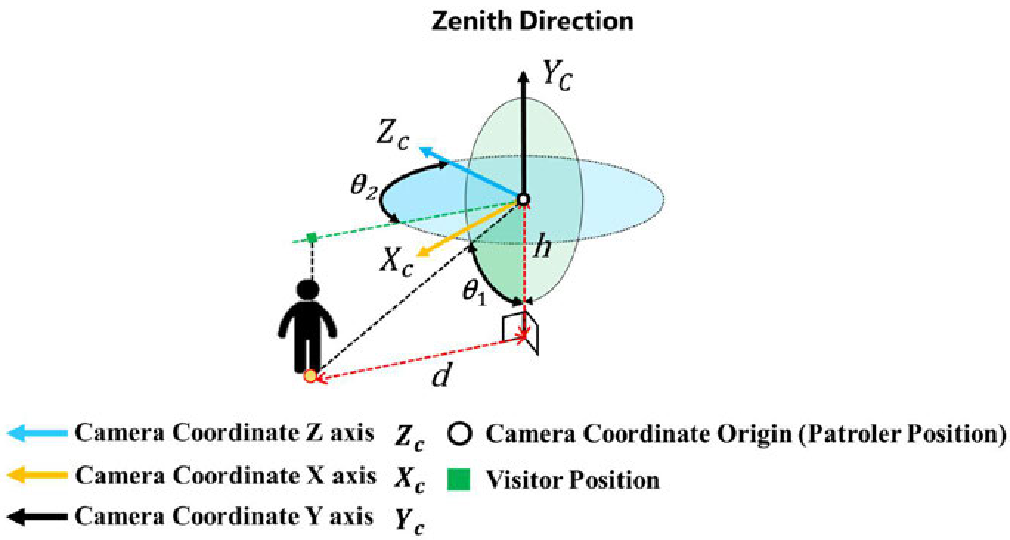

Fig. 10: Position of the camera and the person

Fig. 11 shows the relationship between the SfM model's coordinate system and each camera's coordinate system for each video record. The position of the camera coordinate system is the coordinate system calculated by SfM, which is also the position of the patrolman. Since the Y_c axis of the camera coordinate system and the Y_w axis of the SfM model correspond to the zenith direction, the positions of the persons detected at each shooting point can be integrated into the same coordinate system by rotation and translation on the X_w - Z_w plane. Let $R(\varphi)$ be the rotation and (t_x, t_z) be the camera position relative to the world coordinate; the position of a person (X_w , Z_w) in the 3D model can be calculated from the local camera coordinate (X ,Z) by equation (4).

$$\begin{bmatrix} X_w \\ Z_w \end{bmatrix} = R(\varphi) \begin{bmatrix} X \\ Z \end{bmatrix} + \begin{bmatrix} t_x \\ t_z \end{bmatrix} \qquad (4)$$

Next, the coordinate system X_m-Y_m plane of the floor map image of the facility and the X_W-Z_W plane of the SfM model coordinate system can be transformed into the position of the human on the SfM model by rotation φ_w around the Y axis in the SfM model coordinate system and translation shift, as before. Let S be a scaling matrix, R(φ_w) be a rotation matrix, and the origin coordinates (m_x, m_y) of the SfM model coordinate system in the X_m-Z_m plane and the human's position (X_m, Y_m) can be calculated as follows.

$$\begin{bmatrix} X_m \\ Y_m \end{bmatrix} = S \cdot R(\varphi_w) \begin{bmatrix} X_w \\ Z_{w'} \end{bmatrix} + \begin{bmatrix} m_x \\ m_y \end{bmatrix} \quad (5)$$

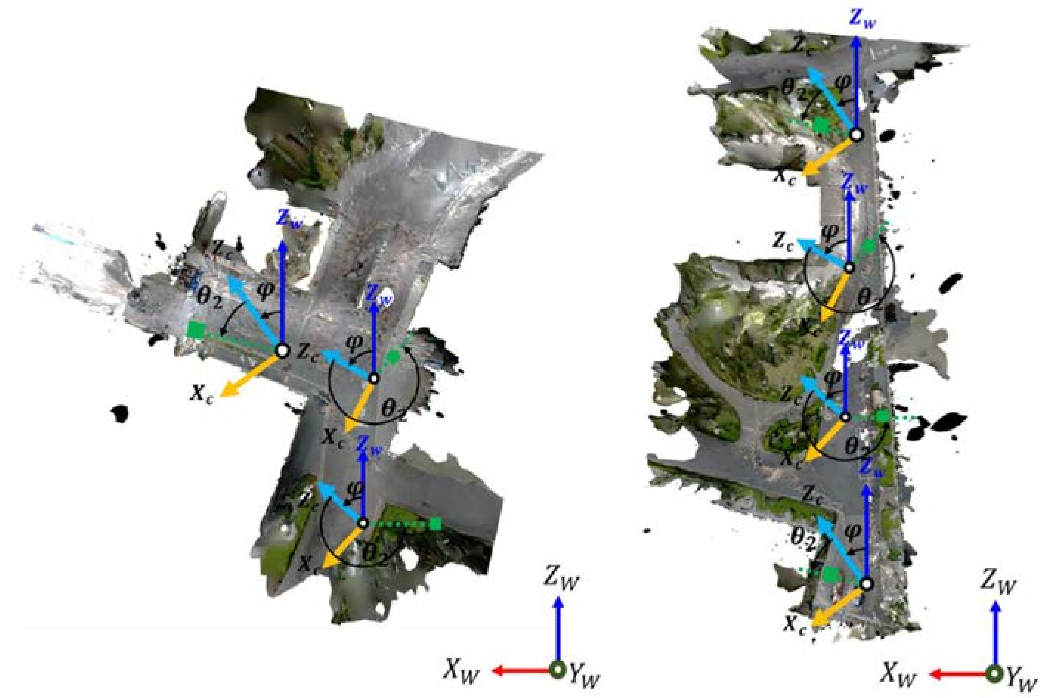

Fig. 11: Relationship between the SfM model coordinate X_w-Y_w-Z_w and the coordinates of the moving camera

3. EXPERIMENT

3.1 Equipment

For the experimental environment, we used a location in front of a convenience store on the Senri-yama campus of Kansai University (area (i) in Fig. 6), assuming a commercial facility crowded with many people. Theta X (RICHO) was used for the omnidirectional camera, with a video resolution of 5760 × 2880, Metashape Professional (Agisoft) for SfM, YOLO-X (Z. Ge et al.,2021) was used for the human detection model, and motpy (motpy - simple multi-object tracking library, 2022) was used for human tracking, as it is easy to combine various object detection models and OpenCV, an image processing library, was used to display the location of the person on the floor map of the target site.

3.2 Construction of coordinate system

As shown in Fig. 12, a 3D reconstruction based on SfM was performed using 91 images taken at the site, and a coordinate system was constructed. The average error was approximately 0.05 m. The number of tie points was approximately 4.7. The number of tie points was about 47,000, and the RMSE (root mean square error) of the re-projection of the feature points estimated from the image set onto the original image was about 3.0 pixels, indicating that the 3D shape is generally accurate. In the mapping between the coordinate system of the SfM model and that of the floor map, first, we visually picked up the corners of buildings and roads in each coordinate system to prepare five pairs of coordinates of (X_w, Z_w) and (X_m, Y_m). Next, the distance from the center of gravity of the five points to each of the five points in each coordinate was calculated, and the average value was calculated. There is a method to calculate the rotation matrix and translation vector in the point set matching problem by SVD (singular value decomposition) (K.S.Arum et al.,1987). In this study, $R(\varphi_w)$ and (m_x, m_y) are calculated by SVD. 5 points on the SfM model are transformed to positions on the floor map by equation (5). The results displayed on the floor map are shown in Fig. 13. The exchanged positions of the five points on the floor map generally corresponded to those of the five points on the SfM model.

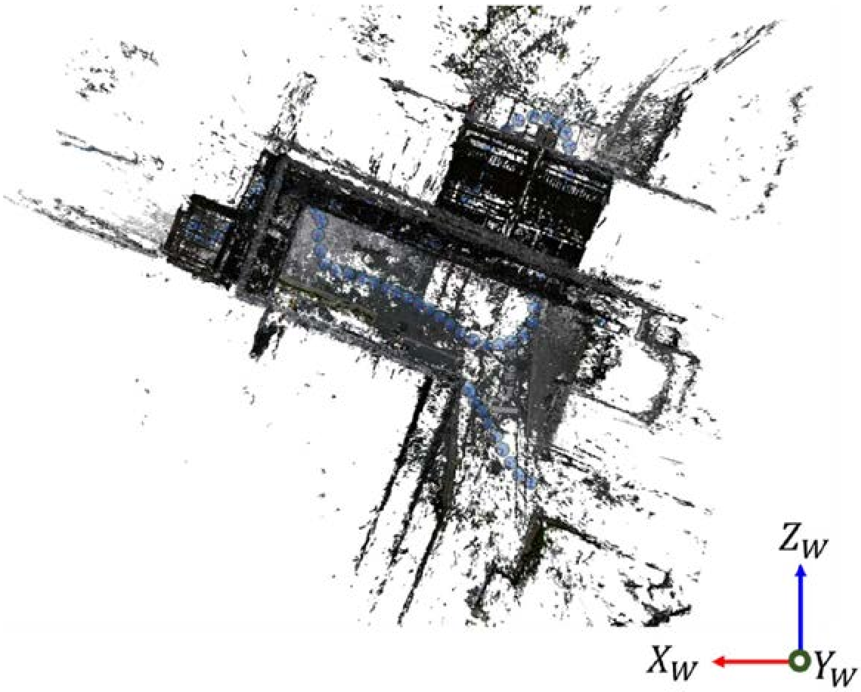

Fig. 12: 3D model and camera shooting position: The blue sphere indicates the shooting position.

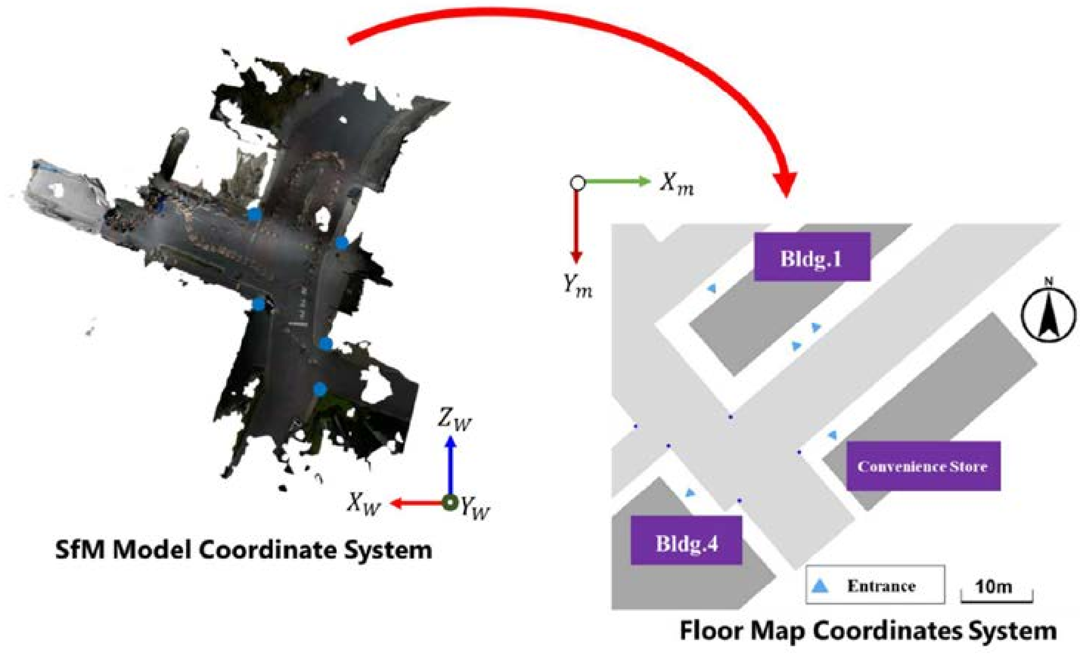

Fig. 13: Correspondence between SfM coordinate system and floor map coordinate system：
blue dots indicate 5 points in each coordinate system

3.3 Integration and display of person location information

YOLO-X was used for performing human detection for obtained image set from each section's video, as shown in Fig. 14. If the detected person has been tracked from a previous image frame by motpy using the video as input, the detected human is integrated into the existing person's information. If the human was not tracked and was newly observed, the observed image was used to estimate the camera position in the coordinate system of the SfM model, and the camera coordinates were calculated. The coordinates of the human's feet and the coordinates of the floor map were used to calculate the position coordinates of the human using Equations (1)-(5) and displayed on the floor map (Fig. 15, 16, and 17). The positions of the people mapped on the floor generally corresponded to the original images, and their positions about the buildings were also confirmed. However, because YOLO-X can detect people even in the case of body parts, and because the images are taken while moving, there are many cases where people in occlusion due to occlusion can be observed and mapped in other locations, making it possible to visualize the distribution of the people quantitatively. In addition, we were able to confirm changes in the degree of crowding at different times, such as around noon (Fig. 15), when the area is crowded at lunchtime, there is extreme crowding near the store entrance, many people move during class breaks (Fig. 16), and the area is empty during class (Figure17). Area (ii) in Fig. 5 was also patrolled around noon on the same day. The distribution of people observed was displayed on the floor map in the same manner as above (Fig. 18). As a result, it was possible to visualize the occurrence and resolution of queues and crowding of people near building entrances and the vicinity of stores, depending on the time of day. In a wide area, it was confirmed that information on the distribution of people could be updated for different areas in parallel by patrolling the area with several people. These functions are practical for visitors and others to know the trend of human distribution.

Fig. 14: Human detection using YOLOX for an omnidirectional image

4. CONCLUSION

In this study, we proposed a method for mapping and updating the distribution of people on a floor map in a fragmented manner, even over a wide area, simply by walking around the site and taking pictures with an omnidirectional camera and confirmed the method's effectiveness through experiments. The proposed method cannot perform synchronized observations because both the observer and the visitor are moving. However, it requires far fewer cameras and is equivalent to observing from many viewpoints because of the moving point observation. Therefore, parallel software processing of visitor observation and mapping will be highly cost-effective in terms of implementation and operation. Although the visitor mapping has time deviations depending on the location of the observation, visualization of the updated time together with the map will help understand the distribution of congestion. In future work, the authors plan to investigate a method of real-time mapping by online processing using the live streaming function of the camera and to construct a system that allows users to view maps showing the distribution of people on the Web.

ISAFE WELDING SYSTEM: COMPUTER VISION-BASED MONITORING SYSTEM FOR SAFE WELDING WORK

Syed Farhan Alam Zaidi, Rahat Hussain, Muhammad Sibtain Abbas, Jaehun Yang, Doyeop Lee & Chansik Park
ConTI Lab, Department of Architectural Engineering, Chung-Ang University, Seoul, South Korea.

ABSTRACT: *The construction industry faces significant challenges, including a high prevalence of occupational incidents, often involving fires, explosions, and burn-related accidents due to worker non-compliance with safety protocols. Adherence to safety guidelines and proper utilization of safety equipment are critical to preventing such incidents and safeguarding workers in hazardous work environments. Consequently, a monitoring system tailored for construction safety during welding operations becomes imperative to mitigate the risk of fire accidents. This paper conducts a brief analysis of OSHA rules pertaining to welding work and introduces the iSafe Welding system, an advanced real-time safety monitoring and compliance enforcement solution designed specifically for construction site welding operations. Harnessing the real-time object detection algorithm YOLOv7 in conjunction with rule-based scene classification, the system excels in identifying potential safety violations. Rigorous evaluation, encompassing precision, recall, mean Average Precision (mAP), accuracy, and the F1-Score, sheds light on its strengths and areas for improvement. The system showcases robust performance in rule-based scene classification, achieving high accuracy, precision, and recall rates. Notably, the iSafe Welding system demonstrates a formidable potential for enhancing construction site safety and regulatory compliance. Ongoing enhancements, including dataset expansion and model refinement, underscore its commitment to real-world deployment and its strength in ensuring worker safety.*

KEYWORDS: *Safety monitoring, scene classification, welding work, fire prevention, construction safety, OSHA rules compliance*

1. INTRODUCTION

The construction industry exhibits a pronounced prevalence of both fatal and non-fatal occupational incidents on a global scale (Hussain et al., 2022; Khan et al., 2023). Among the significant contributors to these casualties and injuries are fires, explosions, and burn-related incidents, often stemming from workers' non-adherence to precautionary safety protocols during hot work. The primary causes of fires at construction sites encompass highly flammable substances, including foam insulation, gas cylinders, chemical storage facilities, and oil-based paints. The proximity of these materials to welding and cutting activities can serve as a precipitating factor for fires at construction sites (Xu et al., 2022). According to the Occupational Safety and Health Administration (OSHA) accident database, a total of 80 accidents occurred between July 2019 and July 2023 related to burning incidents at construction sites attributed to welding and cutting work. Among these recorded incidents, 22 were categorized as fatalities. These accidents occur when workers fail to utilize safety gear properly or neglect its use altogether, leading to exposure to various hazards such as chemical splashes, flying debris, intense light, harmful fumes, and more (Nill, 2019). For instance, during welding or cutting operations, the absence of proper eye protection can result in severe eye injuries, potentially leading to temporary or permanent vision loss. Additionally, if a worker does not take necessary precautions while performing welding or cutting tasks, and flammable materials or chemicals are stored nearby, there is a significant risk of explosions or fires at the workspace, posing serious harm to the worker. It is essential for workers to adhere to safety guidelines and utilize the appropriate safety equipment to prevent such incidents and safeguard their well-being in hazardous work environments.

Nowadays, computer vision (CV) techniques have found applications in monitoring construction sites across various construction scenarios (Jeong et al., 2017). However, with regard to welding processes, researchers have focused on areas such as identifying welding defects (Ramadan et al., 2023; Wu et al., 2023), welding bead detection (JOHN, 2023), detecting welding quality (Yang et al., 2018), and classifying welding types (S. Chen et al., 2023; H. Liu et al., 2023). Chen et al. proposed YOLOv5 based welding helmet use detection during the welding work (W. Chen et al., 2023). However, it is worth noting that there have been relatively limited efforts directed towards ensuring compliance with safety regulations or implementing monitoring mechanisms specifically during welding operations. Hence, the need for a comprehensive monitoring system in construction safety during welding operations is evident, primarily to mitigate the risk of fire accidents. To enhance safety at the construction site, this paper briefly analyzes OSHA rules related to welding work. Further, a computer vision-based monitoring system, "iSafe Welding System," is proposed to ensure compliance with safety protocols during

welding work. The Convolution Neural Network (CNN)-based You Only Look Once (YOLO) version 7 model is trained for the object detection module, and a rule-based algorithm is developed to assess safety rules compliance that classify the scene as “safe” or “unsafe”. Moreover, a new dataset is collected from construction jobsite, web image scrapping, and generated synthetic data from OpenAI’s DALL.E.2.

2. SAFETY RULE ANALYSIS

The OSHA rule 1910.252 pertains to hot work, encompassing welding, cutting, and brazing activities. This regulatory framework is forked into distinct sections: section (a) addresses fire prevention and protection, while section (b) is devoted to personnel protection, encompassing guidelines pertaining to personal protective equipment (PPE) usage and the safe positioning of welding cables and equipment. A careful examination of these regulations reveals that, during the execution of welding operations, workers are mandated to use welding-specific PPE. Furthermore, provisions necessitate the presence of a fire extinguisher in close proximity, the employment of fire prevention measures such as the utilization of fire prevention nets, a prohibition on the presence of insulation or foam in the safe area, and the maintenance of a safe distance from chemicals and gas cylinders during welding activities. For a comprehensive exposition of OSHA rule 1910.252 relevant to welding, along with an outlining of requisite detection objects, readers are directed to Table 1 for further interpretation.

Table 1. The details of OSHA rule 1910.252 related to welding and objects require for detection

Sr. No.	Rule Code	Description	Objects
	a) Fire prevention and protection		
1	(a)(1)(ii)	Use guards to confine heat, sparks, and slag	Fire prevention Net
2	(a)(2)(i)	Combustible Material - Prevent exposure to sparks through floor openings, cracks, walls, doorways, and windows	
3	(a)(2)(ii)	Fire Extinguishers - Maintain ready-to-use fire extinguishing equipment	Fire Extinguisher
4	(a)(2)(iii)(A)(1)	Combustible material in building construction or contents closer than 35 feet (10.7 m) to the point of operation.	Flammable Material
5	(a)(2)(iii)(A)(2)	Appreciable combustibles are more than 35 feet (10.7 m) away but are easily ignited by sparks.	
6	(a)(2)(iii)(A)(3)	Wall or floor openings within a 35-foot (10.7 m) radius expose combustible material in adjacent areas including concealed spaces.	
7	(a)(2)(iii)(A)(4)	Combustible materials are adjacent to the opposite side of metal partitions, walls, ceilings, or roofs and are likely to ignite.	
	b) Protection of personnel		
8	(b)(1)(ii)	Protection of Personnel - Clear placement of welding cable and equipment	Welding machine
9	(b)(2)(i)(A-D)	Eye Protection - Helmets or hand shields for arc welding and cutting	Worker and Helmet with eye shield (PPE)
10	(b)(2)(i)(B)	Eye Protection - Goggles or suitable eye protection for gas welding or oxygen cutting	
11	(b)(2)(i)(C)	Eye Protection - Transparent face shields or goggles for resistance welding or resistance brazing	
12	(b)(2)(i)(D)	Eye Protection - Suitable goggles as needed for brazing operations	

3. METHODOLOGY

This section describes the comprehensive methodology employed in the development and implementation of the “iSafe Welding system”, which comprises three main steps: dataset collection and preparation, training object detection model, and safety rules compliance. The details of these steps are as follows:

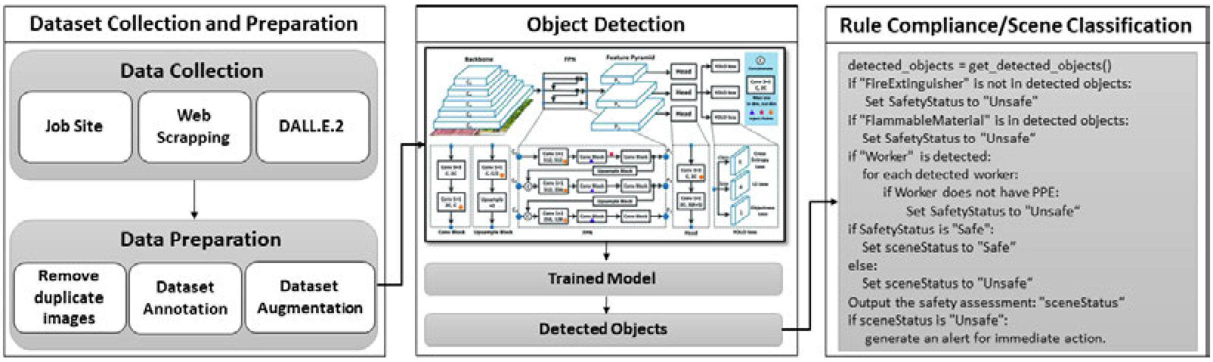

Fig. 1. Methodology for training iSafe Welding System

3.1 Dataset Collection and Preparation

The dataset employed in this research comprises 633 meticulously curated images collected from construction jobsite, web image scrapping, and generated synthetic data from OpenAI’s DALL.E.2. The dataset was divided into training (511), validation (61), and testing (61) sets for the iSafe Welding system. This dataset includes 1,935 annotated instances, categorized into five classes: “Welding Equipment” (621 instances), “Worker with PPE” (607 instances), “Welding Machine” (348 instances), “Fire Extinguisher” (197 instances), and “Flammable Material” (162 instances). These categories represent essential elements and scenarios within welding environments, emphasizing equipment, worker safety, welding machinery, fire prevention measures, and flammable material management. The roboflow platform is used for annotating dataset by drawing bounding boxes. For data augmentation, a series of transformative techniques are employed exclusively on the training dataset using roboflow. These augmentation methods included horizontal flip, shear, hue adjustment, brightness variation, exposure modification, cutout, and the mosaic technique. The training set was increased 3 times of original training set after augmentation.

3.2 Training Object Detection Model

In pursuit of real-time object detection capabilities, iSafe Welding has strategically adopted single-stage detection algorithms. These algorithms are renowned for their efficiency and speed, offering high frame-per-second (fps) rates for rapid and real-time object detection (Diwan et al., 2023). The decision to favor single-stage detectors over two-stage detectors aligns with the project's primary objective of ensuring swift and accurate detection of objects during welding operations within the construction industry. In the realm of real-time object detection algorithms, two prominent options, Single Shot Multibox Detector (SSD) (W. Liu et al., 2016) and the YOLO series detectors, were considered for this research work. After careful evaluation, the YOLO series detectors were selected as the preferred choice due to their notable strengths in achieving a commendable balance between accuracy, as measured by mean Average Precision (mAP), and fps rates. Specifically, YOLOv7 (Wang et al., 2023) was chosen as the model of preference for training, enhancing its capabilities to excel in the task of object detection, a critical component of the iSafe Welding system aimed at enhancing safety and compliance during welding operations in the construction industry.

YOLOv7 is a single-stage anchor-based object detector that uses a custom backbone network and a new head network. The basic YOLO model architecture (Long et al., 2020) is shown in the object detection module of Fig. 1. The backbone is a convolutional neural network (CNN) that extracts features from the input image. YOLOv7 uses a modified ELAN architecture for the backbone, which is more efficient and has better learning ability than the original ELAN architecture. The head is responsible for predicting bounding boxes and object classes. YOLOv7 uses a single-stage head, which means that it predicts bounding boxes and object classes directly from the features extracted by the backbone and neck. YOLOv7 uses a new anchor box selection algorithm that is more efficient and effective than the algorithm used in previous YOLO models. This helps to improve the accuracy of the model, especially for small objects. YOLOv7 has a reduced parameter count and computation compared to previous YOLO models. This makes it faster and more efficient to run on devices with limited resources (Wang et al., 2023).

The training process of the model was conducted using hardware resources consisting of an Intel Core i9-10900 CPU, operating at 2.80GHz, complemented by 32 GB of RAM, and further accelerated by the inclusion of an RTX 3090 graphics processing unit, boasting 24 GB of dedicated memory. The model was trained on 300 epochs, with a batch size parameter set to 16, and an input image size established at 640x640 pixels. In pursuit of model optimization, the YOLOv7 framework uses the default Stochastic Gradient Descent (SGD) optimizer, initialized with a learning rate of 0.01, culminating in a final learning rate of 0.1. Additional optimization parameters encompassed a weight decay factor of 0.0005 and a momentum coefficient of 0.9, collectively contributing to the refinement of the model's performance.

3.3 Safety Rules Compliance/Rule-based Scene Classification

After conducting an in-depth examination of the OSHA regulation regarding welding work, as detailed in Section 2, significant and crucial findings were obtained. It was determined that the presence of specific safety parameters significantly impacts the safety status of a welding scenario. Specifically, if a welding task is being executed and no fire extinguisher is positioned in proximity, or if flammable materials are detected in the surrounding area, the scene is deemed unsafe as per OSHA guidelines. Furthermore, any detection results indicating the absence of PPE on a worker subsequently flag the scene as unsafe. Upon completion of the object detection module, the results are seamlessly transitioned to the safety rules compliance module. Herein, a algorithm is developed to examine the adherence to safety rules, discerning whether the detected scenario should be categorized as safe or unsafe, effectively enhancing safety and compliance during welding operations within the construction industry. The algorithm is described in Algorithm 1.

Algorithm 1: Safety Rules Compliance Module

Input: Results from the object detection module, including detected objects and their attributes.

Output: Safety assessment for the detected welding scenario, categorized as "Safe" or "Unsafe."

```
1. Initialize a variable SafetyStatus to "Safe"
2. if "FireExtinguisher" is not in detected objects:      // Check for the presence of a fire extinguisher
       Set SafetyStatus to "Unsafe"
3. if "FlammableMaterial" is detected:                    // Check for the presence of flammable materials
       Set SafetyStatus to "Unsafe"
4. if "Worker" is detected:                               // Check for worker PPE
       for each detected worker:
           if Worker does not have PPE:
               Set SafetyStatus to "Unsafe"
5. if SafetyStatus is "Safe":                             // Perform a final safety assessment
       Set sceneStatus to "Safe"
   else:
       Set sceneStatus to "Unsafe"
6. Output the safety assessment: "Safety Assessment: sceneStatus"
7. if sceneStatus is "Unsafe":
       Log safety assessment results and generate an alert for immediate action.
```

4. EVALUATION AND DISCUSSION

The evaluation of the iSafe Welding system encompassed two key aspects: object detection performance and rule-based scene classification. These assessments aimed to validate the system's efficacy in real-time safety monitoring and compliance enforcement within construction site welding operations.

4.1 Object Detection Performance

In the context of object detection, essential metrics such as precision, recall, and mean Average Precision (mAP) were rigorously calculated to gauge the system's ability to accurately identify and localize objects of interest. Concurrently, accuracy and the F1-Score were employed for scene classification as "safe" or "unsafe." The results are presented in Fig. 2 and Table 2. A significant observation is the disparity in mAP scores between the validation and test sets. The validation set exhibited a notably higher mAP, suggesting a degree of overfitting to the training and validation datasets. This phenomenon highlights the need for model refinement to enhance generalization capabilities and ensure reliable performance in real-world scenarios. The class-specific analysis reveals that the "flammable materials" class achieved a perfect recall of 100%. This remarkable recall rate can be attributed to the dataset's inherent limitation, featuring only a single type of flammable material. Conversely, the "welding equipment" class exhibited a 67.4% mAP on the test set, primarily due to the small and slender nature of these objects, rendering them challenging to detect accurately.

Table 2. Result of object detection model on validation and testing set with confidence threshold 0.5

Dataset	**Precision %**	**Recall %**	**mAP@0.5 %**
Validation set	97.9	97.9	99.2
Test Set	80.5	92.6	88.5

Fig. 2. Object detection and scene classification results of iSafe Welding System

4.2 Rule-Based Scene Classification

The rule-based scene classification component of the iSafe Welding system demonstrated its effectiveness in categorizing scenes as "safe" or "unsafe." The testing dataset was thoughtfully divided into these two categories, yielding 14 images classified as "safe" and 47 as "unsafe." Applying Algorithm 1 to these scenes led to notable results. The achieved accuracy, precision, recall, and F1-score of 96.72%, 97.87%, 97.87%, and 97.8%, respectively, underscore the algorithm's proficiency in accurately classifying scenes based on safety criteria. These outcomes affirm the algorithm's potential to enhance safety compliance and enforcement in the context of welding operations.

4.3 Future Directions

To address the observed issue of overfitting and to further enhance the system's capabilities, future efforts will primarily focus on expanding the dataset. Additionally, while the dataset used in this study inherently ensures that all depicted workers are equipped with PPE, future dataset extensions will include instances of workers without PPE. Furthermore, this expansion will involve the inclusion of various flammable materials and augmenting the dataset with a more diverse set of welding scenarios set in varied environmental contexts. Such measures are anticipated to significantly enhance the model's generalization and real-world applicability. As the OSHA rules require proximity between welding equipment and flammable materials as shown in Section 2, the future work will utilize real-sense camera to find distance between objects to calculate safe distance. Further, the updated algorithm will classify scene as safe or unsafe based on the safe distance.

5. CONCLUSION

Computer vision techniques have emerged as valuable tools for enhancing safety and efficiency on construction sites. While previous research has concentrated on aspects such as defect identification, welding bead detection, quality assessment, and type classification, there has been a noticeable gap in addressing safety compliance during welding operations. This gap underscores the need for a comprehensive monitoring system to mitigate the risk of fire accidents and ensure compliance with safety regulations. This paper has provided a brief analysis of OSHA rules related to welding work and introduced the iSafe Welding System, a computer vision-based monitoring solution designed to uphold safety protocols during welding operations. The integration of the YOLOv7 model for object detection, along with a rule-based algorithm for safety rule assessment, represents a robust approach to classifying scenes as safe or unsafe. Furthermore, the creation of a new dataset, comprising data from construction job sites, web image scraping, and synthetic data generated using OpenAI's DALL.E.2, enhances the system's adaptability and accuracy. The evaluation results demonstrate the system's effectiveness in real-time safety monitoring and compliance enforcement within construction site welding operations, with high precision and recall rates. The iSafe Welding System offers the potential to significantly improve workplace safety in the construction industry. By addressing the critical need for safety monitoring during welding, this system contributes to a safer construction environment, reducing the potential for accidents and improving overall workplace safety. Its applications extend to various industries requiring safety compliance and object detection, making it a valuable asset for enhancing safety and efficiency in dynamic work environments.

COMPUTER VISION-BASED MONITORING FRAMEWORK FOR FORKLIFT SAFETY AT CONSTRUCTION SITE

Muhammad Sibtain Abbas, Aqsa Sabir, Nasrullah Khan, Syed Farhan Alam Zaidi, Rahat Hussain, Jaehun Yang & Chansik Park
ConTI Lab, Department of Architectural Engineering, Seoul, South Korea.

ABSTRACT:

Efficient forklift operation is critical for construction site safety and project progress; yet, the construction industry deals with recurrent issues, including unauthorized forklift operation, operator drowsiness, visibility challenges, blind spots, and load placement errors. This paper introduces the "iSafe ForkLift," a comprehensive safety framework powered by computer vision, specifically designed to tackle these multifaceted safety challenges associated with forklift operations. The framework provides an array of integrated solutions, encompassing facial recognition for authorization, anomaly detection for behavior monitoring, stereo cameras for improved visibility, blind spot solutions, and load placement monitoring. Aligned with OSHA safety standards, it offers opportunities for enhanced forklift safety by addressing a broad spectrum of potential risks within a single, efficient framework. Systematically addressing multiple safety risks within this unified framework significantly elevates overall safety. Future studies should prioritize enhancing technology by merging computer vision with IoT to boost precision and safety, especially on challenging terrains, thereby elevating construction industry standards' reliability.

KEYWORDS: *Forklift operations, Computer vision, Safety framework, Operator drowsiness, Visibility challenges, OSHA standards, Regulatory compliance*

1. INTRODUCTION

The construction industry, characterized by its dynamic and complex nature, is a realm where innovation and risk coexist. Here, heavy earth-moving machines, including forklifts, are integral, performing tasks that are pivotal for project progression. Forklifts are indispensable tools in this regard, capable of swiftly transporting heavy loads to various locations within the site. However, the operation of such machinery is filled with risks. Accidents involving heavy earth-moving machines are not uncommon and have led to severe, sometimes fatal, consequences, underscoring the critical need for enhanced safety protocols. Approximately 75 to 100 workers lose their lives in forklift accidents annually, with an average of roughly 87 fatalities per year. This number has seen a nearly 30% increase over the past decade (Forklift Accident Statistics, n.d.). According to the OSHA database, 1117 accidents occurred just because of forklifts (OSHA, 2023a). Operating forklifts on construction sites poses various challenges and risks, from unauthorized personnel attempting to use them to blind spots and improper load placement. Notably, there has been a pressing need to propose a comprehensive solution for these challenges, yet no researcher has put forward an all-encompassing approach to address them concurrently.

iSafe ForkLift, a state-of-the-art monitoring framework powered by computer vision, is meticulously proposed to tackle the multifaceted safety challenges associated with forklift operations. The suggested framework provides a range of solutions: (1) Authorization through Face Recognition: Leveraging a camera installed within the forklift, the system ensures that only authorized personnel can operate the machinery. By utilizing advanced face recognition algorithms, it verifies the identity of the operator in real-time, preventing unauthorized access. (2). Anomaly Detection for Driver Behavior: Beyond just authorization, the system is equipped to monitor the behavior of the operator. Through anomaly detection algorithms, it can identify signs of Drowsiness. Detecting signs such as frequent yawning, heavy eyelids, or nodding off, which can be particularly dangerous when operating heavy machinery, Distraction or Physical Discomfort, or other abnormal behaviors, prompting immediate intervention. (3). Enhanced Visibility with Stereo Cameras: Addressing the perennial issue of sight blocks, stereo cameras are installed to provide drivers with a hidden view. This feature not only enhances visibility but also offers real-time data on the distance between the forklift tip and nearby objects, aiding in precise navigation. (4). Blind Spot Solutions: Blind spots, a significant hazard in forklift operations, are mitigated through strategically placed signalers or mirrors. Computer vision techniques continuously monitor these areas, ensuring that they remain clear and alerting the driver to potential obstructions. (5). Load Placement Monitoring: The proper placement of loads on the forklift's tipover is crucial for stability. Using cameras and computer vision techniques, the system assesses the positioning of loads, ensuring they are securely and correctly placed.

2. CURRENT MONITORING TECHNIQUES FOR SAFE FORK OPERATIONS

Forklifts encounter several safety challenges, particularly in dynamic construction environments where loading and unloading activities are prevalent. While forklifts find extensive utilization in construction, the risk of accidents in such contexts is significantly elevated compared to other operational settings. Presently, a range of monitoring techniques are employed to mitigate these safety concerns. While there isn't a specific study focused on checking the authorized forklift operators for driving, numerous authors have explored the issue of abnormal driver behavior. Much attention has been devoted to the development of methods for detecting anomalies in this context (Amin et al., 2023; Okan & Rigoll, n.d.). Blind spot problem has been addressed by different researcher, (Shete et al., 2021) The implementation of an ultrasonic sensor to detect nearby obstacles in a forklift is an effective safety measure. However, to address blind spots and obstacles approaching from corners, the integration of convex lenses at these specific locations becomes imperative. These convex lenses serve as additional visual aids, enhancing the forklift operator's field of vision and ensuring a more comprehensive obstacle detection system Moreover, established standards dictate that forklift operation is restricted solely to authorized personnel, representing a fundamental safety measure in this context. This paper investigates factors influencing forklift operator safety and efficiency, including energy usage, training, IoT integration, ergonomic considerations, and worker drowsiness (Mediavilla, 2023). Emphasizing the significance of the matter, previous research did not encompass critical aspects of forklift operations utilizing computer vision technology, such as driver authorization, detecting abnormal behavior, mitigating blind spots, and optimizing load placement. Nevertheless, OSHA has played a vital role in addressing these factors, recognizing that neglecting them can result in severe accidents. These considerations are pivotal in the context of safety rules analysis, a topic to be elaborated on in the following section.

3. SAFETY RULES ANALYSIS

OSHA has established several crucial safety standards for industrial truck operations to mitigate risks and ensure workplace safety (OSHA, 2023b). These standards include prohibiting unauthorized individuals from riding on industrial trucks (1910.178(m)(3) & 1910.178(l)(3)). This measure prevents potential accidents such as falls, entanglements, or collisions that could result from non-operators being on board. Additionally, operators are required to avoid driving industrial trucks toward individuals positioned in front of fixed objects (1910.178(m)(1)). This rule emphasizes the importance of operator awareness and vigilance to prevent collisions that could lead to severe injuries or fatalities. Operators are also expected to maintain a forward-facing orientation while operating industrial trucks (29 CFR 1910.178(n)(4) & 29 CFR 1910.178(n)(6)). This enhances visibility, reducing the risk of accidents, especially in areas with pedestrian traffic or confined spaces. Furthermore, proper load handling is emphasized through the standards that require loads to be secure and correctly positioned (29 CFR 1910.178(o)(1) & 29 CFR 1910.178(o)(2)). Ensuring load stability is vital in preventing accidents such as tip-overs, which can result in injuries, equipment damage, and hazardous material spills. Lastly, while not explicitly stated in the provided standards, it is crucial for drivers to remain attentive (Abnormal Behavior - General Rule). This means avoiding behaviors that could distract them or impair their ability to operate the vehicle safely, as such actions can lead to accidents and must be strictly prohibited. Table 1 outlines OSHA regulations, providing their associated particulars along with proposed solutions.

Table 1 Safety Rules for Forklift

Sr. No	OSHA Standards	Description	Case Scenario	Proposed Solutions
1	1910.178(m)(3) & 1910.178(l)(3)	No unauthorized operator riding on trucks	Unauthorized Person	Face Recognition
2	1910.178(m)(1)	Never drive trucks toward anyone in front of fixed objects	Struck by	Depth Estimation/Object Detection
3	29 CFR 1910.178(n)(4) 29 CFR 1910.178(n)(6)	The driver must face forward path	Blind Spot/Blocked Vision	Signaler/Barriers/Mirrors
4	29 CFR 1910.178(o)(1) 29 CFR 1910.178(o)(2)	Secure and properly positioned loads	Tip over	Measure distance of load placement on fork tip
5	General rule	Driver must be attentive	Abnormal Behavior	Anomaly Detection

4. PROPOSE FRAMEWORK

This paper introduces a safety-oriented computer vision framework comprising five distinct modules: Signaler Detection, Face Recognition, Anomaly Detection, Signaler Detection, Load Monitoring, and Visibility Enhancement. These modules are seamlessly integrated into a central server, responsible for processing and storing information in a database. Additionally, the system is designed to trigger alarms whenever an unsafe event is detected. The setup employs three cameras: Models 1 and 2 are affixed to internal cameras to monitor operators and identify abnormal behaviors, meanwhile Model 3 utilizes a depth camera mounted on the tip of a forklift to improve visibility and Models 4 and 5 are connected to the Signaler Detection and Load Placement Monitoring components, respectively as depicted in Figure 1.

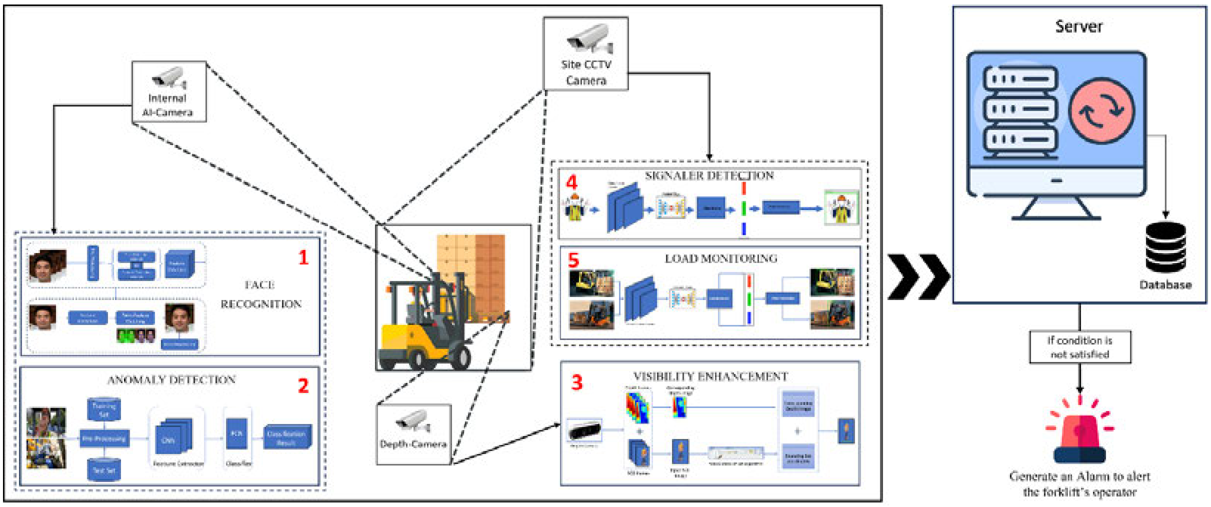

Figure 1: Forklift Operations Framework

4.1 Authorization through face recognition

The proposed framework for authorization employs an advanced facial recognition methodology for identity verification and access control, utilizing cutting-edge algorithms and computational methodologies to scrutinize facial features meticulously as shown in Figure . This comprehensive process initiates with capturing a facial image, subsequently contrasting the unique characteristics of this image against a meticulously curated database of stored facial templates. The seamless integration of state-of-the-art deep learning models, specifically Convolutional Neural Networks (CNNs) (Li et al., 2022), ensures the proficient extraction and meticulous analysis of detailed facial features, granting a high degree of accuracy and security in identity verification. This method emerges as crucial in numerous secure environments, providing swift and efficient determination of access eligibility predicated on the consequential recognition results. The scientific orchestration of our face recognition for authorization unifies the two stages first a facial feature database its elements are pre-processing (Bradski, 2000) to specify faces and feature extraction, attributing a unique ID to each face and storing these features for the second step. The second step involve inferencing for face detection for specific ID in a scenario its components are a deep learning-based feature extractor, a point based matching model (Lindenberger et al., 2023) and a detector for facial feature, while these are for detection part the post processing is crucial step which give authorization.

This amalgamation of techniques ensures the refinement of the recognition results. The subsequent post-processing step manages the comparison results, facilitating the final step of authorization, thereby enhancing the reliability and robustness of the system. In essence, our approach (Figure 2) in blending these advanced technologies and methodologies culminates in the development of a secure, reliable, and efficient system, pivotal in reinforcing security measures and averting unauthorized access. Through the utilization of precise feature comparison and advanced post-processing techniques, our objective is to offer a sophisticated solution that effectively addresses the diverse challenges associated with secure authorization.

4.2 Anomaly detection for driver behavior

In line with the objective of promoting safety and efficiency, the structured framework includes specialized anomaly detection algorithms. These algorithms are tailored to identify signs related to drowsiness, including driver fatigue, physical discomfort, and unusual behaviors requiring immediate attention. This is particularly crucial in scenarios involving heavy machinery operation within the construction industry, where such anomalies can escalate into significant safety risks and losses. The implemented algorithms meticulously observe and analyze various behavioral cues, such as the frequency of yawning, heavy eyelid drooping, moments of nodding off, or any behavior that deviates from the established norm. These cues indicate a potential decline in alertness or an increase in discomfort, both of which can adversely impact machinery operation. The proposed framework aims to identify drowsiness in forklift drivers by analyzing their facial expressions, as depicted in Figure . This system operates in real-time by collecting a dataset of images and labeling them for training purposes. The initial step involves enhancing the image quality and extracting relevant features through image pre-processing. For this purpose, a feature extractor based on the work of (Amir, Gandelsman et al., 2021) is employed. This feature extractor specializes in extracting detailed features from the facial images of drivers.

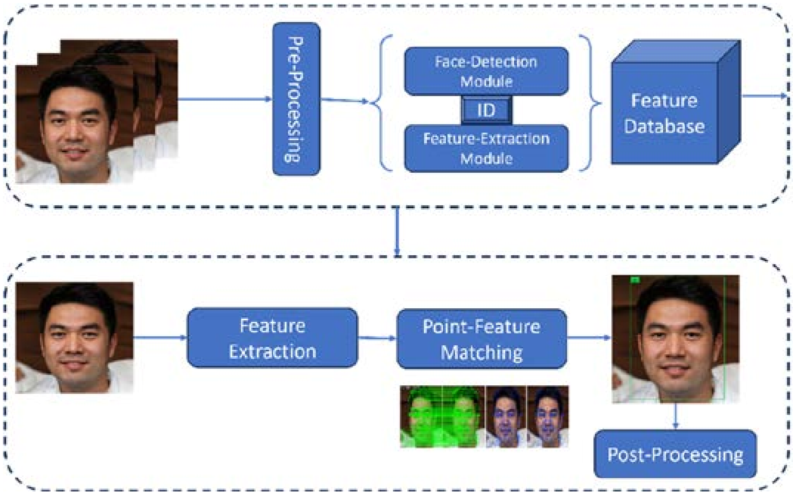

Figure 2: Face-Detection Framework for Authorization

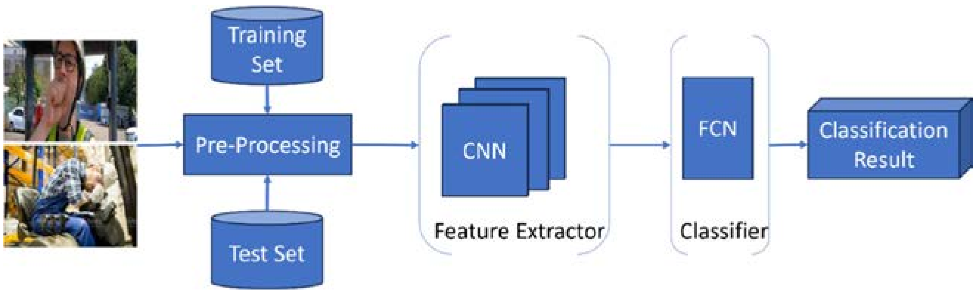

Figure 3: Framework for Forklift drowsiness detection

Once the features are extracted, a state-of-the-art deep learning model is utilized for classification. Specifically, a fully connected network, as described by (Schwing and Urtasun, 2015), is attached to the feature extractor. This network is trained to classify various images based on the driver's condition, distinguishing between normal and drowsy states. By utilizing deep learning, the system can learn intricate patterns and accurately categorize the driver's condition in real-time. After the classification step, a post-processing stage is implemented to activate an alert system based on the identified states. In practical terms, if the system detects drowsiness in the driver, it can promptly issue an alert or trigger a warning mechanism. This rapid response is crucial for preventing potential safety hazards, as it enables corrective actions or interventions to be initiated before accidents or injuries occur.

The application of advanced computational techniques and deep learning models enables the system to achieve a high level of precision in detecting driver states. It can effectively differentiate between normal and unusual behaviors, thereby ensuring the safety and well-being of individuals involved in forklift operations within construction sites. By promptly recognizing and addressing drowsiness, the system contributes to maintaining an overall safe working environment in construction settings.

4.3 Enhanced visibility with stereo cameras

In the scenario depicted in Figure , a challenge arises when the forklift is loaded, blocking the operator's direct line of sight to the area directly in front of the forklift. To tackle this issue, a stereo camera system will be installed at the front of the forklift's fork tip. This setup not only offers an unobstructed view of the concealed area but also employs computer vision-based object detection algorithms, such as yolov8 (ultralytistic, n.d.), to identify objects and determine their distance from the forklift. This comprehensive approach enhances safety by addressing vision obstruction concerns when the forklift is carrying a load.

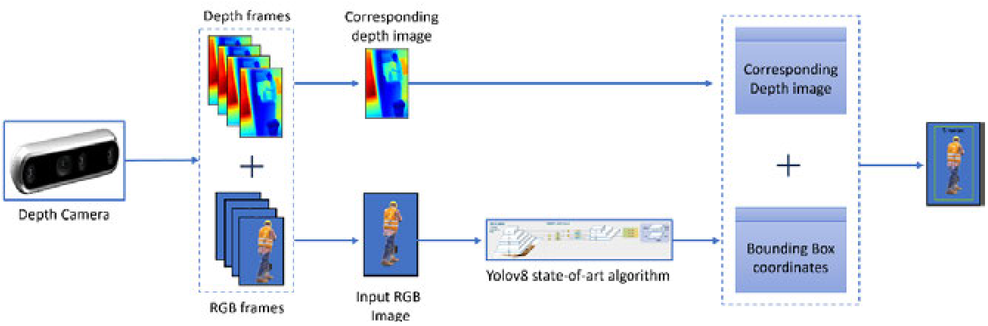

Figure 4: Visibility Framework with stereo camera

4.4 Blind spot solutions

Blind spots that arise when objects approach a forklift from a corner, as illustrated in Figure necessitate specific safety measures. In compliance with [29 CFR 1910.178(n)(4)] and [29 CFR 1910.178(n)(6)] mentioned in (OSHA, 2023b), it is essential to install signalers and convex lens mirrors at every corner within the work area where forklift operations take place. These signalers can be monitored through object detection technology. If a signaler is absent or not in its designated location, an alert message is generated, indicating unsafe conditions.

To ensure comprehensive coverage of the construction site where forklifts operate, multiple cameras need to be strategically installed. These cameras are connected to a server via RTPS (Real-Time Publish-Subscribe) protocol, and an object detection model is deployed on the server to enhance safety and monitor blind spots effectively.

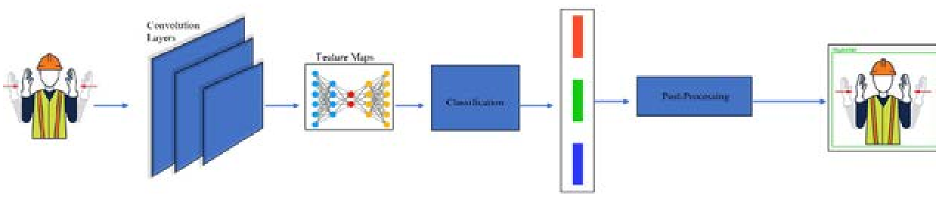

Figure 5: Signaler Detection

4.5 Load placement monitoring

Properly centering the load on a forklift is essential for safety, as highlighted in OSHA's 29 CFR 1910.178(o)(1) and 1910.178(o)(2) regulations. Incorrect load positioning increases the risk of tipping over, potentially causing operator injuries, equipment damage, and harm to nearby structures. Maintaining load stability and preventing tip-over accidents are critical.

Extensive research on forklift safety underscores the significance of load centering. Misalignment of loads elevates the risk of tip-overs, diminishes stability and maneuverability, and can lead to structural damage and injuries.

Adhering to OSHA regulations is imperative. Gavanski's 2022 study identifies safety concerns with forklifts, serving as a valuable reference for safety enhancements (Gavanski, 2022). Furthermore, Xia et al. (2023) introduced a center of gravity estimation algorithm for counterbalanced forklifts, achieving precise position control (Xia et al., 2023).

In this study, we introduce a computer vision-based framework (Figure 6) to oversee forklift operations during material loading and unloading. Utilizing advanced computational techniques and deep learning models, this system accurately identifies objects and reliably estimates the distance between the load's central point and the forklift's front wheel. The proposed framework plays a crucial role in enhancing safety at construction sites, benefiting both forklift operators and the machinery itself. Its primary function is to promptly detect and correct any load positioning issues relative to the forklift's mast, contributing significantly to a safe construction site environment.

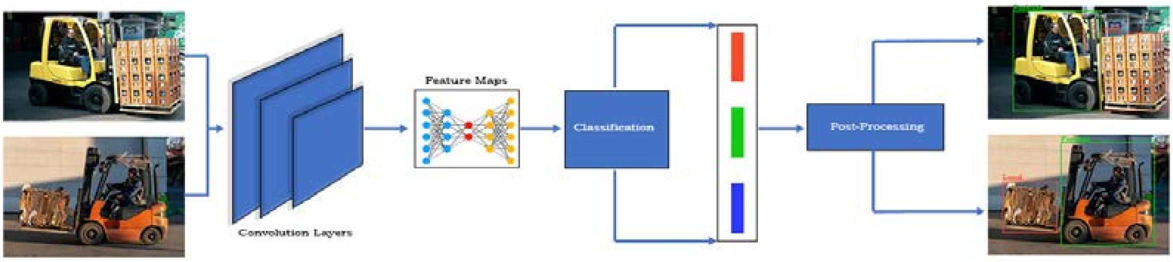

Figure 6: Forklift and Load Detection

5. DISCUSSION & CONCLUSION

The "iSafe ForkLift" framework represents a comprehensive solution aimed at enhancing safety in construction site forklift operations through the integration of advanced computer vision technology. This integrated system encompasses sophisticated features such as facial recognition for driver authentication, anomaly detection to mitigate operator drowsiness, stereo cameras to augment visibility, blind spot solutions, and load placement monitoring to preempt tip-over incidents. This framework stands out due to its holistic approach, a departure from conventional solutions that primarily address safety concerns individually. By systematically addressing multiple safety risks within a singular, efficient framework, it significantly enhances overall safety. However, there are certain limitations that necessitate careful consideration and foster discussions on technology, costs, safety, and compliance, with iSafe ForkLift improving forklift operations and worker well-being. The effectiveness of the framework is contingent upon the dependability of its technology, which may be vulnerable to adverse environmental conditions. Challenges may arise in accurately distinguishing between workers and signalers through computer vision. Acceptance among operators, coupled with concerns regarding data security and privacy management. Pertinent factors such as initial investment costs, ongoing maintenance, and operator training may pose challenges. Furthermore, the framework beckons opportunities for refinement, particularly concerning the reduction of false positives in anomaly detection and scalability. Following OSHA's safety protocols significantly boosts workplace safety. The integration of computer vision and IoT technologies enhances operational precision, while vigilance on uneven or challenging surfaces ensures stability and safety, thereby augmenting overall safety in the dynamic construction industry. In future work, we will delve deeper into these regulations by introducing dedicated computer vision solutions to enhance forklift safety across various industries.

AUTOMATED EXTRACTION OF BRIDGE GRADIENT FROM DRAWINGS USING DEEP LEARNING

Hakan Bayer, Benedikt Faltin & Markus König
Ruhr University Bochum, Germany

ABSTRACT: *Digital methods such as Building Information Modeling (BIM) can be leveraged, to improve the efficiency of maintenance planning of bridges. However, this requires digital building models, which are rarely available. Consequently, these models must be created retrospectively, which is time-consuming when done manually. Naturally, there is a great interest in the industry to automate the process of retro-digitization. This paper contributes to these efforts by proposing a multistage pipeline to automatically extract the gradient of a bridge from pixel-based construction drawings using deep learning. The bridge gradient, a key element of the structure's axis, is critical for describing the elevation profile and axis slope. This information is implicitly contained in the longitudinal view of bridge drawings as gradient symbols. To extract this information, the well-established object detection model YOLOv5 is employed to locate the gradient symbols inside the drawings. Subsequently, EasyOCR and heuristic rules are applied to extract the relevant gradient parameters associated with each detected symbol. The extracted parameters are then exported in a machine-interpretable format to facilitate seamless integration into other applications. The results show a promising 98% accuracy in symbol detection and an overall accuracy of 70%. Consequently, the pipeline represents a significant advance in automating the retro-digitization process for existing bridges by reducing the time and effort required.*

KEYWORDS: *Building Information Modeling, Computer Vision, Deep Learning, Symbol Detection, Optical Character Recognition, Construction Drawings*

1. INTRODUCTION

Bridges play a central role in the transport network, as they are an essential element that creates connections and thus enables the transport of people and goods. To ensure their functionality and safe operation, regular inspections and effective maintenance management are of utmost importance. To support efficient maintenance planning, digital methods such as Building Information Modeling (BIM) can be employed. BIM refers to a digital collaboration method based on the creation and interdisciplinary exchange of digital building models (Borrmann et al., 2018). These models combine semantic information with geometric representations, acting as a single and central source of continuously enriching project information. Informed decisions can thus be made based on accurate and current data. Despite the potential BIM offers for all lifecycle phases, especially for the operation and maintenance (O&M) phase, it is most commonly used in the design phase of a construction project (Durdyev et al., 2022).

The limited utilization of BIM in the O&M phase arises from the requirement for digital as-built models of the structure, which are often not available. In many cases, this is due to the fact that the buildings were designed and constructed without the implementation of BIM. Therefore, these models have to be created retrospectively. Since this is a time-consuming manual task, there is a major research effort to assist or automate the process through the use of artificial intelligence (Schönfelder et al., 2023).

While many different sources of information can be used to create a digital building model of an existing structure, construction drawings are the most accessible. They not only contain geometric and semantic information about the building but also describe the internal structure of the components or building elements that are obstructed, e.g., buried underground. Therefore, drawings are an important source of information. This research contributes to the automatic creation of digital models from construction drawings by proposing a multi-stage pipeline for the automatic extraction of bridge gradient information from pixel-based construction drawings.

The bridge gradient illustrates the elevation profile of the bridge's axis and is, therefore, an essential information for a precise reconstruction of the superstructure's geometry. The course of the gradient is contained in the longitudinal view. It is implicitly described through gradient symbols that hold important details about elevation and slope at specific points along the bridge axis. Therefore, the pipeline encompasses several stages to automatically extract the gradient information from multiple locations and link the information. First, the pipeline utilizes state-of-the-art deep learning-based methods to detect the gradient symbols within the drawings. Subsequently, the text information associated with each symbol is extracted using optical character recognition

(OCR). Finally, the information is consolidated and harmonized into a structured data schema. The paper gives insight into the individual process steps and evaluates the performance of the proposed pipeline on a set of real-world bridge drawings.

The remaining sections of the paper are organized as follows: Section 2 reviews recent research publications on automatic reconstruction of digital models from drawings. The implemented pipeline is described in Section 3, with a detailed explanation of each step. Section 4 shows the results obtained when applying the proposed pipeline to real drawings. Finally, Section 5 discusses the results and limitations of this study and outlines a perspective for further research.

2. RELATED WORK

So far, little research has been published on digitizing technical drawings (Moreno-Garcia et al., 2019). Only a few of these publications deal with the (semi-)automatic analysis of drawings for infrastructures. Poku-Agyemang & Reiterer (2023) proposes a semi-automated process that utilizes the Douglas-Peucker algorithm to detect the corner points of illustrated components. These points are then used to reconstruct the component exterior edges, ultimately creating the bridge's geometry. A different semi-automatic framework is proposed by Akanbi & Zhang (2022). The proposed process involves converting the drawings into a vector-based data format, aligning the contained views, and finally using the extracted information to reconstruct the bridge's geometry. The reconstructed digital model is exported in the IFC (Industry Foundation Classes) data format. An approach based on deep learning methods is introduced by Mafipour et a. (2023). The authors present a pipeline employing YOLOv5 and CRAFT to automatically detect the individual components and texts in the drawings. The detected objects are then clustered based on their labels, as each component may appear in different views of the structure. These views are provided to an expert who uses this information to create the bridge based on a predefined parametric model manually. In contrast, Faltin et al. (2023) proposes a different approach for linking the views in construction drawings. The authors utilize FasterRCNN for detecting section symbols that illustrate the interconnections between views. Each detected symbol is uniquely identified through the section reference, allowing it to be mapped to the corresponding view using OCR on the view title. The interconnections are established across all views contained in a drawing set for a specific structure.

Overall, a larger number of publications exist on the reconstruction of high-rise building models from drawings. Wei et al. (2022) proposes a pipeline for detecting and reconstructing walls from floor plans. Firstly, the drawing is divided into patches, and the ResNet model is employed to identify patches containing walls. The walls are then detected in the positive patches using YOLOv3. All detections are merged to enable the utilization of Dynamo to create the digital model. Similarly, Zhao et al. (2020) uses the YOLO object detector to locate structural elements in the column structure and generate framework plan images. In a subsequent study, Zhao et al. (2021) continues the research by incorporating the superior Faster R-CNN model and introducing the creation of an IFC file from the extracted information. Kim et al. (2021) propose an approach for the detection of rooms, walls, and openings in floor plan images. The authors use a conditional generative adversarial network to create a heat map of the intersections and perform a style transfer to the floor plan image. Using the heat map of the connection points, the walls and openings are vectorized, which provides important information for recreating the building geometry.

However, to the best of the author's knowledge, no publication has been made that addressed the extraction of the bridge gradient from pixel-based drawings. This research aims to close the identified gap.

3. METHODOLOGY

A detailed explanation of the implemented methods is provided in the following section. Fig. 1 presents an overview of the proposed process. The input for the pipeline is a pixel-based longitudinal view of the bridge, as it contains the required gradient information. In this paper, it is assumed that the view has already been extracted from the complete drawing set, which the engineer can do manually in advance. The pipeline first preprocesses (1) the view by dividing it into smaller patches to enable the symbol detection. The gradient symbols (2) are detected within these patches, and for each symbol, the associated gradient parameters (3) are extracted. Finally, the information is exported in a structured format to facilitate its utilization within BIM modeling software.

3.1 Dataset Creation and Annotation

To detect the gradient symbol in the drawings, the state-of-the-art object recognition network YOLOv5 (Jocher et al., 2022) is employed. Training the network requires a dataset of bridge construction drawings manually annotated with the gradient symbol. However, since the gradient symbol only occurs in small numbers in a longitudinal view, this results in a limited number of training data points. This is insufficient to receive a well-trained model. Therefore, the training data is synthetically generated, using a copy-and-paste strategy following Faltin et al. (2023). The real annotated data is only used to test the network.

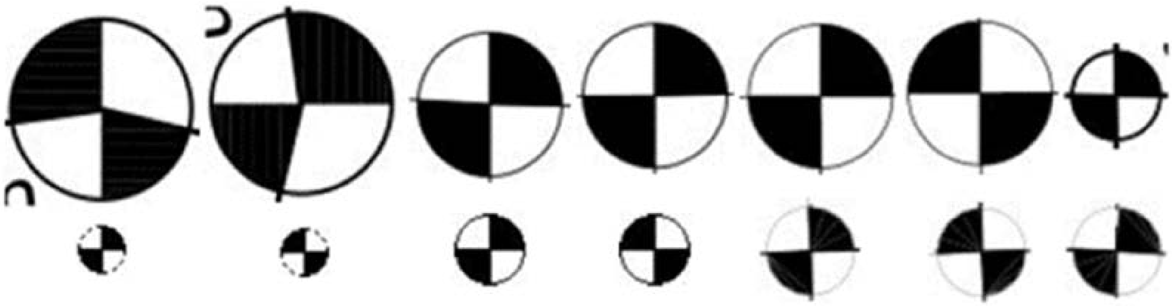

Fig. 2: Variation in created gradient symbols, sizes ranging from 85x85 to 20x20 pixels.

For the synthetic data, a template set of 14 unique gradient symbols is created and employed in the process (cf. Figure 2). These symbols vary in size from 85x85 to 20x20 pixels, shape, and texture, providing increased diversity in order to improve the models' ability to generalize.

The gradient symbol is chosen from the available template set and is randomly inserted into the background images. These background images are randomly cropped from bridge construction drawings which do not contain the gradient symbol and consist of various segments of construction drawings with different pixel sizes. To ensure compatibility with the YOLOv5 model, the background images are uniformly cropped to a standardized size of 640 x 640 pixels. This process is repeated multiple times to generate different combinations enhancing the diversity of the synthetic dataset. Fig. 3 presents some exemplary results of the method.

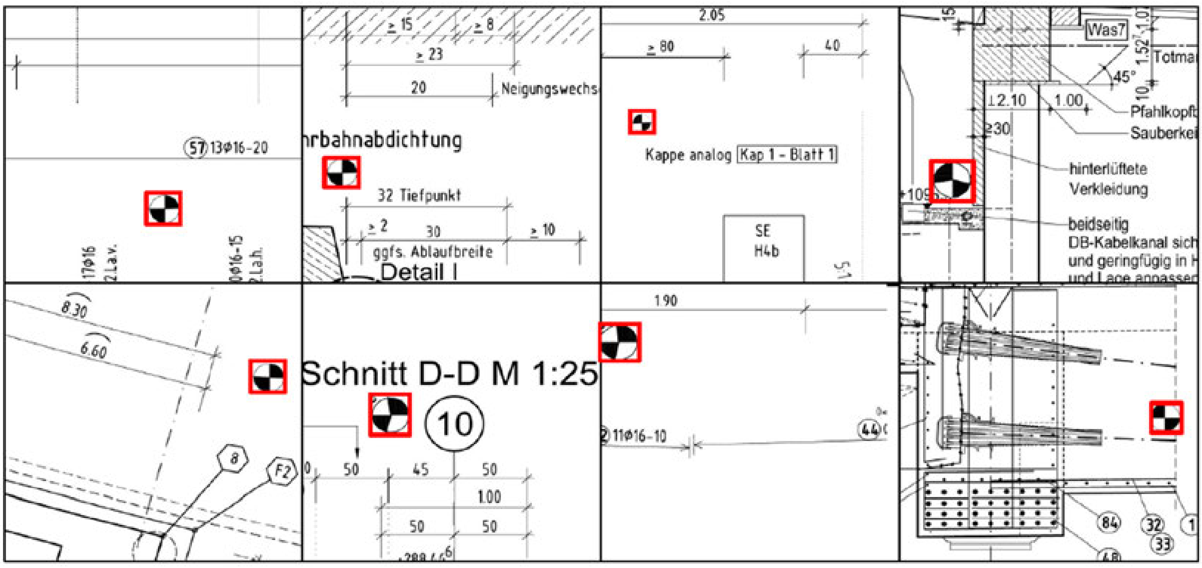

Fig. 3: Exemplary training images with a side length of 640 by 640 pixels synthetically generated using the proposed copy-paste method.

In total a number of 980 training images and 280 validation images are generated, resulting in the dataset named *Symbols*. Additionally, 62 real different images extracted from real bridge drawings are used for testing. According to Jocher et al. (2022) adding up to 10% of empty background images to the training and validation dataset enhances the object detection performance. Hence, 128 images are added to the training data, while 32 images are added to the validation data. This dataset is called *Symbols+BG*. Table 1 provides an overview of the final datasets.

Table 1: Overview of the generated data sets. Synthetic images are only used for training and validation.

	Content	No. of synth. training images	No. of synth. validation images	No. of real testing images
Symbols	Symbols only	980	280	62
Symbols+BG	Symbols and empty background	1108	312	62

3.2 Preprocessing and Gradient Symbol Detection

In order for the YOLOv5 model to handle the large image sizes of the input longitudinal views, a sliding window approach is employed. As shown in Fig. 4, as a first step a 640 by 640 pixel sized window is shifted across the image in increments of 330 pixels, ultimately covering the entire image. This step ensures that the gradient symbol is displayed in its entirety in at least one window, improving the detection performance. The trained YOLOv5 detector individually processes the windows, and the detected symbol is recorded. In cases where a symbol is detected in multiple overlapping windows, non-maximum suppression is employed to mitigate the possibility of double detections. For the final detections, rectangular regions are cropped from the original input image, extending 330 pixels in each direction (see Fig. 4), which is found to be sufficient. These cropped regions are further processed in the gradient parameter extraction, as explained in the following section.

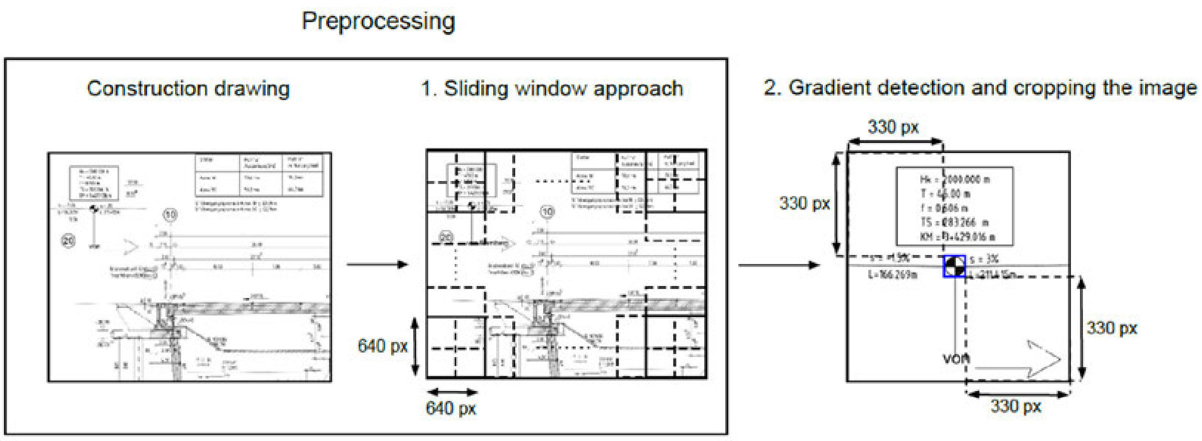

Fig. 4: Preprocessing of the construction drawing and detecting the gradient within the cropped area.

3.3 Gradient Parameter Extraction

After detecting the gradient symbols, the associated gradient parameters are extracted. To reliably recognize the parameters, the EasyOCR[1] text recognition model is used. EasyOCR combines the CRAFT (Baek et al. 2019) network and the text recognition network CRNN (Shi et al. 2018), since it is specifically designed for OCR. Therefore, EasyOCR provides robust capabilities for recognizing and extracting text from images. EasyOCR is employed in each region, as provided by the results from section 3.2. Within these regions, the text may appear rotated, reducing the EasyOCR model's recognition accuracy. To address this issue, the OCR engine is employed on the original region and a 90-degree rotated version. In addition, various image pre-processing techniques, e.g., adjustments to brightness and contrast, are applied to further improve the text recognition results.

An additional challenge is that not all text in the regions is relevant for the gradient reconstruction. Therefore, to ensure that only the relevant text is detected for further analysis, filtering, and string-matching techniques are implemented.

---

[1] EasyOCR: https://github.com/JaidedAI/EasyOCR (Accessed 1 August 2023).

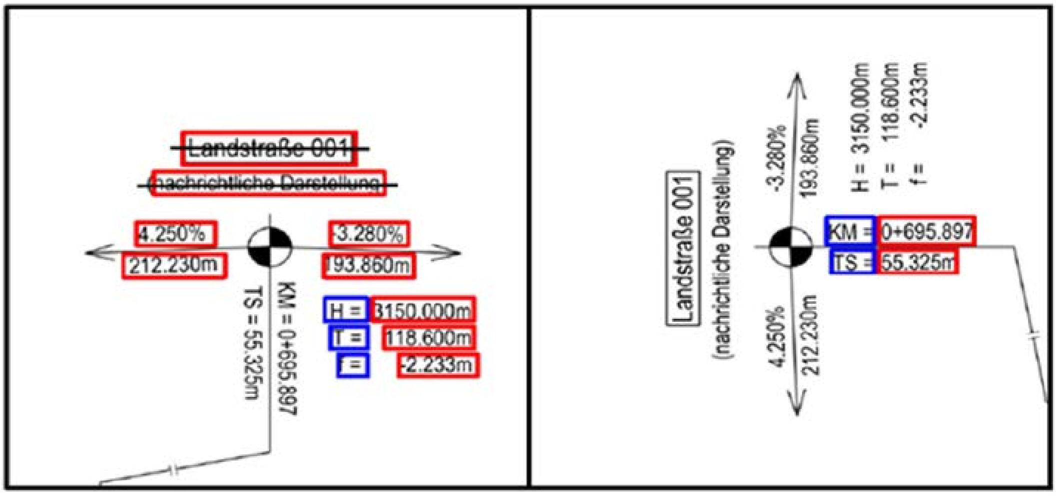

Fig. 5: Exemplary representation of the recognized texts in the original (left) and 90° rotated (right) patches. The recognized texts are marked in red, and the parameters are marked in blue. The crossed-out text passages cannot be assigned to any parameter and are, therefore, ignored.

In Fig. 5, the process of rotation, filtering, and string-matching is demonstrated. For instance, the text 'Landstraße 001' is irrelevant for the gradient detection and thus discarded. This filtering process is accomplished by identifying specific characters, such as *KM, TS,* or *T*, as depicted by blue in Fig. 5. Subsequently, the values that appear in the same horizontal line (cf. Fig. 5 marked with red rectangles) are matched with the identifying specific characters. In contrast, values located far away from the clusters are discarded. This process filters out unwanted text so that only relevant information is used in further analysis.

4. TRAINING & RESULTS

4.1 Training Process

Three different model sizes of YOLOv5 are trained and their performance is compared: YOLOv5m, YOLOv5l, and YOLOv5x. Each model trains on both the *Symbols* and *Symbols+BG* dataset using a NVIDIA A100 SXM4 40 GB graphics card. The models trained on Symbols are referred to as YOLOv5m, YOLOv5l, and YOLOv5x, while the ones trained on Symbols+BG are denoted as YOLOv5m_b, YOLOv5l_b, and YOLOv5x_b. During training a batch size of 56 is used for a maximum of 300 epochs. Backpropagation is performed using a learning rate of 0.01 with a stochastic gradient descent (SGD) optimizer (Robbins & Monro, 1951).

4.2 Symbol Detection Results

The YOLOv5 models are evaluated on 62 test images. Several key evaluation metrics are analyzed: precision, recall, intersection over union (IoU), mean average precision (mAP) at an IoU threshold of 0.50 (mAP@0.50), and mAP across IoU thresholds from 0.50 to 0.95 (mAP@0.50:0.95). The IoU measures the overlap between the predicted and ground truth bounding box. Precision measures the proportion of true positive detections out of all positive detections made by the model, indicating the accuracy of the model's predictions. On the other hand, recall represents the proportion of actual gradient symbols correctly identified by the models, measuring the model's ability to capture all instances of the target object. mAP@0.50 is a metric that enables the evaluation of the model's precision on average when there is at least a 50% IoU with the ground truth bounding boxes. In simpler terms, mAP@0.50 allows the assessment of how well the model performs in accurately detecting and localizing the gradient symbol, even when there is a moderate level of overlap between the predicted bounding boxes and the actual objects in the images. mAP@0.50:0.95 offers a more comprehensive evaluation by considering a range of IoU thresholds, enabling a better understanding of the model's performance across different levels of overlap. Since the gradient symbols are relatively small, this study considers an IoU of 50% sufficient.

The test results of different trained YOLOv5 models are shown in Table 2. It can be observed that the models achieve high precision scores, indicating their capability to accurately detect the gradient symbol in the real image dataset. Moreover, the models show varying levels of recall. YOLOv5m archives the highest recall score of 0.957, while YOLOv5l scores the lowest value of 0.882. Overall, the models successfully identify the gradient symbols but with some variation in recall performance.

Table 2: Gradient detection results for different models. The bold fonts indicate the best results.

	YOLOv5m	YOLOv5l	YOLOv5x	YOLOv5m _b	YOLOv5l_b	YOLOv5x_b
Precision	0.998	**1**	0.984	**1**	0.999	0.999
Recall	**0.957**	0.882	0.906	0.913	0.942	**0.957**
$mAP^{IoU}_{0.50}$	0.965	0.942	0.966	0.958	**0.977**	0.976
$mAP^{IoU}_{0.50:0.95}$	0.878	0.865	0.882	0.874	0.89	**0.894**

For the mAP@0.50 all models demonstrate strong performance. YOLOv5l_b achieves the highest mAP@0.50 of 0.977, followed closely by YOLOv5x_b with 0.976. YOLOv5l achieves the lowest mAP@0.50 score of 0.942. Considering the mAP@0.50:0.95 all models have consistently high scores. YOLOv5x_b achieves the highest score of 0.894, closely followed by YOLOv5l_b with 0.89. YOLOv5l shows the lowest mAP@0.50:0.95 score of 0.865. Overall, the models indicate a good performance across the range of IoU thresholds. Considering the detection speed and mAP@0.50 performance YOLOv5l_b is selected as the best model for this application. Some detection results of gradient symbols are presented in Fig. 6.

4.3 Overall Pipeline Results

The models successfully detect the symbols despite variations such as rotation and partial view. To assess the performance of the overall pipeline, it is tested on four real longitudinal views, each containing multiple gradient symbols. To evaluate the OCR accuracy, a character-level analysis is performed. The recognized characters extracted by EasyOCR are compared to the expected gradient parameters associated with each drawing. The accuracy is then calculated by determining the percentage of correctly recognized parameters relative to the total number of parameters present.

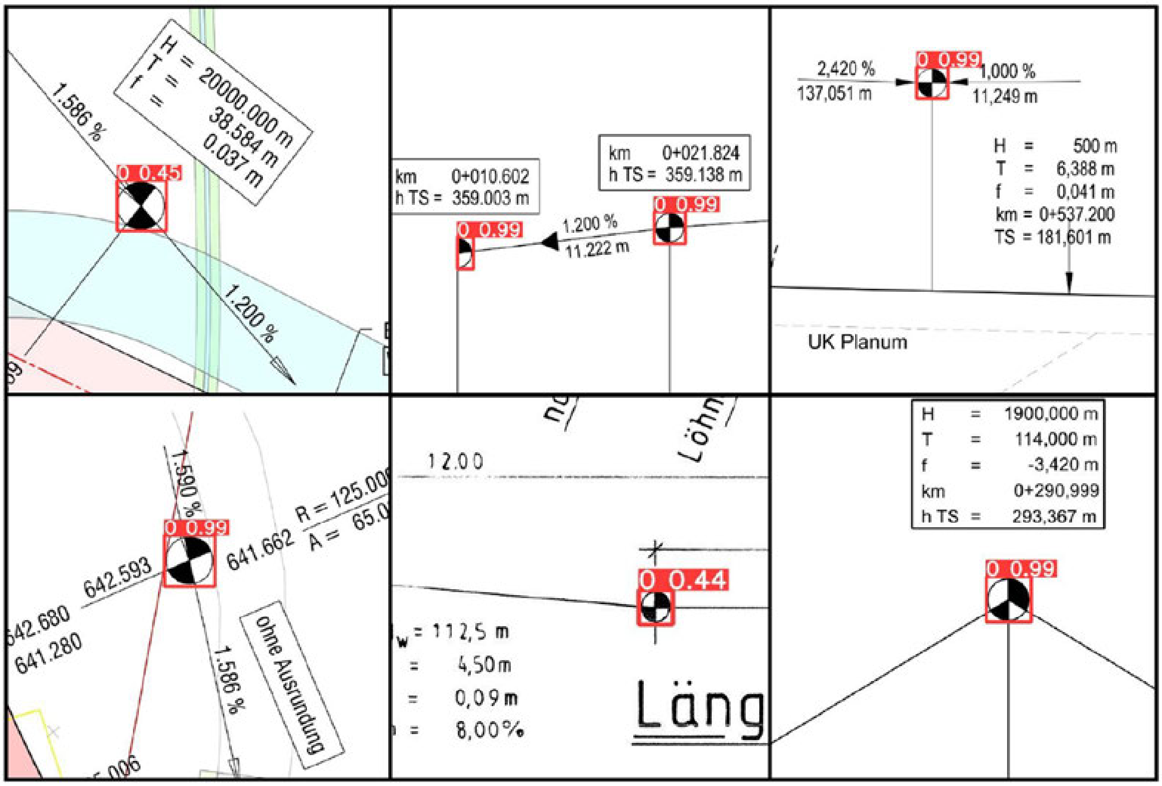

Fig. 6: Example results of gradient symbol detection.

The evaluation results reveal an overall accuracy of 70%. This shows that the pipeline can successfully extract gradient parameters from most of the drawings. However, there is room for improvement, especially in cases where parameter recognition becomes difficult due to variations in fonts and image quality.

5. DISCUSSION & CONCLUSION

The results of this study demonstrate the effectiveness of the proposed multistage pipeline for automatically extracting bridge gradient information from pixel-based construction drawings using deep learning techniques. The YOLOv5 models trained on different datasets showed high precision scores on the test dataset, indicating their capability to detect gradient symbols accurately. The results indicate that training the models on the synthetic dataset is beneficial to overcome a lack of data. The addition of background images has improved the overall performance of the models.

The evaluation metrics, including mAP@0.50 and mAP@0.50:0.95, revealed strong performance across all models. Notably, YOLOv5l_b achieved the highest mAP@0.50 score with 98%, making it the most suitable model for this application considering detection speed and accuracy. The detection results of gradient symbols further illustrate the pipeline's ability to successfully identify symbols despite variations in rotation and partial views. The pipeline's overall performance in extracting gradient parameters from real bridge drawings is promising, with an OCR accuracy of approximately 70%. However, there is still room for improvement, especially in cases with challenging text recognition due to varying fonts, and image quality.

In conclusion, the proposed pipeline presents an effective approach for the retro-digitization of existing bridges, significantly reducing the time and effort required for this crucial task. The successful extraction of gradient information from construction drawings holds great potential for improving bridge asset management and maintenance planning. For future research, fine-tuning, and optimization of the OCR component could further enhance accuracy and pave the way for broader applications.

PREDICTING MENTAL WORKLOAD OF USING EXOSKELETONS FOR CONSTRUCTION WORK: A DEEP LEARNING APPROACH

Abiola A. Akanmu, Adedeji O. Afolabi & Akinwale Okunola

Myers-Lawson School of Construction, Virginia Tech, Blacksburg, VA, USA.

ABSTRACT: *Exoskeletons are gaining attention as a potential solution for addressing low back injury in the construction industry. However, use of active back-support exoskeletons in construction can trigger unintended consequences which could increase mental workload of users while working with exoskeletons. Prolonged increase in mental workload could impact workers' wellbeing and productivity. Prediction of mental workload during exoskeleton-use could inform strategies to mitigate the triggers. This study investigates a machine-learning framework for predicting mental workload of workers while using active back-support exoskeletons for construction work. Laboratory experiments were conducted wherein Electroencephalography (EEG) data were collected from participants wearing active back-support exoskeletons to perform flooring task. The EEG data underwent preprocessing, including band filtering, notch filtering, and independent component analysis, to remove artifacts and ensure data quality. A regression-based Long Short-Term Memory network was trained to forecast future time steps of the processed EEG data. The performance of the network was evaluated using root mean square error (RMSE) and r-squared (R^2). A RMSE of 0.1527 and R^2 of 0.9665 indicating good fit and strong correlation, respectively, were observed between the predicted and actual EEG data. Results of the comparison between the actual and predicted mental workload also show strong correction with an R^2 of 0.8692. The findings motivate research directions into real-time monitoring of mental workload of workers during exoskeleton-use. The study has significant implications for stakeholders, enabling them to gain a deeper understanding of the impact of mental workload while using exoskeletons thereby providing opportunities for mitigation.*

1. INTRODUCTION

The prevalence of work-related musculoskeletal disorders (WMSDs) among the construction workforce is a growing concern in the construction industry. The US Bureau of Labor Statistics reports that workers in the construction industry are 1.23 times more likely to sustain WMSDs compared with workers in other industry sectors (BLS, 2020). The same report explains that the back is the one of the most affected body parts. Construction workers, such as floor layers, suffer from back injuries at 1.7 times workers in other industry sectors. For example, floor layers experience back injuries at the rate 22.5 MSDs per 10,000 full-time workers, and this has been known to result in an average of 26 days' work absence. Exoskeletons are increasingly being perceived as a solution to WMSDs. Exoskeletons, such as back-support exoskeletons, are wearable devices designed to support or augment users' back while performing work (Gonsalves et al., 2023; Ogunseiju et al., 2022). Exoskeletons are classified as passive and active depending on their mode of augmentation. Passive back-support exoskeleton, while less costly than active back-support exoskeletons, provide support to the back using dampers and springs. Whereas active back-support exoskeletons provide support to the back using electrical motors – this makes active back-support exoskeletons bulkier. These devices have been shown to reduce risks factors of back injuries by reducing muscle activity (Theurel et al., 2018), range of motion (Cumplido-Trasmonte et al., 2023), body discomfort (Gonsalves et al., 2021; Kim et al., 2019), and rate of exertion (Alemi et al., 2020; Baltrusch et al., 2021). Despite these benefits, studies have shown that exoskeleton-use in construction can trigger difficulty working in confined spaces (Nussbaum et al., 2019), fall risks due to the weight of the device (Alabdulkarim et al., 2019; Kim et al., 2019; Massardi et al., 2023), discomfort to body parts (Gonsalves et al., 2023; Gonsalves et al., 2021), restrictions in movement (Fox et al., 2020; Poliero et al., 2020), catch and snag risks (de Looze et al., 2016; Kim et al., 2019), and thermal discomfort (Liu et al., 2021). The devices could also be challenging to adjust to fit (Gonsalves et al., 2023; Gorgey, 2018). Moreover, unequal loading and balancing of body parts due to improper adjustment can cause users to be more aware of the device than their task and surrounding, which could increase workers' mental workload (Bequette et al., 2020; Marchand et al., 2021).

Prolonged increase in mental workload can result in distraction, emotional distress, anxiety, and stress, which have downstream implication on workers' overall well-being and performance. Real-time monitoring of workers' mental workload during exoskeleton-use could inform strategies to reduce the triggers. However, scarce efforts

Abiola Akanmu, Adedeji Afolabi, Akinwale Okunola, *Predicting Mental Workload of Using Exoskeletons for Construction Work: A Deep Learning Approach,* pp. 691-700, DOI 10.36253/979-12-215-0289-3.69

have been made to investigate models for predicting workers' mental workload during exoskeleton-use. Electroencephalogram (EEG) can be used to measure brain activity corresponding to mental workload. EEG signals are widely used for inferring mental workload, due to the high temporal resolution, convenience, and cost-effectiveness of the supporting devices. Machine learning techniques, particularly deep learning, provides opportunities for extracting insightful features from EEG data that could be used for predicting mental workload. Long Short-Term Memory network, a variant of recurrent neural network, can learn long-term dependencies between time steps of data and predict future time-series sequences of the data. Long Short-Term Memory (LSTM) network has been used for sequential learning tasks like construction equipment activity analysis (Hernandez et al., 2019), construction workers' safety harness usage (Guo et al., 2023), mixed reality learning environment (Ogunseiju et al., 2023) and, fatigue detection and early warning system (Liu et al., 2020) that need historical time-series data in the decision-making process. Therefore, this study investigates the extent to which workers' mental workload due to exoskeleton-use can be predicted from EEG data using Long Short-Term Memory network. Using a case-study of a flooring task, this paper presents a comparison of the actual and predicted mental workload due to performing work with an active back-support exoskeleton. The results of this study contribute to scarce knowledge on the unintended consequences of using wearable devices such as exoskeletons for construction work.

2. BACKGROUND

2.1 Mental Workload Evaluation with EEG

Mental workload are the mental resources required for task execution (Chen et al., 2017). A previous study (Fan & Smith, 2017) has shown that mental workload is associated with task demand and performance. Mastropietro et al. (2023) showed that low mental workload (underload) and high mental workload (overload) can negatively affect the task being executed leading to increase in rate incidence of errors. Chen et al. (2016) opined that when a person places too much attention on a task, the individual has less attention to focus on other stimuli. In the context of this study, exoskeleton-use may demand attention, thereby reducing the mental resources that may be required for the task or being aware of the user's surrounding to prevent fall risks, and catch and snag risks (Gonsalves et al., 2023; Zhu et al., 2021). These risks can impact the mental workload resulting in exoskeleton users being stressed or distracted, thus retarding their productivity and safety. This makes prediction of mental workload a major interest in ergonomics (Young et al., 2015). Over the years, subjective and objective methods have been employed to infer mental workload. Subjective methods include the use of questionnaires such as NASA Task Load Index and Subjective Workload Assessment Technique. On the other hand, objective methods include the use of data collection instruments such as functional magnetic resonance imaging-fMRI, and electroencephalography (Ryu & Myung, 2005). However, EEG has been touted as one of the most suitable devices for measuring brain activities to infer mental workload (Chen et al., 2016; Qin & Bulbul, 2023).

Borghini et al. (2014) estimates mental workload using theta-to-alpha brain waves ratio from EEG data. Similarly, another study (Missonnier et al., 2006) indicated that using EEG signals, an increase in mental workload is noticed when there is a decrease in alpha brain waves (8-13Hz) and increase in the theta brain waves (4-8Hz) during the execution of specific tasks. In the construction industry context, EEG has been used in some studies (Chen et al., 2016; Chen et al., 2017; Qin & Bulbul, 2023; Yang et al., 2023) to estimate mental workload. For instance, EEG was used to estimate the mental workload of construction workers to on-site safety conditions (Chen et al., 2016). Engagement index, time–frequency indicator in EEG, was used to assess the mental workload of workers when exposed to construction vulnerabilities. Chen et al. (2017) used EEG approach to measure task mental load of construction workers based on the power spectral densities of major frequency bands. In addition, the effect of distractions in construction work zones on drivers' mental workload was measured using EEG (Yang et al., 2023). Despite these efforts and unintended consequences of exoskeletons, there are scarce studies on predicting mental workload due to exoskeleton-use on construction sites.

2.2 Machine Learning for Mental Workload Prediction

With machine learning techniques, EEG data can be transformed into frequency domain representations which can enable extraction of brain rhythms. For instance, Jebelli et al. (2018a) used support vector machine, a supervised machine learning technique, to classify stress levels of construction workers. However, the use of supervised learning technique requires hand-crafting of features which could be labor-intensive and may be insufficient to support real-time monitoring of mental workload (Wang et al., 2023). Deep learning techniques, such as convolutional neural networks (CNN), have been used to extract intrinsic features from time-series data for recognizing occupational stress, fatigue and mental workload (Jebelli et al., 2019; Mehmood et al., 2023; Qin & Bulbul, 2023). Recurrent neural network, a class of CNN, is widely used for forecasting time-series data such as brain activity. Recurrent neural network, such as Long Short-Term Memory (LSTM), has been noted to perform better in learning time-series data due to its high prediction accuracy and ability to overcome problems of overfitting (Wang et al., 2020). Furthermore, LSTM can solve the problem of gradient exploding and vanishing when processing large sequential data (Hochreiter & Schmidhuber, 1997). Jaiswal et al. (2023) noted that LSTM model performed better than other models in predicting cognitive fatigue. Moreover, in their study, LSTM eliminated the need for extensive data preprocessing and feature extraction which could have resulted in loss of useful information in EEG data. Also, Liu et al. (2022) used LSTM for detecting fatigue of drivers. In construction, Qin and Bulbul (2023) used LSTM for predicting the mental workload of workers while using augmented reality head-mounted display for construction assembly. Despite these possibilities, limited studies have harnessed LSTM for predicting mental workload associated with exoskeleton-use for construction work.

3. METHODOLOGY

This section, including Figure 1, describes the procedure employed to achieve the objective of the study including the experimental design to collect brain activity of participants performing flooring task with an exoskeleton, preprocessing of the brain activity data, and prediction of mental workload with the data.

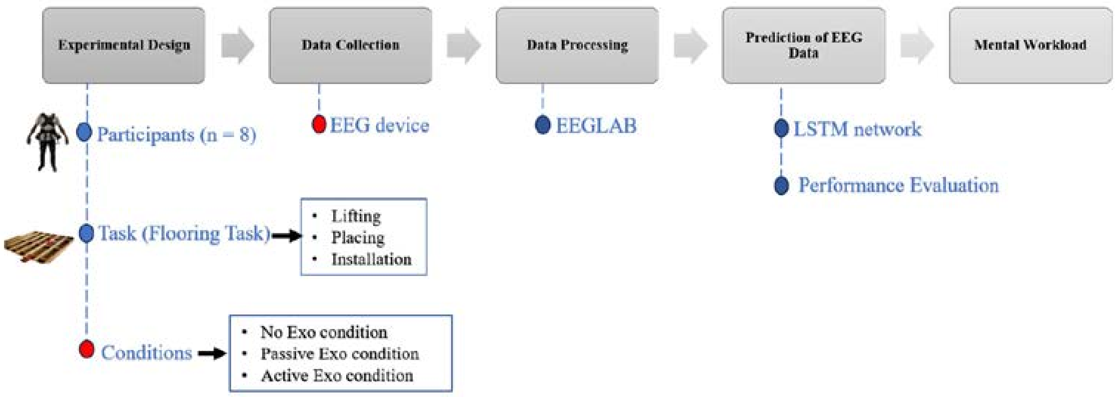

Fig. 1: Overview of Methodology.

3.1 Experimental Design and Data Collection

Eight male graduate students (n = 8) where recruited to perform a flooring task with an active exoskeleton. Similar sample sizes have been used by previous studies (Wei et al., 2020). None of the participants reported any prior musculoskeletal injury that would impact their participation in the study. The active exoskeleton used for the study is the Cray X shown in Figure 2. The Cray X, from German Bionic, weighs 7kg and can provide a lifting support of about 30kg. Cray X consists of a frame and strap pads of different sizes for the legs, chest, shoulders, and waist. The frame includes a 40V battery and motor. The exoskeleton provides different levels of support for bending, lifting, placing, and walking.

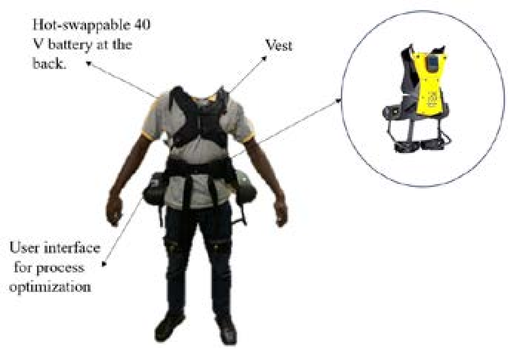

Fig. 2: Active (CrayX) back-support exoskeleton.

The flooring task involved lifting, placing and installing 20 floor tiles in each bay of a wooden frame comprising of six bays. Each bay can fit 20 floor tiles (see Figure 3). The participants were asked to lift and place 20 timber tiles (10kg) beside each bay, and subsequently install the stacked tiles in each bay. Each tile weighs 0.5kg. A cycle of flooring task includes lifting, placing, and installation of the timber floor tiles (20) in each bay. The task comprises of six cycles given that the participants installed the tiles in six bays.

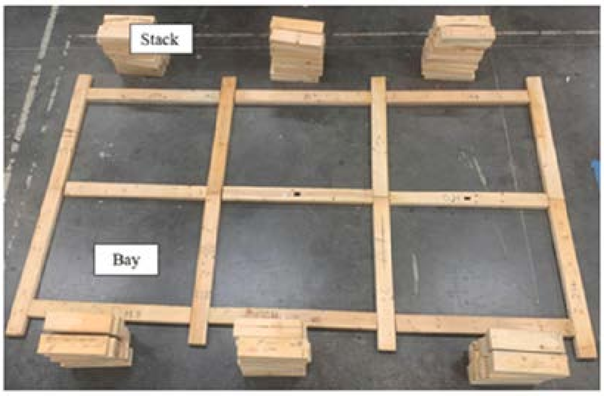

Fig. 3: Experimental layout of the simulated flooring task.

Prior to commencing the tasks, the participants received instructions on how to perform the task. The participants performed the aforementioned flooring task with an active exoskeleton. During these conditions, the participants wore an EEG cap. The EEG device records electrical activity of the brain through contact between electrodes embedded in various portions of the cap and the scalp. The brain produces electrical signals of brain waves at different frequencies such as delta (0.5-4 Hz), theta (4-8 Hz), alpha (8-13Hz), beta (13-30Hz), and gamma (>30Hz) (Chen et al., 2023). The delta, theta, alpha, beta and gamma bands correspond to deep sleep, powered thinking, alertness, concentration, and attentional processing, high mental activity, and information processing respectively (Ke et al., 2021). This study utilized a 14-channel EEG device measuring brain activity at 256Hz.

3.2 Data Preprocessing

EEG data are susceptible to contamination from intrinsic and extrinsic artifacts, particularly when subjects are engaged in physical activities like construction work (Jebelli et al., 2018b). These artifacts impact the quality of the signal. Intrinsic artifacts are triggered by movements such as eye blinking and muscle movement, while extrinsic artifacts are caused by external influences such as noise from wires and electrode popping. This study used the framework proposed by Jebelli et al. (2018b) to reduce the artifacts in the EEG data obtained from the simulated task. The EEG data were fed into EEGLAB, a MATLAB toolbox for processing physiological data. The extrinsic artifacts were removed using a Bandpass filter with cut-off frequencies of 0.5 and 65 Hz (Jebelli et al., 2018b). Another extrinsic artifact due to noise from wires was removed using a notch filter applied at a frequency of 60Hz. The intrinsic artifacts were removed using independent component analysis (ICA) (Mantini et al., 2008). The EEG data was decomposed using Extended Infomax method into 14 components, representing the 14 channels of the EEG device, and displayed using a scalp heatmap (Frølich & Dowding, 2018). Preprocessed data from eight channels (i.e., AF3, F3, P7, O1, O2, P8, F4, and AF4) were utilized for this study. The data points from the channels were split into training, validation, and testing, accounting for 70%, 10%, and 20% respectively.

3.3 Prediction of EEG Data

3.3.1 Long Short-Term Memory network

LSTM network, deep learning artificial recurrent neural network variant (RNN), was leveraged in this study to forecast subsequent values of the preprocessed EEG data. LSTM takes cognizance of the changes that could occur as the user gets used to the use of the device over time. LSTM neural network processes data by iterating over current time steps and retaining useful information to help with the processing of new data points. The regression LSTM neural network consists of four layers: an input layer, the LSTM layer, the fully connected layer and a regression layer. The input layer accepts the input time-series data and transfers this to the LSTM layer. The LSTM layer comprises of a cell, an entry gate, an exit gate, and a forget gate. The cell stores long-term time-series data and uses the gates to control flow of the data within and out of the cell. The forget gate decides which information should be ignored in the cell. The LSTM layer comprises of 128 hidden units. The number of hidden units determines how much information or data is learned by the layer. More hidden units could result in better results but are more likely to result to overfitting to the training data. The fully connected layer does the discriminative learning in the LSTM network. It learns weights that can identify features in the training data. The regression layer determines the performance metrics needed for the prediction task. The LSTM neural network is trained with a time-series sequence of EEG data, where the outputs are EEG values of subsequent time steps. To prevent overfitting and divergence of the training, the predictors and targets were normalized to zero mean and unit variance (Jebelli et al., 2018b). Hyperparameters have a significant impact on the performance of models. The network was trained with the Adam optimizer, an extension of stochastic gradient descent. In addition, 200 epochs, as well as a learning rate of 0.001 was used.

3.3.2 Performance evaluation

The performance of the LSTM model was evaluated using the Root Mean Square Error and R-squared. Root Mean Square Error (RMSE) is a standard statistical metric for computing accuracy. RMSE is generally used to evaluate the difference between the actual and predicted value from the model. RMSE is determined via equation 1, where A_i and P_i are the actual and predicted EEG datasets respectively, and n is the number of EEG datasets. The lower the RMSE, the better a model would fit a dataset. The R-Squared (R^2) which describes the variance in the response of a regression model, was computed following Renaud and Victoria-Feser (2010). The R^2 value ranges from 0 to 1. The higher the R^2 value, the better a model fits a dataset.

$$RMSE = \sqrt{\sum (P_i - A_i)^2 / n} \quad (1)$$

3.4 Mental Workload

The pre-processed EEG data (from Section 3.2) and the predicted EEG data from Section 3.3.1 were decomposed into frequency components to determine the power spectra of the data using Welch (1967)'s approach. The approach uses fast Fourier transformation with a Hamming window to determine the power spectral density of the EEG data. The relative band power of the windowed or segmented data in theta and alpha frequency bands were determined. Xing et al. (2020) mentioned that theta and/or alpha power are suitable indicators of mental workload. The mental workload of each segment was determined by dividing the absolute power in the theta band with the absolute power in the alpha band. The approximate spectral limits of these frequency bands are 4–8 Hz (theta) and 8–14 Hz (Simon et al., 2011).

4. RESULTS AND DISCUSSION

4.1 Performance of the LSTM Model for Each Channel

Table 1 shows the RMSE and R^2 scores for the EEG channels of one of the test participants. The RMSE values are less than 0.3 with the P7 and O1 channels having the lowest prediction errors. A previous study has indicated that a RMSE value closer to zero gives a better predictive power (Miyamoto et al., 2022). Similarly, the low RMSE in this study shows the high predictive power of the LSTM network in predicting mental workload. The R^2 scores of the channels are more than 0.9 which indicates close alignment or similarity between the predicted and actual EEG values.

Table 1: RMSE and R^2 scores for all the EEG channels.

	AF3	F3	P7	O1	O2	P8	F4	AF4	Average
RMSE	0.1174	0.1404	0.0772	0.0975	0.1700	0.1876	0.2090	0.2225	0.1527
R^2	0.9061	0.9144	0.992	0.9899	0.9941	0.9832	0.9755	0.9771	0.9665

4.2 Mental workload

4.2.1 Comparison between Predicted and Actual PSD

Figure 4 shows the predicted and actual power spectral density of the AF3 and O2 channels for the data of one of the test participants. The predicted and actual data are the red and blue lines respectively. At less than 45Hz, both figures show some consistency between the predicted and actual PSD values.

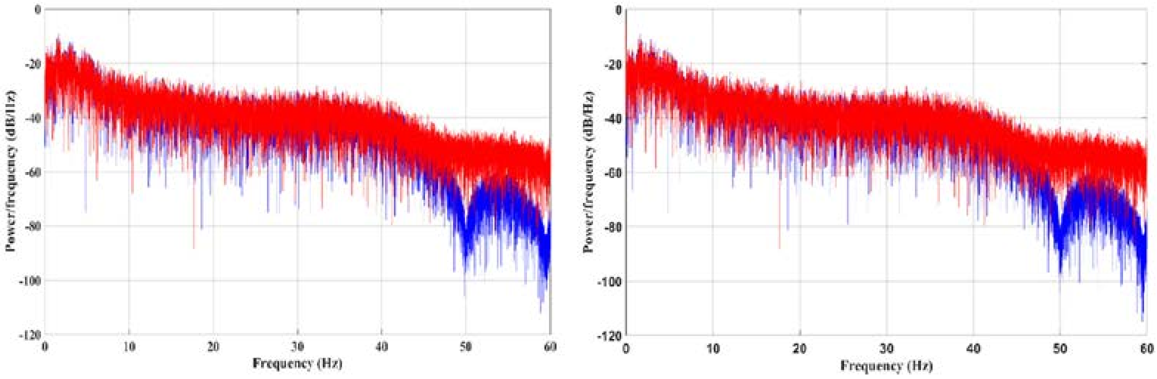

Fig. 4: Predicted and actual power spectral density of the AF3 channel (left) and O2 channel (right).

4.2.2 Mental workload

The extent to which mental workload due to exoskeleton-use can be predicted is illustrated in the scatter diagram in Figure 5. The plot has a R^2 score of 0.8692 indicating a strong correlation between the predicted and the actual mental workload. A previous study (Coulibaly & Baldwin, 2005) has shown that R^2 score between 0.8-0.9 is termed acceptable. The result suggest that it is possible to predict mental workload during exoskeleton-use for construction work. Previous studies have corroborated the assertion that mental workload can be predicted (Borghini et al., 2014; Missonnier et al., 2006; Qin & Bulbul, 2023).

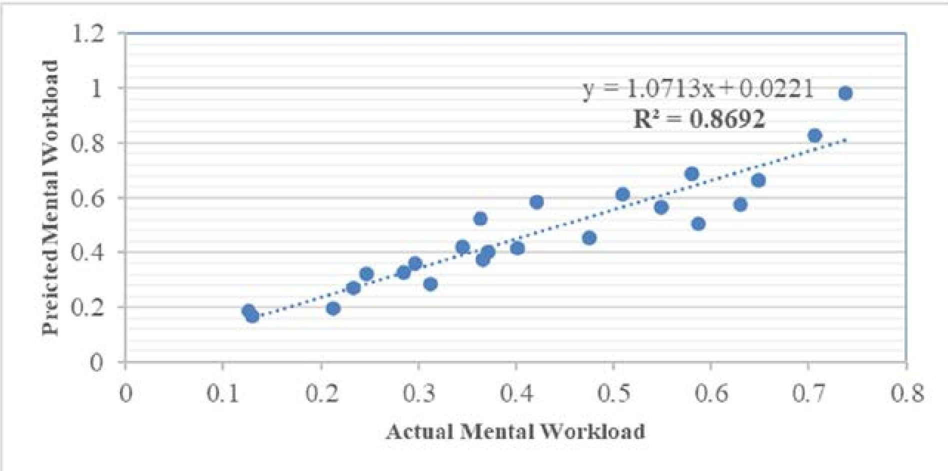

Fig. 5: Comparison of predicted and actual values of the mental workload.

5. CONCLUSIONS, LIMITATIONS AND FUTURE WORK

This study presents the extent to which mental workload due to exoskeleton-use can be predicted from EEG data using Long Short-Term Memory network. EEG data were obtained from an experimental study where participants performed flooring task with an active back-support exoskeleton. The data were preprocessed and trained with the Long Short-Term Memory network to identify unique features for forecasting brain activity. A comparison of the actual and predicted brain activity data indicates close consistency, with average root mean square error and r-squared of 0.1527 and 0.9665 respectively. Similar trends were observed in the comparisons of the predicted and actual power spectrums and mental workload. The results of this study contribute to scarce literature on the impact of unintended consequences of using exoskeletons for construction work. The study motivates investigations into the use of machine learning for real-time performance predictions of technological innovations on construction projects. The study may have been limited due to the sample size of eight participants which was used to train the deep learning algorithm. Training data from a larger sample could improve the performance of the model and its generalizability. This would be achieved by using time-series based data augmentation techniques such as scaling, permutation and generative adversarial networks. Future studies can compare the mental workload of no exoskeleton and active exoskeleton conditions. In addition, further investigation on the suitability of other deep learning networks to identify the most suitable networks for predicting mental workload can be carried out. Besides, future studies can support mental workload prediction with the understanding of the risks influencing mental workload using subjective feedback that describes user experience of exoskeletons.

ABSTRACT: *Computer vision-based safety monitoring requires machine learning models trained on generalized datasets covering various viewpoints, surface properties, and lighting conditions. However, capturing high-quality and extensive datasets for some construction scenarios is challenging at real job sites due to the risky nature of construction scenarios. Previous methods have proposed synthetic data generation techniques involving 2D background randomization with virtual objects in game-based engines. While there has been extensive work on utilizing 360-degree images for various purposes, no study has yet employed 360-degree images for generating synthetic data specifically tailored for construction sites. To improve the synthetic data generation process, this study proposes a 360-degree images-based synthetic data generation approach using Unity 3D game engine. The approach efficiently generates a sizable dataset with better dimensions and scaling, encompassing a range of camera positions with randomized lighting intensities. To check the effectiveness of our proposed method, we conducted a subjective evaluation, considering three key factors: object positioning, scaling in terms of object respective size, and the overall size of the generated dataset. The synthesized images illustrate the visual improvement in all three factors. By offering an improved data generation method for training safety-focused computer vision models, this research has the potential to significantly enhance the automation of the construction safety monitoring process, and hence, this method can bring substantial benefits to the construction industry by improving operational efficiency and reinforcing safety measures for workers.*

KEYWORDS: *360-Degree Images, Computer Vision, Synthetic Data Generation, Game Engine, Object Detection, Construction Safety Monitoring*

1. INTRODUCTION

Effectively monitoring construction sites in real-time demands robust computer vision (CV) models trained on diverse datasets capturing different viewpoints, surface properties, and lighting conditions (Li et al., 2022; Sami Ur Rehman et al., 2022). This diversity ensures accurate and adaptable surveillance for improved safety and efficiency. However, obtaining such extensive and high-quality datasets poses significant challenges. Furthermore, addressing the complexities of dynamic construction environments with numerous elements and rapidly changing conditions is a recognized challenge. To address these issues, the utilization of smart devices for automated progress and real-time construction monitoring through object detection technology and positional data presents a rapid and precise solution (Rho et al., 2020).

Previous methods attempted to address this issue propose synthetic data generation techniques by introducing 2D background randomization with virtual objects in game-based engines (Zhang et al., 2022). While these techniques have shown promise in controlled settings, they still exhibit shortcomings in dynamic construction work environments (Lee et al., 2022). This limitation might arise from the complexity of recreating the intricate interactions among dynamic elements and the complex spatial relationships found in construction sites. Capturing the subtle aspects of depth perception and object occlusion, which are essential for precise object detection, can pose a challenge when working with synthetic datasets (Choi & Pyun, 2021).

This study presents a pioneering method utilizing 360-degree images to craft synthetic data, leveraging the Unity 3D game engine, to comprehensively address these challenges. By adopting this approach, we aim to bridge the gap between synthetic and real-world data, enabling effective training of CV models for construction scenarios. The proposed method efficiently generates a sizable dataset with better dimensions and scaling, encompassing a range of camera positions with day and night lighting intensities. This not only facilitates improved object detection but also opens avenues for applications in construction progress monitoring and site safety analysis. To validate the proposed method, we conducted a thorough analysis, encompassing the examination of three crucial factors: Object Position, objects' size scaling, and dataset size.

Object positioning factor scrutinizes the precision with which objects are localized within the synthetic data. It involves a meticulous assessment of the alignment and placement of objects in relation to their real-world counterparts. Higher accuracy in object positioning indicates closer adherence to reality, crucial for applications demanding precise spatial understanding. Object size scaling refers to the scale at which objects are represented within synthetic data, a critical dimension. This factor entails a meticulous examination of whether the size relationships between objects are faithfully replicated. Accurate scaling ensures that the synthetic data mirrors the real-world environment, influencing tasks where object proportions are of paramount importance. Dataset size describes the magnitude of the dataset generated through the proposed technique, an instrumental metric in its efficacy. A larger dataset not only provides a more comprehensive representation of the construction scenario but also potentially enhances the performance of machine learning models. It enables a broader spectrum of scenarios to be captured, invaluable in training robust computer vision models.

Following the introduction and background section, which provide a thorough overview of the research problem, Section 2 offers an extensive literature review. Section 3 then elaborates on the proposed synthetic data generation method. Section 4 performs a comparative analysis between the proposed approach and conventional methodologies. Finally, the paper concludes by summarizing its contributions and delineating potential avenues for future research.

2. LITERATURE REVIEW

The construction industry encounters formidable challenges in procuring authentic image data, largely stemming from the perilous and dynamic nature of construction sites. In response, synthetic data generated through computer graphics emerges as a promising and cost-effective solution for training machine learning models in the construction sector. This approach proves especially conducive to tasks such as site monitoring, defect detection, and material classification, endowing models with the capability to derive invaluable insights. Consequently, this enhances the efficiency and efficacy of construction processes and outcomes in practical, real-world scenarios.

A suite of techniques, including computer graphics, data simulation, data augmentation, generative adversarial networks (GANs), and synthetic-to-real transfer learning, collectively contribute to the generation of synthetic datasets. Among these, computer graphics entails the creation of three-dimensional (3D) models of objects and scenes through specialized software platforms like Blender, Autodesk 3ds Max, Maya, or the Unity Game Engine. This process culminates in the rendering of these models to generate two-dimensional (2D) images (Frolov et al., 2022). The advantage lies in the controlled environment it affords for data generation, enabling the creation of bespoke datasets with predefined attributes, including controlled variations in lighting, camera angles, or object orientations (Oh et al., 2021; Wong et al., 2019). Data simulation, on the other hand, involves the emulation of the underlying data generation processes and interrelationships between variables. This endeavor yields synthetic images that closely mimic the appearance and geometric characteristics of their real-world counterparts. Concurrently, generative adversarial networks (GANs) represent a neural network architecture comprising a generator network and a discriminator network. This setup empowers the generator to create novel images while the discriminator distinguishes between generated and authentic images, culminating in adversarial training. Moreover, synthetic-to-real transfer learning encompasses the training of a model on synthetic data, followed by fine-tuning on authentic data. This iterative process engenders synthetic data that closely approximates real-world data. These methodologies, whether utilized in isolation or synergy, facilitate the generation of expansive and diverse synthetic datasets for training and assessing machine learning models within the construction domain.

In 2015, Soltani et al. conducted pioneering work in synthetic data generation for excavation tasks, utilizing Autodesk 3ds Max and Google SketchUp in conjunction with Histogram of Gradient (HOG) transformations for precise segmentation (Soltani et al., 2016). Since then, a surge of studies, particularly post-2020, has significantly advanced this field. Neuhausen et al., Kim et al., and Tohidifar et al., turned to Blender software, leveraging its capabilities in constructing intricate 3D models of workers (J. Kim et al., 2022; Neuhausen et al., 2020; Tohidifar et al., 2022). Similarly, Kim et al. extended Blender's utility by creating synthetic images of scaffolds through the integration of point clouds (A. Kim et al., 2022). Barrera-Animas et al., introduced an innovative methodology that combines Blender-based synthetic image generation with automatic labeling, effectively surmounting limitations associated with separate processes (Barrera-Animas & Davila Delgado, 2023).

Wei et al. harnessed Building Information Modeling (BIM) software to create comprehensive 3D models of buildings at various stages of construction. These models were seamlessly integrated with Unreal Engine, facilitating the generation of a synthetic dataset exhibiting diverse light conditions and viewing perspectives (Wei & Akinci, 2022). Sutjaritvorakul et al. and Siu et al. capitalized on Unreal Engine's capabilities to generate images of workers and sewerage pipes, respectively, catering to object detection through closed-circuit television (CCTV) cameras (Siu et al., 2022; Sutjaritvorakul et al., 2020).

More recently, there has been a notable surge in the utilization of the Unity Perception package for synthetic data generation. Another study harnessed Unity Perception to intricately craft building facades in Koto City, employing manual annotation techniques involving polygons and bounding boxes (Zhang et al., 2022). Similarly, few more efforts towards generating datasets tailored for construction workers and excavation tasks, implemented bounding box auto-annotation methods (Assadzadeh et al., 2022; Lee et al., 2022). Notably, the Unity Perception package was initially introduced by Borkman et al. for synthetic dataset creation in computer vision applications (Borkman et al., 2021). This package emerged as an invaluable resource in generating expansive synthetic data sets for our machine learning models. Its rich array of features prompted us to explore its potential with 360-degree images within the construction domain. Noteworthy functionalities such as the Perception Camera and robust data labeling options facilitated the creation of a diverse and highly accurate dataset, crucial for training effective machine learning models. Indeed, earlier studies were constrained by their narrow focus and reliance on manual annotation methods, which limited their scalability and real-world applicability. Moreover, challenges in faithfully replicating dynamic construction environments remained unaddressed. This study pioneers 360-degree image and Unity 3D-based synthetic data generation for construction scenarios, overcoming challenges, and improving object detection for safety and monitoring.

3. METHODOLOGY

The research process outlined in this paper is delineated into five distinct stages, as illustrated in Figure 1. The research process began with Data Collection and Preprocessing, where real-world construction site imagery was gathered and prepared for further analysis. Subsequently, Virtual Construction Site Simulation was conducted to create a digital representation mirroring real-world scenarios. This simulation served as the foundation for generating annotated data through the integration of the Unity Perception package. The package's capabilities, including Perception Camera and data labeling options, played a pivotal role in producing a diverse and accurately annotated dataset. Finally, the Results and Evaluation section scrutinized the performance of the machine learning models trained on the synthetic data, providing valuable insights into their effectiveness in dynamic construction environments. Furthermore, Figure 2 illustrates the complete system architecture.

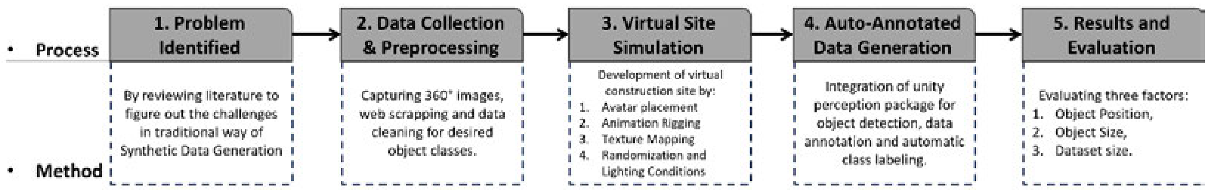

Fig 1: Research Process

3.1 Data collection and preprocessing

The initial phase of constructing our synthetic dataset involved the acquisition of authentic 360-degree images from real-world construction sites. This imperative task was accomplished through on-site visits to various construction locations, where we employed a Ricoh Theta V camera to capture high-fidelity images. A comprehensive set of approximately 49 shots was meticulously taken across three distinct sites. These captures were strategically dispersed across three distinct sites, a deliberate maneuver aimed at ensuring a panoramic representation of both indoor and outdoor contexts. This strategic diversity not only broadens the dataset's scope but also fortifies its ecological fidelity, essential for simulating real-world scenarios accurately.

To uphold the dataset's integrity and applicability, a discerning filtering process was meticulously implemented. This process entailed the deliberate exclusion of instances featuring the target classes or objects slated for subsequent annotation. Moreover, as a supplementary measure to bolster the dataset, an additional 20 images were judiciously selected from reputable online sources. These images underwent a rigorous refinement process, facilitated by Adobe Photoshop, a widely recognized image editing tool. This intervention was crucial in the removal of extraneous elements that might have inadvertently compromised the dataset's fidelity. This meticulous curation was necessitated by the publicly accessible nature of these images.

By rigorously adhering to these meticulous acquisition and preprocessing protocols, we established a robust foundation for the subsequent stages of annotation and synthetic data generation. This methodological rigor ensures that the dataset remains of the highest quality and relevance, serving as an indispensable resource for the accurate training and evaluation of our computer vision models in dynamic construction environments.

3.2 Virtual construction site simulation:

During this pivotal phase, the synthesis of virtual components was meticulously undertaken to construct a dynamic virtual construction site. This critical stage comprised four foundational elements, each of which played a significant role in enhancing the authenticity and diversity of the synthetic dataset. A situation as a case scenario where workers are actively engaged in ladder climbing was meticulously composed to clearly capture the real atmosphere of a construction site environment.

3.2.1 Avatar Placement:

The foundational step involved generating 3D avatars with distinct physical attributes and appearances through Ready Player Me. To augment avatar diversity, human parts from SketchFab were incorporated, with customization of attire and features. Avatars were tailored to emulate team members' characteristics using the Unity 3D avatar maker plugin, and adjustments to facial features and joints were made using Blender and Unity 3D. Six avatars were strategically positioned within the hollow cylinder structure. This included four male workers alternating between two ladders switching on/off at predetermined intervals. Helmets, a safety precaution, were optionally worn during simulation. Dataset diversity was amplified by introducing random alterations in clothing color, pattern, skin complexion, and hair shade. This amalgamation of diverse and realistic avatars not only diversifies the synthetic dataset but also augments its capacity to simulate a broad spectrum of personnel scenarios within a construction site environment.

3.2.2 Animation Rigging:

In the subsequent phase, a climbing animation was seamlessly integrated into the avatars within the unity game engine. A pre-existing climbing animation from Mixamo[1] was utilized and imported into the Unity engine. The animation was then rigged to the avatars, with meticulous adjustment of parameters to ensure perfect synchronization with the ladder model The seamless integration of climbing animations fortifies the dataset by providing a realistic representation of ladder-related actions. This, in turn, equips ML models with the proficiency to accurately identify and classify such actions within the construction site environment.

3.2.3 Texture Mapping:

The Texture Mapping phase was dedicated to seamlessly enveloping the 360-degree background images around the virtual cylinder. Distinct materials were assigned to each image, with meticulous organization within a designated folder named MaterialsBG in the Unity project. To infuse the synthetic data with variety, a script was implemented to randomly select materials from the MaterialsBG folder, generating a diverse array of image frames. This strategic process played a pivotal role in cultivating a truly immersive virtual environment. The judicious mapping of the 360-degree images onto the surface of the cylinder heightened the authenticity of the synthetic dataset, furnishing it with meticulously curated training data of superior quality for ML models.

3.2.4 Randomization and Lighting Conditions:

Dynamic lighting effects were harnessed to infuse our virtual construction site with an authentic and immersive ambiance. The Unity engine's built-in directional light was adeptly employed to replicate a spectrum of natural lighting conditions, spanning dawn, noon, afternoon, and night. A meticulously crafted script dynamically modulated the light intensity, mimicking the natural progression of light over time. This meticulous attention to lighting dynamics further fortified the efficacy of the synthetic dataset, as CV based techniques rely on precise lighting cues for accurate object identification and localization.

3.3 Generating annotated data through unity perception PACKAGE INTEGRATION:

The incorporation of the Unity Perception Package stands as a transformative stride in elevating the authenticity and intricacy of our synthetic dataset. This comprehensive toolset within the Unity environment streamlines the process of automatic labeling and annotation of objects based on pre-defined classes, a critical step for training computer vision models.

At the core of this integration lies the Camera Sensor component. This crucial element faithfully simulates the behavior of a real-world camera, capturing images from the scene with a level of fidelity that closely mirrors actual visual acquisition. This technical facet not only enriches the dataset's realism but also empowers our models to process images in a manner akin to their real-world counterparts. Complementing the Camera Sensor is the Labeler Component, an indispensable tool for training computer vision models. This component meticulously annotates objects within the scene, a vital step in providing the models with ground truth information for accurate object detection and classification. This facet significantly enhances the dataset's utility in training robust models capable of discerning and categorizing objects within complex construction environments. Moreover, the Renderer Component stands as another critical element in this integration. This component harnesses the Unity Perception Package's neural rendering pipeline to meticulously render the scene. By doing so, it imbues the generated images with a level of visual fidelity that is essential for training models to recognize and understand complex, real-world scenarios.

The Labeler Component acts like a foundation in the process of training computer vision models. It interfaces seamlessly with a predefined set of classes and automatically identifies objects within the scene, assigning them appropriate labels based on their class membership. This automated labeling process significantly amplifies the dataset's efficacy in training robust models capable of discerning and categorizing objects within the dynamic and intricate environments of construction sites. The Labeler Component operates in tandem with scripts written in C#, leveraging the Perception API provided by the package. These scripts access object information and apply labels to them based on their class. The API includes functions and methods that facilitate this automatic annotation process. Through the orchestrated interplay of the Labeler Component, Perception API, and scripts, our synthetic dataset gains a precise and detailed ground truth, indispensable for training computer vision models. This annotated data forms the cornerstone of our dataset, empowering our models in object detection and environmental perception tasks within the complex and safety-critical context of construction sites. Through the orchestrated interplay of the Labeler Component, Perception API, and scripts, our synthetic dataset gains a precise and detailed ground truth, indispensable for training computer vision models. This annotated data forms the cornerstone of our dataset, empowering our models in object detection and environmental perception tasks within the complex and safety-critical context of construction sites.

As a result of this integration, the Unity Perception Package generates several key JSON files alongside the image dataset. These files, including 'annotation_definitions.json', 'captures.json', 'metric_definitions.json', 'metrics.json', and 'sensors.json', hold crucial annotation data, capture details, metric definitions, recorded metrics, and sensor information respectively. They play a pivotal role in enriching our dataset for object detection model training and evaluation. The annotation_definitions.json file, for instance, provides detailed information about class labels and object attributes, while captures.json contains information regarding the captured scenes. These JSON files collectively form the backbone of our dataset, empowering our models with the necessary information to accurately perceive and interpret the dynamic construction environment.

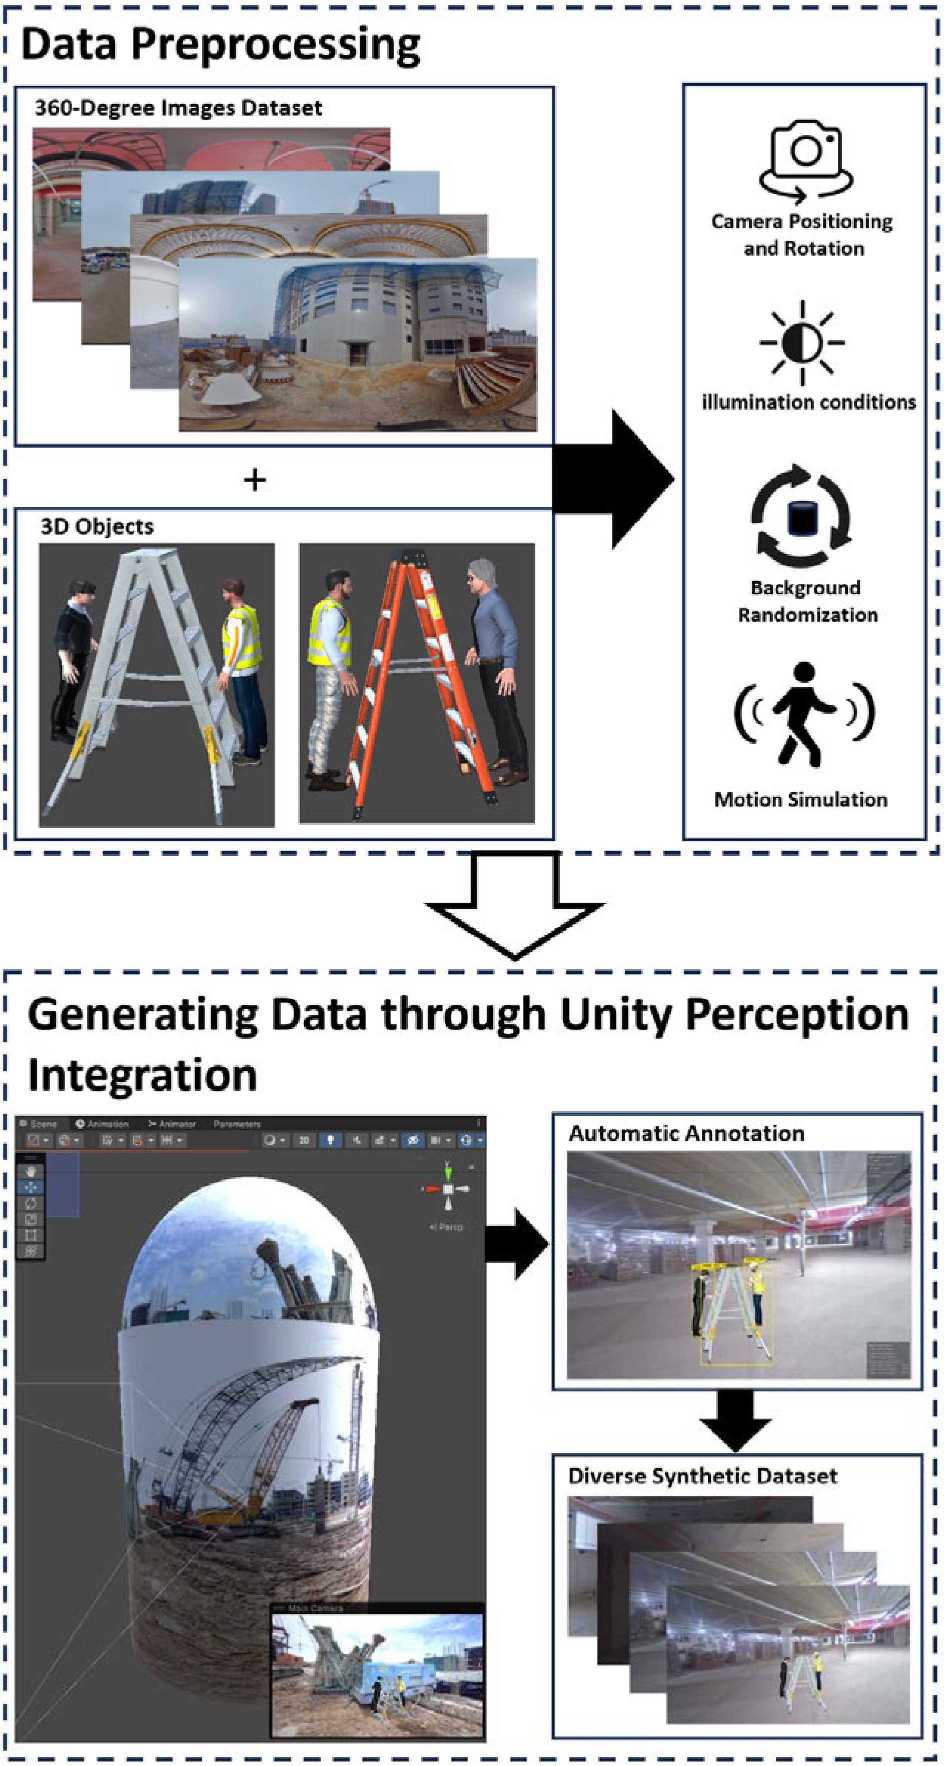

Fig 2: System Architecture explaining whole process of synthetic dataset generation.

4. RESULTS

The synthetic data generated through the proposed approach utilizing 360-degree images was focused on three critical factors: Object Position (Accuracy), Object Size (Scaling), and Dataset Size. The results from proposed techniques are shown in Figure 3.

4.1.1 Object Positioning:

Upon thorough examination, it became evident that the synthetic data derived from 360-degree images demonstrated excellent accuracy in object position determination. The comprehensive perspective offered by 360-degree images facilitated more precise object localization within the construction environment. This was particularly notable in instances where objects were positioned in close proximity or within complex spatial configurations. The enhanced depth perception afforded by the spherical perspective of 360-degree imagery played a pivotal role in accurately pinpointing object locations. Moreover, the capability to observe objects from diverse angles within a single image frame contributed to a deeper comprehension of their spatial relationships within the construction site. This heightened accuracy in object positioning is a critical advantage, especially in safety-critical environments where precise object localization is paramount for accident prevention and worker safety.

4.1.2 Object's Size Scaling:

One of the notable advantages of leveraging 360-degree images was the observed improvement in object size scaling. The spherical perspective offered by 360-degree imagery allowed for a more precise representation of object sizes in relation to their immediate surroundings because it encompassed a comprehensive view of the entire environment without the distortions. This panoramic view allowed for a faithful portrayal of how objects interacted within the construction site, aligning closely with their real-world proportions. This was especially pertinent when considering objects from varying angles or perspectives. The spherical view granted by 360-degree images mitigated distortions, ensuring that object sizes were accurately depicted regardless of the viewing angle. In contrast, data generated from 2D background images often grappled with limitations in faithfully representing object sizes, particularly when objects were viewed from non-standard angles. Additionally, the ability to view objects from multiple angles in a single image frame further contributed to this enhanced accuracy in size representation. This critical improvement in object size scaling with 360-degree imagery contributes significantly to the overall fidelity and accuracy of the synthetic dataset, ultimately enhancing the effectiveness of computer vision models in interpreting real-world construction scenarios.

4.1.3 Dataset Size:

The size of dataset played a pivotal role in influencing the performance of computer vision models. The use of 360-degree images facilitated the creation of a larger dataset. A significant contributor to this considerable dataset expansion is the unique capability of 360-degree images. A single 360-degree image can generate multiple frames, each offering different perspectives while maintaining consistent lighting and camera positions. This efficiency greatly enhances the adaptability and effectiveness of models in real-world construction site scenarios. The substantial dataset derived from 360-degree images significantly broadened the ability of models to generalize and make well-informed decisions across a wide range of construction site scenarios. Undoubtedly, this rich training data strengthened the robustness and competence of models, establishing it as a valuable tool for real-time construction site monitoring.

Fig 3: Results of the proposed approach.

5. DISCUSSION AND CONCLUSION

This study introduces a 360-degree image-based approach for generating synthetic data to train CV models for construction site safety monitoring. The 360-degree dataset excels in object positioning due to its ability to provide a comprehensive view of the construction site from multiple perspectives. This advantage is particularly valuable for precise object localization in complex spatial arrangements common in construction settings. Additionally, the spherical perspective inherent in 360-degree images ensures a more accurate representation of object sizes relative to their surroundings. This accuracy is crucial for effective monitoring in construction environments, as it aligns object proportions faithfully with real-world dimensions. Furthermore, the larger dataset size derived from 360-degree images offers extensive and diverse training data, enabling the model to generalize effectively across various construction scenarios. Unlike 2D images that produce only one synthetic image for one scenario, each 360-degree image can generate multiple synthetic images for one scenario.

The advantages of employing 360-degree images as the foundation for synthetic data generation are multifold. The all-encompassing view offered by 360-degree imagery allowed for a more holistic representation of the construction environment. This comprehensive perspective, combined with the ability to accurately depict object positions and sizes, resulted in a dataset that offered a remarkably realistic simulation of real-world scenarios.

It is important to acknowledge that while this approach demonstrates notable progress, it does have certain limitations. A limitation of using 360-degree imagery, versus prior 2D background images, is handling dynamic elements on construction sites. While offering a broad view, 360-degree images may introduce distortion, especially at the edges, impacting object detection accuracy, especially for peripheral objects. Addressing and correcting this distortion during data generation is crucial for precise computer vision model training. Future research aims to expand the dataset, explore advanced model architectures, and assess data efficacy through computer vision-based model training on actual construction sites. Integration of multimodal information, like combining imagery with LiDAR or other sensors, will enrich the dataset and enhance object detection accuracy. Furthermore, we will objectively measure the effectiveness of the proposed approach by conducting computer vision-based model training and comparing the results with the traditional method of generating synthetic data. This approach holds the potential to serve as a foundational framework for numerous industries, offering a blueprint for the modernization of their safe operations, thereby propelling safety standards and operational prowess to new heights on an international scale.

MACHINE LEARNING-BASED CONSTRUCTION PLANNING AND FORECASTING MODEL

Ahmet E. Keser & Assoc. Prof. Dr. Onur B. Tokdemir

Construction Management, Civil Engineering Department (Istanbul Technical University, Turkey)

ABSTRACT: *Construction planning and scheduling are crucial aspects of project management that require a lot of time and resources to manage effectively. Machine learning and artificial intelligence techniques have shown great potential in improving construction planning and scheduling by providing more accurate insights into project progress and forecasting. This paper proposed a machine learning model that utilizes regularly updated site data to generate predictions of quantity variances from the plan and enable a more accurate forecast of future progress based on historical data on concrete activities. Also, the outputs of this model can be used when creating a schedule for a new project. New schedules created with the help of this model will be more consistent and reliable due to its vast data pool and ability to generate realistic forecasts from this data. The model utilizes data from completed and other ongoing projects to generate insights and provide a more accurate and efficient construction planning and scheduling solution. Within the scope of this study, different attributes of concrete pouring activities of different projects and locations were used as input data for a machine learning process, and then, using this model on test data, the forecast concrete quantities were obtained. This model provides a more advanced solution than traditional project management tools by incorporating machine learning techniques while significantly improving construction planning, scheduling accuracy, and efficiency, leading to more successful projects and increased profitability for construction companies.*

KEYWORDS: *Machine Learning, Planning, Scheduling, Forecasting, Data Visualizing, Construction, Business Intelligence*

1. INTRODUCTION

Developing project schedules is critical to all projects, including engineering, manufacturing, construction, and others (Faghihi, Reinschmidt & Kang, 2014). Creating a reliable schedule and then updating and monitoring it as the project progresses is crucial for project management. A continuous data flow from the site is necessary to monitor project progress correctly. This process creates a vast amount of data. The construction industry deals with significant data from various disciplines throughout the life cycle of a facility (Bilal et al., 2016). Despite the abundance of data generated, its utilization in construction projects is often overlooked, resulting in a staggering amount of unused information. It is postulated that 96% of the data collected during construction projects goes unused (Snyder et al., 2018). In order to harness the potential of this unused data, various techniques such as statistics, machine learning, and artificial intelligence can be employed. Statistics are already commonly studied and applied within the construction sector. However, the importance of machine learning (ML), more generally, artificial intelligence (AI), is mostly overlooked and not being applied by companies as necessary, despite the studies on the matter.

Machine Learning applications have proven to outperform existing techniques, methods, and human decision-making on construction sites (Hammad et al., 2014). These methodologies offer valuable tools for further processing the data, enabling applications such as forecasting, risk analysis, labor allocation, and defect analysis. By leveraging these processes, construction professionals can unlock insights and optimize decision-making throughout the project lifecycle. Exploiting the power of ML data analytics tools can result in significant corporate benefits by enhancing the time performance of construction projects—regarded as one of the critical indicators of a successful project (Gondia et al., 2019). The most important part of construction project scheduling is the selection of resources (e.g., workforce, machines) and harmonizing their work (Jaskowski & Sobotka, 2006). This study aims to create more accurate forecasts for concrete pouring activities for effective planning, such as resource allocation in power plant projects. Often, project planners lack detailed drawings and necessary quantities at the beginning of the project. Even if such information is available initially, these quantities frequently change the project due to various factors. These factors may include unexpected soil features, inexperienced workforce, supplier delays, adverse weather conditions, or suboptimal planning. With the help of Machine Learning, correlations were sought between planned and at-completion quantities for data obtained from construction

projects. Data was collected from various ongoing or completed projects a construction company undertook to accomplish this. This data served as valuable input for machine learning models, enabling us to obtain meaningful and actionable results.

2. MATERIAL AND METHODS

Firstly, data was anonymously collected from 4 different projects (all personal and company-related information was removed). The projects are power plants in the following locations:

- Tashkent, Uzbekistan,
- Ashgabat, Turkmenistan,
- Sulaymaniyah, Iraq (two projects).

The primary data was obtained from the SAP Database ("SAP: Enterprise Application Software," n.d.) of the company, which is updated weekly for every project. SAP export data consisted of detailed weekly progress of the projects. Another data source is the Oracle Primavera ("Primavera P6 Enterprise Project Portfolio Management," n.d.) database. The company database has detailed L3 Updated Schedules and Baselines for each project. These schedules can provide planned and at-completion durations and start/finish dates if needed. At the date of this study, one of the projects was completed, and the other two were still ongoing, so data until the latest data date (30.06.2023) was used even though some of the activities were not completed.

Firstly, concrete pouring activities were filtered. The projects and schedules were taken from the same company and created according to the same procedures. Thus, all concrete pouring activities' wording and coding format are the same, as shown in Table 1.

Table 1: Activity ID and Name Structure of the Schedules

Activity ID	Activity Name
BZC-U-C-UBE-1800	Excavation of Soil - Foundation Level - Control Building
BZC-U-C-UBE-1810	Filling & Compaction - Foundation Level - Control Building
BZC-U-C-UBE-1860	Lean Concrete Pouring - Foundation Level - Control Building
BZC-U-C-UBE-1820	Installation of Formwork - Foundation Level - Control Building
BZC-U-C-UBE-1830	Installation of Rebar - Foundation Level - Control Building
BZC-U-C-UBE-1840	Concrete Pouring - Foundation Level - Control Building
BZC-U-C-UBE-1870	Installation of Formwork for Column - Ground Floor - Control Building
BZC-U-C-UBE-1880	Installation of Rebar for Column - Ground Floor - Control Building
BZC-U-C-UBE-1890	Concrete Pouring for Column - Ground Floor - Control Building
BZC-U-C-UBE-2040	Installation of Formwork for Beam & SLCA - Ground Floor - Control Building
BZC-U-C-UBE-2050	Installation of Rebar for Beam & Slab - Ground Floor - Control Building
BZC-U-C-UBE-2060	Concrete Pouring for Beam & Slab - Ground Floor - Control Building

The wording format of the data is as follows;

"Activity Description" – Level/Element – Building

The concrete activities start with "Concrete Pouring" as Activity Description. After the activity description, another attribute can be "level" or "element": foundation, column, slab, pedestal, wall, or trench. Moreover, there are different buildings of different sizes and floors. However, these projects mostly have concrete structures for mechanical and electrical equipment foundations. The data pool consisted of 263 activities; 180 were foundation concrete, and the other 83 were the other types of concrete activities.

RapidMiner (Mierswa & Klinkenberg 2018) was used as a tool for further processes. Rapidminer is a program that enables modifying the data and applying various Machine Learning techniques with a simple interface.

Raw data consists of planned quantities for each activity, weekly realized quantity for every data date, at completion quantity, project name, and project country for every activity. The data was manually transformed to distribute the attributes in the activity names to different columns for the machine-learning processes. In the early stages of the projects, planned quantity values were set to "1" for some of the foundation activities due to the unavailability of concrete quantity data during the baseline schedule development. As the concrete pouring activities progressed, these 'at completion' quantities for these specific activities were updated to reflect the actual volumes poured.

These activities need to be considered as outliers. The outlier is the data far from the average value of a statistics group. Outliers may affect the statistics and results substantially; therefore, they must be removed from the pool. Normalization is required to detect outliers in data pools with actual values, such as the one in this study, to ensure that variables with different scales are brought to a standard scale, preventing biased results.

In order to apply this process, the model in Fig. 1 was created.

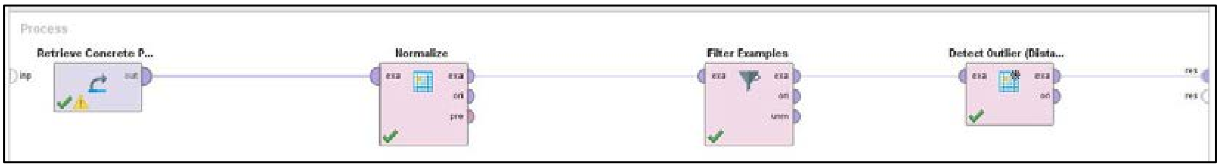

Fig.1: Outlier Detection Model

Due to the abundance of foundation concrete activities, the algorithm considered the "non-foundation" entries as outliers in a previous model. Thus, a "foundation concrete activities" filter was applied to detect outliers only among the foundation activities. The model detected five excessive values (which have value of 1 m^3 as Planned Quantity) as outliers, and these rows were deleted. After clearing the outlier entries, the new model in Fig.2 was created with clean data.

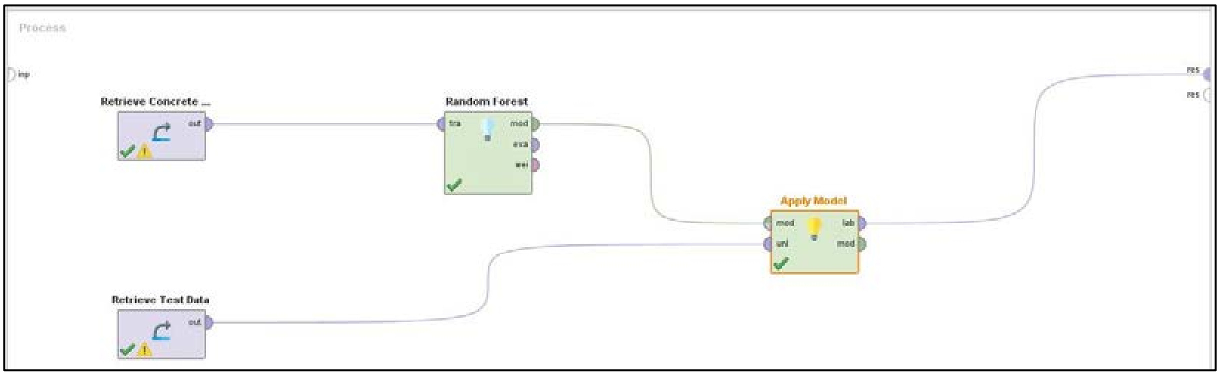

Fig.2: Random Forest ML Model

The input data consists of 5 different columns;

1- Activity ID: It is a unique ID for each activity.
2- Country: It includes the country project taking place.
3- Element Type: Element Type is the type of concrete element, which can be the foundation, column, slab, pedestal, wall, or trench.
4- Planned Quantity: It is the quantity planned at the beginning of the project, according to the baseline schedule.
5- At Completion Quantity: At Completion Quantity is the actual quantity on the site, which often differs from the planned quantity for various reasons.

Activity ID is unique for every row; the country column may include Iraq, Turkmenistan, or Uzbekistan. Element Type is the type of concrete element, which can be a foundation, slab, column, etc. Planned quantity is the quantity specified and planned at the beginning of the project, and At Completion, Quantity is the updated actual quantity throughout the project.

The model learns through the upper arm and applies the process to the Test Data (Table 2) below at the merging point (Apply model). Test Data consists of not started activities from the same three countries; thus, the table does not have at-completion quantities, leaving filling this column to the ML model.

Table 2: Structure of the Test Data

Activity ID	Country	Element Type	Planned Quantity
T_Act1	Iraq	Foundation	286.7
T_Act2	Iraq	Foundation	35.89
T_Act3	Iraq	Foundation	201.49
T_Act4	Turkmenistan	Foundation	31.25
T_Act5	Turkmenistan	Foundation	90.89
T_Act6	Turkmenistan	Foundation	219.19
T_Act7	Iraq	Slab	40.8
T_Act8	Turkmenistan	Slab	23.5
T_Act9	Uzbekistan	Slab	84.5
T_Act10	Iraq	Column	99.21
T_Act11	Turkmenistan	Column	137.69
T_Act12	Uzbekistan	Foundation	140.7
T_Act13	Uzbekistan	Column	175.55
T_Act14	Iraq	Pedestal	121.79
T_Act15	Turkmenistan	Pedestal	132.37
T_Act16	Uzbekistan	Pedestal	212.58
T_Act17	Uzbekistan	Column	90.05
T_Act18	Turkmenistan	Foundation	196.72
T_Act19	Iraq	Foundation	114.84
T_Act20	Turkmenistan	Foundation	108.51
T_Act21	Uzbekistan	Foundation	24.18
T_Act22	Turkmenistan	Wall	131.3
T_Act23	Uzbekistan	Wall	286.66
T_Act24	Turkmenistan	Pedestal	55.83
T_Act25	Uzbekistan	Pedestal	13.6
T_Act26	Iraq	Trench	272.11
T_Act27	Uzbekistan	Trench	155.09
T_Act28	Turkmenistan	Foundation	113.56
T_Act29	Turkmenistan	Foundation	91.76
T_Act30	Uzbekistan	Foundation	96.38

Random Forest regression was selected for the prediction process because more than two parameters affect the at-completion quantity: Country, Element Type, and Planned Quantity. Random Forest Regression is a widely used model in regression and classification problems. The accuracy of predictions increase when there are multiple decision trees.

3. RESULTS AND DISCUSSION

Although the amount is enough for consistency and prediction, usage of a broader data pool enables all the attributes to show effects on the results more clearly. For example, the projects' countries have many hidden variables affecting the quantities; however, this effect could not be seen clearly with only three countries. Also, most of the entries are for foundation concrete activities, so wall or column quantities did not affect the results as intended. Then, using the ML model with the input data in the test table, quantities of the activities were calculated at completion. The Final Table is given in Table.3 Forecasted "At Completion Quantities" are shown in the Prediction Column.

Table 3: Predictions on the Testing Data

Activity ID	Country	Element Type	Planned Quantity	Prediction
T_Act1	Iraq	Foundation	286.7	494.71
T_Act2	Iraq	Foundation	35.89	59.04
T_Act3	Iraq	Foundation	201.49	226.17
T_Act4	Turkmenistan	Foundation	31.25	34.41
T_Act5	Turkmenistan	Foundation	90.89	91.79
T_Act6	Turkmenistan	Foundation	219.19	269.12
T_Act7	Iraq	Slab	40.8	60.73
T_Act8	Turkmenistan	Slab	23.5	31.13
T_Act9	Uzbekistan	Slab	84.5	112.65
T_Act10	Iraq	Column	99.21	159.52
T_Act11	Turkmenistan	Column	137.69	130.16
T_Act12	Uzbekistan	Foundation	140.7	160.31
T_Act13	Uzbekistan	Column	175.55	208.09
T_Act14	Iraq	Pedestal	121.79	206.10
T_Act15	Turkmenistan	Pedestal	132.37	124.42
T_Act16	Uzbekistan	Pedestal	212.58	250.10
T_Act17	Uzbekistan	Column	90.05	122.94
T_Act18	Turkmenistan	Foundation	196.72	227.03
T_Act19	Iraq	Foundation	114.84	221.01
T_Act20	Turkmenistan	Foundation	108.51	66.39
T_Act21	Uzbekistan	Foundation	24.18	154.24
T_Act22	Turkmenistan	Wall	131.3	121.42
T_Act23	Uzbekistan	Wall	286.66	322.51
T_Act24	Turkmenistan	Pedestal	55.83	74.38
T_Act25	Uzbekistan	Pedestal	13.6	32.94
T_Act26	Iraq	Trench	272.11	422.71
T_Act27	Uzbekistan	Trench	155.09	208.74
T_Act28	Turkmenistan	Foundation	113.56	77.91

T_Act29	Turkmenistan	Foundation	91.76	91.79
T_Act30	Uzbekistan	Foundation	96.38	130.45

After inspecting the results and the graph in Fig.3, it was seen that they are consistent. Activities with Iraq in the Country column tend to differ the most from the baseline plan because projects in Iraq suffered from substantial design changes until their completion. On the other hand, the difference is lower in Turkmenistan activities because the baseline plan for the Turkmenistan project was closer to the realized work. Therefore, even if the graph has some more significant gaps, they are because of country and project differences. However, a more extensive data pool would enable predictions with less error if available. The rows with trench, pedestal, and walls do not have as much input data as foundation concrete activities; thus, these predictions may not be as accurate as foundation concrete activities. This study used country and element types as supplementary features to the planned quantities dataset. However, it is worth noting that including more comprehensive variables, such as detailed weather conditions, workforce experience, and material strength, which are known to impact quantities at project completion significantly, can further enhance the predictive accuracy of the model.

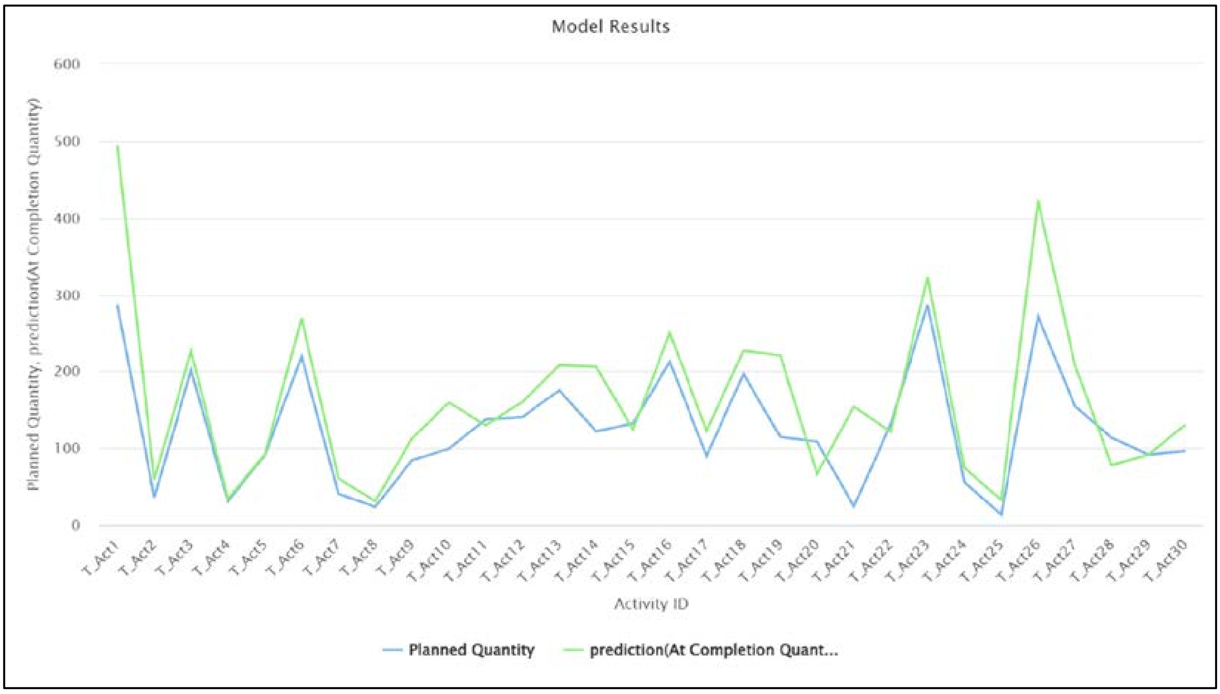

Fig.3: Graph of the Predictions

4. CONCLUSIONS

This study collected data from various ongoing and completed construction projects a construction company undertook, encompassing parameters related to concrete pouring activities. Utilizing advanced supervised learning algorithms, Machine Learning models were trained to establish correlations between planned and at-completion concrete quantities. While the model shows promising potential, it is important to note that future research could obtain more realistic and accurate results with more extensive and diverse data. The optimization of quantity forecasting is a key outcome, and the integration of Machine Learning-based forecasting offers powerful decision support for project management, enabling proactive measures to minimize delays and resource shortages. The successful implementation of Machine Learning underscores the importance of data analytics tools in the construction industry, which, with further exploration and expanded data availability, can lead to improved project management practices, resource utilization, and more profitable projects. It is essential for future research to address data limitations and consider real-time data integration to enhance the reliability and effectiveness of Machine Learning applications in the construction sector.

CONCEPT FOR ENRICHING NISO-STS STANDARDS WITH MACHINE-READABLE REQUIREMENTS AND VALIDATION RULES

Sven Zentgraf, Sherief Ali & Markus König
Chair of Computing in Engineering, Ruhr-Universität Bochum, Germany

ABSTRACT: *During building project planning, various standards, such as material specifications, value ranges, and construction regulations, must be considered. When analyzing a regulation for its BIM-based use, it must be identified which information can be checked directly or indirectly using a BIM model. The basis for the directly checkable information requirements is the explicit description of object classes, object types, properties, and values. Additionally, complex validation rules can be derived from the standards. These information extractions are mostly performed manually and laboriously on text-based regulatory documents. To provide a better data format, the NISO proposed the Standard Tag Suite (NISO-STS), which is an XML format for publishing and exchanging full-text content and metadata of standards. This paper proposes a concept to enrich standards in NISO-STS format with information requirements and validation rules to provide a machine-interpretable semantic knowledge base for BIM processes. To achieve this, the concept utilizes natural language processing (NLP) methods to extract semantic information from the standards. Furthermore, the paper introduces a workflow to transfer the gathered knowledge into the XML-based standard. This allows the acquired semantic knowledge to be used BIM-based and directly updated in future versions of the standards. To show the applicability of the concept an approach is presented in which the obtained information is stored and used as a queryable knowledge base. The resulting database is used by a querying assistant, in which a user can enter keywords and questions that are translated into SPARQL queries to provide answers for the given input.*

KEYWORDS: *Natural Language Processing (NLP), NISO-STS (Standard Tag Suite), Smart Standards, Rule-based model checking, Semantic knowledge*

1. INTRODUCTION

In civil engineering, managing and exchanging information is a non-trivial task due to the complex nature of construction projects and the involvement of numerous stakeholders (Alani et al., 2021; Tomczak et al., 2022). These stakeholders in the Architecture, Engineering, Construction, and Operations (AECO) industry put their priority on ensuring compliance with standards, regulatory documents, and other requirements (Beach et al., 2015). However, formalizing the Information Requirements (IR) and intricate validation rules poses a significant challenge and has hindered the widespread adoption of Building Information Modeling (BIM) practices (Tomczak et al., 2022). The current manual compliance checking process is prone to errors, time-consuming, and costly. Due to the high effort required for the testing processes, in practice testing is only carried out on a random sample and not in its entirety (Z. Zhang et al., 2022, Fauth, 2021). These drawbacks have motivated extensive research into Automated Compliance Checking (ACC).

Acquiring precise IRs and validation rules from guidelines and standards remains a significant obstacle, particularly considering that many of these documents exist in non-machine-readable formats (Schönfelder & König, 2021). Thus, there is a need for a machine-readable and interchangeable format of representation for regulatory documents and standards to extract the desired information for ACC checking. To tackle the challenge of not machine-readable standards, the German Institute for Standardization (DIN) has started the Initiative Smart Standards (Czarny et al., 2021). Their objective is to convert their published standards into machine-readable documents. To fulfill this, they have adopted the NISO Standard Tag Suite (NISO-STS), an XML-based extendable data format introduced by the National Information Standards Organization (NISO). This standardized format is designed to present and preserve the content and metadata of standards and regulatory documents (NISO Standards Tag Suite Working Group, 2017).

This paper presents a concept for enhancing standards and regulatory documents in the NISO-STS format with IR and validation rules. The aim is to establish a machine-interpretable semantic knowledge base that can be seamlessly integrated into BIM processes. To achieve this, natural language processing (NLP) methods are facilitated to extract relevant semantic information from standards in NISO-STS representation. Furthermore, the concept introduces a workflow to transfer the gathered knowledge back into the XML-based standard to link the extracted IRs and rules with the original text. This allows the extracted semantic knowledge to be used on a BIM basis and updated directly when new versions of the standard are created. To show the applicability within BIM

Sven Zentgraf, Sherief Ali, Markus König, *Concept for Enriching NISO-STS Standards with Machine-Readable Requirements and Validation Rules,* pp. 718-728, DOI 10.36253/979-12-215-0289-3.72

workflows, the paper concludes with a demonstrator that can be used to query the semantic knowledge to obtain relevant validation rules and IRs. Overall, this paper aims to address the challenges faced in ACC, information management, and integrating digital information into the BIM workflow.

2. BACKGROUND

This section presents the key terms, concepts, and relevant research for the concept presented in this paper. Initially, the section provides an overview of the Standard Tag Suite developed by the NISO, followed by an introduction to the Initiative Smart Standards proposed by the DIN, which employs this tag suite. Following, an introduction to NLP-based information extraction and knowledge representation is provided. The chapter concludes with a presentation of the current state of research on the topic of code compliance.

2.1 Digital standards

As denoted in Section 1 there is a need for machine-readable, interchangeable, and maintainable regulatory documents and standards for ACC (Schönfelder & König, 2021). For this purpose the NISO in particular the NISO Standards Tag Suite Working Group published the NISO Standards Tag Suite (NISO-STS) in 2017 (NISO Standards Tag Suite Working Group, 2017). The NISO-STS defines a set of XML elements and attributes that describe the complete content and metadata of standards. This includes co-produced standards and standards bodies' adoptions of existing standards, to establish a universal format for publishing and exchanging standards content in all shapes. The primary objective of the NISO-STS is to preserve the content of standards, irrespective of how they were created and delivered. It enables the acquisition of structural and semantic components without being bound to a specific order or textual arrangement. The standard consists of two implementations, referred to as the Interchange Tag Set and the Extended Tag Set. These Tag Sets are constructed from the elements and attributes defined in the NISO-STS and are designed to function as models for publishing and enhanced interoperability of standards and regulatory Documents (NISO Standards Tag Suite Working Group, 2017).

Within Initiative SMART Standards (IDiS) of the DIN, the concepts and implementations of the NISO-STS are used to advance the digitalization of German regulations and standards (Czarny et al., 2021). The IDiS facilitates the establishment of digital standards, which offer information necessary for standardization tasks in a suitable format and scope. A whitepaper has been developed to foster a common understanding and clear action scenarios for implementing digital standards. The document provides a comprehensive understanding of various scenarios concerning standards, encompassing aspects such as maturity, readability, feasibility, interpretability, and even the potential for machine-driven creation. It also addresses the different levels of autonomy in the creation and application of standards and regulatory documents. These levels span from level 0, representing the traditional paper-based format, to a potential level 5, depicting a future scenario where standards are directly influenced and optimized by artificial intelligence (AI). Currently, the DIN is actively engaged in converting all its rules and regulations into a machine-readable XML serialization using the aforementioned NISO-STS model. To effectively implement rules for the ACC of building information models, digital standards at level 3 or higher are necessary. This indicates that the standards must reach a level of autonomy where they can be interpreted and applied by humans and machines (Czarny et al., 2021).

In this contribution, Autonomy Levels 2 and 4 are utilized. A document in Level 2 is a machine-readable XML document and allows the extraction of its textual content and other structural elements for further processing. Within the document's chapters, sentences, graphics, and tables are distinguishable which simplifies a separate examination of the individual components. A Level 4 document contains, in comparison to a Level 2 document, not only machine-readable but also machine-interpretable content that enables a close linkage with execution and application information. These features allow seamless integration of the contained information into other information systems and software tools (Czarny et al., 2021).

2.2 NLP-based information extraction

In the construction industry, the checking of specifications from building codes, regulations, and standards plays a crucial role. Stakeholders involved in a construction project must adhere to precise guidelines in both design and realization, and adherence to these guidelines needs to be consistently proven. One way to ensure compliance is through ACC of building designs. However, for ACC to work effectively, it requires converting the natural language specifications found in regulatory documents into machine-readable constraints (Fuchs & Amor, 2021). To achieve this, NLP methods can be facilitated. NLP is a subfield of AI and computer linguistics that focuses on the interaction between computer or formula languages and human language. It involves the development of algorithms and language models that enable machines to understand, interpret, generate, and manipulate human language effectively (Chowdhary, 2020). NLP utilizes a diverse set of techniques to gain a comprehensive understanding of natural language. These techniques have been applied in various studies to facilitate the full automation of the code compliance process during information extraction from regulatory documents.

Schönfelder and König (2021) proposed a Named Entity Recognition (NER) based model that trained German building code documents on the pre-trained German corpus BERT (Bidirectional Encoder Representations from Transformers). BERT is a language representation model, which is pre-trained on the deep-directional representation of unlabeled text. BERT has shown promising results in eleven natural language processing tasks such as question answering and language inference (Devlin et al., 2019). Schönfelder and König (2021) used the NER technique to label text in the building code as they aimed to train the network based on supervised learning. The study demonstrated results of average performance values of 95.7 % precision and 95.2 % recall. The authors discussed limitations in the study as the proposed concept could provide good results only to the German corpus used.

Some studies employ another technique besides NER as Zhou et al. (2022), and R. Zhang and El-Gohary (2020). Zhou et al. (2022) proposed an approach that deploys NER and Context-Free Grammar (CFG) to formulate a generalized rule interpretation framework. The study focused on analyzing regulatory text to create a syntax tree representing roles and concepts and developing a deep learning network using transfer learning to label the semantic elements in the text. Zhou et al. (2022) presented outcomes with an accuracy of 99.6 % and 91.0 % for parsing single- and multi-requirement sentences. The study stated that it focused on quantitative sentences in the regulatory documents and that more types of sentences will be addressed.

In their work, R. Zhang and El-Gohary(2020)introduced a new machine learning-based approach to automatically match building-code concepts and relations with their equivalent concepts and relations in the Industry Foundation Classes (IFC). The approach was implemented and tested on chapters from the 2009 International Building Code (IBC) and the Champaign 2015 IBC Amendments. The preliminary results achieved a semantic matching performance of 77 % accuracy for matching building-code concepts to IFC elements and 78 % accuracy for matching building-code relations to IFC relations.

2.3 Knowledge representation

There are two fundamental concepts for data and knowledge representation, which are ontologies and knowledge graphs. Ontologies are used widely in various domains to represent the semantics of a specific domain and provide standardized data representation (Ehrlinger & Wöß, 2016). The Interconnected Data Dictionary Ontology (IDDO), developed by Zentgraf et al. (2022), was designed to digitize knowledge from building regulations and construction guidelines. It offers a data schema to describe and manage properties in accordance with ISO 23386 (ISO 23386, 2020). The ontology organizes the digitized knowledge into a hierarchically structured tree of property groups and properties, extracted from natural language texts. Its main purpose is to provide an architecture for transforming building codes into a structured, knowledge-represented format. Encoded in Web Ontology Language (OWL) (Motik et al., 2012), it enables seamless integration and utilization of digitized knowledge in various applications.

Other studies focus on rule formulation from regulatory documents that help the development of ACC frameworks. Wessel et al. (2013) proposed an approach with two parts. The first part involves building an ontology to capture and represent the standards and information found in regulatory documents. In the second part, the enriched ontology is utilized to extract rules. These rules are derived from the information contained within the ontology, facilitating the automated extraction and formalization of regulatory guidelines and requirements. The author states that there are further improvements they are targeting in the future, which aim to enrich the knowledge base and improve automatic reasoning and extraction of rules (Wessel et al., 2013).

2.4 Code Compliance

Building codes are a part of the construction work, which aims to ensure the integrity and compliance of the planned structure. As the review of building codes is a time-consuming and error-prone process, there are a lot of efforts to digitize the process. Accordingly, many research studies use different methodologies to reach the goal of rule extraction. Eastman et al. (2009) stated that the process of rule checking is composed of four steps, which are (1) rule interpretation and logic structuring ; (2) building model preparation; (3) rule checking, and (4) reporting the checking results.

Schwabe et al. (2019) proposed an approach that aims to create a model-based rule checking for the planning of construction site layouts. The study used the open-source rule engine Drools and Industry Foundation Classes (IFC) to extract information from building models and apply rules to the information extracted. Drools is a Business Roles Management System (BRMS) based on Java language, which allows users to create decision models that are based on rules formulated as *when-then* statements, to take an action when a condition is true (Browne, 2009). Schwabe et al. (2019) stated that they are planning to extend the rule sets and experiments with other rule languages in future research.

In their work, Beach et al. (2015)introduced a method that utilizes the semantic web to achieve a comprehensive understanding of regulatory documents. The authors divided the semantic web knowledge into three main concepts, where each concept targets a specific knowledge in the regulation document. Additionally, the authors have used RASE tags to annotate the regulatory document, which is a markup technique applied to text and it is composed of four operators; Requirement, Applicability, Selection, and Exceptions (Hjelseth & Nisbet, 2011). Accordingly, Beach et al. (2015) converted the tags into Semantic Web Rule Language (SWRL), which can conceivably detect if the regulation is in the scope or not.

3. CONCEPT

This paper proposes a concept for the enrichment of digital standards in Level 2 with machine-readable IRs and validation rules to create digital standards at autonomy Level 4. The objective is to establish a machine-interpretable semantic knowledge base that can be integrated into the BIM methodology to support planning processes, ACC, and other BIM practices. To achieve this, an XML-Crawler first processes a digital standard at autonomy Level 2 to extract all contained textual information. This textual information is then forwarded into an NLP pipeline that extracts all relevant IRs and validation rules from the natural language texts. After the extraction the requirements and rules are further processed into suitable data representations and stored in respective databases. The stored data is then used to enrich the analyzed standard to make it compliant with autonomy Level 4 and additional areas of application for the stored data. Additionally, the entire concept is designed to be realized using open data formats and interfaces, aligning with the principles of the openBIM concept.

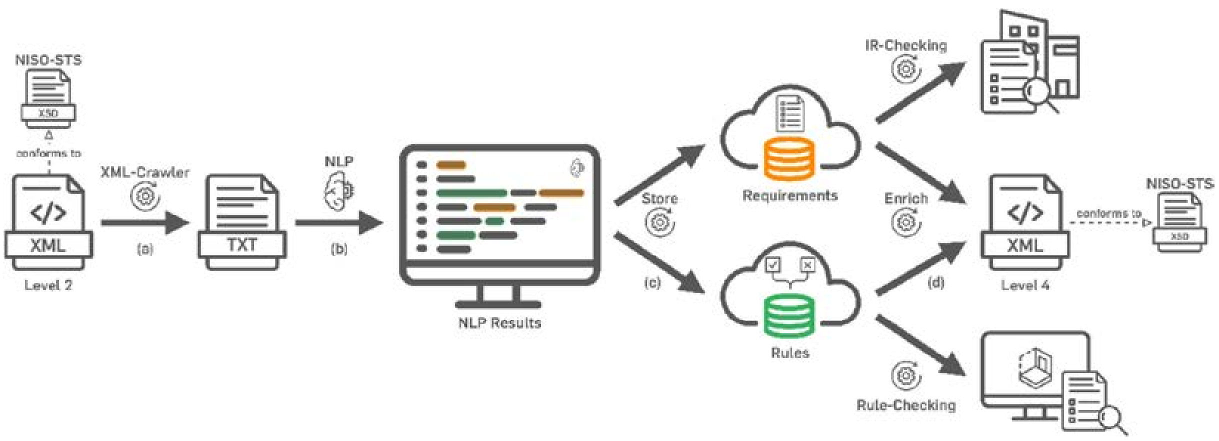

Fig. 1: Schematic representation of the concept

The input for this framework is as mentioned above an XML-serialized digital standard at autonomy Level 2. It complies with the XML Schema Definitions (XSD) specified by the NISO-STS. At Level 2, the document is machine-readable, enabling automated extraction of its structural elements. Granular contents such as chapters, sentences, graphics, and tables can be distinguished and extracted from the document (cf. Section 2.1). Moreover, the separation between representation and content allows a more streamlined and efficient processing of the information (Czarny et al., 2021).

In the initial step of the developed workflow, the uniform structure provided by the autonomy level is utilized. The structure allows the creation of an XML crawler that can efficiently extract all relevant textual information from the standard. A document or in this case, XML crawler is a software or script designed to automatically search and navigate through documents to extract information from these documents and store it for further processing, analysis, or database indexing. Document and XML crawlers are commonly used in search engines and knowledge management systems. The extracted textual data taken from the NISO-STS compliant standard is stored in a plain text format for further processing (cf. Fig. 1 (a)).

Subsequently, algorithms from the field of NLP can be trained using these text-based input data. The aim of the conceptualization, implementation, and training of NLP algorithms within the proposed concept is to find two or optimally one NLP pipeline to find and extract IRs and validation rules which can be further processed (cf. Fig. 1 (b)). To enable the training of such NLP pipelines, further preprocessing of the provided textual information may be necessary. This preprocessing could involve tasks such as sentence tokenization, lemmatization to revert words to their base forms, or conversion of input texts into vectorized representations.

In the third step, the output generated by the NLP pipeline, which includes the identified IRs and validation rules, is further processed (cf. Fig. 1 (c)). The goal is to find suitable data representations for both the IRs and the validation rules. This step involves transforming the extracted information into structured and machine-interpretable formats, making it more accessible for downstream tasks. To achieve this, databases are created to store and manage the extracted IRs and validation rules. These databases are designed to support the creation, storage, organization, exchange, and utilization of data in structured and machine-readable formats. Special attention is given to utilizing open interfaces to ensure interoperability and flexibility. By leveraging open REST (Representational State Transfer) APIs, the databases make the stored information available for seamless integration with other systems and applications.

The last step of the concept is divided into two parts. In the enrichment, IRs and validation rules stored are accessed through REST APIs. Leveraging this extracted data, the analyzed standard of Level 2 is enriched with the extracted elements to a smart standard in autonomy Level 4. As denoted in section 2.1 a Level 4 standard encompasses machine-interpretable content, strongly linked with execution and application information. This capability enables direct executability and seamless integration with other relevant information sources (Czarny et al., 2021). By incorporating machine-readable features, the standard becomes easily interpretable and executable by machines, minimizing the need for manual intervention. This automation enhances efficiency and precision in processes reliant on the standard. Furthermore, the integration of execution and application information allows the automation of specified actions and enables interactions between interconnected systems and data sources. With this enriched autonomy, the standard gains agility in handling dynamic tasks and adapting to changing scenarios. ACC and other complex procedures can be executed with greater effectiveness and consistency, supporting workflows, and enhancing data interoperability.

The second part of the final step focuses on other areas of application of the information extracted from the standards. Fig. 1 (d) illustrates an exemplary area of application of the automatic validation of IRs and validation rules directly at a BIM model, both formally and technically. This type of validation could be integrated into the lifecycle of a construction project during a digital building permit review process. There are several other potential applications for the provided information. For instance, it could be utilized to define the Level of Information Need (LOIN) during the tendering process of buildings or to formulate general modeling guidelines for construction projects. Moreover, it can also support the creation and versioning of new or existing standards, facilitating a more streamlined and efficient standardization process.

By offering different possibilities for leveraging the extracted information requirements and validation rules, this shows the relevance and impact of the NLP-based analysis of standards and regulatory documents in the AECO domains. It enables stakeholders in the construction industry to implement automated validation processes, more streamlined tendering procedures, and maintain consistent modeling practices, leading to improved efficiency and enhanced collaboration throughout the entire construction lifecycle.

4. USE CASE

We aim to develop an approach to convert the knowledge in regulatory documents into a machine-interpretable representation. As the regulatory documents are mostly not computer processable, the purpose is to represent the knowledge in the regulatory document in a knowledge base, which is computer interpretable. Accordingly, the next step is that we apply the rules based on the retrieved data as illustrated in Fig. 1 on a regulatory document.

The regulatory documents used in this demonstrator are from the Research Society for Roads and Traffic (FGSV) (FGSV Verlag GmbH, 2023), which creates the technical regulations for the entire road and traffic system in Germany. The regulation’s language is German, but the concept has broad applicability and can be extended to any other language. The FGSV has multiple regulations in this area, while we focused on FGSV 499 – RStO12

(Forschungsgesellschaft für Straßen- und Verkehrswesen, 2012). The proposed use case places particular emphasis on one chapter of the mentioned regulatory document. The chapter encompasses introductory text, definitions, tables, and interrelated constraints. The approach of knowledge extraction required extensive and comprehensive reading and understanding of the document, to extract the correlations and interrelationships in the text. The knowledge acquisition is performed manually by highlighting the logical sentences, descriptive texts, and the relationships between the tabulated data and the plain texts.

4.1 Data Preparation

The subsequent action entails gathering the knowledge extracted in a machine-readable format, to be able to formulate rules upon the acquired information. The representation of knowledge is based on the semantic web by employing the OWL and the Resource Description Framework (RDF). The ontology hierarchy and relationships between classes is a complex stage that requires a significant amount of attention to achieve the accurate formulation of knowledge extracted. The software used to create the ontology is Protegé (Musen, 2015). The acquired knowledge from the regulatory document is centered around the construction of roadways. The regulatory document encompasses different classes of soils and the requirements for the subsoil or substructure according to frost sensitivity or other constraints. The soil classes have a minimum thickness delegated to each class and this thickness could be increased or decreased whenever exposed to local conditions, for instance depending on the zone, underground water conditions, or drainage of the roadway. Each local condition possesses a value, which has a positive or negative sign, to raise or lower the thickness of the soil class.

Table 1: Increased or reduced thicknesses due to local conditions (translated (Forschungsgesellschaft für Straßen- und Verkehrswesen, 2012))

Local conditions		**A**	**B**	**C**	**D**	**E**
Frost effect	Zone I	±0 cm				
	Zone II	+5 cm				
	Zone III	+15 cm				
small-scale Climate differences	unfavorable climatic influences, e.g., due to North-facing slopes or in ridge locations of mountains		+5 cm			
	no special climatic influences		±0 cm			
	favorable climatic influences with closed lateral development along the street		-5 cm			
Water conditions in the subsoil	No groundwater and stratum water down to a depth of 1.5 m below the subgrade level			±0 cm		
	Groundwater or stratum water permanently or temporarily higher than 1.5 m below ground level			+5 cm		
Location of the gradient	Incision, gating				+5 cm	
	Terrain height up to 2.0 m				±0 cm	
	Dam > 2.0 m				-5 cm	
Drainage of the roadway/execution of the edge width	Drainage of the roadway via swales, ditches, or the embankments					±0 cm
	Drainage of the roadway and peripheral areas via gutters or drains and pipelines					-5 cm

Furthermore, the regulatory document comprises a section on asphalt base courses, where tabulated data shows different types of base layers without binders and each type has a thickness depending on the load-bearing capacity (cf. Table 1).The document encompasses abundant data about how to construct the roadways and the constraints encountered, which affect the substructure or superstructure. The stated knowledge is represented as an ontology through different classes and properties. To ensure the ontology's coherence and compatibility, it is structured based on the IDDO (Zentgraf et al., 2022), which provides an architecture for transferring building codes into a structured format based on the data schema of ISO 23386 (ISO 23386, 2020). As a result, the knowledge is well structured through classes and properties in a standardized way.

4.2 Information retrieval

As a prerequisite, it is assumed that the conversion of the regulatory document into a machine-readable format was achieved successfully. The prevailing stage is to retrieve the information stored in the knowledge base in order to be able to apply rules to the retrieved data. The chosen retrieval method is the SPARQL Protocol and RDF Query Language. SPARQL is selected due to its ease of use and applicability to manipulate RDF data, which supports the proposed framework. The ontology is established and structured using Protegé. To enhance the concept's capabilities and prepare for the subsequent step of formulating rules, the queries are interconnected with the RDF data. The querying stage starts with trials to ensure the functionality of the ontology, whether the data is retrieved correctly or not. The objective is to retrieve the classes, properties, and annotations from the ontology. We used to identify the vocabulary from the ontology precisely as SPARQL queries are sensitive and comply with the class naming pattern in the ontology. As a case in point, to begin with, we utilized the first part of the regulatory document, which aims to find the minimum thickness for soil classes. The soil classes are *F1*, *F2*, and *F3*, where each one has a relationship to a local condition. The main class in the ontology, which stores the soil classes is named *Frostempfindlichkeitsklasse*, thus we call the main class in the queries, to get the subclasses, annotations, and relationships assigned to it. The objective is to retrieve the thickness of the soil class, as well as the thickness assigned to the local condition. As a result, the total thickness of the soil class could be calculated, and the final thickness is the sum of the soil thickness and the local condition thickness variable. The final thickness calculation will not be executed through SPARQL queries. This step will be calculated during the formulation of the validation rule instead.

```
WHERE
{{
        ?frostklasse rdfs:subClassOf ont:{class_name} .
        ?klasse rdf:type/rdfs:subClassOf* ?frostklasse .
        ?klasse ont:hasThickness ?Dicke .
        ?klasse ont:BoundaryValue ?Constraint .
        ?Constraint ont:hasThickness ?ConstraintDicke .
        ?GroupOfProperties ont:DateOfCreation ?DateOfCreation .
        FILTER (regex(str(?klasse), "{klass}", "i") && regex(str(?Constraint), "{condition}", "i"))
 }}
GROUP BY ?frostklasse ?Dicke ?klasse ?Constraint ?ConstraintDicke ?DateOfCreation
```

Fig. 2: Excerpt of an example query for detecting the Soil class, the Thickness, the Local condition, and the Local condition

As an example, Fig. 2 shows an excerpt of a query formulated for Rule 2, which detects the Frostklasse (Soil class), Dicke (Thickness), Constraint (Local condition), and Constraint Dicke (Local condition thickness). The same pattern of query formulation is employed for other knowledge data stored in the ontology, taking into account the distinctions in parameters.

4.3 Rule Checking

Our purpose is to build a framework that consists of three components, which are ontology, SPARQL queries, and the Python programming language for conducting additional analysis on the retrieved data and rule development. The rule's structure consists of a condition part *if statement* and the outcome part *Then and Else statements*. Thus, the rules are formulated to execute the results based on specific conditions.

For instance, a rule logic is *if the user selects a class named X*, and *if the user selects a local condition named Y,* then the data for the assigned class based on the local condition selected by the user will be retrieved. Accordingly, some actions will be executed and applied to the retrieved data. For example, the aim is to calculate the final thickness of the subgrade, where the thickness depends on the minimum thickness. This is specified depending on the soil class and local conditions, to increase or decrease the total thickness of the substructure. As a result, the rules calculate the final thickness of the substructure based on the class selected by the user and the local condition selected as well. One of the significant aspects taken into account is that not all the data can be retrieved from the knowledge base with only one SPARQL query, thus every rule formulated has its query. Three rules have been derived from the knowledge extracted from the regulation document.

4.4 User Interface

In the upcoming step, a user interface is implemented, which uses the created validation rules and the converted excerpt from the regulatory document. The aim is to allow the user to interact with the regulatory document through input provision and rule selection. We developed a user interface, which prompts the user for input, such as keywords, filters, or specific entities directly into the interface. Accordingly, the system uses the input to construct a SPARQL query to retrieve the relevant data in the ontology. Furthermore, the interface provides users with a list of pre-defined descriptive rules, each designed to process data based on a certain logic. Additionally, once the user selects a rule, the interface provides an instruction statement, which guides the user on what the system needs to process the data as illustrated in Fig. 3.

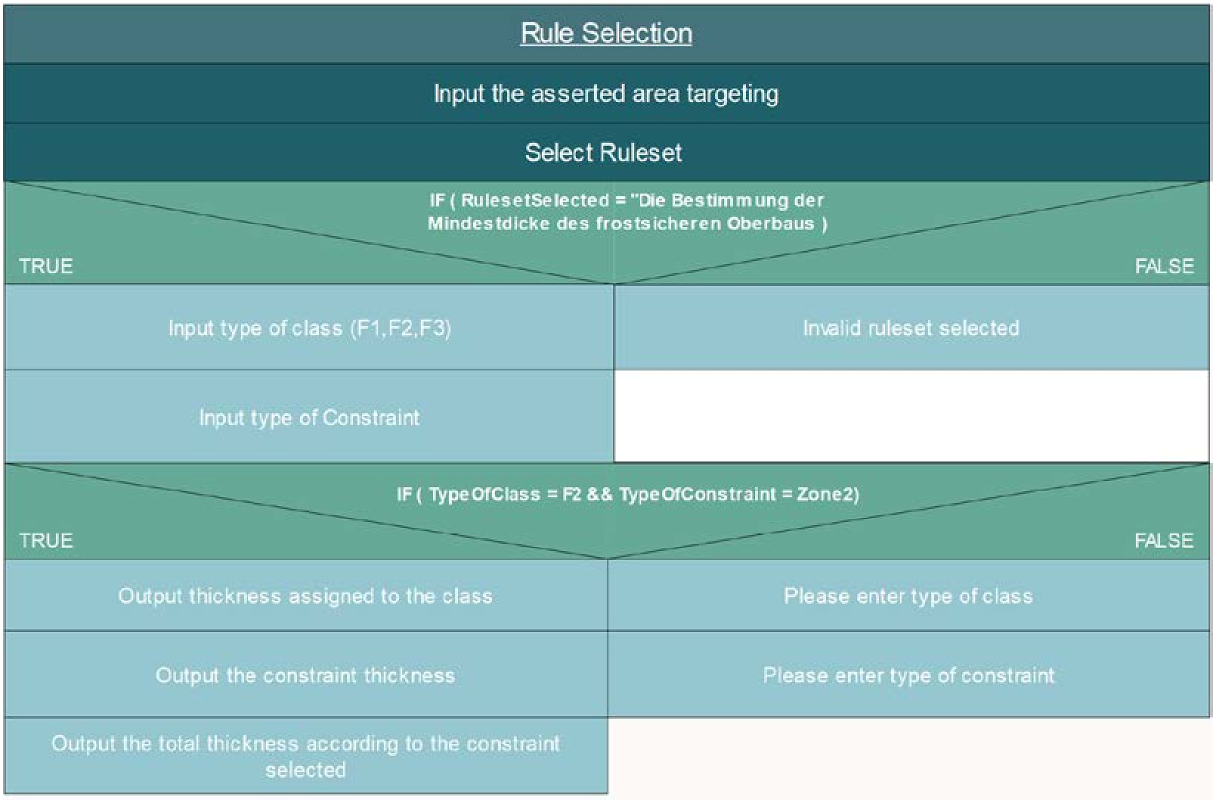

Fig. 3: Nassi-Schneidermann diagram of the program logic of the user interface

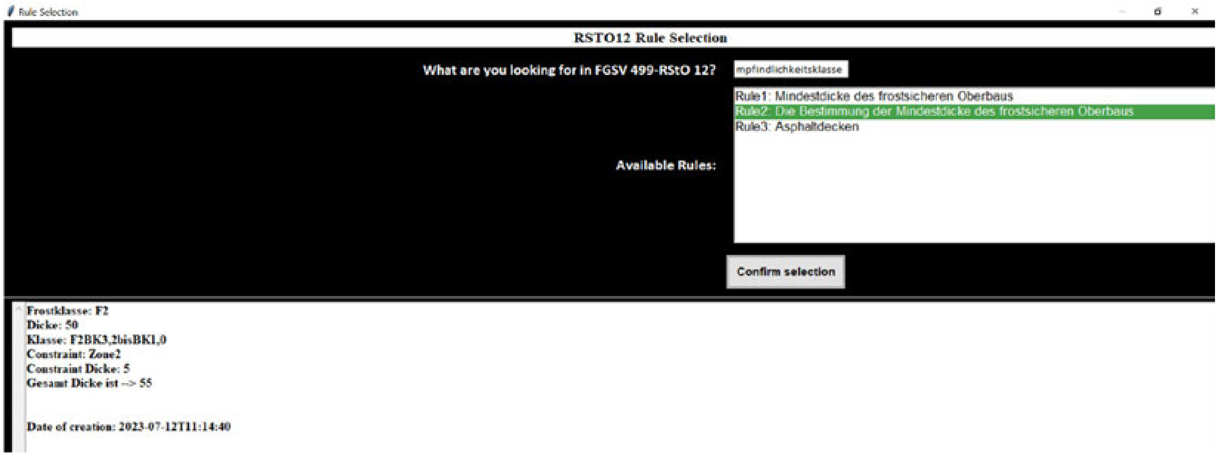

Fig. 4: Results based on the class name specified and the selected rule

The integration of SPARQL and Python rules delivers a comprehensive solution to interact with the knowledge base and perform rule-checking. This process enables the users to interact with the ontology. Fig. 4 shows the prototype of the implemented user interface.

5. CONCLUSION

This contribution provides a concept to enhance digital standards in Level 2 by incorporating machine-readable IRs and validation rules to advance these digital standards into autonomy Level 4. The concept uses an XML document crawler and NLP algorithms to analyze the textual information of an examined standard. The extracted IRs and validation rules are converted and stored in semantic knowledgebases and are made available via open RESTful APIs. With these open interfaces, the rules and requirements can be used to transform the considered standard into a machine-interpretable standard of autonomy Level 4. Furthermore, the gathered rules and requirements can be used in other areas of application within the BIM methodology (cf. Section 3).

One of these application areas is presented in detail in the use case (cf. Section 4). An approach is presented in which the obtained information can be used as a queryable knowledge base. For this purpose, it is assumed that a standard was processed by the NLP algorithm in advance and that the results are available for further processing. In the next step, the obtained information is structured according to the IDDO ontology and stored in a graph database. The resulting database is used as a semantic knowledge base for a querying assistant in the following. Within the assistant, the user can input a fixed set of inputs to query the knowledge base. The entered keywords and questions are translated into SPARQL queries which search the knowledge base to provide the user with an answer to the given input. The presented use case shows the feasibility of the presented concept with a restricted set of possible filters and questions. In future research, it can be considered to extend pre-trained networks, like ChatGPT, by incorporating extracted information from standards and regulatory documents.

Current parts of the concept have already been implemented while others need to be addressed in future work. In their work, Kandt and Zentgraf (2023) presented the implementation of an XML-Crawler for NISO-STS-compliant standards. With the outcome of this contribution, the process step shown in Fig. 1 (a) can be realized. The aforementioned IDDO ontology published by (Zentgraf et al., 2022) can be used to create a graph database for information requirements (cf. Fig. 1 (c)). Apart from outlining the data schema, the paper also introduces a method demonstrating how IDDO can ensure the accuracy of information requirements through the application of Shapes Constraint Language (SHACL) shapes.

In future research, several areas need to be addressed to realize the whole of the presented concept. Firstly, the identification of suitable NLP algorithms for extracting information requirements and validation rules is important. In the following step, it is necessary to define and establish a dedicated database to store, manage, and maintain the extracted validation rules. Building upon this, methods must be developed to automate the enrichment of a Level 2 standard using the extracted information requirements and validation rules, in order to obtain a Level 4 standard. Additionally, potential application areas within the building lifecycle need to be explored. Possible areas where the extracted information could be utilized effectively include Facility Management, refurbishments in combination with sustainability assessments, and other areas.

ABSTRACT: *This paper discusses the potential use of AI in general, and large language models (LLMs) in particular, to support knowledge management (KM) in the building industry. The application of conventional methods and tools for KM in the building industry is currently limited due to the large variability of buildings, and the industry's fragmentation. Instead, relatively labor-intensive methods need to be employed to curate the knowledge gained in previous projects and make it accessible for use in future projects. The recent development of LLMs has the potential to develop new approaches to KM in the building industry. These may include querying a variety of relatively unstructured documents from previous projects and other textual sources of technical expertise, processing these data to create knowledge, identifying patterns, and storing knowledge for future use. A proposed framework is defined for the use of LLMs for KM in construction. We will perform preliminary analyses on how to train models that can generate information and knowledge required to make decisions in the development of specific tasks of fire safety planning.*

KEYWORDS: *Large Language Models (LLMs), Knowledge Management (KM), Fire Safety Planning, Expert Systems (ESs), Artificial Intelligence (AI), Knowledge Graph, Ontology.*

1. INTRODUCTION

In the building industry, ensuring fire safety is of paramount importance. Effective fire safety planning plays a crucial role in mitigating risks, protecting occupants, and minimizing property damage (Kodur et al., 2019). However, the complex and dynamic nature of the building industry poses unique challenges in the realm of fire safety planning such as high fuel (fire) load, improper use of the materials, use of new construction materials with poor fire performance or longer response times for firefighting (Kodur et al., 2019; Parsamehr et al., 2023). Conventional methods and tools for knowledge management (KM) have struggled to adequately address these challenges due to the industry's inherent variability and fragmentation (Nikolic & Dakic, 2015).

Traditionally, fire safety planning has been based on expert knowledge (Maiellaro, 1997; Law & Spinardi, 2021). To curate and leverage the knowledge gained from previous projects for future endeavors, the building industry has relied on labor-intensive approaches. These approaches involve manually extracting and organizing information from disparate sources, making it time-consuming and resource-intensive (Liu, 1995). Consequently, the development and implementation of efficient fire safety planning strategies are hindered, hampering the industry's overall progress.

Expert systems (ESs) have been developed to capture and codify this expert knowledge, making it more accessible to fire safety professionals. However, ESs have a number of limitations, including the fact that they are difficult to maintain and update, and they can be inflexible in dealing with new or unforeseen situations (Tofiło et al., 2013).

Nevertheless, recent advancements in the field of Artificial Intelligence (AI), particularly in large language models (LLMs), offer new opportunities for overcoming knowledge management issues in the building industry. LLMs are a type of artificial intelligence (AI) that are trained on massive datasets of text and code (Shanahan, 2023). This allows them to learn the relationships between concepts and to generate text that is both informative and comprehensive. LLMs, such as OpenAI's GPT-3.5, have the potential to revolutionize the way knowledge is accessed, processed, and utilized.

The utilization of LLMs in fire safety planning offers the potential benefits of accessing and processing extensive data from previous projects, identifying patterns and trends in fire safety data, generating novel knowledge and insights, and adapting to new or unforeseen situations. These advancements can significantly improve decision-making processes and enhance the overall effectiveness of fire safety planning in the building industry.

Therefore, the primary goal of this paper is to investigate and assess the potential of LLMs in the context of fire safety planning. In pursuit of this objective, the current state of the art in expert systems (ESs) employed for fire

safety planning will be conducted and LLMs will be introduced as an innovative approach to help define scenarios to ESs. Finally, the research will demonstrate the preliminary test results and conclude with future research directions in order to realize the full potential of LLMs for fire safety planning.

2. THE CHARACTERISTICS OF ESS AND LARGE LANGUAGE MODELS (LLMS)

AI systems process and analyze large datasets with the view of identifying patterns, relationships, drawing inferences, recommendations and taking action. With the advancement in AI, conversational AI came of age in 2010 to deal with the application of Natural Language Processing (NLP) to enable computers to interact with humans in a conversational way using natural language. The majority of the developed conversational AI agents in the AEC industry are based on the traditional approach to NLP, which requires time for processing the data, and users' interactions are often restricted as the agents are developed with the assumption of happy path users (Saka A. et al., 2023). Large Language Models (LLMs) are neural networks with large parameters and are trained using self-supervised learning and semi-supervised learning on large datasets. LLMs have improved NLP and shifted the direction away from training with labeled data for defined objectives. Generative Pre-trained Transformer (GPT) models which are decoder blocks only from OpenAI have gained significant attention and showed improved performance from GPT-2 (trained with 10 billion tokens) until the latest GPT-4 released in 2023. GPT models use transformer-based models that learn statistical patterns of natural language, enabling them to generate human-like language. One of the main advantages of GPT models is their capacity to produce language that is cohesive, fluent, and nearly indistinguishable from any text produced by humans. These models have been effectively used in a variety of applications, including chatbots, content generation, and machine translation. They can produce answers to open-ended questions, making them an important tool for natural language communication.

Not only have the communication and inference abilities demonstrated to emerge naturally in large language models, but even dedicated experiments have shown that chain-of-thought (COT) prompting improves performance on a range of arithmetic, commonsense, and symbolic reasoning tasks. Indeed, one's own thought process when solving a complicated reasoning task such as a multi-step math word problem entails decomposing that problem into intermediate steps and solving each of them before giving the final answer. A research endowed language models with the ability to generate a chain of thought, i.e. a coherent series of intermediate reasoning steps that lead to the final answer for a problem. It was reported that sufficiently large language models can generate chains of thought if demonstrations of chain-of-thought reasoning are provided in the examples for few-shot prompting (Wei J. et al., 2022). The motivations that led to the development of the chain-of-thought prompting method match the main goals that must be pursued in the field of knowledge management in construction. First, the chain of thought, in principle, allows models to decompose multi-step problems into intermediate steps, which means that additional computation can be allocated to problems that require more reasoning steps. Second, a chain of thought provides an interpretable window into the behavior of the model, suggesting how it might have arrived at a particular answer and providing opportunities to debug where the reasoning path went wrong. Third, chain-of-thought reasoning can be used for tasks such as math word problems, commonsense reasoning, and symbolic manipulation, and is potentially applicable (at least in principle) to any task that humans can solve via language. Finally, chain-of-thought reasoning can be readily elicited in sufficiently large off-the-shelf language models simply by including examples of chain-of-thought sequences into the examples of few-shot prompting (Wei J. et al., 2022). Among the main findings from this study, we would like to stress that chain-of-thought prompting does not positively impact performance for small models, rather it has larger performance gains for more-complicated problems. In addition, chain-of-thought prompting via GPT-3 compares favorably to prior state of the art, which typically finetunes a task-specific model on a labeled training dataset.

Although the construction industry is information-intensive and relies on myriad and diverse information from different stakeholders, there is a lack of information integration, reuse, and efficient management, all of which have an impact on the productivity of the industry. In other words, we must find out how to represent large amounts of diverse knowledge in a fashion that permits their effective use and interaction (Goldstein I, & Papert S., 1977). An expert system is a computer program whose performance is guided by specific, expert knowledge in solving problems. The problem-solving focus is crucial in this characterization because there must be the knowledge of central interest that can guide the search for solutions. The word "expert" implies narrow specialization (or focus) and substantial competence. It is intended to solve problems that are otherwise solved by people having dedicated training and exceptional skills. Thus, the standard of performance for expert systems is in human terms, by comparison with people carrying out a particular kind of task (Stefik M., 2014). Nowadays, expert systems are being used in a wide range of different interactive roles, such as smart spreadsheets, financial advisors, planning assistants, and cognitive coprocessors. In whatever role we employ expert systems, those systems require knowledge to be competent, the so-called knowledge base. Such knowledge must be elicited through effective techniques from multiple human experts. Then, techniques to process such knowledge should be adopted to work out a robust, reliable, and flexible expert system (Fekri-Ershad, S., 2013). Even in the most successful applications where expert systems outperform human experts in their reliability and consistency of results, expert systems have less breadth and flexibility than human experts. In this context, LLMs can help enhance the flexibility and reliability of expert systems, thanks to their ability to manage large amounts of information, even if it is not structured such as written documents, technical standards and regulations. GPT models are trained using vast amounts of unstructured text data, enabling them to generate language almost indistinguishable from human-generated text (OpenAI, 2023). The synoptic chart included below as Table 1, discusses how LLMs can be a potential tool for improving knowledge management in the building industry. LLMs can help widen the scope of expert systems thanks to their ability to scrape information from any (even) unstructured knowledge sources as soon as it is made available. Hence, they can increase and update the knowledge base of an expert system and set up decisional processes that integrate advanced paradigms.

Table 1: Leveraging LLMs to enhance decision-making in combination with expert systems

	Expert Systems	***Large Language Models***
Goal	*Supporting decision-making with a specific task*	*Eliciting additional information to broaden out the expert system*
Input	*Quantitative and structured data*	*Any type of (even) unstructured data*
Approach	*Combination of logical rules and a knowledge base to make inferences*	*Deriving statistical patterns from evidence and performing reinforcement learning*
Method	*Symbolic AI*	*Transformers*
Interface	*Digital*	*Answers to questions in human-like language / chain-of-thought*
Output	*Recommendations and advice for specific scenarios*	*Arguing scenarios representing the dynamics of complex systems*

3. DISCUSSION OF GAPS AND COMPLEMENTARY ASPECTS

Few research works have applied GPT models in construction case studies. They mainly are concerned with information retrieval from BIM models and scheduling and sequencing tasks. These investigations helped find out inherent limitations, and they paved the way to an extended research review, that investigated opportunities and challenges about the practicality of GPT models in the construction industry (Saka A., 2023). These opportunities are categorized into different phases of the construction project lifecycle: predesign, design, construction, operation, and demolition.

In the pre-design phase, GPT models incorporated into predesign processes can help simplify decision-making, enhance communication among stakeholders, and speed up the discovery of design restrictions and possibilities. Similarly, they may support decisions with their powerful natural language processing and machine learning capabilities of evaluating data, delivering insightful suggestions, and promoting more efficient cooperation among stakeholders through real-time information and predictive analysis.

In the design phase, GPT models can automate regulatory compliance checks, reducing errors, and streamlining the design process. Other representative applications could be quantity take-off and costing (because GPT models can be leveraged by providing textual data for the model with necessary cost databases and estimation methods). If provided with information on standards, regulations, passive design principles, and renewable energy systems, GPT models can be leveraged for improving energy efficiency analysis.

In the construction phase, GPT models can capture and interpret textual information, enabling a more comprehensive understanding of construction project scheduling and logistics by means of a more flexible and intuitive approach than mathematical modeling. Other applications include dynamic risk identification and assessment by scrutinizing large volumes of project documents and historical data; enhancing progress monitoring and reporting by analyzing textual project updates and reports; site safety management; resource allocation and optimization; planning and organizing inspection and testing activities; claim and dispute resolution.

In the operation and maintenance phase, GPT can assist in predicting energy demand patterns, allowing for better planning and allocation of energy resources and providing customized recommendations. They could predict an asset's remaining useful life, predicting maintenance and repairs. They can be trained with relevant compliance documents, guidelines, and reporting requirements to capture patterns and embedded knowledge. These models can be used in compliance evaluation of facility management activities. Other applications might be space allocation for the best usage in a facility; generating sustainability reports; analyzing waste-related data.

In the demolition phase, GPT models can process large volumes of data, in order to: determine optimal demolition sequences, and recommend appropriate safety measures; optimize waste sorting and identify recyclable materials; offer the prospect of redeveloping and repurposing the site; analyze various risk factors and provide more accurate and objective assessments by leveraging their advanced natural language processing (NLP) and machine learning (ML) capabilities.

The analysis performed above suggests that some shared challenges must be faced:

1. Models are prone to hallucination, i.e. they give sound and plausible information that is not true, which reduces system performance and users' expectations.
2. Mainly structured data are usually needed in the fine-tuning of GPT models which are often not readily available in the construction industry; besides, availability and quality of data have been a major challenge for the application of artificial intelligence in the industry.
3. Although GPT models are large language models and trained on large data sets, their ability to understand domain-specific knowledge is limited. As such, there is a need for adequate fine-tuning of GPT models and the provision of context to improve their performance in a technical domain like the construction industry. Similarly, the regulations in the construction industry are many and vary over time.
4. GPT models are trained on large datasets. In the construction industry, data such as project design, cost, contracts, and schedules could be used as inputs, raising the concern of confidentiality of GPT models generating output with sensitive information.
5. There is often resistance to change in the industry. With the growing application of AI, industry practitioners and stakeholders are skeptical about trusting and accepting it.
6. Liability and accountability challenges are due to the training on a large amount of data. Bias, incomplete information and inaccuracies in the training data would affect the output generated by the models.
7. Deployment of GPT models in the construction industry requires new skill sets called "prompt engineering" and training programs for professionals. There are several techniques available for prompt engineering such as zero-shot (i.e. no examples are provided for the models to perform specified tasks), few-shot (i.e. provide contexts and examples in the prompts for the model) and chain-of-thought (CoT), i.e. prompting includes a series of intermediate reasoning steps.

In this paper, preliminary experiments about fine-tuning of GPT models for construction applications will be showcased. One of the objectives is to assess whether fine-tuned GPT models can accomplish a range of tasks with greater accuracy. Pre-training may involve unsupervised learning without labels or annotations. After pre-training, the model can be adjusted for a variety of tasks to increase the quality and accuracy of the text that is produced for that activity, such as language modeling, text categorization, or question-answering. Outcomes of our work include preliminary advice about how knowledge sources must be arranged and how queries can be prompted.

4. POTENTIAL FOR INTEGRATION

This paper discusses the hypothesis that the domain models on which ESs are based can be enriched and expanded through the analysis of relevant scenarios with the help of LLMs, by revealing variables and parameters that are relevant but are currently either excluded from the ES or incorrectly defined in it due to the modeler's bias. Four components are essential to apply such an approach: scenarios, a LLM, an ES and a validation process.

Scenarios: the first step is to identify relevant scenarios that represent real-world situations within the domain of the ES. In this case, the relevant domain is fire safety, and scenarios of fire events are therefore collected. These scenarios should cover a wide range of situations to ensure the system can handle various cases (i.e., different types of fire events). Of particular interest are scenarios that may not occur frequently, but that are still important to handle, as they may reveal aspects that will need to be incorporated into the model of the domain.

LLMS: LLMs can be used to identify patterns, trends, and correlations within the scenarios, thus enriching and expanding the domain model. The process of applying a LLM should be iterative, so that the model can continuously be refined as new scenarios are identified or as the domain evolves. By querying the LLM, different aspects of a scenario can be explored. Each query can build on knowledge gained from the previous queries, allowing the analyst to gradually gain a deeper understanding of the domain. LLMs can challenge existing assumptions and preconceptions, by revealing factors that might have been previously overlooked. They may thus help in avoiding confirmation bias and encourage a more open-minded analysis. Scenarios involving complex interactions between different parameters might be better understood by querying the LLM and exploring how the different factors influence each other. In addition, the analyst can vary certain parameters in the queries to understand how the changes might impact the scenario's outcomes, performing what may be comparable to a sensitivity analysis.

ESs: By repeatedly engaging with a LLM through queries to analyze specific scenarios, the analyst may uncover certain aspects that are otherwise ignored, or that are not well understood. By incorporating those aspects in an existing structured knowledge graph of the ES, the accuracy of the recommendations provided by the ES for such scenarios is increased. This is done by converting the information that is gained into explicit logical statements or rule sets to address varying situations, in a way that represents the real-life decision-making process. The logical statements should be structured in a format suitable for their integration into the existing knowledge graph of the expert system, for example by creating new data fields or modifying existing ones to accommodate the additional information. To account for complex relationships between data in the knowledge graphs, hierarchies of rules can be established, where higher-level rules encompass general scenarios, and lower-level rules handle exceptions and specific cases. This hierarchical structure may support a more detailed and accurate decision-making process.

Validation: The updated knowledge graph of the ES, and the logical statements on which it is based, should be validated by consulting with domain experts, to ensure their accuracy and completeness. Once the enriched knowledge graph is integrated into the existing ES, the system should be thoroughly tested with both previously used and new scenarios to ensure that it performs accurately and reliably. The iterative nature of the process of continuous improvement ensures that the system stays up-to-date and relevant as it learns from new data and insights over time.

To summarize, by enriching and expanding the knowledge graph of an ES through the analysis of relevant scenarios with a LLM, the system can become more robust and capable of supporting informed decision-making in complex real-world situations. By incorporating the aspects uncovered through the querying of a LLM, and defining relevant logical statements, the ES can improve the accuracy of its recommendations for a broader range of scenarios.

5. PROPOSED APPROACH FOR THE USE OF LLMS TO HELP DEFINE SCENARIOS FOR ESS

In the first stage, a LLM is queried that has embedded documents describing scenarios. In GPT (Generative Pre-trained Transformer) models, relevant documents can be embedded to help the model better understand context, and thus improve the accuracy of answers to queries. The embedded documents can be used to fine-tune the GPT model for a specific task. By linking the documents with a query in a single prompt, a unified input is created for the model, allowing it to use the context from the documents to provide more accurate answers to the given queries. Naturally, the quality and relevance of the documents used in the prompt will play a significant role in determining the accuracy of the answers provided, and their selection is therefore crucial.

In the second stage, the answers provided by the LLM are used to enhance the ES. This can be done directly in the ES's knowledge graph, or indirectly through an ontology on which the knowledge graph is based (Figure 1).

The ES's knowledge graphs can be enhanced directly with a set of knowledge units gained from the scenarios by querying the LLM. To do so, the LLMs answers, which are provided in the form of natural language text, must be converted into a structured format that is suitable for their incorporation into the knowledge graph. Typically, entities, relationships, and attributes are extracted from the text, and converted into corresponding nodes, edges, and properties in the knowledge graph, while maintaining the graph's integrity. Depending on the knowledge units that are extracted, existing nodes in the knowledge graph may need to be updated or merged, or new nodes added. Preferably, the newly added knowledge units are linked with the relevant scenarios on which they are based, to maintain traceability and support additional future updates.

Alternatively, the ES's knowledge graph can be enhanced indirectly through an ontology on which it is based. To do so, a semantic ontology needs to be defined and used to create a conceptual bridge between the two systems. This ontology is on the one hand used to define the ES's knowledge graph and is on the other hand repeatedly updated based on the information gained through the interaction with the LLM. The knowledge units, acquired by querying the LLM, are used to define new classes, properties, and relationships in the ontology, thus extending the ontology to better represent the domain. Following this, the ES's knowledge graph is updated based on the extended ontology. Preferably, version control is implemented for the ontology to support the tracking of changes and management of updates. By repeatedly applying the previously described process, the ES can become over time capable of handling a broader range of scenarios with greater accuracy and relevance.

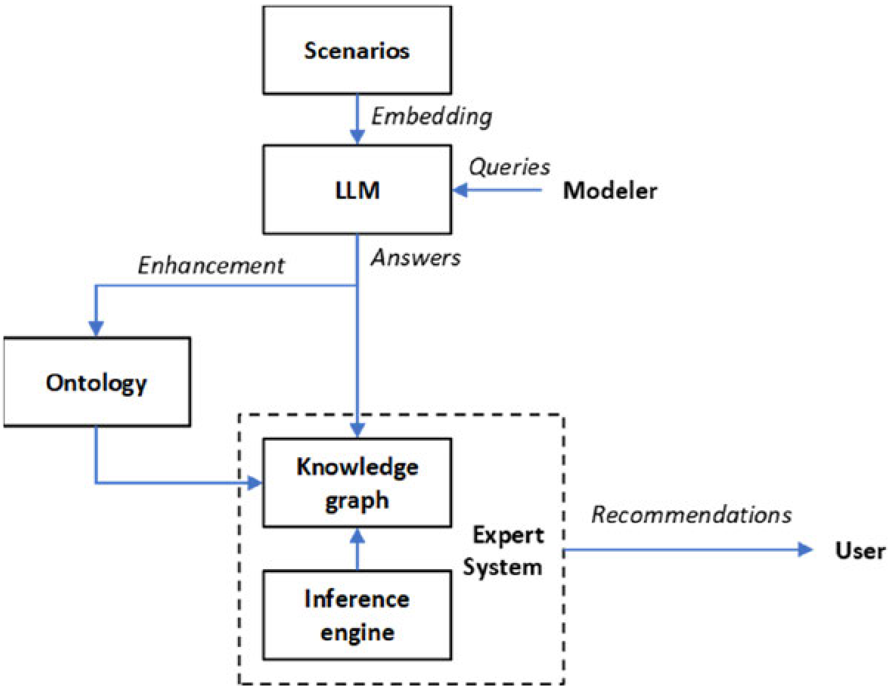

Figure 1: Enhancement of an Expert System using a Large Language Model

6. CHOICE OF THE APPLICATION DOMAIN

The application domain of fire safety planning was chosen for its paramount significance in the building industry and the intricate challenges it poses in safeguarding human life and property from the devastating impacts of fire incidents. Fire incidents in buildings can lead to devastating consequences, including injuries, fatalities, and significant property damage.

By leveraging Large Language Models (LLMs) to systematically analyze reports of real-life fire events, pertinent insights into the factors influencing fire incidents and the efficacy of existing fire safety measures can be extracted. The LLMs provide natural language responses, which can be converted into structured knowledge units suitable for integration into the Expert Systems (ESs) knowledge graph.

Querying reports of fire events and subsequently expanding the ontology based on these queries aligns coherently with the standards set forth by the National Fire Protection Association (NFPA), particularly in Chapter 5, clause 5.5.3. (National Fire Protection Association, 2017). The NFPA emphasizes the criticality of selecting pertinent scenarios, both from predefined options and those deemed relevant by designers, to ensure a comprehensive approach to fire safety planning.

The process of querying, extracting insights, and expanding the ontology facilitates the inclusion of diverse scenarios, encompassing not only common cases but also rare and significant events. The adherence to NFPA standards ensures that the fire safety planning process remains thorough and adaptive, contributing to informed decision-making and improved fire safety strategies in building environments. Consequently, this integration demonstrates the potential to advance knowledge management in the fire safety domain, elevating the overall efficacy of fire safety planning measures.

In the upcoming chapter, a series of tests will be conducted using selected case studies as examples such as, NFPA case study of nightclub fires (Duval, R.F., 2006):

- Rhythm Club, Natchez/Mississippi
- Cocoanut Grove, Boston/ Massachusetts

These case studies, derived from published reports, have been carefully chosen to represent diverse fire safety scenarios encountered in real-world building environments. The adherence to NFPA standards ensures the appropriateness and validity of utilizing published reports for the case studies. These tests will provide valuable insights into the efficacy of the proposed approach, showcasing its potential to enhance knowledge management in fire safety planning and inform more informed decision-making processes.

7. IMPLEMENTATION

To expand the relevant ontology, a modular and contextually aware approach is devised to querying a knowledge corpus for "low temperature" knowledge of a predetermined format, as represented in the ontology. For this, the following components are used.

7.1 Agent-based Methodology

To support the querying of the said corpus, agents will be created and utilized. When creating an LLM-based agent, understanding the nature of the action, or "step" executed by the agent is paramount. The steps can be categorized into:

- User-guided: A user aligns the agent with the target by adding specific information.
- Pre-prompted: The system operates with a generic instruction set to achieve the desired outcome.
- Autonomous: The agent compiles a list of tasks before engaging in user-guided or pre-prompted tasks.

Each of these steps necessitates a mechanism for handling context, as all prompts require appropriate context to yield optimal results. The context influences the stochastic and statistical process of token generation. In this article, we have focused on one step, node querying, which is a pre-prompted step. All steps must be accompanied by the right context. The essence of context handling lies in the creation, storage, and injection of the right bit of context in the proper format (length, form, keywords, wrapping), providing an agent with a solid foundation for action. This mechanism embodies an object-oriented, modular scheme where pre-prompts and context are treated as retrievable objects for injection. These objects are stored in a tree graph, and their predefined format can be utilized for stable injection. Context objects must be designed according to the types of steps and the theme of the project. Each theme presents different objects and relationships, demanding specific syntax to harness hidden semantic information.

The creation of context, being paramount, can be realized through two processes:

- Demanding a Specific Output Format: As part of the agent's response, a certain output format is required for the context object.
- External Ingestion of Information: Utilizing an external mechanism to ingest existing information and represent it in a context object.

As the methodology suggests, the step presented here could be used to continuously enlarge the scope of querying or enable working in parallel on other tasks while offering the right context for them.

7.2 Prompting

To establish the correct behavior for the agent, a system prompt is created first, based on the ontology description and a leading "persona" statement (a role with which the agent's behavior will be aligned).

Example:

```
You are a Fire Evacuation Specialist working with an ontology.

The evacuation of buildings in fire emergency situations is a problem for
which solutions must be found that can help the occupants of these spaces,
guiding them along their route until they are safe. The purpose of the
ontology is to build a knowledge Graph that can contribute to a better
understanding of this topic, as well as to the development of solutions or
systems for the evacuation of buildings more capable of guiding the
occupants of these spaces to a safe place.

Ontology Domain and Scope are:
```

```
Domain: Evacuation of buildings under fire emergency

Focus: Recommendation of evacuation routes in real time based on contextual
information obtained from loT devices.

Contribution: Contributes to a solution for the evacuation of buildings
under fire.

Usage: In fire building evacuation systems.

Purpose: Support interoperability between IoT devices, occupants and other
systems.
```

Next, a ontology python class is created, which is an object-oriented, programming language-resembling representation of an ontology class. The instance can have a description generated for it using the `str` function.

Example:

```
data_property1 = DataProperty("Class_Name", "Property_Name1",
"Description1")

ontology_node = OntologyClass(name="Class_Name", comment="Comment about the
class.", dataproperties=[data_property1, data_property2])
```

The attributes are described as:

```
f"The attribute {self.name} (an attribute to {self.name}) asks:
{self.question}"
```

And the class is then described as:

```
f"The class {self.name} is (are) {self.comment}\nFor finding information to
fill in attributes, consider the following:\n{dataproperties_str}"
```

This representation is used as the "query_node_description".

Next, an example of the "output_format" we demand the agent to follow is given:

```
Formulate your response based on the rule:

1. If you don't know the answer, just respond "Don't know". DO NOT try to
make up an answer.

2. If the question is not related to the context, respond that you are
tuned to only answer questions that are related to the context.

3. DO NOT add anything else to the response.

4. Be clear and precise.

5. Fill the template with information from the context, fill all the
requested data types with information.

Response generic format:

Name: <name>, Description: <description>, Data properties: [<data
properties>]
```

This information is then accompanied by context queried from the knowledge corpus. Texts are extracted from a PDF file and converted into numerical vectors using a specialized PDF processor. This vector representation of the text is stored and then queried using the node description for the retrieval of the top-k results - the context holding the "high-temperature" information.

The augmented prompt is constructed using this formula:

```
Use the following pieces of context to formulate an ontology class instance
representation.

Context:

{context}, {query_node_description}, {output_format}
```

The augmented prompt is then sent to the GPT-4 API for processing and lowering the information's temperature into the required structure.

The above described process will result in the successful curation of information, in a desired structure of one class instance, as it is portrayed in the text. The following are key aspects of the process:

- Data Collection: Utilizing the GPT API to get data from a knowledge corpus to aggregate and accommodate data.
- Knowledge Base Enrichment: Briefly describing the methodology to enrich the knowledge base, including the integration of ontologies, vector handling, and prompt engineering.
- Class Instance Formation: Achieving the structured representation of one class instance from the text, adhering to the defined ontology and prompt templates.

8. CONCLUSIONS

In conclusion, this paper discusses the transformative potential of Large Language Models (LLMs) in Knowledge Management (KM) within the building industry, with a particular focus on fire safety planning. By harnessing the computational prowess of LLMs, a framework is delineated capable of mining unstructured documents from previous projects, processing this data into actionable knowledge, and preserving it for future endeavors.

The challenges for future development of such a framework are multifaceted, and include:

- Accuracy Benchmarking: Creating a mechanism to assess the correctness of the curated information is crucial for ensuring the agent's trustworthiness. This involves evaluating the relevance and consistency of the curated low-temperature information, and employing a back-propagation process to analyze its alignment with the specific domain, ontology, and templates.
- Step Size in Respect of Token Attention Span: The token attention span of the model must be meticulously managed to ensure that the curated information is accurate and properly compiled when augmented into the prompt template. This encompasses careful handling of tokenization, embedding, prompt consciousness, and robust mechanisms for large ontology structures and knowledge corpus.
- Fractured Information Retrieval: Addressing the challenge of incomplete knowledge sources is vital to collect comprehensive information without resorting to premature termination by the model.
- Unwanted Event Amalgamation: Further refinement in the ingestion of PDF files is needed to prevent the creation of class instances that may not be accurately represented in the text.

The outlined challenges, such as accuracy benchmarking and token attention span, underscore the complexities inherent in this approach. Nevertheless, surmounting these hurdles may pave the way for transitioning from labor-intensive curation methods to an automated, intelligent system. This paradigm shift has the potential to change how knowledge is managed in an industry characterized by fragmentation and variability, offering a more streamlined and effective method for capitalizing on past insights to fuel future innovation.

SCHEDULING OPTIMIZATION OF ELECTRIC READY MIXED CONCRETE VEHICLES USING AN IMPROVED MODEL-BASED REINFORCEMENT LEARNING

Zhengyi Chen, Changhao Song, Xiao Zhang & Jack C.P. Cheng*

Department of Civil and Environmental Engineering, The Hong Kong University of Science and Technology, Hong Kong, China

ABSTRACT: *Decarbonizing the construction sector has become an imperative global agenda, with electric machinery playing a pivotal role in realizing this objective. This research concentrates on devising an operational scheduling optimization method for electric ready-mixed concrete vehicles (ERVs) – a groundbreaking, eco-friendly intervention for the construction sector. We commence by outlining a systematic problem definition for the ERV operational process, considering the distinctive characteristics of electric vehicles and ready-mixed concrete (RMC) delivery tasks. The entire process is then conceptualized as a Markov decision problem (MDP), which enables sequential decision-making. We subsequently develop an enhanced model-based reinforcement learning technique, named parallel-masked-decaying Monte Carlo Tree Search (PMD-MCTS), for efficient resolution of the MDP. The entire system is authenticated via a real-world case study, and the PMD-MCTS's performance is juxtaposed against existing benchmarks. The results demonstrate the appropriateness of the proposed MDP formulation for tackling RMC delivery tasks. The PMD-MCTS algorithm and one of its ablation algorithms (PM-MCTS) have demonstrated superior performance compared to other benchmarks in either cost reduction or delay minimization, with PMD-MCTS requiring 30% less computation time than PM-MCTS.*

KEYWORDS: Electric vehicle, Ready-mixed concrete delivery; Scheduling optimization; Model-based reinforcement learning; Monte Carlo Tree Search

1. INTRODUCTION

The escalating issue of carbon emissions, largely attributing to global warming, has necessitated decarbonization as a global imperative for sustainable development (Sinha & Chaturvedi, 2019). As a result, decarbonization has emerged as a global priority for sustainable development (Bogachkova, Guryanova, & Usacheva, 2022). Construction industry activities are a significant source of environmental pollution, responsible for approximately one-third of carbon emissions (Gan, Chan, Tse, Lo, & Cheng, 2017). Specifically, the ready-mixed concrete (RMC) production accounts for a large portion of global emissions (Olanrewaju, Edwards, & Chileshe, 2020). In addition, RMC is a still-growing market due to the rise of green building construction and the urbanization in developing countries (Hart, Nilsson, & Raphael, 1968). Palaniappan, Bashford, Li, Fafitis, and Stecker (2009) indicated that the transportation of RMC represents a major component of energy use and emissions. Therefore, optimizing the scheduling of RMC delivery is crucial for a greener construction industry. Due to the significant development of battery technology and automation, the electric drive technology has been regarded as a promising solution for improving the sustainability of the construction industry (T. Lin et al., 2020). Truck manufacturers have recently developed several electric RMC trucks that aim to implement emission-free transport in the construction industry (*Volvo Trucks delivers the first heavy-duty electric concrete mixer truck to CEMEX*, 2023). However, the academic focus on construction electric vehicles (CEVs), a cross-domain technology integrating the unique properties of electric vehicles (EVs) and the construction industry, has been limited. This research aims to bridge this gap by focusing on the scheduling optimization of electric ready-mixed concrete vehicles (ERV) to further the cause of greener construction.

In the EV domain, several battery-related factors have been extensively studied, such as battery status, charging rates and prices, and charging station locations (Turan, Pedarsani, & Alizadeh, 2020). However, most EV-related studies are not directly applicable to the construction industry due to its unique characteristics and requirements. Furthermore, existing CEV-related studies mainly focus on hardware improvements such as drivetrain (Tong, Jiang, Tong, Zhang, & Wu, 2023) and transmission system (Tan, Yang, Zhao, Hai, & Zhang, 2018), with little attention paid to the management-related topics. Studies related to RMC production and delivery have primarily focused on developing optimization formulations and optimization algorithms. For instance, P.-C. Lin, Wang, Huang, and Wang (2010) formulated the RMC delivery as a job shop problem, where each RMC delivery represents a job operation carried out by one of the trucks that correspond to the workstations. Z. Liu, Zhang, Yu, and Zhou (2017) proposed a time-space network that combines RMC production and vehicle dispatching, and the problem is

optimized by a heuristic algorithm. Nonetheless, these studies overlook the specific properties of ERV, especially those related to the battery, such as charging and energy consumption.

To bridge this gap, our study proposes a scheduling optimization methodology for ERV dispatching. We first provide a detailed problem definition for ERV dispatching, incorporating the unique features of both EVs and RMC delivery tasks. The problem is then modeled as a Markov decision process (MDP) to capture the sequential logic of the RMC dispatching task. Finally, we propose an improved model-based reinforcement learning algorithm to solve the MDP problem. This algorithm, developed using a state-of-the-art Monte Carlo Tree Search (MCTS), is enhanced with a state-dependent action masking and a decaying searching strategy.

2. METHODOLOGY

2.1 ERV Operation Problem Definition

The operation of Electric Ready-mixed Vehicles (ERVs) comprises five components: a) The construction site and b) the ready-mixed concrete (RMC) plant, which are the locations where ERVs are prepared and RMC is poured. c) RMC mixer and d) charging station, which are machinery installed at the RMC plant for loading RMC and charging EVs respectively. Lastly, e) ERVs are the vehicles for dispatching RMC. For the purposes of this study, we assume pumps are pre-installed. The operational process of ERVs can be partitioned into three sections: the in-plant process (IP), the midway process (MP), and the on-site process (OP).

2.1.1 In-plant process

Prior to the delivery of the RMC batch to the construction site, it is imperative that an ERV is adequately prepared with the required RMC and sufficient battery power at the RMC plant. The specificities of two in-plant processes are as follows: **(1) IP1-RMC Production and Loading**: The RMC mixer produces and loads RMC onto ERVs according to the demands, which are typically determined based on the specific requirements of various construction sites. The following assumptions are made: a) RMC mixers can produce any type of required RMC, and the loading rate is set constant in this study for efficient validation. b) The RMC plant can load RMC onto multiple ERVs simultaneously, eliminating any queuing time for the loading (Z. Liu et al., 2017). c) Each ERV should be fully loaded unless it delivers the last batch of the target construction site, which can be smaller than an ERV's capacity. d) The plant owns various types of ERVs, and their loading capacities and operation costs are different (Z. Liu et al., 2017). **(2) IP2-Charging of ERVs**: When an EV's battery is less than its required degree, it will be recharged by charging stations. All the charging stations are installed only in the RMC plant, which is a regular practice in current ERV providers. a) We assume that the charging rates and costs are constant, but a basic cost is set to avoid frequent charging since launching the charging station is power-consuming. b) Multiple ERVs can be recharged simultaneously using multiple charging stations. c) ERVs have different battery capacities, and they can be recharged to a certain level between the existing status and the fully charged status.

2.1.2 Midway process

Following proper preparation, all ERVs should depart from the RMC plant to their corresponding construction sites. Two types of midway processes can be considered: **(1) MP1-Plant to Site**: a) A qualified pump is assumed to be installed on the construction site before the first arrival of ERV. b) To avoid unnecessary battery drainage while waiting with loaded RMC, it is assumed that the ERV will depart only if its arrival time is not earlier than the demand time of the target site. If the arrival time is earlier than the demand time, the ERV's RMC loading time, battery charging time, and travel time will be delayed. c) This study assumes that the ERV has the same traveling speed and battery consumption rate under the loading status. **(2) MP2-Site to Plant**: After unloading a batch of RMC at the construction site, the ERV returns to the plant and prepares for the next delivery batch of RMC. a) It is assumed all RMC have been unloaded, and the ERV is in an empty status. b) All ERVs return with a fixed traveling speed and energy consumption rate in the empty-load status.

2.1.3 On-site process

ERVs are assumed to arrive at the construction site not earlier than the demand time, which allows for the pouring task to commence promptly upon the ERV's arrival. a) Pourings are preferred to be consecutive, but delivery delays are also allowed in real applications. The construction sites claim a maximum for the delivery interval. b) Although static during the pouring process, ERVs remain operational, and a fixed battery consumption rate is assumed. c) This study supposes each construction requires only one ERV for pouring, and the pouring rate is fixed.

2.2 Modeling the ERV Operation Processes via an MDP Model

Based on the ERV operation problem definition, the maximum RMC batch of each construction site can be inferred by considering the minimum ERV capacity and site demands. This allows the ERV operation process to be modeled as a sequential decision-making problem, with the goal of optimizing the dispatch sequence of all the ERVs. During each dispatch, the ERV delivers a batch of RMC to a certain construction site with a certain battery level. Markov Decision Process (MDP) is a potent model-based method for sequential decision-making, which can be solved byiteratively evaluating the reward function for all potential states and actions until convergence to the optimal value (Zhang et al., 2020). Therefore, an MDP formulation is proposed for sequential coverage pattern analysis, represented by a four-element tuple (S, A, Ts,a, Ra). S is the state space, A is the action space, Ts,a is the state transition operator, and Ra is the reward function. These elements are discussed below.

2.2.1 State

S is the state space, $s \in S$ is the current state, which is a tuple of $2N_1 + 2N_2$ components. N_1 denotes the maximum number of ERVs owned by the RMC plant, while N_2 represents the maximum number of construction sites in demand. The MDP state comprises four parts, namely ERV's latest available time (LAT), ERV's battery status, the construction sites' latest demand time (LDT), and the quantities of undelivered RMC. The details of the MDP states are illustrated in Table 1.

Table 1 The definition of the MDP state.

State number	Meaning	Related component	Format
[1, N1]	The latest available time (LAT) of the 1st to the N1th ERVs.	ERV	Day-hour-minutes
[N1+1, 2N1]	The ERVs' battery states on their corresponding LAT.	ERV	kWh
[2N1+1, 2N1+N2]	The latest demand time (LDT) of the 1st to the N3th construction sites.	Construction site	Day-hour-minutes
[2N1+N2+1, 2N1+2N2]	The quantities of undelivered RCM for a certain construction site.	Construction site	m3

For clarification, we consider a scenario with two ERVs, two construction sites, and the state is (9:00, 9:30, 120, 60, 10:30, 12:00, 50, 25) (as shown in Fig. 1). It means that the first ERV is available after 9:00 with a 120-kWh battery, and the second ERV is available after 9:30 with a 60-kWh battery. The first construction site has a latest demand time (LDT) of 10:30 and requires 50 m^3 of RMC. The second construction site has an LDT of 12:00 and requires 25 m^3 of RMC.

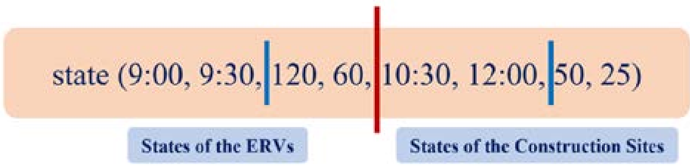

Fig. 1 An illustration of the MDP state

2.2.2 Action

A is the action space, where $a \in A$ is the action taken based on the current state. Each action is denoted by (*e*, *c*, *b*), where *e* is the serial number of the ERV, *c* is the serial number of each construction site, and *b* is the departure battery level. For the battery level, 0 means that the battery is kept unchanged, and its accuracy can be determined based on the user's computational capacity. Following the same scenario in section 3.3.1, we assume a battery accuracy is 5. Then, action (1, 2, 4) means the first ERV deliveries a batch of RMC to the second construction site with an 80-percentage battery, and action (2, 1, 0) means the second ERV is dispatched to the first construction site without charging.

2.2.3 Transition

$\boldsymbol{T_{s,a}}$ is the absolute transition that action *a* in state *s* at step *t* will lead to state *s*' at step *t+1*, as the transition is fully under control in this study. Apart from the state information, additional parameters are clarified for the state transition (Table 2).

Table 2 Fixed parameters for the state transition.

Fixed Parameters	Definition	Related element	Unit
l	The RMC loading rate of the mixer.	RMC mixer	m^3/min
p	The power of the charging station.	Charging station	kw
$g[e]$	The battery capacity of an electric vehicle	ERV	kWh
x	The battery accuracy	ERV	/
$m[e]$	The RMC capacity of the e^{th} ERV.	ERV	m^3
v_1	The vehicle speed of loading status.	ERV	km/hr
v_2	The vehicle speed of empty status.	ERV	km/hr
r_1	The battery consumption rate for the ERVs to travel under loading status.	ERV	%/km
r_2	The battery consumption rate for the ERVs to travel under empty status.	ERV	%/km
r_3	The battery consumption rate for ERVs to conduct the pouring task.	ERV	%/m^3
$d[c]$	The distance from the plant to the c^{th} construction site.	Construction site	km
w	The RMC pouring rate.	ERV	m^3/min

Firstly, the quantity of the RMC required by the target construction site ($s[2N_1 + N_2 + c]$) is compared with the capacity of the ERV ($m[e]$) to get the quantity of delivered RMC $RMC_{deliveried}$ (Eq.(1)). Subsequently, the loading time $t_{loading}$ can be obtained by Eq.(2). Given the action component b and the battery status ($s[N_1 + e]$), the charging time $t_{charging}$ can be calculated using Eq.(3). The departure time from the factory to the construction $t_{departure}$ can be determined by Eq.(4). Based on Eq.(5), the start time of the current dispatch t_{start} can be obtained by comparing the ERV's arrival time ($s[e] + t_{charging} + t_{loading} + t_{departure}$) with the construction site's LDT ($s[2N_1 + c]$). Further, Eqs.(6) and (7) are used to calculate the pouring time $t_{pouring}$ and return time t_{return}.

$$RMC_{deliveried} = \min(s[2N_1 + N_2 + c], m[e]) \quad (1)$$

$$t_{loading} = RMC_{deliveried}/l \quad (2)$$

$$t_{charging} = (\frac{b}{x} * g[e] - s[N_1 + e])/p \quad (3)$$

$$t_{departure} = d[c]/v_1 \quad (4)$$

$$t_{start} = \min\left(s[e] + t_{loading} + t_{charging} + t_{departure}, s[2N_1 + c]\right) \quad (5)$$

$$t_{pouring} = RMC_{deliveried}/w \quad (6)$$

$$t_{return} = d[c]/v_2 \quad (7)$$

The LAT of the current ERV $s[e]$ is updated by adding the pouring time and return time to the start time (Eq.(8)). The ERV's battery level $s[N_1 + e]$ is updated according to Eq.(9), where the second term is the battery consumption during traveling, and the third term is the battery consumption during the pouring task. The target construction site's LDT $s[2N_1 + c]$ is updated by adding the pouring time to the start time (Eq.(10)). Further, the required quantity of RMC $s[2N_1 + N_2 + c]$ can be updated by subtracting the quantity of delivered RMC from the target construction site's initial requirement, as shown in Eq.(11).

$$s[e] = t_{start} + t_{pour} + t_{return} \quad (8)$$

$$s[N_1 + e] = \left(\frac{b}{x} - d[c] * (r_1 + r_2) - RMC_{deliveried} * r_3\right) * g[e] \quad (9)$$

$$s[2N_1 + c] = t_{start} + t_{pour} \quad (10)$$

$$s[2N_1 + N_2 + c] = s[2N_1 + N_2 + c] - RMC_{deliveried} \quad (11)$$

2.2.4 Reward

R_a is the immediate reward of action *a*. In the RMC dispatch task, the objective of the RMC plant is to minimize the operational costs and adhere to the dispatch rules, such as avoiding exceeding the maximum pouring interval. Meanwhile, the construction sites aim to minimize the total delay for the pouring task. Therefore, the total operation costs r_c and the dispatch delay r_d are selected as the two primary reward components. r_c can be calculated by Eq.(12). c_1 ($/min) is the unit cost of the ERV operation, c_2 ($) is the fixed cost of opening the charging station, which aims to avoid frequent charging, and c_3 ($/kWh) is the unit price for ERV charging. The relevant costs of RMC production are not considered as the quantity of the RMC demand is fixed. According to Eq (13), r_d can be calculated by comparing ERV's arrival time with the construction site's LDT.

$$r_c = -c_1[e] * (t_{loading} + t_{charging} + t_{departure} + t_{pouring} + t_{return}) - c_2 * Boolean(t_{charging} > 0) - c_3 * (\frac{b}{x} * g[e] - s[N_1 + e]) \quad (12)$$

$$r_d = -\max(s[e] + t_{charging} + t_{loading} + t_{departure} - s[2N_1 + c], 0) \quad (13)$$

In addition, a significant negative reward r_p is generated if an invalid action is taken. Three types of invalid actions have been identified: 1) Actions that head to the construction site without any demand for RMC, as shown in Eq.(14); 2) Actions with a battery level below the current battery level or the minimum battery requirement (Eq.(15)). 3) Actions that result in a dispatch delay that exceeds the maximum interval δ (Eq.(16)). When the RMC demands of all the construction sites are fulfilled, a great positive reward r_f is generated. Finally, the total reward can be calculated by Eq.(17), where α_1 and α_2 are importance hyper-parameters. Apart from r_f, all other reward components are negative.

$$\boldsymbol{InvalidAction\ 1}: s[2N_1 + N_2 + c] > 0 \quad (14)$$

$$\boldsymbol{InvalidAction\ 2}: b > \max(s[N_1 + e], d[c] * (b_1[e] + b_2[e]) - RMC_{deliveried} * b_3[e]) \quad (15)$$

$$\boldsymbol{InvalidAction\ 3}: s[e] + t_{charging} + t_{loading} + t_{departure} - s[2N_1 + c] \le \delta \quad (16)$$

$$r = r_f + \alpha_1 * r_c + \alpha_2 * r_d + r_p \quad (17)$$

2.3 Optimization Using PMD-MCTS

Many reinforcement learning methods have been developed to solve the MDP problem, including model-free algorithms and model-based algorithms (Sutton & Barto, 2018). Specifically, the model refers to the state transition function $T_{s,a}$ and the reward function R_a of the MDP problem. Compared with model-free methods, model-based reinforcement learning has the great potential to make RL algorithms more sample efficient (Wang et al., 2019). MCTS is a model-based RL algorithm that plans the best action at each time step (Browne et al., 2012). It is an effective heuristic search algorithm for solving episodic decision-making problems when the underlying search spaces are computationally expensive (B. Huang, Boularias, & Yu, 2022). However, MCTS relies on a large number of interactions with the environment emulator to construct the search trees for decision-making (Browne et al., 2012). To mitigate the high time complexity of classical MCTS, this section develops an improved MCTS algorithm， named parallel-masked-decaying MCTS (PMD-MCTS). Specifically, the state-of-the-art parallel MCTS algorithm, WU-UCT (A. Liu et al., 2018), is adopted as the fundamental model. It is further improved by incorporating a state-dependent action masking operation and a decaying search strategy. The details of the algorithm are introduced as follows.

2.3.1 Fundamentals of WU-UCT-based parallel Monte Carlo Tree Search

MCTS adopts a tree-search method that incrementally extends a search tree from the current environment state (Luo et al., 2022). Each node denotes a visited state, and each edge from this state denotes an action that can be taken at that state, leading to a landing node that denotes the state after the transition. Typically, MCTS performs four sequential steps repeatedly: selection, expansion, simulation, and backpropagation (Fig. 2 (a)). The selection step starts from the root node (current state) and recursively selects an existing child node according to a tree policy. The process ends when it reaches a leaf node or other termination conditions. One of the most commonly used node-selection policies is the Upper Confidence bound for Trees (UCT), and the UCT value a_s can be calculated by Eq.(18). Here, *C(s)* represents the child node set of the current node *s*; $V_{s'}$ is the average value estimation for a certain child node s', denoting the exploitation; The second term is the uncertainty of the value estimation, denoting the exploration. N_s and $N_{s'}$ denote the number of times that nodes s and s' have been visited, while β is the factor that controls the trade-off between exploitation and exploration. During the expansion state, a new child node is added to the selected node, and the value of the expanded node is estimated by performing a model-based simulation until termination. The simulation process follows a certain policy (e.g., random). Finally, backpropagation recursively updates the statistics $\{V_s, N_s\}$ from the expanded node to the root node along the selected path. According to Eq.(19), the visit count of each node is increased by 1. The latest value estimation of each node can be obtained by Eq.(20), where γ is the reward discount factor, and a_t is the action that turns the state s_t to the state s_{t+1}. It should be noted that the leaf node s_T obtains its value from the simulation step. Finally, each node's average value estimation is updated according to Ep. (21).

$$a_s = \underset{s' \in C(s)}{\operatorname{argmax}} \left\{ V_{s'} + \beta \sqrt{\frac{2 \log N_s}{N_{s'}}} \right\} \tag{18}$$

$$N_{s_t} = N_{s_t} + 1 \tag{19}$$

$$V'_{s_t} = R(s_t, a_t) + \gamma V'_{s_{t+1}} \tag{20}$$

$$V_{s_t} = \left(\left(N_{s_t} - 1\right) V_{s_t} + V'_{s_t}\right) / N_{s_t} \tag{21}$$

Parallelizing MCTS over multiple workers is an efficient method to improve the optimization speed. During the parallel computation, workers typically operate at different steps as the simulation and expansion processes are slow (Fig. 2 (b)). As a result, the update of statistics $\{V_s, N_s\}$ may become outdated for workers, and the statistics loss becomes inevitable. However, the latest N_s is available as soon as a worker initiates the computation since we only need to know if the node is selected. Therefore, the WU-UCT algorithm partially addresses the information loss by introducing another quantity O into the classical UCT (Eq.(22)), which counts the number of computations that have been initiated but not completed (light dashed blue lines in Fig. 2 (b)). The updated UCT effectively balances exploration-exploitation tradeoff by considering incomplete samples, and the node values can be updated according to Eqs.(23) and (24).

$$a_s = \underset{s' \in C(s)}{\operatorname{argmax}} \left\{ V_{s'} + \beta \sqrt{\frac{2 \log (N_s + O_s)}{N_{s'} + O_{s'}}} \right\} \tag{22}$$

$$\text{Incomplete update:} \quad O_s = O_s + 1 \tag{23}$$

$$\text{Complete update:} \quad O_s = O_s - 1, \quad N_s = N_s + 1 \tag{24}$$

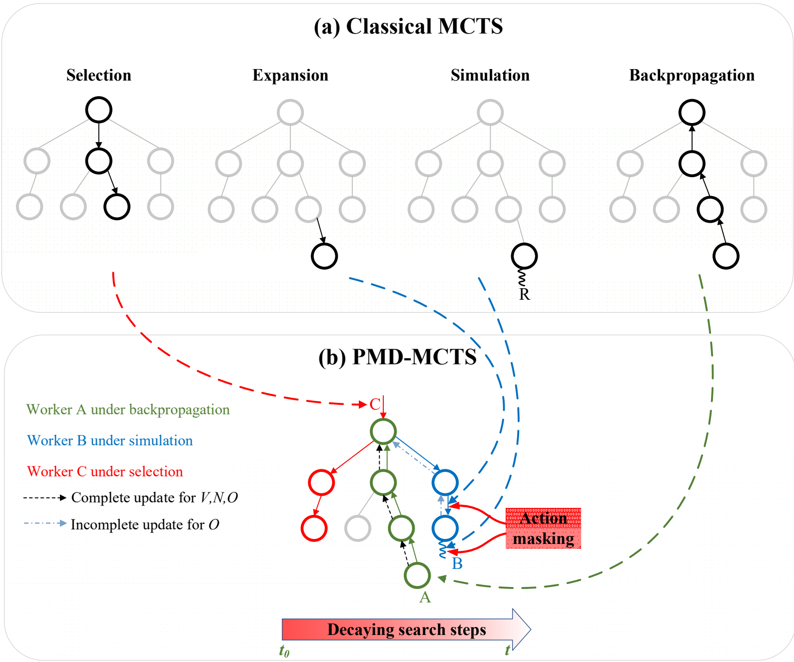

Fig. 2 The relationship between classical MCTS and PMD-MCTS

2.3.2 Action masking

The ERV operation involves complicated rules, and the valid action spaces usually vary under different states. Typically, RL algorithms sample the action from a space containing actions of all states and assign a significant negative reward for invalid actions. However, this kind of invalid action penalty is challenging to explore, particularly when the state is complicated, even for the very first reward (S. Huang & Ontañón, 2020). Hence, this section proposes a state-dependent action masking method to improve MCTS's efficiency (Fig. 2 (b)). First, a complete action space A_0 is generated, which contains all combinations of the ERV's serial number, each construction site's serial number, and the departure battery level. Then, invalid actions (Eqs.(14)-(16)) of A_0 are updated under each state (circles in Fig. 2 (b)), followed by invalid action masking. Specifically, $V_{s'}$ (Eq.(22)) of invalid actions are set as a large negative number M (e.g., $M = -1 \times 10^8$) during the expansion stage. Consequently, only valid actions will be expanded. During the simulation stage, actions are randomly selected from valid candidates, while invalid ones are ignored. In practical implementations, vectorization is adopted for speeding up the masking operations.

2.3.3 Decaying search strategy

During the implementation of MCTS, an initial MDP state is set as the start for optimization. The best child node of the current state is set as the output when the number of iterations is larger than a threshold value of N_δ. Then, the updated state becomes the new start, and the process iteratively continues until the MDP ends. Intuitively, the size of the Monte Carlo tree will decrease gradually, as the quantity of undelivered RMC decreases. Hence, the last stages of MDP may not require many iterations, and this section proposes a decaying threshold to ensure both optimization accuracy and efficiency. The decaying strategy is designed based on the remaining demand for RMC, as shown in Eq.(25). $N_{\delta 0}$ is the maximum number of iterations determined by the users, Q_{left} is the remaining required quantity of RMC, Q_{left} is the total RMC demand, and e is the Euler's number.

$$N_\delta = N_{\delta 0} * \frac{e^{\frac{Q_{demand}}{Q_{total}}}}{e} \tag{25}$$

3. VALIDATION

3.1 Scenario Setup

As the use of electric RMC vehicles is a relatively new solution in the construction industry, a customized dataset for this purpose is currently unavailable. Therefore, it is reasonable and acceptable to utilize data from previous RMC delivery studies to establish the proposed MDP model. Hence, we extracted the basic configurations of sites and RMC vehicles from the dataset of (Z. Liu et al., 2017). The dataset was determined based on a real case, including distances between the sites, RMC demands of the construction sites, RMC loading rate, ERVs' capacities, and relevant costs. We updated certain assumptions from (Z. Liu et al., 2017) in more detail. For example, we provided vehicle speeds for traveling time calculation and determined the battery-related factors based on actual reports (e.g., the charging rates). Table 3 describes the shared parameters, Table 4 indicates the information on the construction sites, and Table 5 shows ERV information. Two objectives are optimized: a) objective 1 aims to minimize the operation costs for the RMC plant, and b) objective 2 aims to minimize the dispatch delay for the construction sites.

Table 3 Information of the shared parameters.

Shared parameters	Value	Unit
RMC loading rate	2	min/m^3
Battery charging power	20	kw
Battery accuracy	5	/
Vehicle speed of loading status	40	km/hr
Vehicle speed of empty status	80	km/hr
Battery consumption rate for ERVs to travel under loading status	1	%/km
Battery consumption rate for ERVs to travel under empty status	0.8	%/km
Battery consumption rate for ERVs to conduct the pouring task	0.25	%/ m^3
RMC unloading rate	0.5	m^3/min
Cost of opening the charging station	5	$
Unit cost for ERV charging	2	$/kWh
Importance hyper-parameters α_1	1 for objective 1, 0 for objective 2	/
Importance hyper-parameters α_2	0 for objective 1, 1 for objective 2	/
Reward for an invalid action r_p	-1000	/
Reward for completing the task r_f	1000	/
Maximum pouring interval δ	90	min

Table 4 Information of the construction sites.

No.	RMC demand (m^3)	Distance (km)	Start time (hr:mm)
C1	6	6.2	8:30
C2	60	4.0	8:40
C3	26	5.5	9:30
C4	3	3.4	10:40
C5	64	12.0	11:20
C6	64	4.1	10:00
C7	24	6.6	15:10

Table 5 Information of the ERVs.

No.	1	2	3	4	5	6	7	8
RMC Capacity (m^3)	8	8	8	7	7	6	5	2
Unit cost ($/min)	1.3	1.3	1.3	1.2	1.2	1.1	1.0	0.8
Battery capacity (kWh)	160	160	160	160	160	120	100	50
Initial battery capacity (kWh)	80	80	80	80	80	60	50	25
Initial LAT (hr:mm)	6:00	6:00	6:00	6:00	6:00	6:00	6:00	6:00

3.2 Benchmark Setup

To validate the performance of our proposed PMD-MCTS algorithm under the given scenario setup, we compared it with three benchmarks, including GA-based optimization from (Z. Liu, Zhang, & Li, 2014), and two ablation studies. All algorithms were run ten times to minimize the impact of random errors. The two most common metrics, namely a) the average reward and b) the average computation speed, were used as the first two evaluation criteria. To test the stability of the algorithm, three additional metrics were selected, namely c) the success rate, d) the standard deviation (SD) of the average reward, and e) the SD of the average computation speed. Instead of terminating the MDP process when an invalid action occurs, we adopted a great negative number as a penalty and continued the MDP simulation. To avoid a negative battery state, the negative battery level was modified to the smaller one between the current battery status and the minimal battery requirement.

3.2.1 Genetic algorithm

Three-layer chromosome: The chromosome structure was designed based on the concepts of (Karakatič, 2021; Z. Liu et al., 2014). As described in (Z. Liu et al., 2014), the maximum number of vehicles to be dispatched is fixed, which is set as the chromosome length. The chromosome of (Z. Liu et al., 2014) has three layers: a) sequence of construction site ID, b) sequence of the accumulative number of vehicles to the construction site, and c) sequence of vehicle ID. The second layer was removed as it can be inferred from the first layer. In addition, we added a layer for battery level according to (Karakatič, 2021), and used the same battery definition as our PMD-MCTS method. An illustration of the chromosome is shown in Fig. **3**.

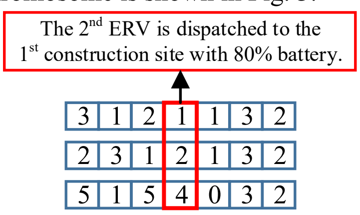

Fig. 3 An illustration of the GA chromosome

Selection: The chromosome represents a set of sequential MDP actions that can be input into the MDP model to obtain the accumulative reward (fitness). It should be noted that action will not be taken if the target construction site has been satisfied.

Crossover: This study adopted one-point crossover, but the crossover operation may change the maximum number of vehicles required by each site. Hence, the probability mapping method of (Z. Liu et al., 2014) was adopted for the first layer crossover, as shown in Fig. **4**. Specifically, each gene in the first layer has a mapping probability, and the crossover is conducted on the probability layer. The new chromosome is generated by mapping the probabilities to a basic chromosome in descending order, and the basic chromosome can be user-defined ([1,1,1,2,2,3,3] in Fig. **4**). The crossovers of the second and third layers are conducted directly. We conduct the crossover layer by layer, which can generate six children during one crossover.

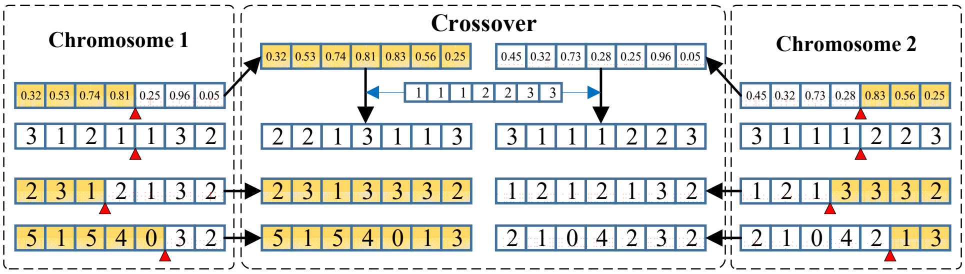

Fig. 4 The crossover of two chromosomes

Mutation: One-point mutation is adopted, as shown in Fig. **5**. Similar to the crossover operation, the mutation of the first layer is realized by probability mapping, while the genes in the other two layers are mutated according to their ranges.

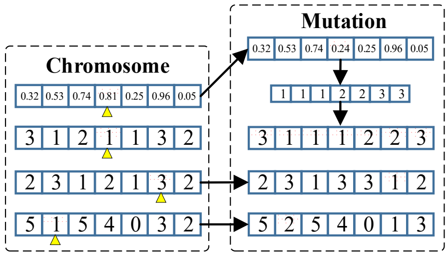

Fig. 5 The mutation of the chromosome

Table 6 Hyperparameters of genetic algorithm

Hyperparameters	Value
Population size	20
Parent number	3
Mutation rate	0.3
Maximum generation number	200000

3.2.2 Ablation studies

We have made two improvements based on WU-UCT-based MCTS. To evaluate the effectiveness of these improvements, we conducted two ablation studies: a) PD-MCTS, which is PMD-MCTS without action masking, and b) PM-MCTS, which is PMD-MCTS without decaying search strategy. The hyperparameters used in the MCTS algorithms are listed in Table 7.

Table 7 Hyperparameters of MCTS algorithms

Hyperparameters	Value
Number of expansion workers	8
Number of simulation workers	16
Maximum search step ($N_{\delta 0}$)	3000
Maximum search depth	100
Maximum search width	200
Discount factor	0.9
Expansion policy	Random

3.3 Results

Experiments for PMD-MCTS and four benchmark algorithms were conducted on the designed scenario. The entire procedure was executed on a laptop with the specification of Intel i9-10980H 3.10GHz CPU and 32GB RAM. The the scheduling performance of each algorithm is shown in Table 9 and Table 8.

.

Table 8 Scheuling performance of each algorithm in objective_1 (minimizing the costs)

	Average reward	SD of average reward	Success rate (%)	Average computation time (s)	SD of average computation time
GA	-8313.1(-6494.3*)	1283.1	0	102.0	**1.7**
PD-MCTS	-6950.0 (-5421.5*)	1040.6	0	320.8	26.3
PM-MCTS	-3095.2 (-3004.5*)	**120.4**	**100**	385.6	40.1
PMD-MCTS	**-3064.0 (-2862.4*)**	123.0	**100**	260.0	19.9

Table 9 Scheuling performance of each algorithm in objective_2 (minimizing the delay)

	Average reward	SD of average reward	Success rate (%)	Average computation time (s)	SD of average computation time
GA	-837.9 (479.4*)	1076.5	30	93.27	2.0
PD-MCTS	-484.1 (182.8*)	503.3	**100**	497.8	78.1
PM-MCTS	969.0 (1000*)	18.2	**100**	292.4	10.4
PMD-MCTS	**991.6 (1000*)**	**6.7**	**100**	203.0	**1.6**

* indicates the optimal performance

The empirical results indicate that our PMD-MCTS algorithm demonstrates superior performance, achieving the highest rewards across both objectives. Specifically, the average reward of the PMD-MCTS in objective 1 is 3064.0, which translates to an average cost of $4064.0. In objective 2, the average reward of the PMD-MCTS is 991.6, representing an average delay of 8.4 minutes, and the most optimal solution can eliminate any delay entirely. Furthermore, our findings suggest that only algorithms implementing action masking (i.e., PMD-MCTS and PM-MCTS) can consistently ensure a feasible solution for both objectives. These two algorithms also display the smallest standard deviation of average reward, indicating their superior stability. Although PM-MCTS exhibits a performance similar to PMD-MCTS in terms of reward and success rate, the PMD-MCTS requires 30% less computational time than PM-MCTS.

4. DISCUSSIONS

This study's outcomes substantiate the effectiveness of our proposed scheduling optimization approach for managing ERV operations. This methodology mainly contributes to the field in three ways.

Firstly, this study addresses an existing gap in on-road Commercial Electric Vehicle (CEV) research. We are pioneers in examining CEVs, particularly on-road CEVs, marking a significant stride towards sustainable advancement in the construction sector. By incorporating the demands of Ready-Mixed Concrete (RMC) dispatching and Electric Vehicles (EVs), we have holistically examined the characteristics of ERVs. This problem definition can potentially be extrapolated to other CEV studies in the future. Secondly, we have crafted a novel formulation for the RMC delivery problem, utilizing the Markov Decision Process (MDP) based on the temporal dynamics of the RMC delivery process. Compared to its predecessors, the MDP formulation is a more rational choice as it facilitates sequence decision-making. This approach prevents invalid decisions at each stage and ensures the decision-making process is far-sighted, considering all decisions in a comprehensive manner. Lastly, we introduced an enhanced Monte Carlo Tree Search (MCTS) algorithm, named PMD-MCTS, to optimize the ERV operation process. When compared with four benchmark algorithms, it proved to be the most effective. Two key advantages of the PMD-MCTS were identified: Both PMD-MCTS and PM-MCTS displayed superior performance in terms of average reward and success rate, outperforming the Genetic Algorithm (GA) by employing the MCTS optimization strategy. The GA algorithm fails to ensure a feasible solution for both objectives, owing to its limitations in managing sequential requirements. PMD-MCTS surpassed PM-MCTS on computational speed. Our PMD-MCTS saves over 30% of the computational time required by PM-MCTS, without compromising on accuracy, by implementing a decaying strategy.

5. CONCLUSION

In the face of pressing concerns over carbon emissions, the construction industry can expect to see an influx of more sustainable technologies. Electric Ready-mixed Vehicles (ERVs) are a promising technology geared towards enhancing the sustainability of the construction industry. However, the interdisciplinary nature of ERVs has led to a considerable gap in this field. This study addressed this gap by proposing a scheduling optimization methodology for ERV dispatching. It introduces a systematic problem definition for the ERV operation, which integratively considers the properties of both EVs and RMC delivery tasks. Moreover, the ERV operation process is modelled as an MDP problem, thereby breaking down the entire process into sequential sub-processes. The proposed PMD-MCTS algorithm, equipped with parallel computing, invalid action masking, and decaying searching capability, has been validated through a meticulously designed experiment. This study, thus, provides a comprehensive evaluation of ERV operations and offers a solid foundation for future research in this domain.

TESTING CHATGPT-AIDED SPARQL GENERATION FOR SEMANTIC CONSTRUCTION INFORMATION RETRIEVAL

Yuan Zheng & Prof.Olli Seppänen
Aalto University, Finland

Sebastian Seiß & Prof. Jürgen Melzner
Bauhaus-University Weimar, Germany

ABSTRACT: *Recently there has been a strong interest in using semantic technologies to improve information management in the construction domain. Ontologies provide a formalized domain knowledge representation that provides a structured information model to facilitate information management issues such as formalization and integration of construction workflow information and data and enables further applications such as information retrieval and reasoning. SPARQL Protocol And RDF Query Language (SPARQL) queries are the main approaches to conduct the information retrieval from the Resource Description Framework (RDF) format data. However, there is a barrier for end users to develop the SPARQL queries, as it requires proficient skills to code them. This challenge hinders the practical application of ontology-based approaches on construction sites. As a generative language model, ChatGPT has already illustrated its capability to process and generate human-like text, including the capability to generate the SPARQL for domain-specific tasks. However, there are no specific tests evaluating and assessing the SPARQL-generating capability of ChatGPT within the construction domain. Therefore, this paper focuses on exploring the usage of ChatGPT with a case of importing the Digital Construction Ontologies (DiCon) and generating SPARQL queries for specific construction workflow information retrieval. We evaluate the generated queries with metrics including syntactical correctness, plausible query structure, and coverage of correct answers.*

KEYWORDS: *Semantic web, Ontology, ChatGPT, SPARQL, RDF, Information retrieval, Construction*

1. INTRODUCTION

Construction is an information-intensive and dynamic industry, which requires effective information management and exchange. Especially, construction professionals need always to retrieve demanding information about the construction process to be aware of the prompt situation to support their decision-making and action-taking (Akinci, 2015). With the ongoing advancements of digital implementation in the construction domain, a large amount of semantic data can be collected from heterogeneous systems, which requires a systematic solution to formalize, integrate, and manage the data (Kosovac et al., 2000). Therefore, researchers in the construction domain have investigated the application of semantic web technologies to facilitate information formalization and interoperability issues (Zhou et al., 2016). For example, numerous ontologies have been developed in the construction domain, to provide a formalized construction domain knowledge representation and comprehensive semantic vocabulary. These ontologies support the conversion of construction information into Resource Description Framework (RDF) format and the establishment of an integrated semantic graph database.

Such integrated semantic graph database has been proven to the advantageous in the application of information integration, reasoning, and retrieval by academic scholars in the construction domain (Akinyemi et al., 2018). However, in terms of the practical implementation, one drawback of the graph database can be identified. To retrieve the demanding information from the graph database, the SPARQL Protocol and RDF Query Language (SPARQL) queries are needed. However, the construction sector has limited practitioners with sufficient knowledge of ontology and proficient skills to code the SPARQL queries at the moment. This makes it difficult for end-users to interact directly with the graph database and retrieve the particular construction information they need. While there have been various attempts to employ web-based lists or templates to assist users in crafting SPARQL queries without coding skills, generating SPARQL queries quickly and easily remains a challenge for end-users. Given this challenge, it would be beneficial to develop an intuitive and self-explanatory method that allows end-users to create SPARQL queries more easily.

ChatGPT is an AI-empowered language generation model, which uses the Transformer algorithm and large language model (LLM) principle as the basis to generate human-like text based on the given prompts and context

Yuan Zheng, Olli Seppänen, Sebastian Seiß, Jürgen Melzner, *Testing ChatGPT-Aided SPARQL Generation for Semantic Construction Information Retrieval,* pp. 751-760, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.75

with rapid response time (van Dis et al., 2023). After its public release at the end of 2022, ChatGPT received huge attention from academia, industries, and consumers. ChatGPT also can analyze and generate structured syntax-based contents such as codes, scripts, and ontology syntax (Lin et al., 2023). ChatGPT can also generate the SPARQL query sentences based on the predefined ontology inputs since its database involves numerous examples of SPARQL and ontologies in the OWL representation (Tan et al., 2023). Based on this feature, using ChatGPT could be considered to be an alternative approach for information retrieval for the RDF data, which would be easy and simple to use. ChatGPT can also be used to directly retrieve information from a provided ontology, including instance data, without using SPARQL queries. However, due to the private and sensitive nature of company and construction-related instance data, it is imperative not to share this kind of data with a self-learning LLM model.

However, the accuracy and real capability of ChatGPT to generate practical SPARQL queries for achieving specific information retrieval in the construction domain have not been tested. To assess whether if it is a feasible solution to aid construction information retrieval tasks, in this paper, we aim to test and evaluate the current capability of ChatGPT to generate the SPARQL queries for accomplishing domain-specific construction information retrieval tasks. The Digital Construction Ontologies (DiCon) (Zheng et al., 2021) previously developed by our research group is used as a case study for the test. We first feed the DiCon ontologies to the ChatGPT for the initial ontological parse as the fundamental context of generating the SPARQL queries. We experimented on the generated SPARQL with four different scenarios and used the metrics of syntactical correctness, plausible structure, and the coverage of the correct result to assess the generated SPARQL queries.

The paper is structured as follows. Section 2 provides a review of related works of ontologies and ChatGPT. Section 3 introduced the research methodology and the architecture of the DiCon-ChatGPT system. In Section 4 the tests and results are illustrated. This is followed by the discussion, limitation, and future research in Section 5. Finally, in section 6 the conclusion of the paper is given.

2. BACKGROUND

2.1 Semantic Web and construction information

Data and information are the key resources of the construction industry to guarantee smooth collaboration for the operations. However, data and information are also influenced by the segmented nature of the construction industry and the diverse software solutions in use. The data is generated in isolated systems by the different stakeholders in the different disciplines and is usually formed into various file formats (Kosovac et al., 2000). Such interoperability issue is notorious in the construction domain. The semantic web and associated Linked Data concept is considered as an approach to facilitate the information interoperability problem, which provides technical standards for a comprehensive heterogeneous information integration and machine-readable representation of the data for further implementation (Beetz et al., 2021).

Ontologies serve as the foundation of the semantic web, which provides a shared and machine-readable conceptualization of domain knowledge and could be further used as a data structure to formalize and integrate data and information. Recently, ontologies have become increasingly relevant in the construction domain, to address challenges like data integration and knowledge management (Pauwels et al., 2017). Various iconic domain ontologies have been created in the construction field, including generic ones like e-COGNOS (El-Diraby et al., 2011) and IC-PRO-Onto (El-Gohary et al., 2010). Our research team also developed the DiCon, which defines construction workflow-related entities with the Semantic Web Ontology Language (OWL) representation and achieves integrating data from diverse systems. DiCon also aligned with other ontologies such as IFCOWL (Pauwels, 2016), the Building Topology Ontology (BOT) by Rasmussen et al. (2020), and SOSA/SSN ontology (Janowicz et al., 2019) to link the construction information with building information modeling, topological, and sensor data.

The foundational language of the semantic web is the Resource Description Framework (RDF). The data structure of RDF is organized into a triple format of a subject, predicate, and object, or subject, property, and value (Manola et al., 2004). The RDF triples constitute an RDF graph and store it in RDF graph stores for further utilization such as information retrieval (Hitzler et al., 2008; Allemang et al., 2020). SPARQL Protocol and RDF Query Language (SPARQL) is a semantic graph query language specifically designed to query RDF data (W3C, 2013). SPARQL allows users to query RDF data by specifying patterns to match against the triples in the RDF graph. Utilizing an RDF-based ontology together with SPARQL can significantly enhance the efficiency of information extraction.

2.2 ChatGPT and related works

ChatGPT is a state-of-art large language model (LLM) developed by OpenAI. The G to refers to generative, which means the ability to generate human-like responses and demonstrate a level of language understanding that has been groundbreaking in the field of natural language processing. P refers to pre-trained because the model is pre-trained on a massive dataset containing a diverse range of text from the internet. The T refers to Transformer, the architecture of a deep-learning model designed for natural language processing tasks (van Dis et al., 2023). It learns to predict the next word in a sentence, which enables it to understand grammar, context, and semantics in the text. Currently, ChatGPT has four versions, including GPT-1, GPT2, GPT3.5, and the latest GPT4.

As an AI language model, ChatGPT's responses are based on patterns learned from a diverse range of data during training, which includes general information on ontologies, SPARQL, and RDF. Therefore, ChatGPT also can collaborate with Semantic Web technologies. Several scholars have explored the combination of ChatGPT with semantic web technologies in different directions. Lin et al. (2023) involved context-based ontology modeling with ChatGPT to represent database semantics in natural language representation for supporting database management in data integration. Tan et al. (2023) assessed the capability of ChatGPT to conduct knowledge-based question-answering with generated SPARQL queries. The experimental results showed that ChatGPT is a promising tool for question-answering under continuous updating and iterating of the model. Meyer et al. (2023) conducted a set of experiments using ChatGPT with the knowledge of graph engineering. The result showed ChatGPT has a remarkable capability to support knowledge graph engineering in constructing knowledge graphs, translating natural language queries into precise and organized SPARQL queries, tailored to the provided knowledge graphs, and diagrams illustrating expansive schemas of knowledge graphs.

In summary, the existing tests indicate that ChatGPT can generate SPARQL queries for information retrieval tasks. Therefore, ChatGPT could be a potential tool for the automated generation of SPARQL queries for construction information retrieval and management. However, the previous related works focus on assessing the capability of ChatGPT in general Linked Data and knowledge graph domains. The capability of ChatGPT to generate domain-specific SPARQL queries for construction information retrieval has not been explicitly tested or validated. Therefore, in this paper, we aim to test and evaluate the current capability of ChatGPT to generate SPARQL queries for retrieval-specific construction workflow information.

3. METHODOLOGY

3.1 Research design

To achieve the identified research objective, the research is designed as shown in Fig.1. We set up an experimental case study of feeding the DiCon ontologies to ChatGPT to test its current capability of generating the SPARQL for retrieval construction information. The results of the experiment are the generated SPARQL queries. To evaluate these queries, we followed Meyer et al. (2023) who selected syntactical correctness, plausible structure, and the coverage of the correct result as three metrics to assess the generated SPARQL queries. First, syntactical correctness aims to check whether the query is following the correct syntax of SPARQL. A query is considered syntactically correct if it can be executed by an SPARQL engine without encountering errors. Second, the plausible structure is used to assess if the query has missing prefixes, wrong use of the classes and properties, or ChatGPT creates the classes and properties out of the given ontologies. The plausible structure is evaluated by manual assessment. Third, the coverage of the correct results is investigated by comparing the query result of the generated SPARQL with the ground truth data.

To evaluate the capability of the ChaptGPT in different scenarios four tests are designed. In the first test, we asked the ChatGPT to create SPARQL queries for direct construction information retrieval. The second test was to ask ChatGPT to generate the SPARQL queries based on different natural language expressions of prompts. In terms of the third test, we asked ChatGPT to generate CONSTRUCT-type SPARQL queries based on updating information based on the given ontology. Finally, we guide ChatGPT to refine the SPARQL queries which are not performing well, to assess the performance of the refinement. Finally, the results of the four tests are assessed based on the previously defined metrics.

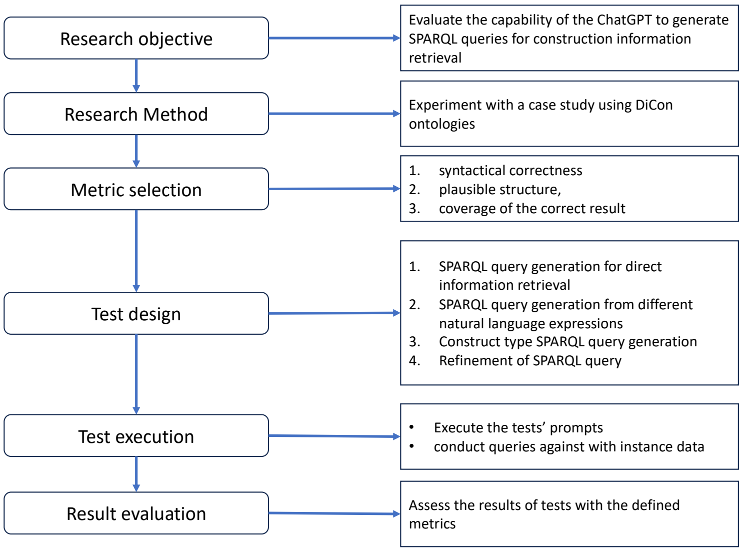

Fig. 1: Research design

3.2 The technical architecture of the experiment

To conduct the above pre-defined tests, we set up a technical architecture of the experiment following the ChatGPT prompt engineering guideline (White et al., 2023) shown in Fig.2. First, due to the large size and high complexity of the original DiCon ontologies, in tests we created a subset of the DiCon ontology contains all essential classes and properties that mapped with the example data graph. Such a process could keep the essence of the ontology but reduce the cost of ChatGPT tokens. ChatGPT 4.0 is the latest model that can directly read textual files (OpenAI, 2023). Thus, we select this version and feed the ontology subset file in Turtle format to ChatGPT 4.0 as the prime prompt. Based on the context feature of the ChatGPT, further SPARQL generation experiments can use the prompt-input ontology subset as the basis of generating the SPARQL queries. Then, the predefined four tests are conducted with the different prompt inputs. The generated SPARQL queries are also used against the instance data stored in GraphDB, a commercial graph store platform by Ontotext (Ontotext, 2023), to retrieve the target information as an evaluation of the syntactical correctness and coverage of the correct result.

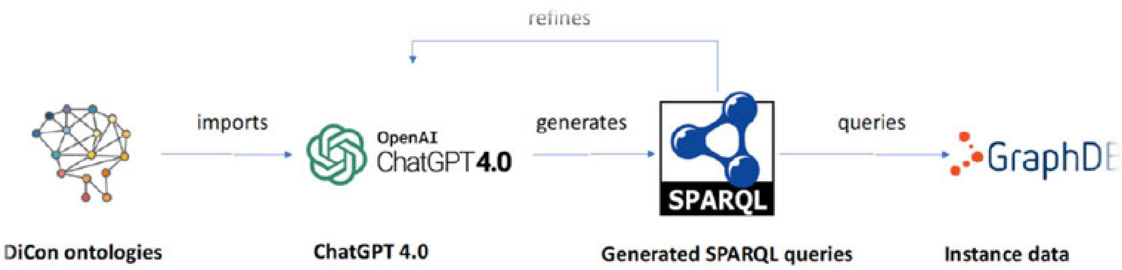

Fig. 2: Technical architecture of the experiment

4. TEST FOR DICON-CHATGPT TO GENERATE SPARQL QUERIES

In this section, a detailed description and result of the aforementioned tests are demonstrated. We also obtained the practical data from previous projects as the ground-truth data to test the SPARQL queries answering.

4.1 Test 1: SPARQL query generation for direct information retrieval

In our first test, we wanted to determine the general capability of ChatGPT to generate SPARQL queries based on the given DiCon ontology subset, to accomplish direct construction information retrieval task. Thus, we asked ChatGPT with Prompts 1.1 and 1.2 to retrieve essential construction information. Both Prompts only utilize terminologies from the DiCon (Zheng et al., 2021).

Prompt 1.1: *Based on the given ontology, create a SPARQL query to find the activity and its related agent and location.*

Prompt 1.2: *Based on the given ontology, create a SPARQL query to find the activity information about its start time and end time.*

Prompt 1.1 aims to retrieve information about construction activity, including its assigned location and agent. This prompt is simple in that in the DiCon class a *dicp:Activity* has direct properties of *dicp:hasLocation* and *dica:hasAgent* towards *dice:Location* and *dica:Agent*. Prompt 1.2 aims to extract the information of the start and end time of the activity. This prompt has an indirect relationship between activities and their start or end times. Because in DiCon, we define the property dicp:occupiesTimeInterval to represent the temporal information of an activity. The range of the *dicp:occupiesTimeInterval* is a *dice:TimeInterval*, which has beginning and end to *dice:TimeInstant* to indicate as the start and end time.

Each of the prompts was asked five times, and the generated results are partially shown in the Appendix due to the length of the paper. In terms of Prompt 1.1, for the five times of the generation, there are four times the ChatGPT uses the correct terminologies in the provided ontology. One time, it was not sure if *dicp: location* was the correct property to use, thus it defined a location property but with the wrong prefix dice: in the query. For Prompt 1.2, ChatGPT generates only one own property to describe the start and end time of an activity. To check the coverage and syntactical correctness of the query, we queried the generated SPARQL to GraphDB with the example data graph. For both of the prompts, all the queries can be successfully executed by the SPARQL engines of GraphDB, which confirms all the queries are syntactically correct. In terms of coverage, all the queries with the correct structure can query the correct answer from the example graph. The metrics results for Prompts 1.1 and 1.2 are listed in Table 1.

Table 1: Metric results of generated SPARQL queries in Test 1.

Prompt	**Metric**	**Result**
1.1	Syntactical correctness	*5/5*
	Coverage of the correct result	*4/5*
	Plausible query structure	*4/5*
1.2	Syntactical correctness	*5/5*
	Coverage of the correct result	*4/5*
	Plausible query structure	*4/5*

4.2 Test 2: SPARQL query generation from different natural language expressions

The second test intends to evaluate the capability of the ChatGPT to generate SPARQL queries based on different natural languages but with the same information retrieval target as Prompt 1.1. This test also analogs the practical nature and scenario that the different end users may have different natural language expressions for the prompts.

Prompt 2.1: *Based on the given ontology, create a SPARQL query that lists the agent and location of an activity*

Prompt 2.2: *Based on the given ontology, create a SPARQL query that lists the worker, workplace of an activity*

In terms of Prompt 2.1, we provided a different expression of Prompt 1.1 but still used the terminologies from the DiCon. In terms of Prompt 2.2, we use similar terminologies that have been mixed usually in the construction domain from describing the classes, to check if the ChatGPT can generate SPARQL with the terminologies out of the ontology. Each of the prompts was asked for five times. For Prompt 2.1, four times it generated the same queries as Prompt 1.1, and one time it used the wrong prefix of the dicp: *location* property. All the queries can be executed in GraphDB, the query with the erroneous prefix returned no location data, while the other four returned correct answers. For Prompt 2.2, only one generated SPARQL was correct to link the term 'worker' to the class agent and the term 'workplace' to the location. ChatGPT created the classes of worker and workplace one time, and the other three times it managed to link the term 'worker' to the class *dica: Agent* but failed to link the term 'workplace' to the class *dice:Location*. All of the generated queries are syntactically correct, but only one query provided us with the correct answer. The metrics results are shown in Table 2.

Table 2: Metric results of generated SPARQL queries in Test 2.

Prompt	**Metric**	**Result**

2.1	Syntactical correctness	*5/5*
	Coverage of the correct result	*4/5*
	Plausible query structure	*4/5*
2.2	Syntactical correctness	*5/5*
	Coverage of the correct result	*1/5*
	Plausible query structure	*1/5*

4.3 Test 3: Infer construction information with SPARQL

SPARQL is not just limited to querying data by using the SELECT statement. It also provides other functionalities such as INSERT, UPDATE, and CONSTRUCT statements to update or create new graph contents (W3C, 2013). Therefore, this test aims to evaluate the capability of ChatGPT to generate a SPARQL query using the CONSTRUCT statement to infer additional construction information by creating a new RDF graph. We provide the Prompt 3 to ChatGPT:

Prompt 3: *Based on the given ontology, create a SPARQL query to construct a new graph, in which if the activity has an agent, construct new triples that the agent "is an agent in" the activity.*

This prompt is based on the predefined ontology that *dica:hasAgent* property has the inversed property of *dica:isAgentIn*, which was not included in the example data graph. This test aims to assess whether ChatGPT can generate CONSTRUCT SPARQL queries that utilize the inversed properties in the ontology to construct new graphs. Similar to the previous tests, Prompt 3 was also asked five times, and we analyzed the syntactic correctness and coverage of the generated queries. The evaluation results for the prompt are listed in Table 3. The metrics results show all the generated queries with plausible query structures, are syntactically correct, and cover the correct result.

Table 3: Metric results of generated SPARQL queries in Test 3.

Prompt	Metric	Result
3	Syntactical correctness	*5/5*
	Coverage of the correct result	*5/5*
	Plausible query structure	*5/5*

4.4 Test 4: Refinement of SPARQL query

In terms of Prompt 2.2, which did not perform well in the test 2. Therefore, in this test, we try to use the contextual feature of the ChatGPT to refine the result by providing more explicit prompts based on the ontology structure. We provide the prompt P4 to the ChatGPT:

Prompt 4: *Refine the previous SPARQL query based on the given ontology, that a "workplace" should link to the class dice:Location.*

Similar to the previous tests, the refinement was also conducted five times, and we analyzed the plausible query structure, syntactic correctness, and coverage of the generated queries. After the refinement, the structure of the query has been significantly improved. All of the queries use the correct terminologies from the provided ontology without misused prefixes, are conductible, and can generate correct answers. The analyzed results for the Prompt 4 are listed in Table 4.

Table 4: Metric results of generated SPARQL queries in Test 4.

Prompt	Metric	Result
4	Syntactical correctness	*5/5*
	Coverage of the correct result	*5/5*
	Plausible query structure	*5/5*

5. DISCUSSION

Corresponding to the above four tests and their results, we assess the current capability of the ChatGPT with three predefined metrics. The overall results of different prompts with three metrics as shown in Fig.3. In the following, we will provide a detailed summary and discussion of the experiment results. First, in terms of syntactical correctness, it is obvious from the experimental results that all the ChatGPT-generated queries in the experiment avoid syntax errors. Such absence of syntactical errors across all generated queries proves ChatGPT comprehends and applies the syntactic rules inherent to SPARQL. This accomplishment is not merely an incidental outcome, but a demonstrable indication of the underlying capabilities that ChatGPT harnesses in generating high-quality, error-free SPARQL queries.

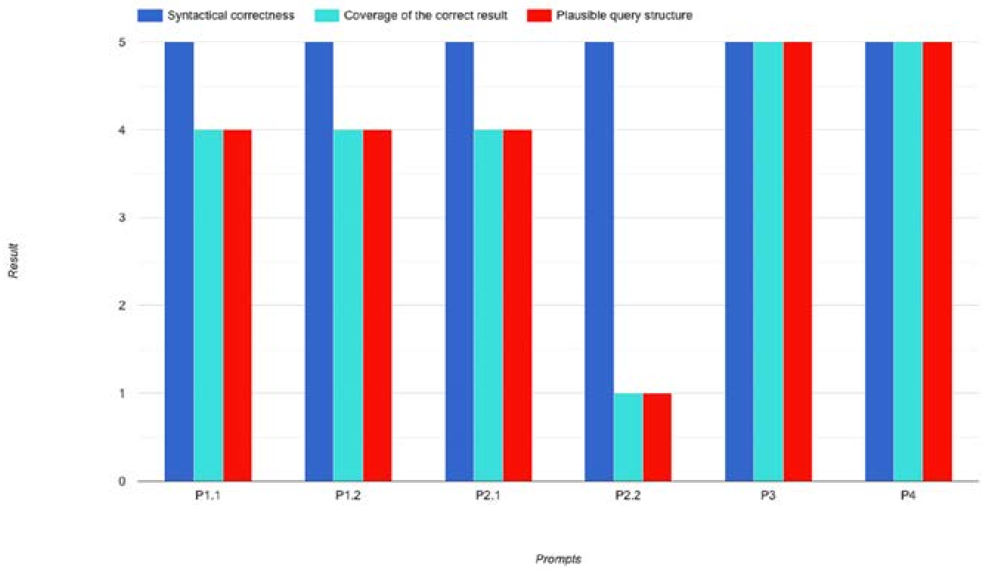

Fig. 3: Overall metrics result of the generated SPARQL for different prompts

Second, when examining the plausible query structure, the detailed analysis revealed that some of the generated results contain structure mistakes. For example, both Prompts 1.1 and 1.2 have one generated query that did not use the correct property in the given ontology but defined a new property as an assumption to complete the query. Although the used terminology is compliant with DiCon, the prefix used was incorrect. For Prompt 2.2, when faced with terminologies outside the ontology, performance had reduced significantly. In this case, it generates only one correct query using the classes and properties defined in the given ontology. The term 'worker' was successfully mapped to the class *dica:Agent*, but the system failed to map 'workplace' to the class *dice:Location* and its associated properties. In test 4, by providing a more explicit mapping instruction prompt to ChatGPT as a refinement, the performance improved. This result reveals that the current ChatGPT still requires explicit prompts using the terminologies defined in the ontology to ensure the generation of plausible queries.

Third, the test results indicate a significant and noteworthy correlation between the structural accuracy of the queries and the subsequent performance of the AI-generated queries in producing accurate query results. In essence, this observation highlights the pivotal role that query structure plays in determining the efficacy of AI-generated queries. Meanwhile, if the generated result is unsatisfactory, ChatGPT can refine the generation by providing new prompts with the correct information to fix the errors.

In summary, the current version of ChatGPT has demonstrated impressive capabilities. It successfully translated natural language questions into syntactically correct SPARQL queries for the DiCon ontology. A detailed analysis revealed some mistakes in the generated results, which can be refined with extra explicit prompts, to elaborate more precise instructions.

6. LIMITATION

This research is just the first research of our research teams to explore the usage of Natural Language Processing (NLP) tools to combine and support semantic construction informatics. Admittedly, this research has the following limitations. First, this research is limited by testing scale. The performance of ChatGPT with entire DiCon ontologies has not been tested and limited numbers of tests have been made. In the future, the test volume and velocity should be enlarged to improve the accuracy of the research. In the future, the full DiCon ontology suite will be also tested with ChatGPT and more comprehensive prompts. Additionally, as DiCon is aligned with other ontologies, such as Building Topology Ontology (BOT), SOSA/SSN, IFCOWL, etc., these ontologies will also be included in the upcoming more complex tests. Second, this research is only tested using ChatGPT. Currently, ChatGPT is the most used NLP tool and is easy to deploy and test. Although ChatGPT is under continuous updating, as a commercial solution, its closed source and black-box nature makes it difficult to optimize and train. Therefore, besides the ChatGPT, in future research, other LLM models and NLP tools should be also tested and explored, for example, the Falcon LLM (Technology Innovation Institute, 2023). More construction domain-specified training based on the open-sourced LLM will also be conducted. Third, the prompts themselves would affect the generated query results. Throughout this research, the prompts provided to ChatGPT have been intentionally kept simple and straightforward to gauge ChatGPT's performance in generating SPARQL queries. However, recognizing the multifaceted nature of semantic querying and the potential intricacies within construction information, future studies will necessitate a broader spectrum of test cases with more specific construction information retrieval tasks. By incorporating more intricate prompts, further research will better evaluate ChatGPT's capacity to handle complex query generation tasks in the construction domain. Another research track is also studying the prompt development manner based on the readability score.

7. CONCLUSION

This paper tested the capability of ChatGPT to generate SPARQL queries with a case study based on the DiCon ontologies for construction workflow information retrieval. We designed and conducted a set of tests to assess the current capability of ChatGPT to generate the SPARQL query for solving the construction domain-specific task of information retrieval.

Overall, as observed from the result, ChatGPT has demonstrated its impressive capability of generating SPARQL queries for the given ontology to retrieve target information on the construction domain level. The experiments show that ChatGPT can avoid syntax errors, and read and utilize the given ontologies as the basis of SPARQL generation. However, the execution of the test process and evolution of the generation result also reveal several current limitations of ChatGPT in generating SPARQL queries. For example, ChatGPT cannot fully understand the given ontology, and the quality of the generated SPARQL queries highly relies on the explicitness of the given prompts.

In future research, we would also continue the exploration of using LLM solutions, including ChatGPT and other tools, to combine with the Semantic Web implementation in the construction domain. One future research topic is to illustrate the construction information, from SPARQL queries generated by Chat-GPT on Extended Reality devices. Simultaneously, we would also test the feasibility of ChatGPT to create RDF converters, which will convert tabular data into RDF format mapped with the DiCon ontology.

ABSTRACT: *The construction industry has long been recognized for its complex safety regulations, which are essential to ensure the well-being of on-site employees. However, navigating these regulations and ensuring compliance can be challenging due to the volume and complexity of the documents involved. This study proposes a novel approach to extracting information from construction safety documents utilizing Large Language Models (LLM), called CSQA, to provide real-time, precise answers to queries related to safety regulations. The approach comprises three modules: (1) the construction safety investigation module (CSI) collects safety regulations for building the information needed. By leveraging a collection of safety regulation PDFs, the system follows a process of text extraction, preprocessing, and global indexing for efficient search. (2) The safety condition identification module (SCI) retrieves the CSI database; after that, the LLM, with its extensive training, processes user queries, searches the indexed regulations, and retrieves pertinent information. (3) the safety information delivery (SID) would provide the answer to the user and incorporate a feedback mechanism to further refine system accuracy based on user responses. Preliminary evaluations reveal the system's superior performance over traditional search engines, owing to its ability to grasp query context and nuances. The CSQA presents a promising method for accessing safety regulations, with potential benefits including reduced non-compliance incidents, enhanced worker safety, and streamlined regulatory consultations in construction.*

KEYWORDS: *Construction safety document, extraction, LLM.*

1. INTRODUCTION

Safety has consistently been seen as a vital concern within the construction industry. Workplace safety catastrophies can result in major loss of life and damage to property with severe repercussions (S. V.-T. Tran et al., 2023; S. V. T. Tran et al., 2021). According to the latest statistics from the Occupational Safety and Health Administration (*OSHA Fatality Report*, n.d.), the construction industry witnessed an annual total of 1,008 fatalities in 2020. Notably, falls from elevated positions constituted around thirty-three percent of these. According to data from Statistics Korea (*Construction Work | Statistics Korea*, n.d.), the construction business in South Korea accounted for more than 50% of all fatal accidents within the industry. To prevent accidents at construction sites, several scholars and professionals have demonstrated that implementing enhanced safety measures in the workplace might reduce and prevent accidents (Bao et al., 2022; S. V. Tran et al., 2022; S. V. T. Tran et al., 2022). Therein, field compliance checking is a crucial endeavor to identify non-compliance with construction safety standards, with the primary objective of safeguarding employees against potential safety events (Jeong et al., 2023; Kang et al., 2023).

Analyzing construction safety documents with natural language processing (NLP) techniques enables automatic information extraction of safety requirements. For instance, Feng and Chen (Feng & Chen, 2021) proposed a framework based on deep learning to extract event-related information (e.g., date, location, and type of accident) from accident news reports for construction safety management. Rupasinghe and Panuwatwanich (Rupasinghe & Panuwatwanich, 2021) proposed a rule-based technique for extracting information about hazards from accident reports. Baker et al. (Baker et al., 2020) suggested employing NLP (a collection of text patterns) to uncover injury precursors. These works together focused on either the study of injury and accident records or the extraction of hazard variables. Despite these studies, there is a dearth of research aimed at automatically extracting requirements from construction safety rules in order to enable field compliance. Besides, the information extraction should provide users with precise and timely responses to their inquiries within human natural language.

Large Language Models (LLM) have emerged as a game-changing technology, displaying extraordinary ability in natural language processing jobs. Incorporating LLMs into construction safety provides a distinct benefit in its capacity to customize to particular, project-centric data. This is especially important given the vast volumes of

Si Tran, Nasrullah Khan, Emmanuel Charles Kimito, Akeem Pedro, Mehrtash Sotani, Rahat Hussain, Taehan Yoo, Chansik Park, *Extracting Information from Construction Safety Requirements Using Large Language Model*, pp. 761-767, DOI 10.36253/979-12-215-0289-3.76

private paperwork that projects often require. Every project in the construction environment is unique, with its own blueprints, safety regulations, and vendor-specific rules, often encased inside PDFs and other digital forms. LLMs have the capacity to be trained or fine-tuned on project-specific datasets. Once a company uploads its confidential documents, the LLM can absorb this data, guaranteeing that when queries are posed, the solutions are general and suited to the context of that specific project's data.

This research proposes CSQA approach, a unique method for extracting construction safety documentation using Large Language Models (LLM), to answer real-time safety regulatory questions and fill the knowledge gap for industry experts. The method has three parts: (1) The construction safety investigation module (CSI) gathers building safety rules. The system uses safety regulation PDFs for text extraction, preprocessing, and global indexing for efficient search. (2) The safety condition identification module (SCI) obtains the CSI database, then the LLM analyzes user queries, examines the indexed rules, and retrieves relevant information with its thorough training. (3) Safety information delivery (SID) would address the user and offer feedback to improve system accuracy depending on user replies. Section 2 discusses the current state of construction safety information retrieval and LLM. Section 3 will present the recommended approach. The authors produce case scenarios in Section 4 to validate the approach. Subsequently, the discussion and conclusions of the study are presented.

2. LITERATURE REVIEW

2.1 Current state of construction safety information retrieval and extraction

Over the years, the construction industry, renowned for its complex projects and the resulting safety imperatives, has accrued a vast repository of safety regulations, guidelines, and best practices. Traditionally, retrieving and extracting relevant safety information was primarily a manual process (Zhong et al., 2020). Professionals frequently find themselves navigating through extensive physical binders or digital documents. This approach, while exhaustive, is fraught with difficulties. Due to the time-consuming nature of manual searches and the possibility of human error, there are frequent voids in the incorporation of vital safety directives(S. V. T. Tran et al., 2021). Moreover, the dynamic nature of construction projects, with their distinct challenges and parameters, necessitates a customized understanding of safety regulations, which manual searches cannot provide efficiently(Wu et al., 2022).

Efforts have been made since the advent of the digital age to expedite this procedure (S. V. T. Tran et al., 2021). Initially, safety information was migrated to digital databases, enabling keyword-based searches. Even though this change facilitated the retrieval process to some degree, it was not without limitations. Keyword searches frequently return many results, necessitating additional sorting to locate relevant information. The lack of contextual comprehension and the static nature of these databases provided a wealth of information without the nuanced interpretation required for specific project scenarios. For instance, Feng and Chen (Feng & Chen, 2021) proposed a framework based on deep learning to extract event-related information (e.g., date, location, and type of accident) from accident news reports for construction safety management. Rupasinghe and Panuwatwanich (Rupasinghe & Panuwatwanich, 2021) proposed a rule-based technique for extracting information about hazards from accident reports. Baker et al. (Baker et al., 2020) suggested employing NLP (a collection of text patterns) to uncover injury precursors. This context paves the way for investigating more sophisticated AI-driven methodologies capable of efficient information retrieval and contextual comprehension and understanding.

2.2 Information extraction using Large Language Model

Natural language processing allows a computer to interpret and process natural language text similarly to a person. Information extraction (IE) is a branch of natural language processing that obtains needed information from text sources. In general, there are two techniques for information extraction [11]: (1) machine learning (ML) and (2) rule-based approaches. However, research has focused on using rule-based techniques because training samples are few. Large Language Models (LLM) have transformed natural language processing, providing a game-changing answer to this problem.

Within the realm of construction, safety stands as a paramount pillar, with documentation and guidelines serving as the backbone to ensure the welfare of all stakeholders. Extracting relevant, actionable information has been a persistent challenge with the sheer volume and complexity of safety documentation. The potency of LLMs in safety information extraction lies in their ability to discern the context of a query and retrieve information that is not just relevant but also actionable. For instance, when asked about safety protocols for handling specific machinery, an LLM can sift through a vast repository of safety guidelines, pinpointing the exact procedures, precautions, and best practices.

Besides, construction safety may benefit from Large Language Models (LLMs) since they can be tailored to project-specific data, particularly given the vast volumes of private paperwork projects frequently include. Every construction project has plans, safety regulations, and vendor-specific rules, frequently in PDFs. LLMs may be trained or fine-tuned using project-specific datasets. The LLM may integrate confidential materials uploaded by a company to provide project-specific solutions to inquiries. Project secrecy and relevance are greatly affected by LLMs' project-specific customization. Traditional search engines and databases may provide general results or need substantial human labeling to identify project-specific data. LLMs automatically comprehend the context after being fine-tuned on a project's papers, ensuring that every answer meets the project's particular characteristics and criteria. This improves information retrieval accuracy and relevance and keeps sensitive project data in that context, protecting private project information.

3. METHOD

The primary purpose of developing an approach of extracting construction safety requirements using large language model. The structure and key features of the system are shown in **Figure 1**, which comprises three modules. (1) The construction safety investigation module (CSI) gathers building safety rules. The system uses safety regulation PDFs for text extraction, preprocessing, and global indexing for efficient search. (2) The safety condition identification module (SCI) obtains the CSI database, then the LLM processes user queries, examines the indexed rules, and retrieves relevant information with its thorough training. (3) Safety information delivery (SID) would address the user and offer feedback to improve system accuracy depending on user replies.

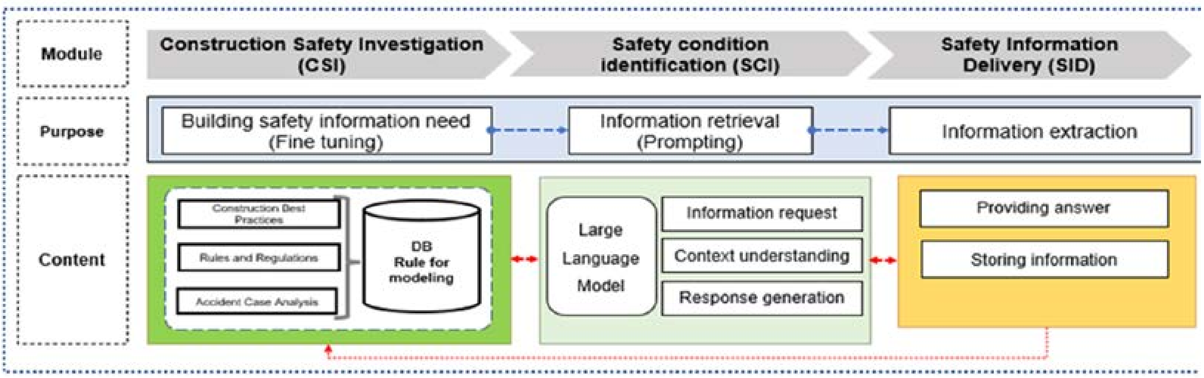

Fig. 1: Proposed approach of Extracting Construction Safety Requirements using Large Language Model

The Construction Safety Investigation (CSI) module is the foundational block in this approach, concentrating on the meticulous collection of safety regulations essential for creating the requisite information database. This module predominantly handles a variety of PDF safety regulation documents and serves as the entry point for raw safety data. The CSI module has multiple functions, including text extraction, preprocessing, and global indexing. Text extraction is crucial, as it converts the information in PDFs into a structured format. Preprocessing then entails cleaning and normalizing the extracted text to prepare it for the subsequent phases.

The Safety Condition Identification (SCI) module serves as the interface between the foundational database created by the CSI module and the user-facing delivery module in this approach. The primary responsibility of the SCI module is to interact with the CSI database and retrieve pertinent safety information based on user queries. The Large Language Model (LLM) incorporated into this module plays a crucial role, utilizing its extensive training to process and comprehend user queries in real time. The LLM examines the indexed regulations in the CSI database and retrieves relevant information, considering the context and subtleties of the user's query. Incorporating LLM into this module ensures that the retrieval process is accurate, context-aware, and efficient, providing instantaneous responses to user queries.

This approach also includes the Safety Information Delivery (SID) module, which focuses on delivering the retrieved and processed safety information to the end-user. It serves as the user interface, providing plain, concise, and pertinent responses to user queries. Beyond merely delivering information, the SID module includes a feedback mechanism that allows users to rate the accuracy and relevance of the provided answers. This user feedback is crucial for refining the system's precision and improving dependability. By perpetually incorporating user feedback, the SID module ensures that the system evolves and adapts to the users' changing requirements and preferences, maintaining its relevance and effectiveness in delivering precise construction safety information.

3.1 Prototype development

Figure 2 depicts prototype development process and tool uses for the proposed approach. The authors used Langchain, an open-source Python library for building LLM-powered applications. Utilizing LLMs with vector indexing via embedding provides a foundation for the solution. Initially, a comprehensive safety regulation database is accessed and processed to collate information predominantly housed in PDF formats. Subsequently, this information is extracted, followed by a data cleaning procedure to omit redundant elements, such as punctuation, commas, and line spaces. For this operation, a smaller LLM from the Spacy library is deployed. The information is segmented into manageable chunks to facilitate efficient filtering, aligned with the embedding model's chunk size within the embedding space. After the initial processes, the refined information is fed into a text embedding model to formulate and archive the information in a vector database, commonly referred to as a vector store, pivotal for advanced information retrieval mechanisms. The essence of the embedding model is to transmute high-dimensional textual data into a more condensed representation, aligning with the operational frameworks of LLMs, as we can't put our whole PDF textual information in user query or Prompt. For this critical transformation, the OpenAI text embedding model is employed. The formulated vector database harboring safety regulation information is then integrated into the pipeline, allowing LLMs to perform advanced retrieval of information pertinent to user queries.

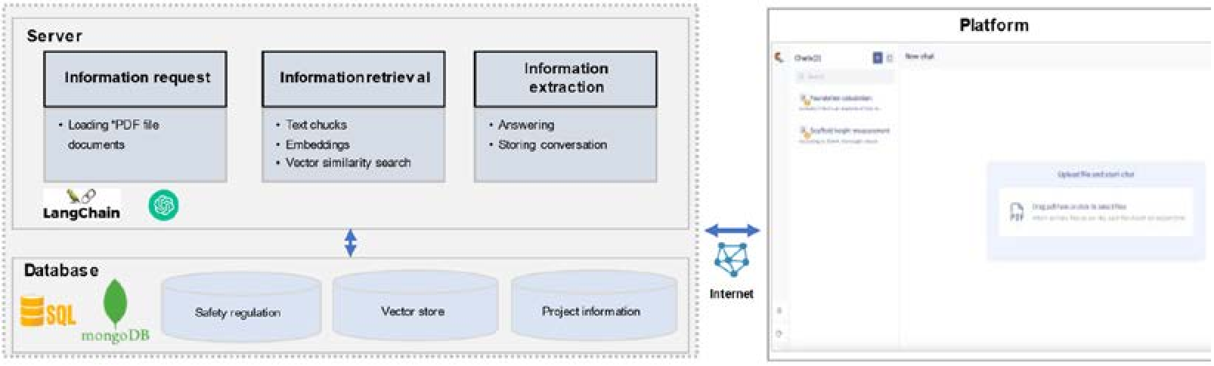

Fig. 2: System architecture

The creation of the vector store is facilitated using FAISS for efficient similarity search and clustering analysis of high-dimensional vector databases. Upon establishing the vector database, it is intricately interwoven within the operational pipeline, enabling LLMs to execute sophisticated information retrieval and interaction, utilizing OpenAI's GPT-4 through Langchain, a versatile open-source framework for building AI apps and Chatbots. The streamlined process integrates FAISS, user queries, and LLMs responses in a seamless flow. When a user initiates a question, it is directed to FAISS's sophisticated similarity search algorithm, which extracts relevant information from the vector database used by LLMs in embedding form.

4. CASE STUDY

The authors performed a case study of safety information extraction related to scaffolding during construction by implementing the CSQA approach, as illustrated in Figure 3. The extraction of safety regulations, specifically OSHA 1926 Subpart L, is pivotal in maintaining a high level of safety in construction environments where scaffolding is utilized. To do this, the authors download A Guide to Scaffold Use in the Construction Industry as a PDF file and then upload it to the CSQA prototype system. After that, the safety managers query the information related to their needs. By meticulously extracting and implementing each safety provision laid out by OSHA, construction companies can significantly mitigate the risk of scaffold-related incidents, protecting workers from falls, structural collapses, and falling objects. This process of extracting and adhering to OSHA's stringent safety regulations is essential in fostering a culture of safety within the construction industry, emphasizing the importance of the well-being of every individual on the construction site and ensuring the successful and safe completion of construction projects.

Fig. 3: The construction jobsite using both fixed and mobile scaffolding

In the case study, both fixed and mobile scaffolding were used at the construction jobsite (as illustrated in Fig. 3). To prepare for the safety inspection process, the safety manager considers some potential hazards situation that may occur during using scaffolding system. The results of the prompting process were illustrated in Fig. 4. In the scenario, the safety manager would request information about the maximum number workers allowed to use the scaffolding simultaneously. After prompting, the results of extractions were described in Fig. 4.

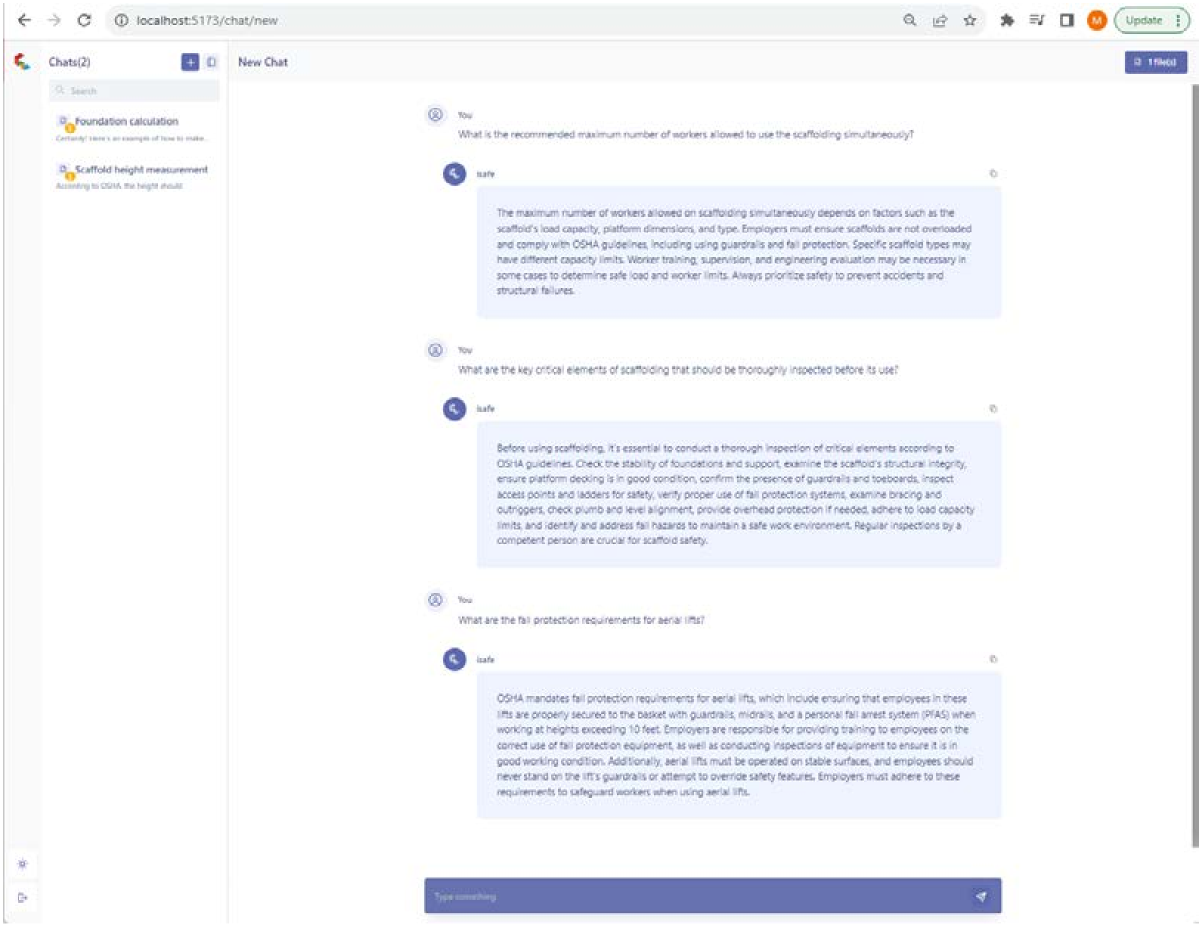

Fig. 4:The results of safety information extraction

5. DISCUSSION AND CONCLUSION

The study aimed to improve construction safety by proposing an approach to extracting safety requirements using a large language model. A thorough literature review highlighted the significance of safety information retrieval and extraction. Accordingly, the safety requirements were collected and tailored for building the database, which is contained in the safety investigation module (CSI). The system uses safety regulation PDFs for text extraction, preprocessing, and global indexing for efficient search. The safety condition identification module (SCI) obtains the CSI database, then the LLM processes user queries, examines the indexed rules, and retrieves relevant information with its thorough training. Safety information delivery (SID) would address the user and offer feedback to improve system accuracy depending on user replies. Hence, the safety requirements could be extracted following the request of site employees. The authors developed the prototype of an LLM-powered application by using Langchain to validate the approach. The results show that the maximum number of workers allowed to use the scaffolding simultaneously was retrieved from the guide to scaffold use in the construction industry.

However, the research has the following limitations: (1) The study concentrates on optimizing a database of safety requirement information; however, it does not discuss the algorithm's architecture and precision. (2) The case study is only used to extract scaffolding-related information. For future studies, the authors will analyze additional accident reports and regulations to develop potential hazard situations associated with a specific activity. Additionally, the authors will concentrate on developing a system based on the proposed method. Then, we examine the effectiveness of the system with larger initiatives and more project members.

ABSTRACT: *Classical and industrial archaeologies are a complex cultural field where singularity and uniqueness are expressed through past memory evidence and identity recognition. In order to obtain these values acknowledgement, it is compelling to highlight the material and intangible knowledge by using suitable ICT tools capable of handling complexity and managing large sets of heterogeneous data usually subjected to changes, different interpretations, inconsistencies and sometimes uncertainty. Although the HBIM method has been largely used in the past years, it shows significant limits when dealing with large and heterogeneous information requiring the introduction of advanced methods and tools. In this context, this study presents an approach to the architectural heritage and historical manufacturing activity representation based on integrating the HBIM process with a structured knowledge base, demonstrated through its application to the Sanctuary of Hercules and the former Segrè Papermill case study. The work develops an ontology-based system using existing ontologies for the three domains of interest: architectural artefact, cultural heritage and industrial processes directly connected with the informative model. The intent is to give an overall support system for the complex semantics formalization of these assets to aid the interpretation, intervention and valorization activities.*

KEYWORDS: *Archaeology, Industrial heritage, Knowledge representation, HBIM, Ontologies, Linked data*

1. INTRODUCTION

The widespread of various digital approaches in the built heritage field has raised multiple issues related to the effectiveness of those different methodologies. In this context, it is compelling to comprehend the complex nature of the these specific sites and to define reliable methods to document research and investigation processes for the recovery, intervention and valorization activities. Particular assets distinguished by multiple archaeological stratifications are emblematic cases that perfectly outline the critical aspects of current practices. The knowledge representation and management activities play a crucial role alongside the historical and archival research, the integrated survey and the information modelling of these artefacts, to address the challenges of complex heritage assets related to their uniqueness and singularity/rarity and to solve critical issues of interoperability, alignment of cataloguing systems, in order to make knowledge shareable among the various actors involved in decision-making processes.

Within such peculiar applications, this study tries to apply effective digital knowledge technologies to address the main research question, or rather the knowledge representation in a complex evolutionary scenarios, such as multiple archaeological sites, by integrating information modelling (BIM) and semantic web technologies (ontologies). In particular, with a specific focus on modelling the Segrè papermill historical industrial process, linked to the architectural artefact and its historical evolution. The aim is to highlight comprehensively the industrial archaeology aspects which is defined as an interdisciplinary study field related to both the historical issues of the industry's world and the material culture (processes, machines, workers life). In fact, the industrial archaeology represents a combined form of technological and humanistic culture, whose value extends and matures overtime. Therefore, the experiment focuses on covering the gap in digital data documentation of industrial archaeology and historical manufacturing processes to represent multidisciplinary concepts correlations in a machine-readable way. Furthermore, the study proposes an approach to the knowledge representation and global management for the investigation process of this unique heritage field.

1.1 Current digital documentation and investigation processes for built heritage

Over the past decade, we have observed a growing focus on Building Information Modeling in the area of heritage architecture also, referred to as Heritage (or Historical) BIM / HBIM. Currently, the most established HBIM workflow consists of surveying the building by point cloud used as a reference to reconstruct simplified geometries employing BIM objects, which are assigned attributes and linked documents, boards and databases helpful in enriching the model with information produced and used by specialists in the field (Logothetis et al., 2015; López et al., 2018; Pocobelli et al., 2018).

If, in the case of the design of new buildings, the definition of accurate and complete documentation of what is to be built goes hand in hand with the progressiveness of the definition of the project itself, and is, therefore, fully consistent with the information practices imposed by BIM environments, in the case of the processes that characterize the activities of investigation and restitution of an existing asset the knowledge we have of the latter, in addition to coming from extremely heterogeneous sources, is subject to continuous changes, interpretations, uncertainties and gaps that must be able to persist until the end of the process and beyond (Bianchini, 2014). In fact, information management in this field is still mainly based on a documentary approach (Moscati, 2021) in which information is stored by presenting it in a linear and orderly manner but in a flat and static form that does not allow the possibility of movement and connection between the information itself. The need to overcome these limitations led to the research of new systems that could allow machines to automatically combine knowledge from different sources and, even better, derive new knowledge from them.

Following linked data principles, ontologies are languages used by semantic web resources to represent knowledge and concepts within a specific domain (Gruber, 1993). In the case of cultural heritage and more in detail built heritage fields, ontologies have been developed to organize and structure information related to buildings, historical monuments, archaeological sites, and other forms of architectural heritage. These ontologies enable better management, search, sharing, and data interoperability in the built heritage field.

The direction in which major international research infrastructures are moving (DARIAH, Etc.) seeks to transform the 'Web of documents' into a 'Web of data', consisting of concrete 'objects' that machines can process (machine understandable). The aim is to provide computers with the ability to combine data to create new knowledge, form new connections and draw new conclusions from indexed data, automating what has hitherto been the exclusive preserve of humans and minimizing the separation between discovery (locating bibliographic news) and delivery (finding the document) so that an ecosystem of metadata can be created. This operation will soon allow global data availability within a larger framework of openness and interconnection of information, enhancing the effectiveness and visibility of information available online.

1.2 Existing ontologies for industrial processes representation

Significant efforts exist to standardize ontologies across industries. Organizations such as Industrial Ontologies Foundry (IOF) (Drobnjakovic et al., 2022) and Manufacturing Enterprise Solutions Association (MESA) (Kazil et al., 2020) are collaborating to develop common ontologies and data models to improve interoperability among manufacturing systems. To date, the mid-level manufacturing ontologies available are the Manufacturing Semantics Ontology (MASON) (Lemaignan et al., 2006) and the Manufacturing Reference ontology (MRO) (Usman et al., 2013). However, they are only able to represent the production and design part of the manufacturing domain (Sanfilippo et al., 2021) and have limited mutual interoperability (Francesconi et al., 2010).

The Supply Chain Reference Ontology (SCRO) (Ameri et al., 2020) is a pilot ontology that extends BFO and IOF Core able to provide the basic ontological constructs needed to represent a supply chain in terms of structure (members and their roles, functions, capabilities, relations, and resources) and operations (processes and flow of material and information). Similarly, the Supply Chain ONTology (SCONTO) (Vegetti et al., 2016) formally describes a supply chain at various abstraction levels. Resources such as workstations, machines, tools and fixtures are formally represented in the Manufacturing Service Description Ontology (MSDL) (Ameri & Dutta, 2006).

Furthermore, with the advent of the fourth industrial revolution (Industry 4.0) and the expansion of the Internet of Things (IoT) into the industrial sphere, ontologies become even more important for organizing and understanding data from an increasing number of connected devices and intelligent systems (Sampath Kumar et al., 2019). Industry 4.0 is mainly based on robotic agents that are responsible for performing the main operations in a smart manufacturing environment. The standardization of the knowledge representation is based on standard ontologies, which are the CORA Ontology for robotics and automation (Prestes et al., 2014) and ROA Ontology (Cheng et al., 2016) that defines the main notions of behavior, function, and goal. Focusing specifically on the manufacturing resources, in literature we can find a variety of standard and ontologies that understand resources differently. Based on industrial standard, resources are defined as " any device, tool and means, except raw material and final product components, at the disposal of the enterprise to produce good and services" (ISO 15531-1; ISO, 2004a). "The types of resources involved in the manufacturing operational management are: personnel, material, equipment" (IEC 62264; IEC, 2013); "Means used by an activity to transform input into output" (ISO 20534; ISO, 2018). As we can see the terminology relies on not aligned vocabularies and we can define three different approaches that have distinct views on manufacturing resources. The first one relates the manufacturing activities occurrences with the resources model (Sarkar & Šormaz, 2019), the second one connects the resource to the activities primarily (Sanfilippo, 2018), the last one presents the resources directly related to the agents goals (Sanfilippo, 2018). The user case needs should rely on adopting one or the other. Furthermore, as we can see in the literature, many studies and approaches exist for contemporary manufacturing processes and Industry 4.0. At the same time, it lakes in the representation of historical industrial processes, therefore in the ontology reuse process, we adapted existing classes, relations and proprieties to our specific use case.

1.3 Existing ontologies for cultural heritage representation

Several knowledge structures have been developed to represent and manage cultural heritage data (Doerr et al., 2020; Hellmund et al., 2018). For instance, the Getty Foundation developed a SPARQL version of its thesaurus (Harpring, 2010). In addition to those mentioned above, one of the most widely used conceptual models to describe cultural heritage in general with extensions possibility to fit built heritage is the CIDOC Conceptual Reference Model (CIDOC-CRM) (Martin Doerr, 2003). CIDOC-CRM provides a conceptual model to describe cultural heritage in general but can be broadened to fit built heritage aspects.

Extensions of CIDOC-CRM include the CRMba model (Ronzino, 2015) conceived to support the archaeological documentation of buildings with an emphasis on recording stratigraphic units and the evolution of the structure over time. Furthermore, other specific ontologies have been developed to address specific issues in built heritage, such as conservation, documentation, and management. For example, Acierno et al. (2017) extend the domains of CIDOC with an ontological structure that covers aspects concerning both the typological and the constructive entities of historic buildings, and the documentation and investigation activities conducted by specialists for the artefact study and preservation. Colucci et. al. (2021) deal with the formal conceptualization to represent the built and architecture domain by proposing an ontological scheme that focuses on connecting semantic and geometric information to generate a parametric and structured model from point clouds.

In a broader context, not confined exclusively to the ontologies field, initiatives such as the EUROPEANA (Europeana, 2017) and ARCHES (Myers et al., 2016) projects aim to create open digital infrastructure to enhance the semantic representation of data related to built heritage. It is clear that the development of ontologies for built heritage is an active field of research and development. New ontologies and approaches continue to be proposed and developed, especially to integrate ontological approaches with 3D and HBIM models (Cursi et al., 2022) to improve the representation and interoperability of information related to this domain.

1.4 Digital approaches for classical and industrial archaeologies

In the archaeological field, the structures and the architectural elements are usually partially visible, restored or modified, often with missing parts and multiple transformations during time. Digital representation is a big challenge since the archaeological reports on the excavations and related documentation are usually the only available data. The models tested in this field primarily deal with virtual reconstruction, starting from different survey techniques to immersive and virtual fruition. Most of the case studies considered are as-built BIM to represent the actual state of the remains with a BIM semantic structures through manual operations or automatic segmentation algorithms (Achille et al., 2015; Bosco et al., 2019; Di & Wu, 2011; Guerrero Vega & Pizzo, 2021; Moyano et al., 2021; Scianna et al., 2021; Trizio et al., 2018). In Garagnani's work (2016), they defined a process of information cataloguing ArchaeoBIM as useful for documentation and consultation and for analytical studies to accompany the reconstruction activity. The main focus of some of them is on the stratigraphic analysis in the HBIM workflows (Diara & Rinaudo, 2020) and the development of the HBIM cloud platform for archaeological analysis and documentation (Diara & Rinaudo, 2021). While in some other cases, these applications have been implemented for preventive archaeological projects, for instance in Banfi et al. study (Banfi et al., 2020) they developed an open-source BIM platform able to merge BIM sensors, monitoring, historic building information modelling and VR, with a specific focus on complex scenarios with heritage sites subjected to flood risks and water level changes. At the same time, Saricaoglu et al. (2022) defined a method for data-driven conservation actions alongside the decision-making process to integrate both levels of geometrical accuracy and the multi-level data for the interventions.

For the industrial archaeology digital process in literature, we can find, from a larger scale, GIS approaches for the creation of databases, spatial analysis and visualization (He et al., 2015), to similar approaches related to the definition of as-built models, from UAV survey to BIM environment (Barrile et al., 2019). In particular, there are some cases where the main focus is the machine apparatus inside the former factories. The integrated survey process of the main components of this architecture type is followed, in one case by an HBIM modelling with a deepening aspect of LOD (Currà et al., 2022), in one other with the creation of a virtual tour (Shults et al., 2019).

Hence, the literature review shows a clear gap in documenting industrial archaeology and the historical manufacturing processes. Furthermore, the applications could be more extensive in the data representation and relation between different domains to address the possibility of making interdisciplinary concept correlations. These gaps represent the starting point for our study which tries to delineate an approach towards industrial archaeology and other archaeologies by considering its valuable aspects, defined in the next paragraph, and through the integration with semantic web technologies to overcome the evident difficulties in the investigation process of a complex heritage site.

2. COMPLEX ARCHITECTURES OF MULTIPLE ARCHAEOLOGIES: RESEARCH, DOCUMENTATION AND INVESTIGATION PROCESSES

Complex architectural sites, defined by the stratification of multiple archaeology, are a peculiar heritage field rooted in the Lazio region. The Sanctuary of Hercules and the former Segrè Paper Mill site in Tivoli – selected case study for our research - are unique evidence of the past Roman empire that crossed centuries up to industrial time. In fact, the actual state is a combination of classical and industrial archaeology. In this case, the main focus of the study regards the semantic definition and knowledge modelling of the industrial processes of the Segrè papermill, which is the latest industrial reuse of the Sanctuary, built for some parts of the former manufacturing structures such as the ironworks and the powder magazines. This area stands mainly between the podium and the northern portico, made of iron and reinforced concrete structures. Although quite invasive, the different reuses over the centuries contributed to preserving the porticos dated II century B.C. A second expansion occurred in the former ironworks, where another paper machine expanded the production cycle (Cairoli & Ten, 2016). The plant had an automated production, and hydroelectric turbines followed later on by an electric cabin serving it. The whole complex was decommissioned in 1956, and today, it is partially reused as a museum.

The factory, machines, objects and documents are explored as part of a system that has historically, socially and economically determined the territory and has shaped the landscape. The evidential value reflects activities that had and continue to have profound historical consequences and is based on this evidence's universal value (TICCIH, 2003). Moreover, the social and cultural aspects are related to an industry, a specific company, an industrial community or a particular trade or skill. It may also carry technological and scientific value in manufacturing, engineering and construction history or have aesthetic qualities deriving from its architecture, design or planning (Douet, 2016). Therefore, documenting the industrial processes represents a way to enhance the possibility of continuously perceiving its values and to highlight, in this specific case, how the multiple stratifications and different industrial reuses have helped maintain the ruins of classical archaeology for centuries. The purpose is to give valid support in the digital processes for built heritage by leaving intact the specific features and historical evidence of different periods, actively working to enlighten these diversities during the intervention and valorization activities. It is not a simple and pure conservation process since the past transmission proceeds through its continuous re-interpretation and through a global and interdisciplinary approach.

3. KNOWLEDGE BASE FOR HISTORICAL ARCHITECTURE AND INDUSTRIAL PROCESSES

3.1 Ontology development methodology

The first step to develop the knowledge-based system is choosing the most appropriate methodology that best addresses the specific case study. As described in paragraph 2, it is necessary to define and consider representation from multiple domains, in particular, it is compelling to highlight how the whole process interacts with the existing and new building spaces, related to different evolution phases and how it is combined with the other archaeology and study fields. Some ontologies already cover parts of the domains of interest, while in other cases, integration of new representations schemas is needed to provide a full coverage of the information for a complete comprehension of the artefact.

In the ontology engineering discipline and, more recently, in its application in the AECO field, the Linked Open Terms (LOT) methodology has recently been introduced and developed from the NeOn methodology (Suárez-Figueroa et al., 2015), which places particular emphasis on the reuse of existing ontologies - both general and domain ontologies - already prevalent in the relevant industry, fostering interoperability and optimizing the definition of concepts, attributes and relationships. In a field as complex as multiple archaeology, the potential benefits of such a methodology are clear: the presence of different disciplines involved, seemingly far apart, with their terms, concepts and general knowledge structures, requires, first of all, an effort of correlation between the various domains and, secondly, the work of building the missing knowledge networks or adapting the existing ones. In the specific object of this study, for example, the reuse and integration of ontologies dedicated to the representation of construction and buildings, those dedicated to the documentation of cultural heritage, and those used to describe industrial processes and/or production facilities are important.

3.2 Ontology requirements specification

The use case and purposes concern the documentation of archaeological and industrial heritage to support the investigation and knowledge processes for the intervention and recovery of complex palimpsest. The data exchange needed for this study is based on different sources. All the information necessary for this study has been gathered from many sources starting from a historical and archival study composed of written sources and cartographic, iconographic and photographic ones from the two central archives (Segrè family and Emo Salvati). Besides these historical studies, it is essential to combine them with the archaeological ones, that is, the analysis of all the remaining on surfaces and excavation necessary to reconstruct the whole industrial process. The data acquisition through an integrated survey is then combined with the information collected through the other sources to get a complete information framework.

The *non-functional requirements*, which refer to the characteristics, qualities or general aspects, can be identified by defining a system able to manage heterogeneous data from multiple domains, to assure flexibility, adherence and coherence. Furthermore, consistency should be considered to avoid duplicate information or over-constrained property assertion. Extendibility can be achieved by using standardized languages and existing patterns and concepts for ontology development (Suárez-Figueroa et al., 2009). For scientific data management, the ontology should also be findable, accessible, interoperable and reusable.

The *functional requirements* are the ones related to the use case. The documentation of industrial processes requires the definition of the activities performed in the process stages and the different resource types used (machines, humans, raw materials, semi-finished products). A detailed description of each production stage is necessary for a comprehensive understanding of the process, the machines and the humans/workers, all valuable and fundamental aspects for documenting and investigating industrial archaeology. Along with defining the manufacturing activities, the ontology needs to determine the spaces or rooms where the activities used to be performed, in terms of architectural and technological aspects through spatial and technological entities and the relation between production process, machines and building components and spaces. Layered archaeologies are complex sites where interpretation is usually a complex activity. Therefore the representation of the evolution phases should concern the whole complex and single building elements to interconnect these three domains of interest in an interdisciplinary way by covering all the knowledge useful for the intended documentation activity.

3.3 Ontology conceptualization

From the sources listed in paragraph 3.1, the first attempt in the conceptualization work was to delineate the complete cycle highlighting classes or concepts necessary to describe the whole production system.

In 1935 the mill was expanded, presumably introducing this cycle. The raw materials used for paper making were rags and wood logs. The process based on the rags, our main focus in this case, started from the arrival at the factory in bales where they were stacked temporarily in large deposits. The processing of rag consisted of cleaning and sorting according to various qualities and cutting them in special cutting machines. Once they were selected and separated, they were cleaned a second time by tumblers and beaters, then shredded and leached under pressure with lime or soda in spherical or cylindrical kettles. These operations were followed by fraying in Hollander piles, sort of tanks filled with water where a cylinder with knives reduced the rags into filaments. After that, the produced “half pulp” was conveyed in special tanks and subjected to bleaching with calcium chloride before being fed into the Hollander refining machines. In the Hollander refiners, the half pulp was beaten by other rotating cylinders and converted to “all pulp”, ready to be transformed into paper. Thus the pulp was coloured and glued with resin soap to give texture and to prevent ink from spreading on it. In the paper machines, the pulp was stretched into a thin layer of thick water on a wire cloth, which was then detached into a veil and it was passed over a long woolen felt around a series of huge drying cylinders, heated by steam, and finally dried, it was rolled up as a raw product .

The long ribbons produced by the paper machines were directly pressed and smoothed by giant calenders and then passed to the rolling machines. In the preparation rooms, the paper was cut into sheets and reams were assembled; in the end, the sheets were sorted one by one to be packed and shipped or for other finishing works.

Space	Activity description	Input components	Activity requirement	Resource in Automatic solution	Resource in manual solution
-	1. wood defibration	wood logs	handling tooling (machines) loading	mechanical defibrators	operator, power tool
rags room	2. rags sorting and preparation	raw rags	handling tooling (machines) workholding	hedge cutter cement sack dusting shredder Lannoye	operator
half pulp processing area	3. under pressure leaching	cleaned rags lime soda	handling tooling (machines)	spherical boiler	operator
half pulp processing area/hollander beater room	4. fraying and pasting	impurity-free fibers resin soap water	handling tooling (machines)	hollander beater for fraying hollander beater for pasting	operator
half pulp processing area/hollander beater room	5. whitewashing	"half" pulp calcium chloride	handling tooling (machines)	hollander beater for whitewashing	operator
half pulp processing area/hollander beater room	6. refining	whitened pulp	handling tooling (machines)	hollander beater for refining	operator
paper machine room	7. unfold the paper	pulp	handling tooling (machines) workholding	paper machine	operator
preparation and finishing rooms	8. pressing, smoothing, cutting, packaging	raw paper	handling tooling (machines) workholding	Haubold rotary cutter winding machines packaging presses calender	operator Diamont paper cutter and cutting table Verny rectangular cutter turntable

Fig. 1: Use case data of the latest production process of the Segrè papermill.

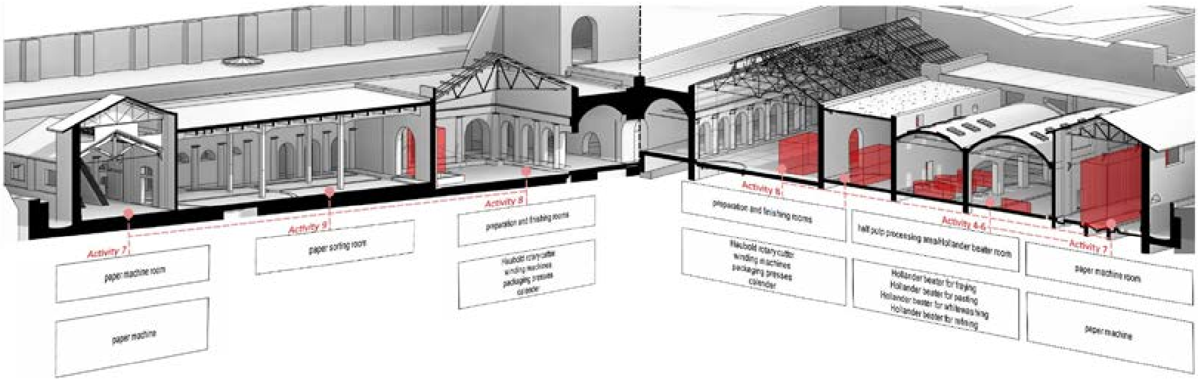

Fig. 2: Spaces, activities and machines in the latest Segrè papermill production process. BIM model carried out by Andrea De Pace and Riccardo Rocchi under the supervision of Edoardo Currà.

Based on the studies conducted by Sanfilippo et al. (2021), we detailed the definition of the process plan, the set of sequential activities decomposing the process, the input component or materials for each activity and the requirements to execute each activity. As shown in the figure, table 1 defines the critical aspects of the use case by listing the activities and their description, input components of each activity, and resources needed to execute each activity, which can be subdivided into manual and automated resources.

After that, it was necessary to identify key concepts to relate the papermill cycle with the building spaces where it used to be performed, which is represented in the first column of Figure 1. The spaces and the building components are required to describe the different halls built in overlapping periods of time. For this reason, it is fundamental to briefly sum up the significant historical stages of the investigated area and, consequently, the evolution of the construction methods related to the different phases. As we already have introduced, the latest industrial production was installed in the northern portico and sacred area of the Sanctuary of Hercules. Over the centuries, many different productions and constructions intersected. In particular, in the 1920s, the mill already had three paper machines, with a layout maintained until its dismission. Between 1923 and 1926, took place the elevation and expansion of the paper machine room in the sacred area. Thanks to the new technologies, a radical change occurred in the 1930s through the widespread use of reinforced concrete structures and prefabricated frames for large roofs.

In this period, the rag room was renovated and expanded, preceding the construction of a paper storage room and a paper sorting room on a two-level building. During the war, the roofing of the sacred area rooms suffered substantial war damage. Three wooden truss roofs were replaced with reinforced concrete structures and two barrel vaults with SAP technology. Overall, there was no real expansion but a simple consolidation of the overall preexisting layout. In Figure 2 some of the spaces/areas, activities performed and machines are represented in the informative model.

Once the main domains, concepts and classes are described, the following step of this study, detailed in the next paragraph, concerns the research and reuse of existing ontologies and the encoding activity.

3.4 Ontology reuse and encoding

The three domains considered for this case study are the *Production Process*, the *Architectural Artefact* and the *Historical Evolution* and they are all connected since the process and the manufacturing tasks are performed in specific spaces that belongs to different areas or rooms of the site which are built in various phases of the papermill production. After reviewing the existing ontologies for all the listed domains we used for the Building spaces and elements the IFC Standard, while for the production process we chose an extension of the IFC and the FA ontology that is mainly focused on the relation between the used resources and activities performed. For the historical evolution documentation we based the whole reconstruction process on the CIDOC-CRM (Fig. 3).

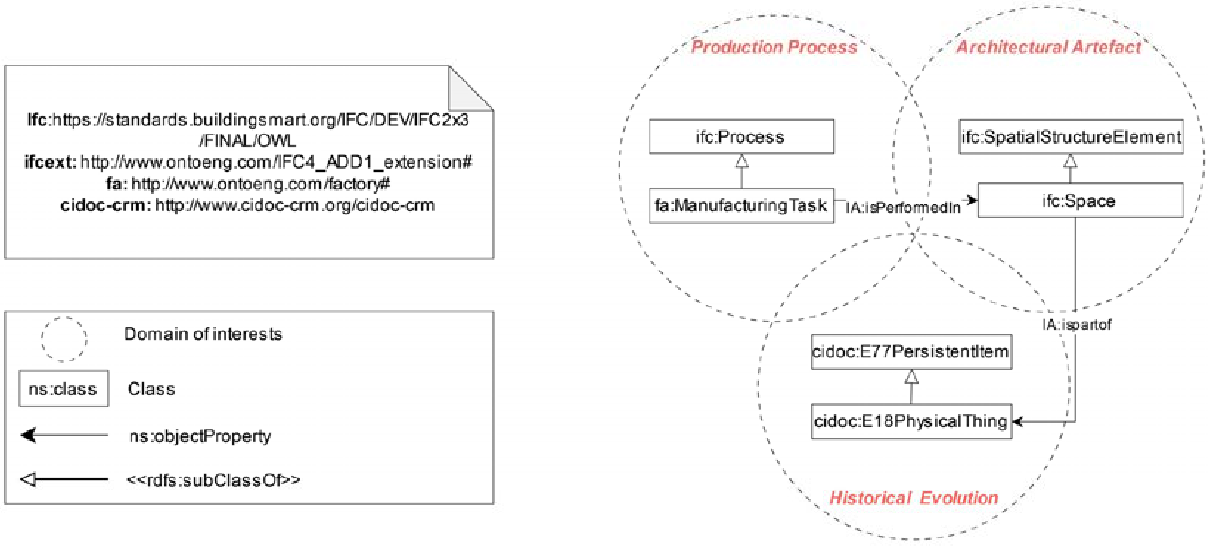

Fig. 3: Knowledge modelling of the three domains considered: the production process, the architectural artefact and the historical evolution.

The chosen ontologies for the production process modelling provide an extendible representation of the factory entities related to production systems, resources and products. The starting point was a simplified version of the IFC based on two main classes. A process (*ifc: IfcProcess*) "is an event that transforms input-output products while making use of resources under specific control rules. A resource (*ifc: IfcResource*) represents an entity that is needed to perform the process. In turn, various objects, such as physical products, people, and materials, can be employed as resources". Then we integrate this approach with the one proposed by Sanfilippo et al. (2021). They started considering three existing high-level approaches and trying to unify them in a single and complete framework. In this way, it was possible to consider and represent manufacturing by taking into account activities, goals and activities occurrences during the entire process since the IFC-based modelling is not able to distinguish alone between the entities and their relations. On the other hand, through this integrated methodology, the properties are explicitly stated, and they can provide a useful explanation of the case study. For instance, the *activity description* is a class that describes the specific manufacturing process description where *whitewashing* is an individual and refers to conveying the *half pulp* in special tanks and subjected to bleaching with calcium chloride. The *input components* for each activity list the components needed for that singular operation and they are detailed through the property *hasComponentReq*. For the activity whitewashing, the input components are *half pulp* and *calcium chloride*, and the output of the same activity, which is expressed through the propriety *hasOutput* is the *whitened half pulp* that is combined with other components and becomes the input resources of the next activity. The activity requirements list the resources and capabilities that are necessary to perform specific tasks. For instance, the whitewashing activity *hasResourcesReq tooling* and *handling* that are individuals of *CapabilityDescr*. The *Resource in Automatic solution* and the *Resource in Manual solution* list the description of resources either in the automatic or manual configuration that can execute the activity; *Whitewashing Hollander machine* and *Operator* satisfy the two resource requirements and are correspondingly individuals of *ArtifactDescr* and *Descr*.

The production process domain and the building artefact domain are connected since the *fa: Manufacturing Task*, a subclass of *Ifc: Process*, *isPerformedin* a specific place of the papermill complex. In fact, the architectural artefact knowledge modelling started from the class *Ifc:IfcSpace* which is defined as "an area or volume bounded actually or theoretically. Spaces are areas or volumes that provide for certain functions within a building". The main classes considered are both subclasses of the *Ifc:IfcProduct*, in detail, the *Ifc:IfcBuildingElement* indicates "all elements that are primarily part of the construction of a built facility, i.e., its structural and space separating system. Building elements are all physically existent and tangible things". The latter class was useful to describe the building components, and it was divided into *Load Bearing Skeleton* itself subdivided into *Steel Frame* and *Concrete Frame*; *Horizontal Closures* divided into *Horizontal Base Closing*, *Horizontal Intermediate Closing* and *Horizontal Top Closing* that can be Plane, Sloped or Curved; and *Vertical Closures*. For instance, considering the manufacturing task *whitewashing,* it was performed in the *Hollander Beater Room*, an individual of *Ifc:IfcSpace*, and it is enclosed in *Industrial floor1* as *Horizontal Base Closing*, and *Barrel Vaults* as *Horizontal Curved Closing*, which replaced the *Horizontal Sloped Closing Wooden Truss Roof* that was damaged during the second world war. For the *Vertical Closing*, we identified two different closings instantiated as *Tuff Wall 1* and *Tuff Wall 2*, probably built in two different periods, and they have incorporated the structures derived from the Hydroelectric and hydraulic canals Construction.

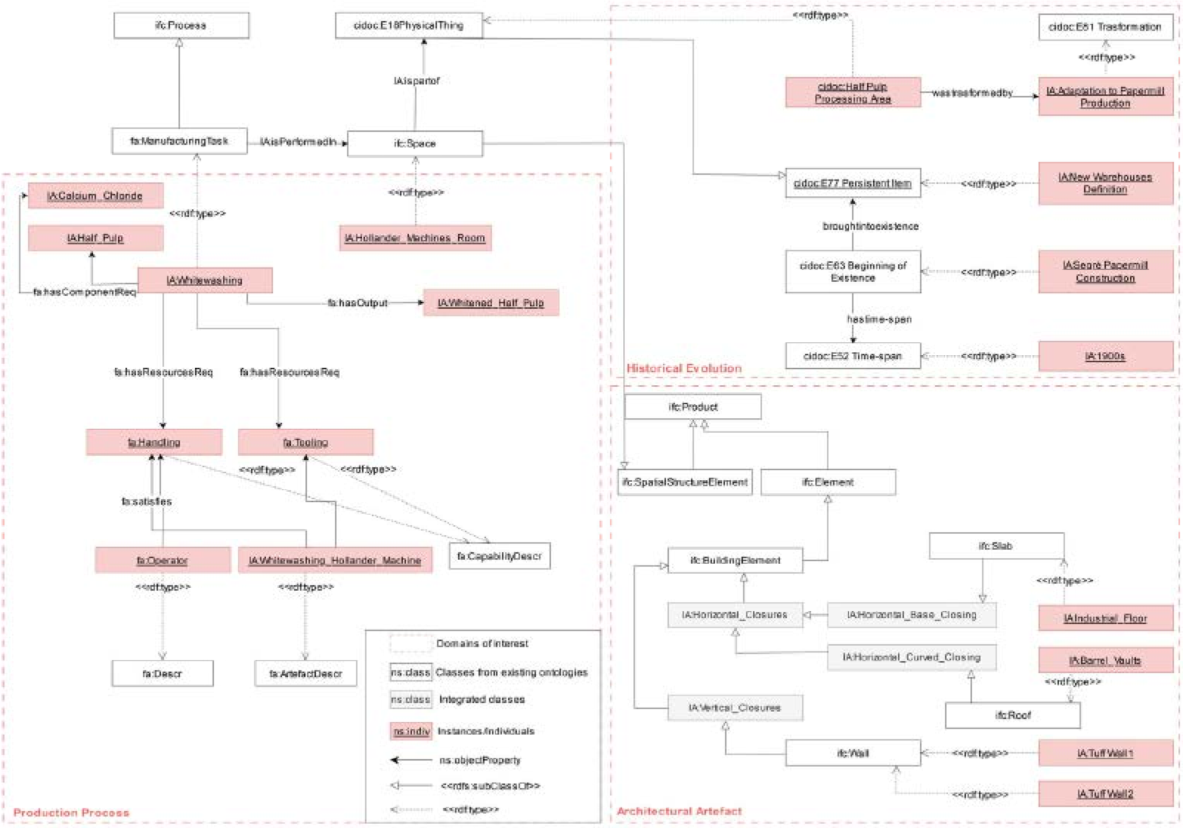

Fig. 4: Instantiation process of the whitewashing activity performed in the Hollander Beater Room.

Moreover, the building construction phases are very intricated due to the multiple overlapping structures, and therefore a clear explanation is necessary for a deep understanding of the artefact elements. For this reason, the Spaces defined in the architectural artefact domain are connected with its historical evolution through the property *ispartof,* that associates the *Ifc:IfcSpace* with the E18 class of the CIDOC-CRM *PhysicalThing*. As explained in paragraph 1.1, the CIDOC-CRM provides a common and extensible semantic framework for evidence-based cultural heritage information integration. The classes used are E18 Physical Thing appropriate for the definition of different rooms where the production process took place, i.e. the *"Half Pulp" processing area*. The E18 is a subclass of the E77 Persistent Item, which defines items with a persistent identity, sometimes known as "endurants" in philosophy. For example, in our case, it could be interpreted as *New Warehouses Definition*, considering the latest papermill production. E66 Beginning of Existence is instantiated as *Papermill*

Construction and it is connected with the E77 Persistent Item through the propriety *hasBroughtintoExistence* and through the property *hasTimeSpan* it is related to E52 Time-Span instantiated as 1900s. Those classes are fundamental to documenting a specific state of the artefact, and we also considered other CIDOC classes to document the transformations that modified the physical structures and also functions. To express the transformation, we considered E81 Transformation, instantiated as *Adaptation to Papermill Production.* Other more detailed classes and proprieties can be helpful, such as E11 Modification and its subclasses E79 Part Addition and E80 Part Removal, which can be directly related to the E18 Physical Thing through the propriety *hasModified.*

In Figure 4 is represented a small portion of the instantiation process which regards one of the activities performed in the Hollander Beater Room. All three domains are represented and are interconnected with each other. Each single manufacturing task is then connected with the following tasks through the input components defined as Component requirements and the outputs which are the input of the subsequent activity. The tasks are then connected with the spaces and the historic evolution domain as explained above. As defined in the picture, we combined classes from existing ontologies with integrated classes, we represented the individuals of each class in red, correlating them with object properties.

4. INTEGRATING KNOWLEDGE-BASED REPRRESENTATION AND HISTORIC BUILDING INFORMATION MODELLING

The knowledge formalization related to the latest papermill production, which includes the disciplines presented above, is then integrated with geometrical and technological aspects of the artefact components. The first connection between the knowledge structure and the informative model has been made through the correlation between the *Ifc:IfcSpace* of the knowledge base and the *Ifc:IfcSpace* of the BIM model. The IfcSpace is defined, for our case study, as the rooms or areas where the activities were performed. The integration of the two models is a critical process. It is necessary to carefully decide which information can better connect these two environments to ensure interoperability and data alignment.

In the BIM environment, each room has a label, for instance, *Paper Machine Room* or *Hollander Beater Room*, individuals of the *IFCSpace*. The label correspondence is between the name of the room in BIM and the individuals of the knowledge base *Paper Machine Room* or *Hollander Beater Room*, instances of the *IfcSpace* Class.

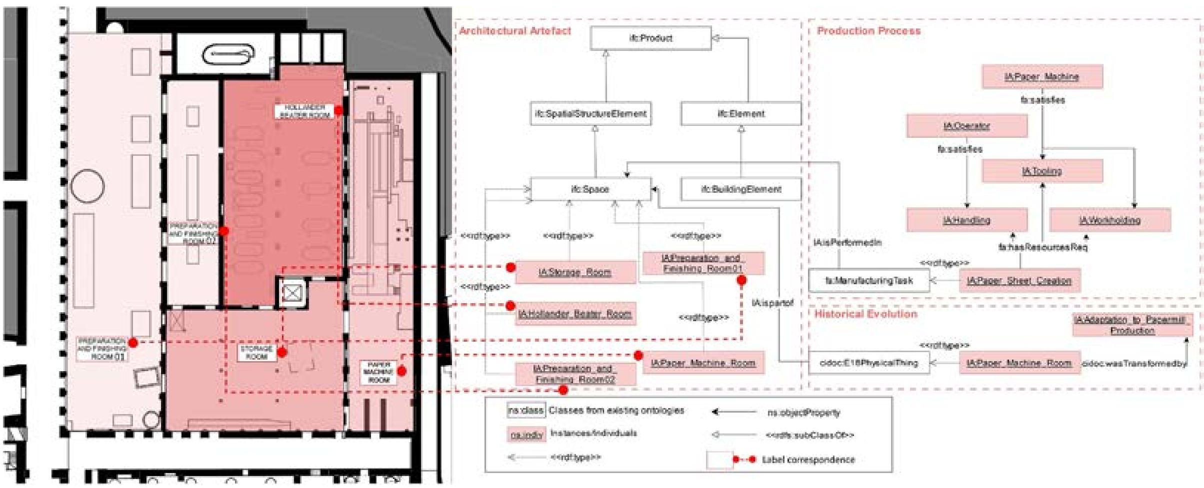

Fig. 5: Label correspondence between the rooms in the model and the individuals in the knowledge base.

The label corresponding process is represented in Fig. 5, through this integration activity is possible to underline a fundamental aspect of this approach. In fact in this way, we can connect the entities with other concepts, abstract or concrete which belongs to different domains in a cross disciplinary way. Using only the BIM representation schema is quite limited since many relations and concepts cannot be fully interpreted and represented. This approach can answer some of the critical issues related to the current practices in the digital built heritage processes. The documentation of the artefact requires the representation of a broader domain of knowledge, which includes extremely diverse and specific aspects such as historical, cultural contexts, construction techniques, and the history of materials which guide its accurate interpretation. Therefore it is possible to represent and manage information from an incremental and recursive perspective and from heterogeneous sources. The complex nature of built heritage fields needs appropriate tools and approaches to better address the multiple and open issues.

While in the first case, the label correspondence was between spaces and rooms, in this second case, we focused on the building elements. The *ifc* schema has a rigorous hierarchy representation, and sometimes to represent the heritage buildings, we are forced to use this schema even if it does not address the singularity and uniqueness of these artefacts. The building components of a historical building may not precisely correspond to specific classes in the *ifc* structure, especially when considering overlapping structures where every element may have acquired different meanings and functions over time, embedding a wide range of historical, cultural, social and technological values. In Figure 6, we can see the label correspondence between the two models by considering some of the building elements. For the architectural artefact representation, it was included in the knowledge base another class level as a subclass of the *ifc:BuildingElement* defined by *Ia:HorizontalClosures* subdivided in *Ia:HorizontalBaseClosing* and *Ia:HorizontalSlopedClosing*, and *Ia:VerticalClosures*. The instantiation process represented within the red boxes in the diagram is conformed to the individuals in the BIM model, which are likewise instances of *ifc:Wall*, *ifc:Slab* and *ifc:roof*.

The possibility of correlating concepts outside the informative model helps us to represent the authenticity of the heritage artefacts, the overlapping structures of the building components, the inconsistencies, and the different interpretations of single or multiple elements. These are all steps of the documentation and investigation processes that all the specialists perform in their field and, through this integrated approach, can be represented consistently in a machine-readable way.

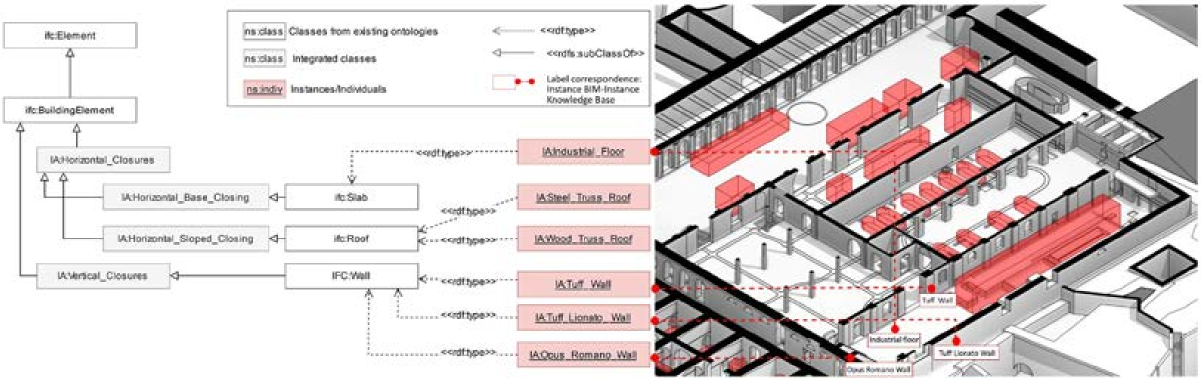

Fig. 6: Label correspondence between building elements in the model and the individuals in the knowledge base. BIM model carried out by Andrea De Pace and Riccardo Rocchi under the supervision of Edoardo Currà.

5. CONCLUSIONS

This research focuses on modelling the main features of industrial archaeology in a multi-layered historical site. We developed a structured knowledge base integrated with the BIM model to document the latest papermill production of the Segrè family. The historical industrial process and the manufacturing machines have shaped over time the architectural assets built on the remains of the Roman sanctuary and the former iron and powder productions. The knowledge base creation started by defining the domain of interests: production process, architectural artefact and historical evolution, followed by the knowledge base creation through an ontology conceptualization, reuse and encoding activities. Finally, the last part deals with integrating the knowledge base with the informative model made through a label correspondence between the same IFC classes.

The novelty of this integrated approach addresses some issues presented in section 1. Starting from a clear gap in the digital documentation process of the industrial heritage field, we proposed a methodology for the knowledge representation that considers all the domains of interest, with a specific focus on the industrial process, to customize the existing ontological approaches for contemporary manufacturing and Industries 4.0. Over time, the aggregated work on multiple industrial heritage sites can extend the queries on a large amount of data and scale to define similarities through the use of computable knowledge, highlighting differences and multiple interventions and recovery actions based on regional and transnational cases of industrial archaeology.

The application and validation of the proposed approach in similar contexts are necessary to highlight improvement aspects, extend the concepts and relations of the considered domains, and implement other valuable domains. Moreover, the difficulties faced during the knowledge acquisition process, caused by data inconsistency and uncertainties, could be managed by new ways of knowledge representation systems able to document and grade multiple interpretations schemas. Indeed, the following step of this research is to overcome the above-presented limits of this approach to better represent and manage the built heritage knowledge.

ABSTRACT: *Assessing the structural integrity of unreinforced masonry structures is a complex and time-consuming process that necessitates the knowledge of various experts and meticulous cross-referencing of diverse data to achieve a comprehensive understanding of the building. In recent years, the Architecture and Construction Industry has witnessed a digital transformation, largely driven by Building Information Modeling (BIM). BIM has proven immensely valuable in the conservation of historic buildings. However, while it excels in new construction projects, its full potential is not fully realized when dealing with existing structures. A clear example of this limitation can be observed in the Industry Foundation Classes (IFC) format, which lacks instances necessary for accurately representing existing building features. This research contribution aims to advance the process of semantic enrichment of BIM for existing buildings, building upon findings from existing literature. Leveraging the Linked Data Approach and utilizing both existing ontologies and newly proposed domain ontologies, the objective is to facilitate the identification of vulnerabilities and potential local failure mechanisms. The geometric information of the building is represented in the IFC STEP format and enriched semantically by establishing new relationships between classes that are not present in the standard IFC. This approach is applied to a case study in the historical center of Castelnuovo di Porto, Italy. The results of this work demonstrate how the proposed model, enhancing the BIM representation of existing buildings and enabling better identification of potential weaknesses, contributes to improved preservation and seismic resilience of historic structures.*

KEYWORDS: *BIM, Linked Data, Semantic Modeling, Historic Constructions, Structural Masonry.*

1. INTRODUCTION

Before the advent of modern construction techniques, buildings were raised employing local materials and construction methods, resulting in a large percentage of the built heritage being composed of unreinforced masonry structures. The effectiveness of unreinforced masonry constructions depended on adhering to a set of empirical rules known as the 'rule of the art (Antonino Giuffré et al., 2010). This aspect becomes particularly critical in seismic scenarios, as past seismic events demonstrated that following the 'rule of the art' ensures walls exhibit a *monolithic behavior*, fundamental to being resistant to earthquakes. Furthermore, the proper connection between structural elements is another critical factor that helps prevent out-of-plane local failures. These failures can happen when walls or portions of walls collapse outward during an earthquake, posing a significant danger to both the structure and its occupants (Antonino Giuffré, 1993; Antonino Giuffré et al., 2010).

The Italian Code, which is a major reference for the assessment of historic buildings, provides three levels of analysis of the structural behavior of existing unreinforced masonry buildings: (i) Identifying the shear strength of the masonry under examination, (ii) Verifying local mechanisms, and (iii) Conducting global numerical analyses. (Norme Tecniche per Le Costruzioni, 2018). The three levels of assessment become increasingly more comprehensive, with their accuracy contingent on the modeling assumptions. Consequently, opting for the simplest level of assessment would be preferable when knowledge is limited.

Considering these principles, a precise evaluation of the structural behavior of existing non-reinforced masonry buildings, utilizing more advanced methods, necessitates a thorough examination of the structure, involving

experts from diverse fields. (ICOMOS, 2005). Consequently, a systematic methodology is needed to allow the integration of data of different types, avoiding the repetition or defeat of pivotal information.

With the introduction of Building Information Modeling (BIM), the architecture and engineering industries have significantly changed their processes. This technology, although it was developed for the construction of new buildings, has not gone unnoticed in the field of rehabilitation of historic buildings. Today, the term HBIM (Historic Building Information Modeling) identifies the application of BIM technology to historic buildings (Maurice Murphy et al., 2009). The HBIM methodology has been explored as support to various areas of conservation (Pocobelli et al., 2018; Volk et al., 2014). Relevant efforts have been done to improve the representation of complex geometry, mainly with the integration of advanced survey acquisition methods (Cotella, 2023). HBIM applications exploit the potentiality to map damage and deformation accurately (Barontini et al., 2022; Moyano et al., 2022), conduct simulations (Gigliarelli et al., 2017; Ursini et al., 2022), manage the intervention on site (Biagini et al., 2016) and optimize facility management (Piselli et al., 2020).

Despite its widespread use, HBIM encounters challenges in its application, mainly because the original BIM methodology was primarily introduced for new construction projects. In reality, even the use of Industry Foundation Classes (IFC) needs to be enhanced to digitize existing constructions. Consequently, the semantic enrichment of HBIM models has emerged as an increasingly researched area. Due to the multidisciplinarity of the conservation field, the use of Semantic Web Languages through a Linked Data approach is gaining momentum (Cursi et al., 2022). The advantage of this methodology is that it allows modeling domain-specific information using specialized ontologies, which can be employed as external links to enhance the content of the BIM models.

From a broader perspective, the use of semantic web standards such as Resource Description Framework (RDF) and Web Ontology Languages (OWL) has the advantage of providing interoperability between data of different domains which are published on the web. On the other hand, IFC is written in EXPRESS language, and has a strong emphasis on the tridimensional representation of the geometry, while remaining difficult to integrate with other web sources (Rasmussen et al., 2020).

The ifcOWL ontology has been a pioneering attempt to extend the content of IFC to the semantic web (Beetz et al., 2009). However, due to its extensive length and complexity, it becomes challenging to implement and utilize in practical applications. As an alternative, other more contained ontologies have been proposed to represent construction instances in the semantic web. Under this approach, spaces are defined using the Building Topology Ontology (BOT) (Rasmussen et al., 2020), building elements with the Building Element Ontology (BEO) (Pauwels, 2018), and materials with the Material Property Ontology (MAT) (Poveda-Villalón & Chávez-Feria, 2020). The tendency of *modularization* of information based on different domains also interested the BuildingSmart Technical Room. Indeed, for the next generation of IFC, it is proposed to have a common base layer, connected to several extensions belonging to different domains (Berlo et al., 2020). In addition, the IFC base schema will be language-independent, ensuring greater interoperability with formats currently in use in other fields, including RDF.

In the past, there have been proposals for large and complex ontologies to represent historical data. The CIDOC-CRM for instance (Crofts et al., 2003), has been mainly developed for museums, but then extended to other domains such as the representation of non-destructive testing techniques (Kouis & Giannakopoulos, 2014), annotation of degradation phenomena of stones (Veron et al., 2015), and also for the semantic enrichment of HBIM models (Acierno et al., 2017). However, currently also in the field of historic constructions, there has been a recent preference for using a network of modular ontologies instead of a single complex ontology (Bonduel, 2021). This facilitates the better management of the ontology and the connection with different domains.

This paper aims to propose a method to digitize current methods for structural assessment of existing unreinforced masonry buildings. The purpose is to improve the management of the alphanumeric data associated with three-dimensional models, stressing standardization and interoperability. Two new domain ontologies are proposed: (i) Historic Masonry Ontology (HMO); (ii) Failure Mechanism Ontology (FMO). The first represents masonry material, while the second represents the vulnerabilities associated with specific types of masonry collapse. The two ontologies can be used together or combined with other domains. In particular, they can be used for the semantic enrichment of BIM models, combining geometry representation and alphanumerical data. This is demonstrated using a web app to map IFC and Turtle files (A. Donkers et al., 2023).

This paper is organized as follows. After this introduction, the next chapter is 'Materials and Methods', followed by 'Results and Discussion', and 'Conclusions'.

2. MATERIALS AND METHODS

From a structural point of view, masonry is a heterogeneous material, constituted by *units* and *joints*. Units are bricks or stones which actively contribute to the load-bearing capacity and stability of the wall. Joints are the junctures between masonry units and can be either dry or filled with mortar. The most resistant masonry should have an arrangement of discrete elements such that monolithic behavior is ensured.

When the wall exhibits monolithic behavior, structural simulations can be conducted by considering a corresponding homogeneous material. However, even in such cases, the wall's morphology needs to be assessed, to define the most appropriate modeling assumptions. Indeed, the Italian Building Code designates specific mechanical parameters of reference, considering the type, size, materials, and arrangement of units and joints.

With these premises, it is evident that for the structural analysis purpose, it is necessary to provide a comprehensive representation of the masonry material, considering its heterogeneous features. In the already existing representation schemas, such as the IFC or the MAT ontology, there is no possibility of having such a detailed description. Wall instances are indeed associated with 'material layers', and to each layer, it is attributed and homogeneous or even heterogeneous material, but where the different material's constituents are not defined as classes. In this way, it is possible to represent discontinuities only along the cross-section of the wall, which is not representative of the typical configuration of masonry walls (Figure 1).

To fill this gap, a new ontology was designed. This *Historic Masonry Ontology* (HMO), was conceived as a *foundation* ontology, to be used for the structural assessment of historic masonry structures, independently from the type of analysis (i, ii, or iii level). Then, based on the specific analysis level, other ontologies can be merged into the HMO. As a proof of concept, the Failure Mechanism Ontology (FMO) was subsequently developed to model the causes and consequences of failure mechanisms in masonry walls. The FMO is linked to the HMO ontology due to the relationship between masonry quality and wall vulnerability.

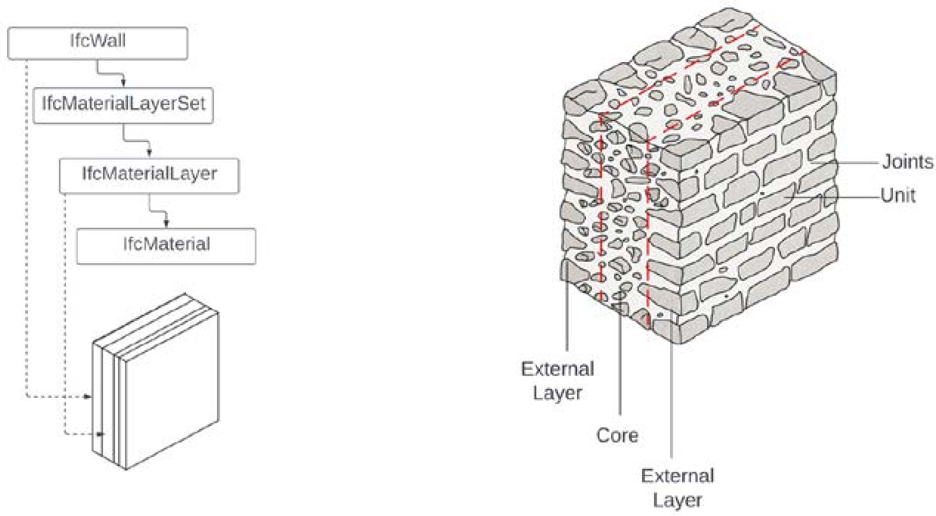

Figure 1. Morphology of an historic masonry wall compared to material modeling in IFC.

Both the HMO and the FMO ontologies were integrated with existing ontologies, exploiting the interoperability of the Semantic Web Modeling. In particular, the connection with the BEO and the MAT allows a direct mapping between the semantic model and the BIM model in IFC.

To link data between the model BIM and the model in Semantic Web Language, information is mapped between IFC model classes and corresponding ontology classes, using a common GUID. Damage elements do not have a direct equivalent in IFC, but can still be modeled as IfcElementy proxies and mapped to the ontology via GUID as well.

As shown in Figure 4, building elements, damages, and materials serve as a bridge between the IFC and the semantic model, allowing geometries to be associated with the semantic model based on the HMO and FMO ontologies.

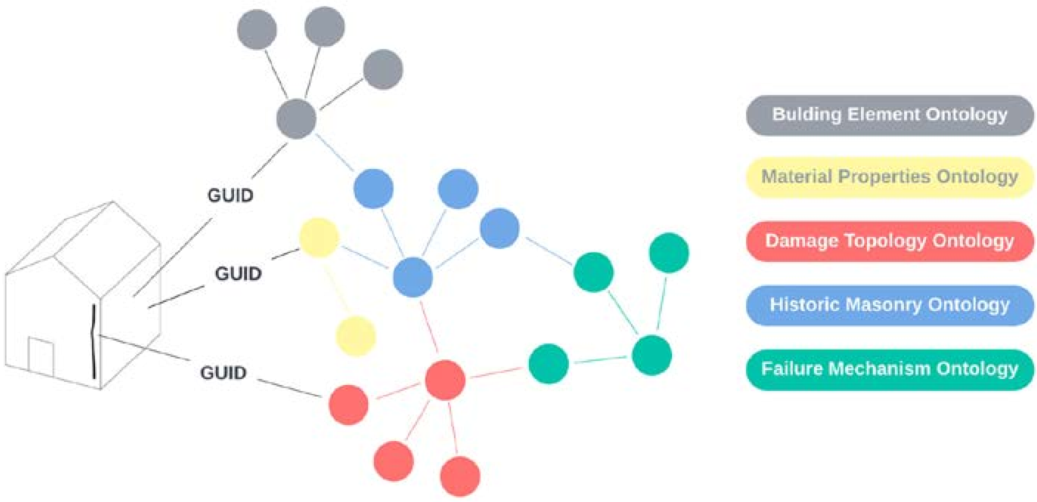

Figure 2- Methodology for the semantic enrichment of the BIM model

2.1 Historic Masonry Ontology

The Historic Masonry Ontology was implemented for the detailed modeling of masonry materials. Given the wide variety of masonry types, it was decided to propose a rather generic ontology that could be used to represent all types of masonry, regardless of units and mortar materials and morphology.

The walls are modeled with the class hmo:MasonryWall, which is a subclass of beo:Wall. The connection between the HMO and BEO ontologies is fundamental, both for interoperability between domains and semantic enrichment of the BIM models. An hmo:MasonryWall is defined by two data properties: (i) hmo:wallName and (ii) hmo:quality. The hmo:wallName allows the identification of different masonry walls in a human readable manner; the hmo:quality is intended to provide a qualitative description of the wall's quality to represent compliance with the rules of art in a synthetic manner.

The masonry layers are modeled by the class hmo:MasonryLayer, which is related to hmo:MasonryWall by the property hmo:isLayer of, the inverse of hmo:hasLayer. Each masonry layer may contain one or more hmo:Patterns. A pattern refers to a specific section of the layer, characterized by well-defined units and joint types that can be easily standardized.

The necessity for employing more than one pattern to describe a certain masonry type becomes especially critical when attempting to represent masonry types that involve various brick resources. These diverse brick resources contribute to the formation of walls comprising units with irregular compositions, interspersed with brick elements, as shown in Figure 1Figure 3.

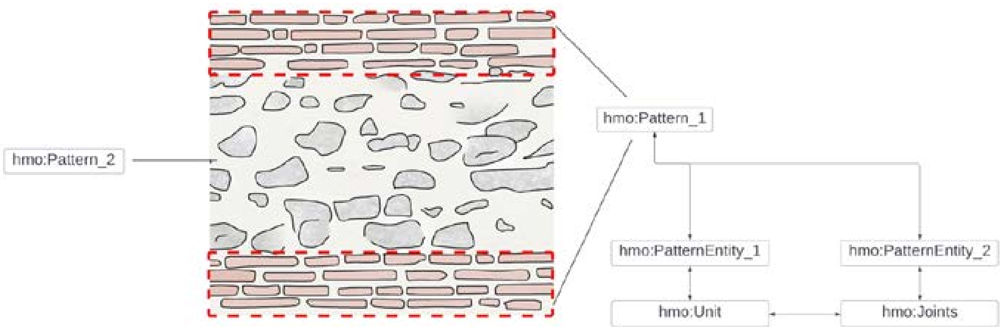

Figure 3. Elevation view of an example masonry and corresponding classes in HMO ontology modeling.

Units and joints can be modeled employing specific subclasses of the hmo:PatternEntity, which are hmo:Units and hmo:Joints. Joints are modeled as interfaces of the units, referring to the class bot:Interface. Units and joints present specific features, modeled as data properties. These classes refer in a general way to all the units and joints of the wall, so general information, such as the maximum and minimum dimensions of the units, or the horizontality and verticality characteristics of the morrtar, are assigned.

Both hmo:Unit and hmo:Joint henerith the mat:Materials from the superclass hmo:PatternEntity. The class related to the material to be associated with units and mortars does not need to be re-modeled in this ontology. In fact, it is intended to refer to and link to the MAT ontology. In addition, material characteristics can be linked to a database. This approach, derived from the Building Performance Ontology (BOP) (Donkers et al., 2021) developed for building performance assessment, is well-suited for masonry applications. The complexity of defining certain parameters leads us to rely on established Databases (Vanin et al., 2017). Finally, the ontology relates to the ontology of Damage Topology Ontology (DOT) damage, since the presence or absence of certain damage is an indicator of quality (Hamdan et al., 2019).

Figure 4 presents the Historic Masonry ontology and the link with other existing ontologies.

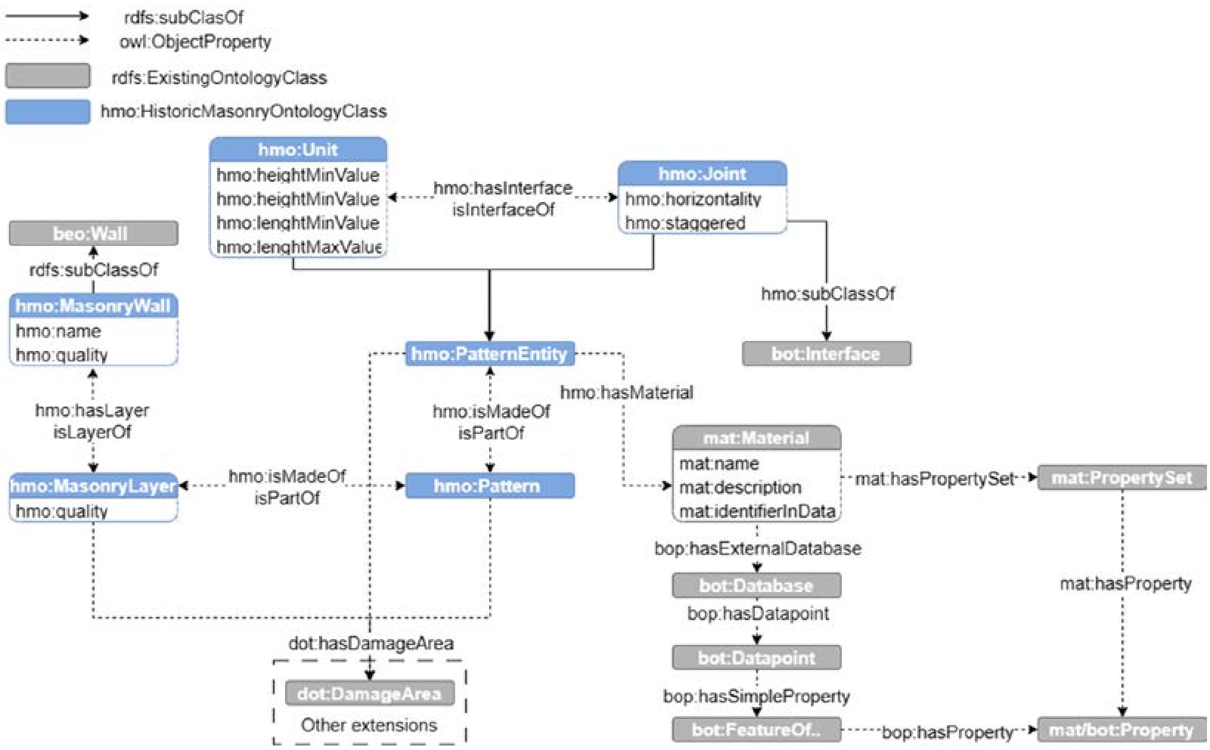

Figure 4 - Overview of the Historic Masonry Ontology

2.2 Failure Mechanism Ontology

The ontology for Failure Mechanisms enables the modeling of expected failure mechanisms by modeling the vulnerabilities that cause them.

The ontology consists of two primary classes, namely, 'fmo:Vulnerability' and 'fmo:FailureMechanism'. These classes are interconnected through the object property 'fmo:isFacilitatedBy', which establishes a relationship between mechanisms and vulnerabilities. A specific mechanism can be facilitated by one or more vulnerabilities.

To account for the qualitative nature or a combination of qualitative and quantitative aspects in vulnerability descriptions, distinct sub-classes are defined for 'fmo:Vulnerability'. This approach enhances comprehensiveness by providing dedicated classes for different types of vulnerabilities.

One of the subclasses within 'fmo:Vulnerability' is 'fmo:BadMasonryQuality', which relates directly to the previously described ontology. Defining masonry quality requires detailed description of its morphological characteristics. The object property 'fmo:isInfluencedBy' serves as a connection between the 'hmo' and 'fmo' ontologies. It is anticipated that other vulnerability subclasses can connect with various domain ontologies to address specific aspects. For example, determining whether floors are pushing and causing the presence of horizontal thrusts (e.g., 'fmo:HorizontalThrust').

Within the 'fmo:FailureMechanism' class, several subclasses exist, such as 'fmo:InPlaneFailure', 'fmo:HorizontalBending', and 'fmo:VerticalBending'. These classes require enrichment with a set of properties, which can indicate the associated load conditions for a particular mechanism. Additionally, the 'fmo:FailureMechanism' class is related to the 'dot:DamageArea' class from the DOT ontology. This relationship acknowledges that the presence of damage may be a result of an ongoing mechanism.

An overview of the complete ontology is shown in Figure 5.

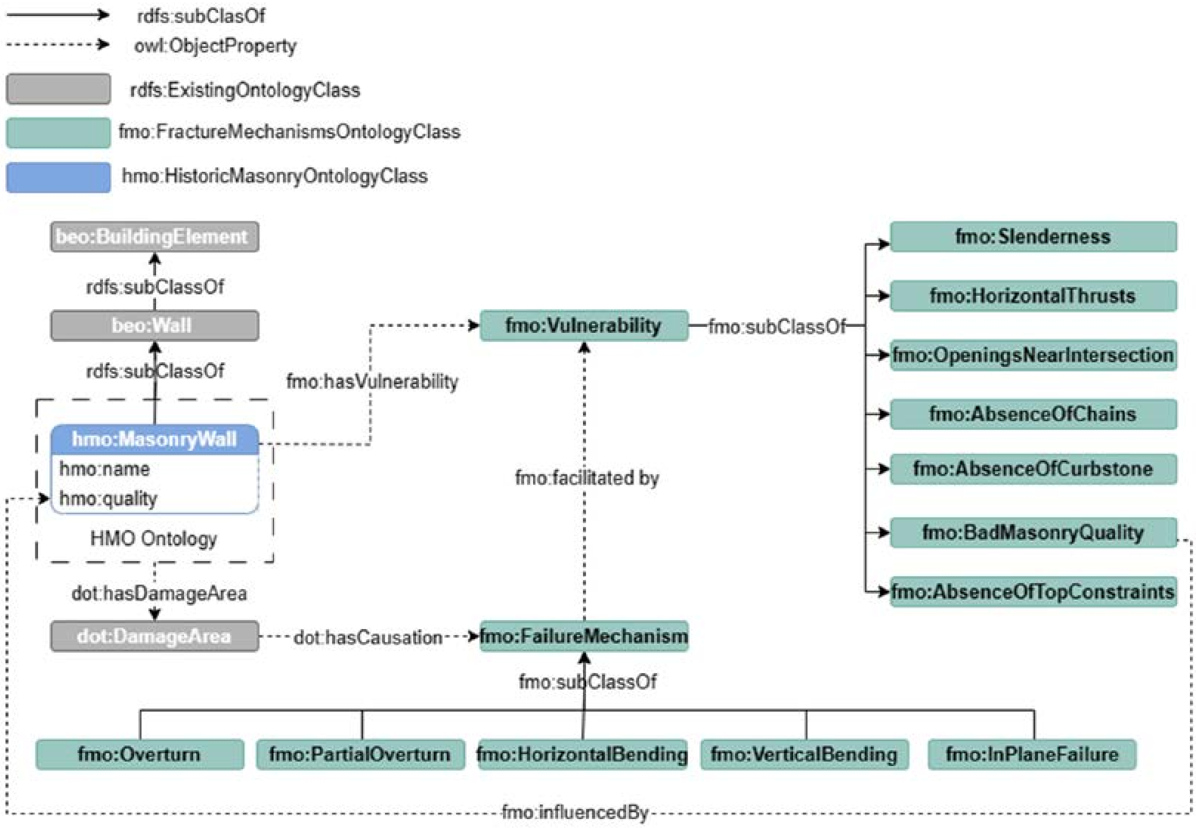

Figure 5 - Failure Mechanisms Ontology

3. RESULTS OF THE PRACTICAL APPLICATION AND DISCUSSION

To concretely illustrate the application of the proposed methodology, a residential building located in the historic center of Castelnuovo di Porto was selected. Castelnuovo di Porto is a town in central Italy known for its rich heritage of historical buildings and a diverse range of architectural styles, including residential structures, churches, and public facilities that reflect the area's rich history and architectural evolution over the centuries. The choice of Castelnuovo di Porto as a case study was driven by its structural complexity and the need to address specific challenges associated with evaluating historic buildings situated in urban environments with dense historical and cultural value.

The chosen methodological approach was particularly applied to a building that presented a set of structural and conservation challenges. This specific building, labeled as 'Wall_417_a' in the model, is part of a group of interconnected masonry structures, forming an architecturally significant complex.

In the BIM environment, the construction was modeled using proprietary software, and exported according to the IFC schema. Load-bearing walls were modeled, adding windows and doors as simple holes, modeling arches where present. Damages were included using the *IfcBuildingElementProxy* class. These elements simply serve to visualize, in the geometric model, the location of the damage. In the IFC file, there are no identified alphanumeric properties for the damages, nor any taxonomic relationship with other building elements. Regarding masonry materials, in the IFC these are identified as homogeneous, to be associated with a certain MaterialLayer.

A turtle file was created to proceed with the semantic enrichment. This particular application concentrates on the main facade of the building, referred to as 'Wall_417_a,' which is modeled using the BEO ontology. The name attributed to the façade refers to the number of the urban parcel: *417*, followed by the letter *a* as it is the first façade assessed. The wall is further represented in the model as a *hmo:MasonryWall* along with its corresponding *hmo:MasonryLayer*. Due to the initial survey's limited accessibility, only the external layer was accounted for. Therefore, the focus remained on modeling the *hmo:ExternalMasonryLayer* and associating it with a *hmo:Pattern*. The details regarding the entities of the *hmo:PatternEntity* are shown in Figure 6.

The structural damage is modeled as both *dot:StructuralDamage* and as a *fmo:Symptom*, since the presence of a crack could be a symptom of an out-of-plane mechanism. In detail, the presence of damage in one facade can be indicative of an out-of-plane mechanism occurring on the orthogonal facade. Through semantic modeling, this can be made explicit, as it was done for this model.

The roof was added to the semantic model as a *beo:Roof*, modeled as a *fmo:HorizontalThrust*, which is a subclass of *fmo:Vulnerabilities*, since a 'pushing' roof can cause the overturning of a wall. Consequently, the mechanism was modeled as *fmo:Overturning*, associating the mechanism instance to (i) the wall where it occurs; (ii) the pushing roof that caused it, (iii) the structural damage which represents its symptom.

The interactive mapping of the IFC model to the semantic model can be facilitated through web-based integration, leveraging JavaScript modules like IFC JS and COMUNICA. In this process, elements from both models are correlated using their respective GUIDs, allowing seamless cross-referencing between the two representations. This approach has been already proposed in the literature (A. Donkers et al., 2023) to query the information of the semantic model by clicking on the IFC geometry.

Figure 6 presents a comprehensive overview of what is described above. Within the IFC model, the classes corresponding to the semantic model are visually indicated by distinct colors. Notably, the semantic model consists of a network of interrelated classes, showcasing its capacity to define relationships that surpass the limitations of the IFC model. An example of the query interface is shown as well.

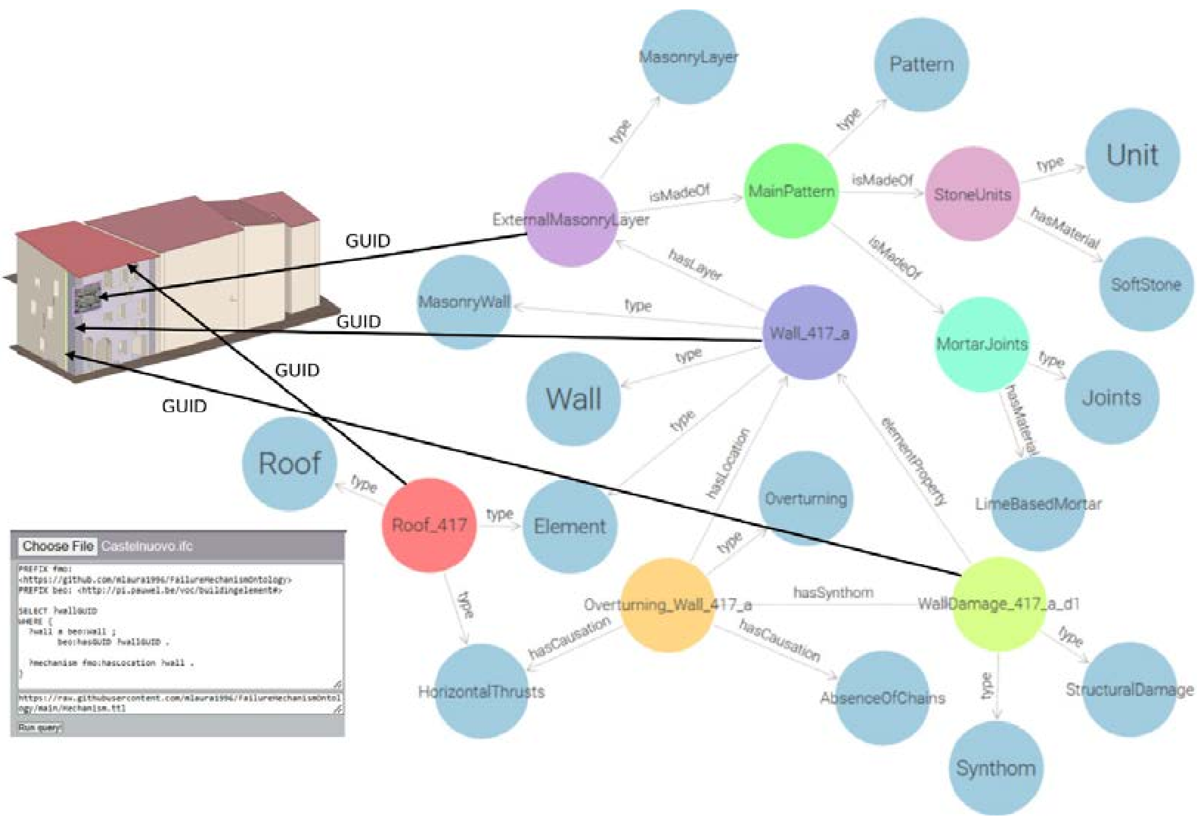

Figure 6. Mapping the IFC and the Semantic Model.

The employment of the Historic Masonry Ontology enables the modeling of diverse wall thicknesses while considering the patterns formed by units and joints. This domain ontology offers versatility and conciseness, accommodating various masonry typologies. Moreover, its seamless integration with established ontologies like BEO, MAT, and DOT enhances its utility, particularly in enriching IFC models with semantic data. Addressing the limitation of standard representations, it allows accurate association of material properties with specific masonry elements, such as bricks, stones, or mortar.

The adoption of semantic language within these ontologies results in enhanced interoperability, with the potentiality of extending into fields like chemistry and facilitating the assessment of material degradation. The possible interaction with databases presents valuable opportunities for deriving mechanical properties from data and integrating ontologies into practical applications, including inspections and monitoring processes. By integrating the Historic Masonry Ontology with the Failure Mechanism Ontology it was possible to consider, in a single semantic model, masonry characteristics and vulnerabilities. This comprehensive view allows for an objective definition of masonry quality by comparing qualitative and quantitative data.

The systematic organization of masonry quality data with other relevant wall-related information, such as near-wall damage or the presence of lateral thrusts, is another innovative aspect. These data are presented as instances of classes, incorporating a range of characteristics. For instance, the damage is described not just descriptively but also as a potential symptom of an ongoing mechanism. Similarly, the representation of the roof as a structural element and a possible pushing element further enhances the objectivity of assessments.

4. CONCLUSIONS

This contribution belongs to the field of research debating the role that digital tools assume in the activities of investigation, documentation, representation, and analysis of the built heritage. In particular, the illustrated work proposes a workflow that aims to integrate the HBIM digital environment with an ontological structure, seeking to raise the semantic level offered by current digital models for the built heritage and in particular for the analysis of building systems from a structural point of view.

In the last decade, various solutions for collecting, organizing, and managing cultural heritage information have given rise to a series of tools each with its database classification system, dedicated to representing a cultural artifact and its diverse contexts of investigation and interpretation. However, the same cannot be said of the built heritage, where on the one hand the complexity of the artifact itself and its historical evolution, and on the other hand, the presence of multiple disciplines in its processes of investigation, recovery, and intervention, have left the field effectively unexplored and lacking an organic approach to knowledge modeling. In this context, this article discusses the progressive adoption of two specific techniques - computer ontologies and the and HBIM models - highlighting their possibilities and ability to balance on the one hand the flexibility in dealing with the different disciplines involved on the other hand the rigor in information management necessary to effectively document the artifact.

The real change, therefore, is not to be found in new models for cataloging and documenting the building and its aspects but, rather, in approaches capable of integrating and making consistent the different cognitive models of the built heritage, fostering mutual understanding and collaboration among the different skills involved in such a complex process as that of investigation and documentation.

In this application, the primary focus was on the structural assessment of historic load-bearing masonry buildings. To achieve this goal, two new domain ontologies were developed, one for modeling masonry as a heterogeneous material and the other for defining vulnerabilities and related local mechanisms. This innovative contribution enables the semantic enrichment of BIM models using a Linked Data approach, effectively mapping the IFC and semantic model.

The results obtained from applying the proposed methodology allowed for the identification of its strengths and existing open issues. Among the advantages achieved, the methodology provides a more objective basis for structural assessments by considering diverse modeling assumptions. Moreover, it offers potential benefits in training new preservation experts, as the inclusive representation of the structure, materials, and preservation state fosters a better understanding of the structural behavior in existing unreinforced masonry buildings.

However, certain open issues require further development. One crucial aspect pertains to the integration of new domain ontologies into the methodology, especially for the development of global numerical models. This pioneering contribution lays the groundwork for future developments in this regard. Additionally, enhancing the user experience with the ontology is essential, and the creation of a platform that presents the ontology representation in the backend, capable of working with queries, and offering user-friendly interactions, would be highly valuable.

Furthermore, applying the proposed methodology to a larger case study with more extensive data could yield additional insights and demonstrate further benefits. Such an expanded application would reinforce the methodology's effectiveness and real-world applicability.

In conclusion, the development of the new domain ontologies and the application of the methodology present promising advancements in the field of structural assessment for historic masonry buildings. While it demonstrates numerous advantages, ongoing efforts to address open issues and explore potential enhancements will undoubtedly contribute to the continuous improvement and adoption of this innovative approach.

5. ACKNOWLEDGMENTS

We extend our gratitude to Professor Pieter Pauwels for sharing his knowledge and helping us understand the details of semantic modeling for building. His precious advice throughout this application has been invaluable to our work's success.

ABSTRACT: *Virtual reality (VR) offers promise as a tool for building performance simulations, especially when considering human-building interactions in buildings or spaces still under design. However, the absence of standardized data protocols impedes the consistent sharing of VR-related experiments and findings. This makes advancing VR experimentation as a reliable method for studying human-building dynamics challenging. The authors introduced the Virtual Human-Building Interaction Experimentation Ontology (VHBIEO) to address the challenge. VHBIEO seeks to standardize experimentation details as a domain-specific ontology, enhancing their interoperability. It includes essential experimentation concepts and employs semantic web technologies to ensure machine readability. Moreover, it integrates an application view (APV) to tailor details to specific experiments. Using VHBIEO-based metadata, this paper presents a case study aiming to standardize experiments that validate thermal sensations in immersive virtual environments (IVE), encompassing experimental protocol, variables, design, and data gathering. By exploring the main characteristics of VHBIEO-based metadata, the authors discuss its potential to improve the reliability of human-building interaction research.*

KEYWORDS: *Ontology, Metadata, Human-building interaction, Occupant behavior, Virtual reality, Building*

1. INTRODUCTION

Integrating virtual reality (VR) in studying human-building interactions has brought many novel opportunities to building design (Zhu et al., 2018). However, this integration is not devoid of inherent complexities. Foremost among these is the pressing requirement for rigorous standardization and systematic management of experimentation data. The present practice, characterized by non-standardized experimentation protocols, impedes researchers from optimally utilizing extant results and sharing their empirical findings efficiently. Therefore, advancing the reliability and validity of research within this domain necessitates the commitment to cultivating and adhering to the standardization of main experimentation data.

The Virtual Human-Building Interaction Experimentation Ontology (VHBIEO) was designed to standardize data pertaining to virtual human-building interaction experimentation (Chokwitthaya et al., 2023). It was developed by extending the ontology of scientific experiments (EXPO) at the domain level (Soldatova & King, 2006). The construction of VHBIEO employed the DOGMA methodology, ensuring a detailed and interconnected internal structure (Jarrar & Meersman, 2008). This ontology incorporates terms and concepts from pre-existing ontologies and semantic models and emphasizes terminologies intrinsic to virtual human-building interaction experimentation. Notably, VHBIEO possesses attributes of machine readability, accessibility, and processability. Additionally, its structure integrates Application Views (APVs), facilitating the accommodation of distinct information tailored to specific applications.

VHBIEO-based metadata thus contains the operational and application-specific information associated with VR-based experimentation. The metadata includes specific information about an experiment's components, such as the experimental protocol, design, setting, variables, and data collection procedures. The paper presents a case study showcasing the benefits of using VHBIEO-based metadata in retrieving virtual human-building interaction experimentation data. The case study specifically focuses on validating thermal sensation in an immersive virtual environment (IVE) and demonstrating how VHBIEO-based metadata can effectively capture and represent various elements of the experimental protocol, design, setting, variables, and data collection. The authors discuss how the metadata can improve the reliability of human-building interaction research by highlighting its main characteristics, including its use of the description logic, machine-readable, accessible, and processable, and inclusion of unique information through the application view (APV).

2. VIRTUAL HUMAN-BUILDING INTERACTION EXPERIMENTATION ONTOLOGY (VHBIEO)

Virtual human-building interaction experimentation (VHBIEO) is an ontology developed specifically for the domain of virtual human-building interaction experimentation. It contributes to enhancing various aspects of the domain. First, it provides standardized information for VR-based experimentation, thus making information more consistent for researchers to share and reuse. Secondly, it allows for the production of machine-readable, accessible, and processable information. Finally, it aims at overcoming challenges caused by the diversity of experimental design and limitations of VR experiments. Therefore, VHBIEO can potentially accelerate the development of virtual human-building interaction experimentation as an emerging research approach. Furthermore, it can enhance collaboration between researchers, making it easier for them to share knowledge and build upon each other's work.

VHBIEO extended EXPO (Soldatova & King, 2006) and reused terms and concepts from spatial-temporal event-driven modeling (STED) (Saeidi et al., 2018), the ontology to represent energy-related occupant behavior in buildings (DNAs) (Hong et al., 2015), ifcOWL ontology (Pauwels & Terkaj, 2019), the semantic sensor network ontology (SSN) (Compton et al., 2012), the survey ontology (SUR) (Scandolari et al., 2021), and the units of measurement ontology (UO) (Gkoutos et al., 2012). The development of VHBIEO followed well-defined ontology development approaches, namely ONTOLOGIES (Uschold & Gruninger, 1996), METHONTOLOGY (Ferndndez et al., 1997), Ontology Development 101 (Noy & McGuinness, 2001), and NeOn (Suárez-Figueroa et al., 2012). It comprised three major steps: initiation, construction, and evaluation. Competency questions (CQs) were used to regulate the development process. A total of fourteen CQs represented four major requirements, which included VHBIEO must 1) provide terms describing aspects regarding virtual human-building interaction experimentation, 2) explicate its internal structure, 3) assist in the inclusion of unique information regarding particular experiments, and 4) promote machine-readable, accessible, and processable data files associated with virtual human-building interaction experimentation. VHBIEO used semantic web technologies to make it machine-readable, accessible, and processable. DOGMA methodology was applied to developing the internal structure of VHBIEO, which involves describing interconnectedness and commitment of terms, using Lexon and organizing groups of Lexons to support specific applications (Jarrar & Meersman, 2008). The commitment involves three groups, namely general, virtual, and in-situ commitments. The scheme of VHBIEO is illustrated in Fig. 1. APVs were established by adopting the concept of Model View Definition (MVD) implemented in Industry Foundation Classes (IFC) for allowing the inclusion of unique information for particular applications (Hietanen, 2006). The resources defined in VHBIEO are publicly available through a URL as https://w3id.org/vhbieo, and individual terms can be accessed using a unique URI as https://w3id.org/vhbieo#term. The ontology editor Protégé was used to support the development of VHBIEO (Musen, 2015).

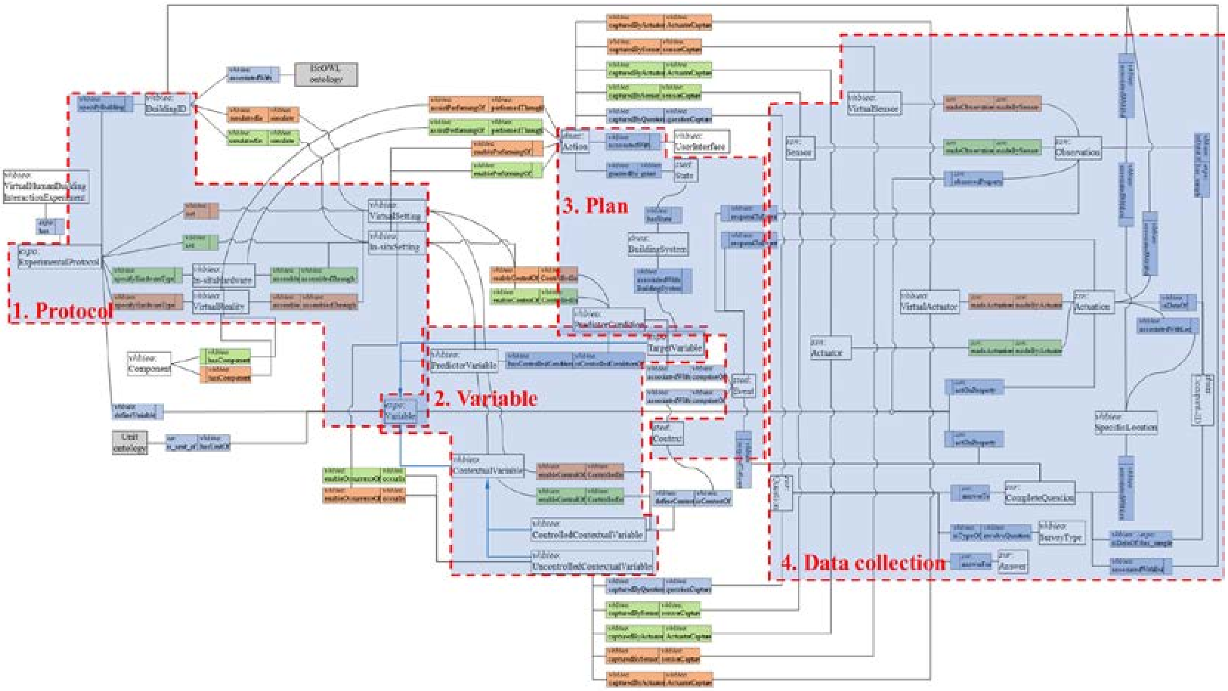

Fig. 1: Scheme of VHBIEO (Chokwitthaya et al., 2023).

The evaluation of VHBIEO was performed, consisting of two parts: taxonomy evaluation and application evaluation. The taxonomy evaluation assessed the logical sequence, the completeness of the ontology, and the redundancy of terms. It ensured that VHBIEO provided a comprehensive and coherent representation of the domain of virtual human-building interaction experimentation. The application evaluation tested the ability of VHBIEO to describe and integrate information from real-world experiments. It also showed that VHBIEO promoted machine readability, accessibility, and processibility by providing several examples of querying information in the data files. VHBIEO was able to incorporate unique information (e.g., 7-point Likert scales) using APV. The evaluation revealed the efficacy of VHBIEO in providing standardized information and enabling machine-readability, accessibility, and processability, which is crucial for promoting consistency and accelerating the maturity of the virtual human-building interaction experimentation approach.

3. CASE STUDY

The case study aims to illustrate data described in VHBIEO-based metadata and prove that the metadata was machine-readable, accessible, and processable through query using a standardized query language (SPARQL). This objective is significant because it ensures the effective utilization and interoperability of the data marked in the metadata. When metadata is machine-readable, accessible, and processable, it can be leveraged to develop sophisticated analyses and applications. The accessibility and processability of the metadata mean that it can be dynamically engaged, enabling researchers and developers to manipulate and interpret the data efficiently, enhancing the comprehensibility and utilization of the information contained within the experimentation.

The case study involves retrieving and analyzing information related to a VR-based experiment performed in an existing study (Rentala et al., 2021). The experiment primarily focused on evaluating the influence of outdoor temperature variations on participants' thermal states within IVE. It was grounded in detailed and methodical experimentation aimed at dissecting the intricacies of thermal states in varying conditions, utilizing various events to simulate diverse environmental settings. The structure of the experimental data reflected the comprehensive nature of the research and the diversity of the variables considered. The variables range from environmental conditions (e.g., indoor and outdoor temperatures and humidity) to participants' physiological (e.g., skin temperatures at various body locations and heart rate) and perceptual responses (e.g., thermal perceptions at different body locations), providing a multidimensional perspective on the impact of outdoor temperature variations on thermal states in IVE experiments. These variables provide a robust and comprehensive dataset that allows for a thorough exploration and understanding of the thermal states of participants under different environmental conditions within IVE. The comprehensive dataset allowed the creation of the VHBIEO-based metadata, exploring all commitments and the majority of Lexons and rules defined in VHBIEO. In addition, the dataset enabled the exploration of APV since the experiment included the use of 7-point Likert scales, which needed customization in VHBIEO.

The metadata was formatted in the Resource Description Framework (RDF) format, which is a standard format for representing ontologies and linked data. It was deployed on the Dataverse, a data repository platform, for testing. It was uploaded as a tabular data file that provided context and description of the data. It included information such as the experiment title, authors, funding sources, and descriptions of the data structure, variables, and observations.

3.1 VHBIEO-based metadata

The structure of VHBIEO-based metadata revolved around four core components of VHBIEO: experimental protocol, variable, plan, and data collection. This section discusses such components and their associated data pieces. The discussion aims to elucidate these components by exemplifying the key data elements pertinent to the experiment, thereby underlining the efficacy of VHBIEO in developing the metadata.

3.1.1 Experimental protocol

The experimental protocol, referred to as the backbone of the experiment, laid down the research's overarching strategy. This information was essential for understanding the core of the experiment. Fig. 2 delves into data intricately associated with the experimental protocol, illustrating several instrumental components, namely the protocol itself, experimental setting, hardware, and building, each playing a role in steering the experiment toward its intended objectives.

Within the detailed protocol (*expo*:ExperimentalProtocol), a holistic introduction and thorough description covering experimental statements, background, hypothesis, and methods sections - including inclusion and exclusion criteria - are encapsulated. Notably, the procedural roadmap for conducting the experiment, study timelines, visits, potential risks, and confidentiality assurances are also placed within this component.

The settings utilized during the experiment are distinctly described using *vhbieo*:VirtualSetting and *vhbieo*:In-situSetting, denoting the use of a fully immersive virtual environment and a climate chamber setting, respectively.

The hardware associated with these settings, integral to the execution of the experiment, is detailed through *vhbieo*:VirtualReality and *vhbieo*:In-situHardware. The critical element of a building, significantly tied to the protocol, is narrated via *vhbieo*:BuildingID. The building elements, representing architectural or design specifics, were meticulously described using the IfcOWL ontology.

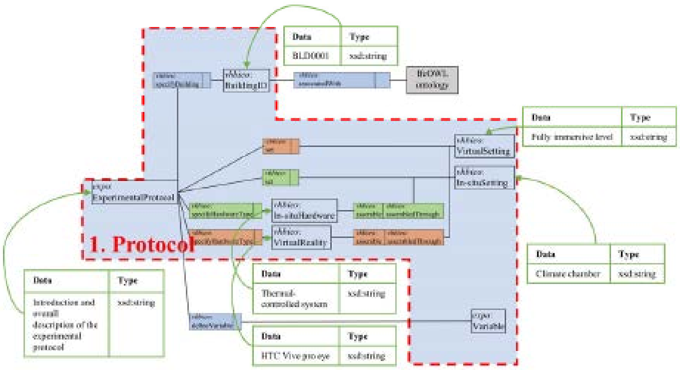

Fig. 2: Example of data associated with protocol.

3.1.2 Variable, plan, and data collection

While the concepts of variable, plan, and data collection are distinct, it is vital to recognize their interconnected nature. Variables define what data is collected, the plan dictates how to navigate and observe through the variables, and data collection strategies depict the methodology for gathering insights on these variables and aligning with the plan. Fig. 3, 4, and 5 exemplify this integrative relationship, offering a consolidated perspective through discrete examples and thereby facilitating a coherent understanding of the experiment's structure and methodology. Noteworthy is that the components spotlighted in each figure represent selective excerpts from the experiment, highlighting particular elements that significantly contribute to the focus of each example. To streamline and succinctly encapsulate the discussion, components not directly pertinent have been judiciously omitted.

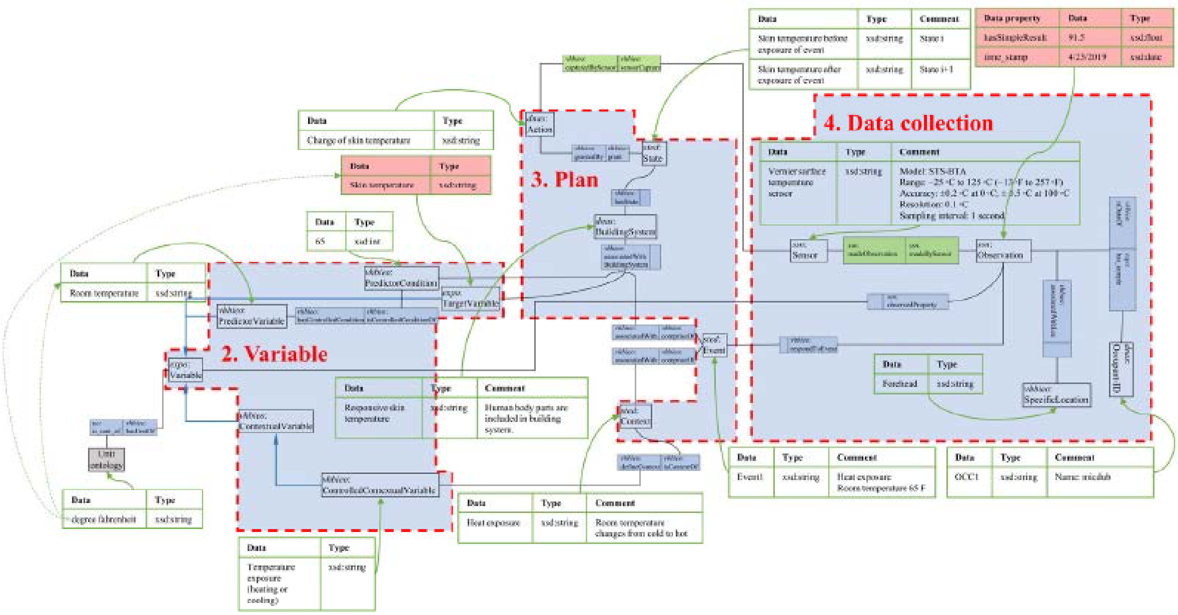

Fig. 3: Example of data associated with skin temperature.

Fig. 3 narrates variable, plan, and data collection components, specifically focusing on the human-skin temperature, particularly at the forehead. This temperature was identified as the target, or the dependent variable (*expo*:TargetVariable), for the experiment. Its measurements were taken in degrees Fahrenheit, referencing the Unit ontology. The predictor or independent variable was set as the room temperature, with a controlled setting fixed at 65 degrees Fahrenheit. This was described under *vhbieo*:PredictorVariable and *vhbieo*:PredictorCondition, respectively. The controlled contextual factor was temperature exposure (*vhbieo*:ControlledContextualVariable).

The temperature exposure outlined the context (*sted*:Context) of heat exposure as a trajectory from a cold to a hot environment. Drawing upon this setting, the predictor condition and context conjoined to devise an event (*sted*:Event) introduced to a participant in the IVE. The human body was conceptually integrated as part of the building. Consequently, the responsive skin temperature was described in the *dnas*:BuildingSystem, linking it directly to the target variable of skin temperature. Invoking the concept of "state" from STED (as elaborated by Saeidi et al., 2018), a state embodies the dynamic status of the building system. It is susceptible to variations stemming from occupants' interactions and responses to the events they are subjected to. As a result, the skin temperature responses manifested in multiple states, including the temperature recordings before and after event exposure (*sted*:State). These recordings translated into the very act of skin temperature alterations encapsulated under *dnas*:Action.

To hone in on data collection specifics, Fig. 3 illustrates using the Vernier surface temperature sensor under *ssn*:Sensor. This sensor was strategically positioned on the forehead described under *vhbieo*:SpecificLocation of the participant, uniquely identified by *dnas*:Occupant-ID. The resulting data was systematically chronicled in *ssn*:Observation. It showed a recorded forehead skin temperature of 91.5 degrees Fahrenheit, timestamped precisely to mark the experiment's execution on 23rd April 2019.

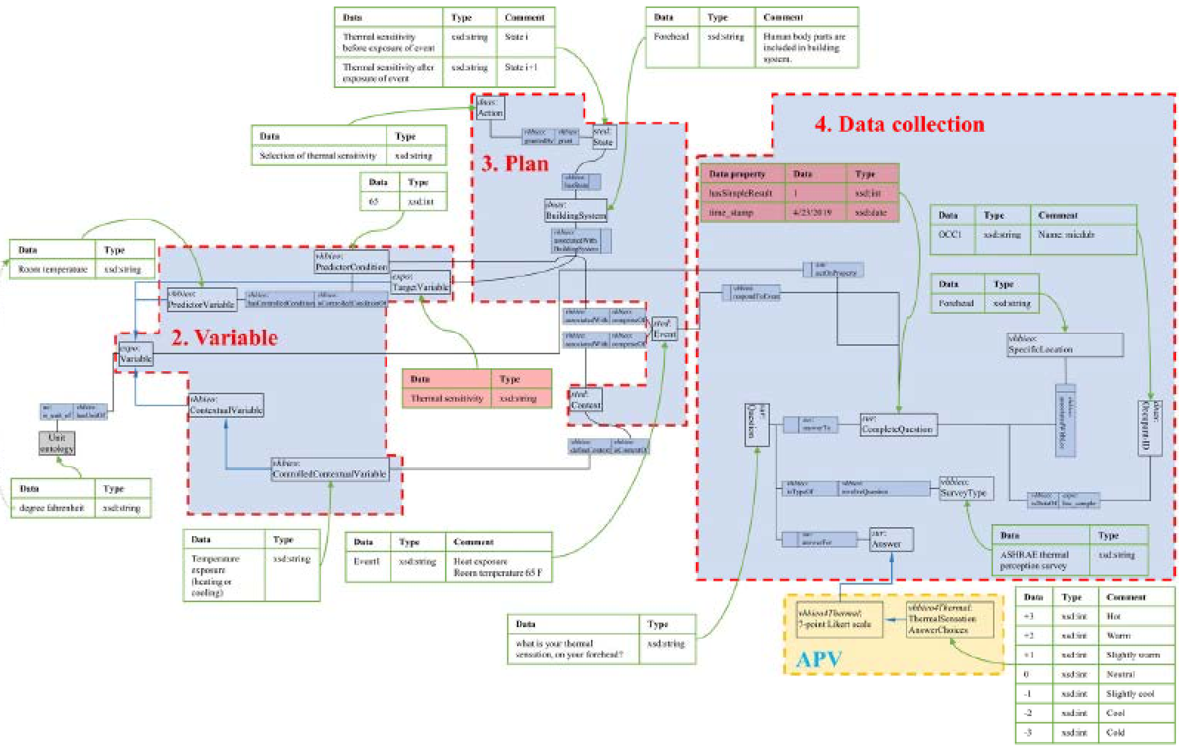

Fig. 4: Example of data associated with thermal sensation.

Fig. 4 provides a detailed examination of the variable, plan, and data collection components with a concentration on thermal sensation—another distinct target variable within the experiment. The structures of the variable and plan components mirrored those elaborated upon in Fig. 3. However, the method of data collection exhibited notable differences.

In the context of thermal sensation, data was accumulated through a survey mechanism, described in *sur*:Question. Significantly, the application view (APV) was utilized to annotate and clarify the 7-point Likert scale, which constituted the unique response choices in the experiment. This scale was referenced as (*vhbieo4Thermal*:ThermalSensationAnswerChoices). The nature of this question aligned with a thermal perception survey, a standard defined and endorsed by ASHRAE (American Society of Heating, Refrigerating and Air-Conditioning Engineers) and cataloged under (*vhbieo*:SurveyType). The culmination of this survey's execution was preserved under *sur*:CompleteQuestion, which depicted the participant's thermal sensation as being "slightly warm". It was anchored with a timestamp, noting the date of conducting the experiment.

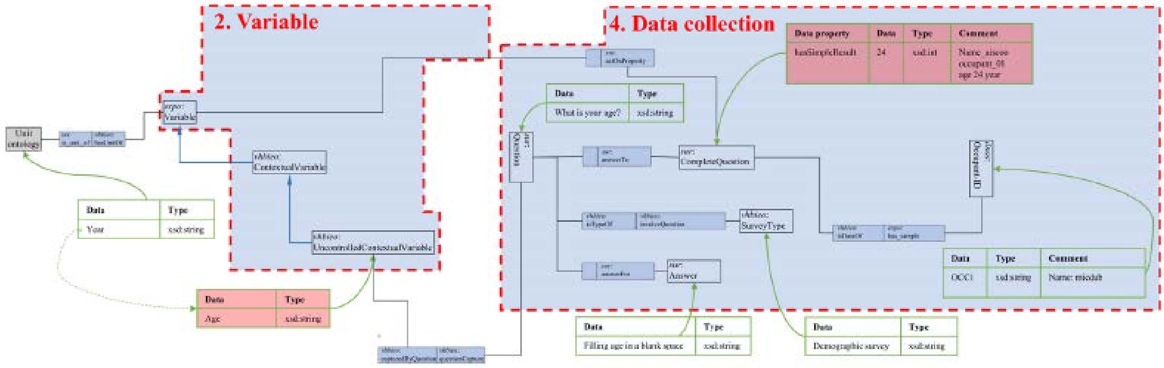

Fig. 5: Example of data associated with age.

Fig. 5 shifts its focus from target variables and delves into an uncontrolled contextual variable encountered in the experiment—specifically, the age (*vhbieo*:UncontrolledContextualVariable) of a participant. The unit used to measure age was "year", which draws reference from the Unit ontology. For data collection pertaining to age, a demographic survey (*vhbieo*:SurveyType) was employed. Participants were prompted with a straightforward question, "What is your age?", which was recorded under *sur*:Question. Responding to this question required participants to fill in a blank space, indicating their age, and this form of response was described in *sur*:Answer. In a manner akin to the thermal sensation data collection, the resultant age data was encapsulated under *sur*:CompleteQuestion. This documented an instance of a participant's age being 24 years old.

3.2 Querying VHBIEO-Based Metadata

The executed data query was instrumental in validating the machine-readability, accessibility, and processability of the metadata. To resonate with the provided examples, the query was formulated to extract specific data points corresponding to variables such as the skin temperature at the forehead, thermal sensation, and age. In conjunction, the computation of averages for each variable within the query further attested to the metadata's machine-processable nature. This ability to programmatically access, read, and compute values from the metadata substantiates its utility and robustness in supporting research and data-driven applications.

Fig. 6 presents the specific queries crafted to extract data pertaining to the skin temperature (Fig. 6a), thermal sensation (Fig. 6b), and age (Fig. 6c) of all participants. These queries are structured to target the data points within the dataset precisely. It also conveys the outcome of the queries. Notably, the result encapsulated the computed averages of the obtained data, underlining the machine-processable nature of the metadata.

For Fig. 6a, the query primarily focuses on obtaining data related to the forehead skin temperature of participants. Such data held significant relevance, as skin temperature could provide insights into a participant's thermoregulation response in a given environment. By furnishing both individual temperature data points and an overall average, the query aided researchers in discerning patterns and anomalies within the data.

The emphasis in Fig. 6b shifts from physiological responses to perceptual experiences. Querying the thermal sensation looked into how participants subjectively felt about the thermal environment they were placed in. The provision of an average sensation value offered a summarised perspective. Such data could be vital in studies aiming to align objective environmental parameters with subjective human comfort levels.

The query in Fig. 6c acknowledges the demographic diversity of the participants. Age is a potential confounding variable in many human studies, as age might influence a person's physiological or perceptual response to environmental factors. Researchers could factor in age-related nuances in their analysis by procuring both individual age data and its average.

In essence, these queries demonstrate the versatility and depth of VHBIEO-based metadata. Furthermore, the structure of each query, particularly the incorporation of averages, emphasizes granularity and summarization, ensuring that the metadata is machine-readable, accessible, and processible.

4. DISCUSSION

The primary objective of this work was to demonstrate the efficacy of the Virtual Human-Building Interaction Experimentation Ontology (VHBIEO) in supporting the development of VHBIEO-based metadata. This metadata aims to create a structured representation of experimental data, promoting machine-readability, accessibility, and processability. Reflecting upon the objective, development of VHBIEO-based metadata, and query results, this section broke down the accomplishments, implications, and broader impact on the research horizon.

Systematic Representation: At its core, VHBIEO is an ontology that aims to systematically represent knowledge in the domain of human-building interaction experiments. The VHBIEO-based metadata took advantage of this structured knowledge representation, ensuring that every aspect of an experiment was adequately documented, from the broader experimental protocol to the minutiae of data collection methodologies.

Data Accessibility and Processability: The design of VHBIEO ensures that data is machine-readable, accessible, and processible. This was evident in the queries we discussed (e.g., Fig. 6), which retrieved data efficiently and could also compute statistics such as averages, showcasing the power and flexibility of this ontology-based metadata.

Facilitating Advanced Analyses: The granularity offered by the VHBIEO-based metadata, segmenting data into categories like skin temperature, thermal sensation, and age, paved the way for more complex and nuanced analyses. Discerning patterns or influences among these variables became relatively straightforward when they were clearly organized.

Overall, VHBIEO provides standardization for virtual human-building interaction experimentation as a robust mechanism for associated experimental data. Such standardization diminishes the scope of ambiguities, ensuring the data remains consistent across different stages and platforms of its utilization. Furthermore, data exchange across diverse platforms and researchers is inevitable. VHBIEO potentially enables researchers to transfer, match, and integrate data from varied sources without the nuances of interpretation. This is akin to creating a seamless bridge where data flows without errors.

5. LIMITATION

Despite the evident advantages and the transformative potential of VHBIEO, certain limitations need to be considered.

Continuous Maintenance and Refinement: A pressing challenge associated with ontologies, VHBIEO being no exception, is their continuous upkeep. Changes in domain knowledge or enhancements in ontology capabilities require periodic revisions. This process demands not just a technological revamp but also the infusion of domain-specific expertise to ensure the ontology stays relevant and accurate.

Potential Overlaps with Existing Ontologies: It is conceivable that some terms introduced in VHBIEO might overlap with those in existing ontologies or semantic models. The authors, in their initial sweep, might not have identified these overlaps. Should such duplications be spotted in the future, VHBIEO will be updated to reflect a more harmonized structure.

Scalability with Evolving VR Technology: Virtual Reality (VR) technologies are in a state of flux, constantly evolving. As VR matures, simulating intricate simulations over prolonged durations might become feasible. In such scenarios, the foundational structure of VHBIEO, anchored on STED, might demand reevaluation and fine-tuning.

Potential Limitations in Collaborative Experiments: As research becomes increasingly collaborative, the experiments often span multiple geographies and phases. This dynamic nature of collaboration, marked by continuous data exchanges and iterative updates, could pose challenges for VHBIEO in its current form. Future iterations of VHBIEO will need to address this aspect to stay relevant in an interconnected research ecosystem.

Lack of Advanced Features in APV: Although the current APV supports unique terminology descriptions tailored for specific experiments, it falls short in several other features. Features such as internal structure customization, automation capabilities, and bridging with other ontologies are crucial for enriching VHBIEO's utility. The integration of these features could significantly expand its scope and application.

6. CONCLUSION

The study showcased the advantages of using VHBIEO in human-building interaction research. By providing a structured approach to document experimental protocol, design, settings, variables, and data collection, VHBIEO-based metadata paves the way for better experiment reusability, comparability, and reproducibility. This is especially crucial for experiments relying on IVE-based experimental information and results. Yet, it is crucial to acknowledge the limitations inherent in this preliminary implementation. Specifically, the research's scope was constrained mainly due to the limited number of validation cases. As the field progresses, it is essential to continually refine VHBIEO by addressing these limitations and validating its utility across a broader array of experimental contexts.

7. ACKNOWLEDGEMENT

This study is based upon work supported by the National Science Foundation, the United States, under grant No. 1805914 and grant No. 1640818, and the Kempestiftelserna under grant No. JCK-2136. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation and the Kempestiftelserna Foundation.

CONSISTENCY VERIFICATION BETWEEN COST AND GEOMETRIC INFORMATION BASED ON IFC: APPLICATION ON STRUCTURAL ELEMENTS

Jacopo Cassandro & Claudio Mirarchi & Alberto Pavan
Polytechnic of Milan, Italy

Maria Grazia Donatiello & Carlo Zanchetta
University of Padua, Italy

ABSTRACT: *Cost estimation for tendering is one of the leading causes of legal disputes in the architecture, engineering, construction, and facilities management (AEC/FM) industry.*

The lack of a standardised support procedure to verify the association of cost data with the objects model causes waste of time and inaccuracy in the cost estimation.

This research work, starting from a previous study where the research group integrated a cost domain in the IFC data schema, investigated the possible applications of this IFC based cost domain integrated with an IFC geometrical information model. The current paper investigates a specific case study focused on a structural model to verify current and future applications.

Furthermore, rules for BIM information requirements will be defined through the Information Delivery Specification (IDS) to ensure an easy way for humans and computers to understand it. This will allow to specify which data must be present in the geometric model to subsequently ensure validation and verification of uniqueness of the cost data associated with geometric data.

The results show the possibility to define a structured cost items in IFC associated through relationships to other entities and then verify their association to geometric data to guarantee its consistency and uniqueness.

KEYWORDS: *IFC, cost ontology, BIM, cost item, Information Delivery Specification (IDS)*

1. INTRODUCTION

Cost estimation is one of the most critical tasks and still unresolved problem in the architecture, engineering, construction, and facilities management (AEC/FM) industry.

To be able to obtain a cost estimate for a building, it is generally necessary to classify all objects in the building project using articles and to record their quantities. Although this is an objective process, human errors can often be encountered relating to both the incorrect association of prices and the incorrect calculation of quantities. One of the problems facing the AEC industry today is precisely the lack of a standardised support procedure to verify the association of cost data (Adeli et al., 2001; Lu et al., 2016). With the advent of BIM, computing tools have changed and evolved digitally. Wu et al., (2014), Sacks et al., (2018), Elghaish et al., (2020), and Olatunji et al., (2021) reported on the possibilities of BIM to improve and support cost estimation, but the approach to computing has remained the same. So, the problem remains; in fact, while previously the costs were associated with measurements, they are now associated with model objects but there is no certainty that this association is correct and consistent.

Currently the computation software receives the information from a model exported in an open format, Industry Foundation Classes (IFC) and retains the cost listing within it. With this study, the aim is to compensate for the lack of standardisation in cost validation by creating an IFC-based cost semantics, thus identifying a common language between model objects and costs.

The IFC is standardized according to ISO 16739-1. This could provide a solid basis for the exchange of information resources between information systems (Froese T et al., 1999). The IFC standard published by Buildingsmart International plays a very important role in the process of exchanging BIM data between the various participants in a building construction or management project, as it is an open specification. IFC provides some entities to represent information in building management, including *IfcConstructionManagementResource* (building resource) *IfcWorkPlan* (planning), *IfcTask* (task), *IfcScheduleuleTimeControl* (task time information),

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)

IfcCostSchedule (cost planning), *IfcCostItem* (unit cost estimation item) and *IfcCostValue* (value).

This research work, starting from a previous study in which the research team integrated a cost domain into the IFC data model (Cassandro et al., 2023), investigates the possible development of a standardised support procedure to verify the uniqueness and correctness of the association between the new cost items and their written information within the IFC standard and the geometric objects contained in a specific case study, a structural model.

Currently, in Italy, the cost items are contained in the list of public works (in the specific case of the Price List of the Lombardy Region) a document based on unstructured data and characterized by a natural language.

Starting from a work previously developed by the research team (Cassandro et al., 2023), it was possible to initially create an IDS file for the definition of the requirements that must be present in the geometric model. This is fundamental to guarantee both the correct association of the entities of cost but also the analysis and the interrogation of the data in the successive phases of verification. Subsequently it is possible to verify the association between the cost items and the geometric objects to ensure the uniqueness and correctness of the cost-object relationships created.

Specifically, this would allow to:

- check the correct price association;
- ensure validation, uniqueness and comparison between attributes of a certain cost class and the attributes of the object to which it is associated;
- consider cost elements as standardizable and query-able computer classes.

The example of a structural model has been taken and a structure of relations between costs and geometry has been created to allow the verification of the uniqueness of associated data and validate the code developed.

The paper is structured as follows. First an analysis of the existing literature on cost estimation via IFC classes, current methods of checking compliance and the Information Delivery Specification standard (IDS) is presented. Currently there are not BIM authoring software that can write the *IfcCostItem* entity and as a result you cannot check this information; so, it was decided to rely on the IfcOpenShell library to initially create the cost items and then verify the association and accuracy of the data of the entity through the code developed for this research.

2. THEORETICAL BACKGROUND

Within the BIM process, one of the most relevant parts is undoubtedly the validation of the model and the information it contains for a proper exchange of data. There may currently be different types of project's validation, or model checking, and they may be the following:

- verification against geometry (clash detection);
- verification against design settings (e.g. the specifications within the BEP, BIM validation);
- checks against regulations (code checking)

The purpose of these checks is to ensure that all data entered within the model is correct from a geometric and informative point of view, and that it meets all standards.

Currently, this check is a process that, while being facilitated using software and tools, still remains time-consuming, expensive and prone to errors (Dimyadi & Amor, 2013). The main problem of model checking always concerns the validation process (Ghannad et al., 2019).

2.1 Model Checking

Model checking is a key element in information modeling and management (Ciribini et al., 2015). In standard design processes, according to studies, only 5-10% of the information content of the project is systematically checked (Trebbi et al., 2020).

Clash detection means the verification of geometric interference; this could become a problem during the construction of the work which is not checked in advance within the 3D model (Akponeware & Adamu, 2017). These are divided into two types; the "hard clash" referred to two objects that collide and occupy the same physical space, and the "soft clash" referred to objects that do not collide but are too close.

Code checking is the verification of the compliance of the digital model with the corresponding regulation (Trebbi et al., 2020). The use of specific software that supports these controls can reduce time and error, thereby improving several aspects of building design, including efficiency and model quality (Greenwood et al., 2010).

It is essential to verify the compliance of the models with regulatory and technical requirements, and therefore an automatic control of the frequency and uniqueness of the information would have a significant value within the AEC industry (Solihin & Eastman, 2015). Furthermore, it may be necessary to verify compliance with the requirements of "Employer Information Requirements" (E.I.R.) or of "BIM Execution Plan" (B.E.P.) (PAS 1192-2:2013).

The first study on automated code compliance checking is the Singapore project CORENET (Construction and Real Estate Network) an initiative based on the complete integration of the life cycle phases. Similarly, in the USA SMARTCodes was born and Autodesk Revit provided some plug-ins such as UpCodesAI which supports some parts of the International Building Code but also some parts of other standards from other jurisdictions, in Australia DesignCheck.

2.2 Existing Applications

Model checking is normally done by use of standalone applications as Solibri Model Checker, SMARTcodes, ePlanCheck, AEC3 Compliance or EDM Model Server (Ismail et al., 2023). An often used example of model checking is clash detection to validate if for example different types of pipes intersect each other. Another example can be to check if the width of the doors is according to codes of accessibility in the regulations or national standards. The most used for model data verification are Solibri Model Checker and Naviswork.

Solibri Model Checker (SMC) is a prominent BIM software application which assist designers in visualizing any issues or problems regarding the design model before and during construction. It is one of the few software packages that leaves the end user with a minimum of scope for action. The rules set in SMC are set for the Norwegian State Administrative Agency handbook but can be modified by the end user by changing the rule set or deleting some. The creation of new rules is possible but has limitations. To be able to create new rules, it is necessary to act on the API, which is not public.

Naviswork, is one of the most widely used tools on clash detection and coordination of models from different disciplines. The software detects intersections or conflicts between elements in the 3D model, helping to identify and resolve construction or design issues promptly, reducing errors and costs during project execution.

3. PROBLEM STATEMENT

As can be seen from the literature analysis above, typically the verification is done within the geometric model considering only one domain (that of the model itself). Instead, the goal of the research is to validate data between a plurality of domains linked together (in this case the geometric domain and the cost domain) and that can be contained in the same model. The architectures of cost items cannot be considered exclusively as strings of text in natural language because they are not machines readable. For this reason, to verify and validate the consistency and uniqueness of the data, it is necessary to structure according to a semantic defined cost items in more complex architectures thus creating a cost domain. This should ensure that the consistency of associated data between cost and geometry can be verified.

Starting from this statement, the research focuses on the key aspect of:

- How to define a procedure for checking and verifying data between geometric and cost domains.

4. RESEARCH AIM & METHODOLOGY

This research investigates the development of a standardized support procedure to verify the correspondence between the cost items and the data they contain with the objects contained in the information models.

The cost data in this research are stored in a new cost database based on architectures developed in openBIM format and structured according to the IFC data model (Cassandro et al., 2023); currently, in Italy and in the specific case of the list of public works of the Lombardy Region, cost items are present in unstructured format within textual documents in natural language. This causes problems and possible errors both in the association and in the verification of the associated costs. In fact, currently one of the most challenging issues for building design compliance checking is the translation of human-readable rules/documents into a computer processable code to allow the understanding also by computer tools.

For this work a specific case study focused on a structural model containing cost items, structured and in IFC format, already associated with their geometric objects, is analazyed to verify the current and future applications of this methodology.

Furthermore, rules for BIM information requirements are defined through the Information Delivery Specification (IDS) to ensure an easy way for humans and computers to understand it. This allows you to define which data must be present in the geometric model to ensure first a correct cost association and later validation and verification of the uniqueness of the cost data associated with geometric data.

First, it is described the state of the art of current practices and research related to compliance checking. The idea is to standardize cost element data as a structured class in the IFC data model. This in fact contains a set of attributes that allow cost data to be stored, as is already the case for model objects.

A simple unit cost database has been created (the new digitised price list) based on IFC files relating to cost items of structural works (concrete casting, reinforcement laying, formwork laying, etc.). These files can be called in any geometric model for the definition of the cost to associate to the objects of the model.

The next step is characterized by the definition of the requirements that must be present in the geometric model for a better and correct association between IFC entities, *IfcCostItem* and *IfcElement*.

It is defined the Information Delivery Specification (IDS) that will be delivered to the modeler and after that a code is developed that will allow to verify if the association of the cost is coherent or not with the object identified.

The entity will allow to translate the current cost items, in natural language, in a defined and standardized data structure (definition of the framework and the semantics of the costs through the entity *IfcCostItem*).

The methodology adopted is characterized by the steps presented in Figure 1.

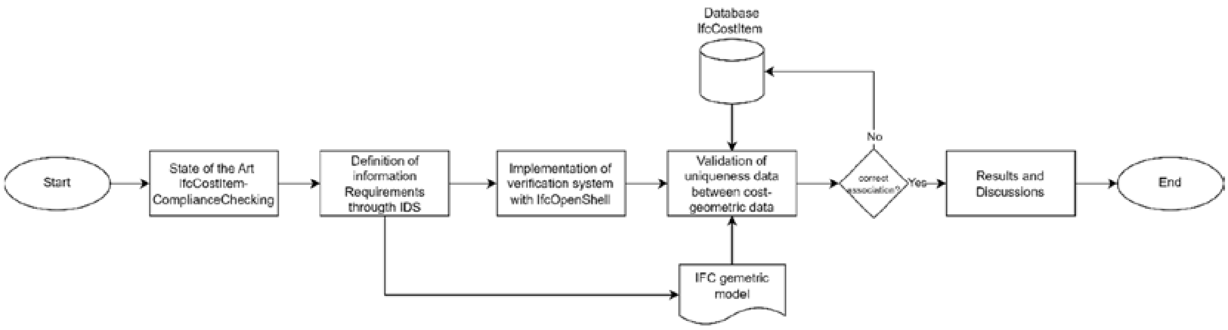

Fig. 1: Research Methodology

5. KEY CONCEPT

The IFC, an open and interoperable standard, aims to "allow interoperability between industrial processes of all different professional sectors in civil engineering projects by allowing IT applications used by all project participants to share and exchange information about the project" (BuildingSMART, 2023). It is an open international standard, standardized according to ISO 16739-1:2018; it is designed to be a vendor-independent data model and usable in a wide range of hardware devices, software platforms and interfaces for many different use cases.

5.1 IfcCostItem

IfcCostItem is a non-geometric entity, subclass of *IfcControl*, within IFC. *IfcCostItem* describes a cost or financial value with descriptive information that describes its context (BuildingSMART, 2022). It represents the cost of assets and services, the execution of works by a process, lifecycle cost, cost estimates, budgets, and more.

IfcCostItem is also described through a set of attributes. Some of them are inherited instead the attributes PredefinedType, CostQuantites and CostValue are those owners of the class. An *IfcCostItem* can link one or many

IfcCostValue's representing a unit cost, total cost, or a unit cost with one or many quantities used to generate the total cost. The quantities can be given as individual quantities, or those quantities are provided as element quantities by one or many building elements. Another key aspect is that *IfcCostItem* can activate some different relationship. Among these it can be nested to create cost assemblies through the relation *IfcRelNests*, it can be assigned to a *IfcProduct* through the relation *IfcRelAssignsToControl* but may also have a product associated through the relation *IfcRelAssignsToProduct* or a resource through the relation *IfcRelAssignsToResource*.

5.2 Information Delivery Specification

The Information Delivery Specification (IDS) is a standard defined by BuildingSMART to define the required level of information in the specific project (BuildingSMART, 2023). IDS defines the information requirements that a geometric model must contain for the correct exchange of data in a way that is easily readable by humans and interpretable by the machine. It defines how to deliver and exchange objects, property, even values and units of measurement. An IDS file may contain several requirements independent of each other and without reference to other requirements in the file. This allows you to create replicable blocks and use them in different files.

Currently the information requirements are shared through excel sheets or PDFs; these are not directly interpretable by a machine and difficult to read by people given the large amount of data.

The IDS focuses on 'information delivery specifications' defining what information is needed and how it should be structured. This should improve automated workflows by receiving information that can be processed automatically. The definition of an IDS also serves to standardize all the different approaches that there may be in modelling. An example of different approaches may be the use of slabs instead of landings.

6. EXPERIMENTATION & RESULTS

In this article, part of a larger research work carried out by this research group, the uniqueness and correctness of the association of cost items with geometric objects has been analysed and validated. This has been achieved by defining a standardized data structure translated within the IFC standard, as cost data is in natural language (unstructured data). This allows you to define a database of cost data within the IFC standard through the classes currently present (*IfcCostItem*, *IfcCostValue*, etc.) and the relationships that these can activate.

The current paper investigates a specific case study focused on a structural model.

Not being the objective of the article and having been analysed in (Cassandro et al., 2023), it will not be explained as it has been defined the structure and the relations of the single item of cost inside the standard IFC and as this is related to the geometric entity. Figure 2 shows a simplified example of the possible architecture behind the cost item related to the concrete casting for a foundation; this item like all the others will be stored in the new database of cost items.

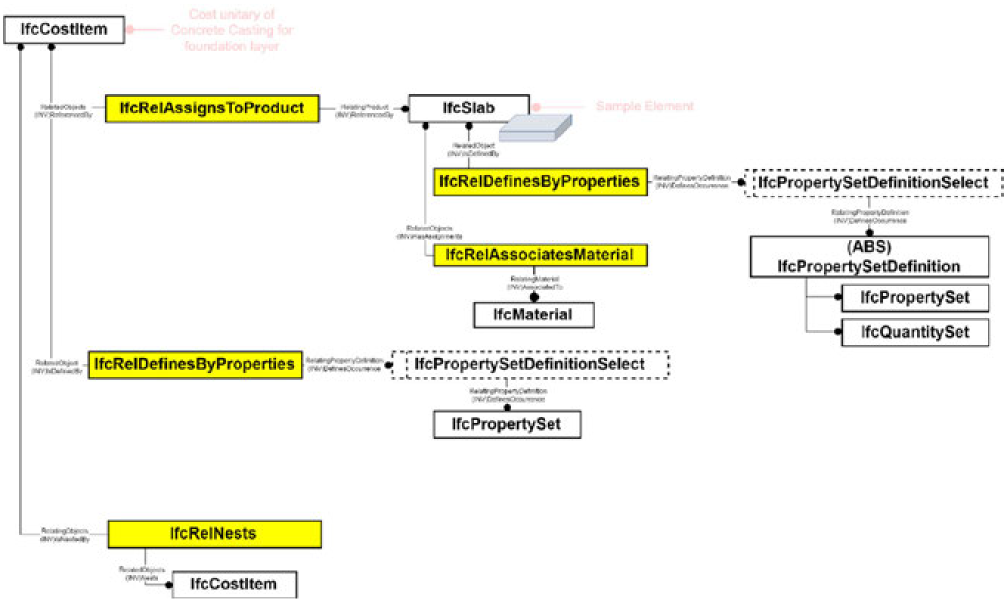

Fig. 2: Simplified example of architecture behind the cost item related to the concrete casting for a foundation.

All data used and related to cost items come from the price list of the Lombardy Region. In Italy the estimation of the prices in public tendering takes place using a price list. Each region has a catalogue containing price items, called price list, which is the basis of the economic offer and regulates payments in public contracts.

6.1 Model Requirements

Starting from a detailed analysis of the cost items, the minimum requirements (Level Of Information Need) that the geometric model must contain to ensure the subsequent association, verification and validation of data between geometric objects and cost items have been identified. It was possible to define the basic requirements to be delivered to the modeler on the basis of a work of analysis and breakdown of the current cost items for the identification of a new standardized architecture in which to insert and structure the current cost items.

The information that a single geometric entity must have in the model (called Facet in the standard IDS) have been defined. In the first part of the facet (applicability section), it was defined to which type of objects the specification applies and then it was defined the requirements (requirements section) that is required for the objects specified in the first part, such as required properties or classifications. Each specification has metadata (name, description, or instructions) to help describe the goals and instructions of how to achieve it before the applicability section (Figure 3, Figure 4). In the following example we ask as fundamental requisites that all *IfcSlab* entities of the geometric model (applicability) have compiled both the attribute "PredefinedType" according to the specific values defined by the standard (only these values are accepted: BASESLAB, FLOOR, LANDING, ROOF, NOTDEFINED, USERDEFINED) and the attribute "Name" with unspecified value (requirements).

THE ENTITY IFCSLAB MUST HAVE NAME AND PREDEFINEDTYPE

APPLIES TO:

ALL *SLAB* DATA

REQUIREMENTS:

SHAL BE *SLAB* DATA WITH A TYPE OF EITHER BASESLAB OR FLOOR OR LANDING OR ROOF OR NOTDEFINED OR USERDEFINED

THE *NAME* SHALL BE PROVIDED

Fig. 3: Simplified IDS user visualization with "IfcTester" web application.

    </ids:requirements>
</ids:specification>
```

Fig. 4: IDS document in machine-readable xml format.

The rules for the BIM information requirements that have been defined have been collected in Table 1. Two examples of requirements for modeling structural and non-structural foundations are given. We can see how the "Req.1" defines the requirements that each individual object of the model exported as *IfcSlab*.BASESLAB with Loadbearing value false (applicability) must have.

The ACCA software "usBIM.IDS" was used to verify the requirements and the correctness of the geometric model. It was therefore possible to verify the information contained in the geometric model and to detect discrepancies from the requirements initially defined and necessary.

Table 1: Examples of requirements for modeling structural and non-structural foundations

	Applicability	Requirements		
Requirement 1	*IfcSlab*.BASESLAB	Attribute	Name	-
	Loadbearing FALSE	Pset_ConcreteElementGeneral	ConstructionMethod	In Situ

6.2 Verification of the uniqueness and completeness of data

As already widely discussed in the section of "RESEARCH AIM & METHODOLOGY" the article aims to identify a method of verification of the uniqueness and correctness of the association between cost item and geometric object.

Starting from structured cost data and a geometric model that meets the information requirements identified by IDS, a code has been developed for the association of IFC cost entities - *IfcCostItem* with IFC geometric entities - *IfcElement* (will not be discussed in this article), and after that another code has been developed for the verification and validation of the correctness and uniqueness of the process of association of cost items to geometric objects. This verification process is completely different from the current ones; in fact, currently the verifications are focused exclusively within the same domain. What the research does is verify the correctness and uniqueness of the information between two different domains (in the specific case geometric domain and cost domain).

The developed code was implemented using Python 3.10, IfcOpenShell, an open-source library (IfcOpenShell v0.7.0) and the IFC4_ADD2_TC1 - 4.0.2.1 (currently the official version).

Through the developed code it is possible to perform an analysis of the geometric model containing the price items. The analysis involves a detailed verification of the information contained in the geometric object of the model (PropertySet, Material, etc.) against the information contained in the price item (Sample Element, PropertySet, Material of Sample Element, etc.) stored in the cost database. In fact, the architecture of the cost item is not present inside of the analyzed geometric model, which contains instead the single entity of cost (*IfcCostItem*) useful for the definition of the estimate of the costs (cost schedule); this retrieves some key data from the unit cost item, such as name, description, or unit cost value (*IfcCostValue*). This will allow to maintain a constant relationship between the item from cost estimation and the unit cost item without weighing down the model of information stored in an external queryable database (Figure 5).

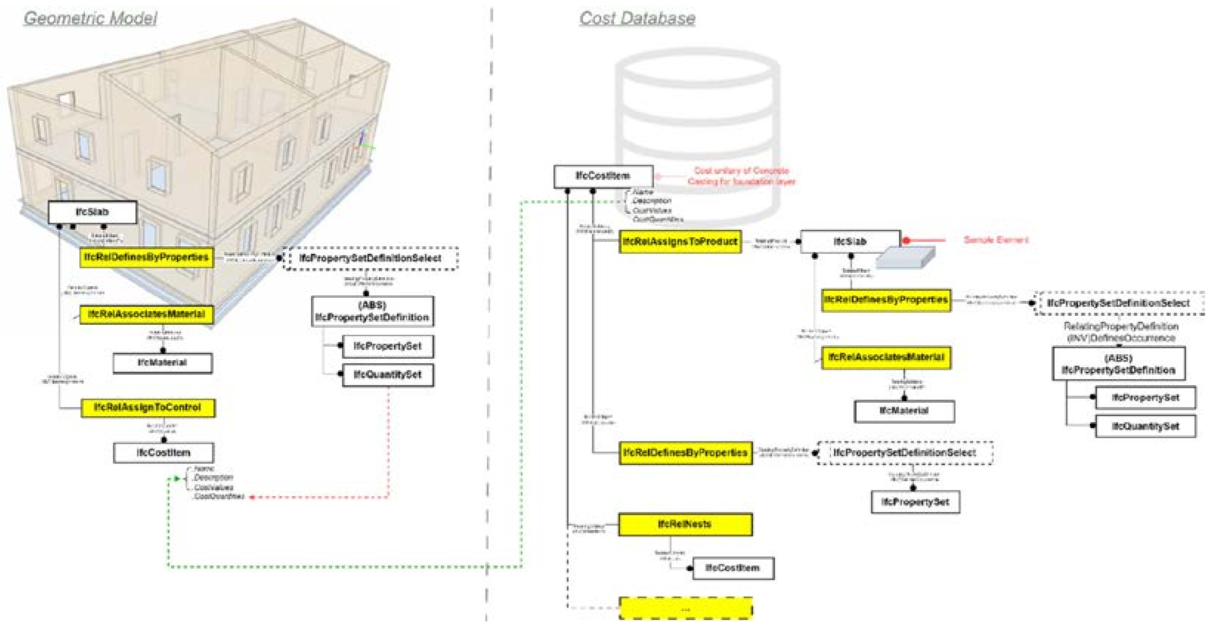

Fig. 5: Relation between geometric object data and cost item data

Due to the scope of the article the verification was performed on a limited number of geometric entities of the structural model: a sub foundation, a foundation, a slab and concrete masonry. Each of these entities is made of concrete cast in place and armed but having different characteristics (exposure class, strength class, structural class, etc.).

The data analysis begins by first identifying the geometric entities to which a cost had been associated. After that through a user interface based on manual input it comes chosen which relation object-cost to analyze. Starting from this choice, the code allows to extract the cost item associated with the geometric entity and, through a predetermined key (*IfcCostItem*.Name + *IfcCostItem*.Description), search the corresponding unit cost item within the cost database. Once the cost item is identified, the code proceeds by analyzing the properties and extracting the data to be verified; for example, the sample element associated with the cost item and the relative Pset_SlabCommon are analyzed to understand if it is a structural element (Loadbearing = True) or non-structural (Loadbearing = False), Figure 6.

```
#97=IfcCostItem('1$8jCZH8bFE97CyJuzD_2b',$,'Concrete casting for foundation layer', '...',.USERDEFINED.,(#96),(#95))
 - #45=IfcRelAssignsToProduct('3f5uwtK8r0ivS67zJKTVQU',$,'Rel cost-element','Rel between cost item and sample element',(#12),$,#14)
 - #14=IfcSlab('2942YU3sLCEvWbpvY3ug5Y',$,'Sample element of concrete foundation slab', '...',$,$,$,$,.BASESLAB.)

   ‣ #24=IfcRelDefinesByProperties('1qS4DR7EH8Yw0pP$KWTsjd',$,'Rel Pset','Rel between Pset-Sample Item',(#14),#23)
   ‣ #23=IfcPropertySet('3eHYyWf$j3o9iq4HBQt0uP',$,'Pset_SlabCommon',$,(#15,#16,#17,#18,#19,#20,#21,#22))
     ◦ #22=IfcPropertySingleValue('LoadBearing','Whether this component is carrying (YES) or not carrying (NO)',IfcBoolean(.T.),$)
```

Fig. 6: Query the cost item and the data it contains

The analysis continues by questioning the geometric entity and identifying the corresponding properties analyzed in the cost item; For example, we analyze the element class (*IfcSlab*), the PredefinedType attribute (BASESLAB) and its Pset_SlabCommon to check whether the element is structural (Loadbearing = True) or non-structural (Loadbearing = False), Figure 7.

```
#1881=IfcSlab('1r$167n5fDrxE0IVJzq9my',#19,'FND_PLA',$,'Platea:FND_PLA_30',#1868,#1880,'242873',.BASESLAB.)

 - BASESLAB
   ‣ #1900=IfcRelDefinesByProperties('2zqfiK0TxYZV_kPQ7PQE8u',#19,$,$,(#1881),#1887)
   ‣ #1887=IfcPropertySet('2Unrwa5Dqbjdie587QU4TO',#19,'Pset_SlabCommon',$,(#242,#718,#719,#1883))
     ◦ #242=IfcPropertySingleValue('LoadBearing',$,IfcBoolean(.T.),$)
```

Fig. 7: Query the geometric object and the data it contains

After the IFC model query phase, the results are analysed and validated. A comparison of the data identifies any inconsistencies (Figure 8). These are reported to the user who can then decide which choice to take:

- keep the cost-object association unchanged while knowing that the cost item is not completely congruent with the geometric object. to identify a cost item;
- modify the cost item originally associated through the query of the cost database and choosing between the proposals identified or if they are not present to create a new cost item to be added to the database.

This last mode (creating a new entry to be added to the database) has not yet been implemented and will be part of the future developments of the research.

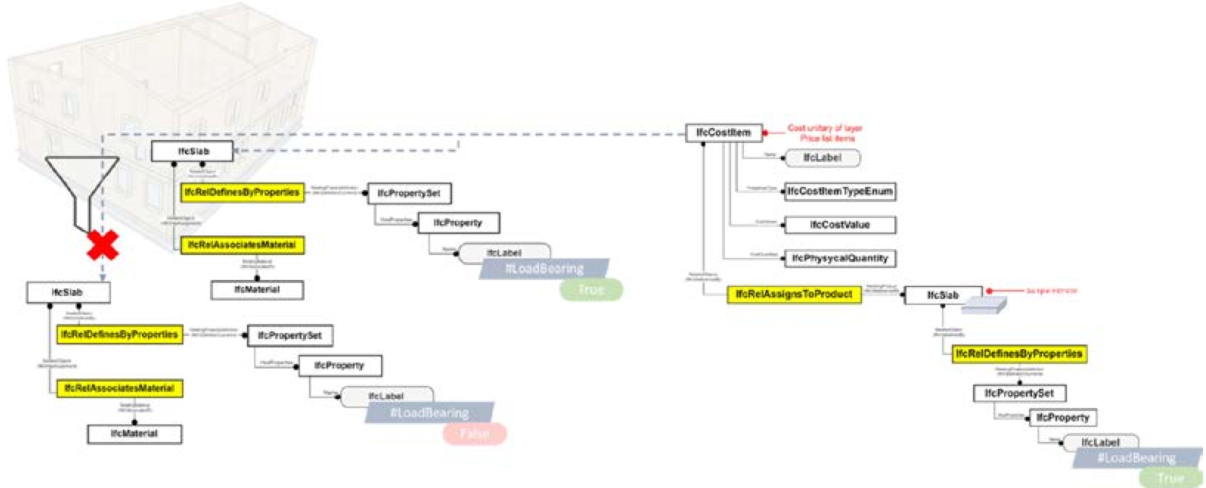

Fig. 8: Example of verification of the correctness of the association of the cost item to a geometric object

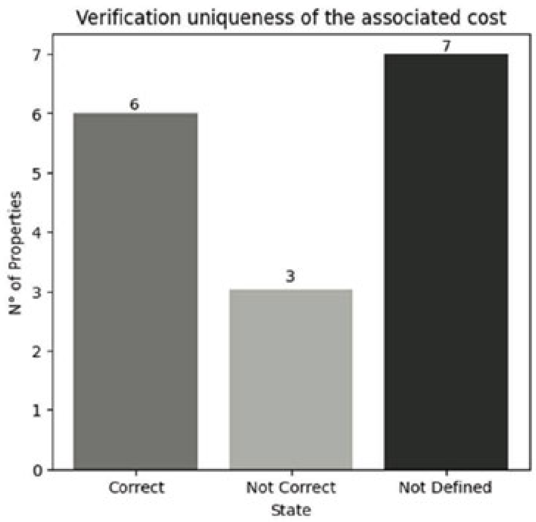
A report on the analysis of the output data is also saved in parallel with the display of the results; this report is for each individual association. In Figure 8 is shown an example of test verification performed on the association of the cost item of concrete casting for structural foundations and its geometric object (foundation) with relative data feedback. As we can see from the report obtained at the end of the test (Figure 9), the verification of the association of the cost item to the analyzed object provides the assessments on the current data. Therefore, it will be possible to understand the consistency or not of the data that the geometric object contains with the data contained in the associated cost item as visible in Table 2.



State	N° of Properties	Percentage
Correct	6	37.50%
Incorrect	3	18.75%
Not Defined	7	43.75%
Total	16	100.00%

7. DISCUSSION

This study is part of a larger research work that aims to digitize and standardize cost data and identify a new costs domain, that can ensure the verification of the correct association between cost items and geometric objects.

Considering the high uncertainty and inaccuracy of the information during the estimation processes is of fundamental importance:

- define the information requirements that the model must contain (Level Of Information Need) for a correct economic management;
- define an automated control procedure for the same information requirements (IDS) to avoid errors and time wasting;

- check the correctness and uniqueness of the cost items associated with geometric objects to ensure greater correctness of the cost estimate.

Nowadays cost estimation is one of the most critical tasks in the AEC/FM industry. Therefore, to support, verify and improve the quality of cost estimates, in public tendering, and reduce human error-prone, the study proposes the identification and applicability of a procedure for the verification of uniqueness of cost data assigned to geometric object within IFC data model. This scientific research has led technological attempts through the writing of a code in Python and through the support of the library IfcOpenShell. The results obtained are real, effective and scalable. The scalability of the hypothesized method has been demonstrated as it can also be implemented for other models. Currently, however, you can get these results only through code because current commercial applications do not allow user friendly implementations. The possibility of developing an executable to facilitate the verification of the model by an external user is being studied.

Currently, as seen in the literature, the approaches used do not provide for a verification of the correctness and uniqueness of the association between two different domains, cost and geometry. Typically, the verification is done within the geometric model considering only one domain (that of the model itself). In fact, usually only geometric interference and checks with the current regulations are carried out. While the goal of the research is to validate data between a plurality of domains (in this case the geometric domain and the cost domain) linked together and that can be contained in the same model. This causes numerous problems both in the phases of cost estimation and in the phases of construction of the work with consequent cost increases and possible disputes between customer/commissioning body and enterprise.

Nowadays, the only possible checks on the association of cost with a geometric object are made manually; there is no possibility for machines to understand information not structured and in natural language. For this reason, the goal of the research is to create a cost architecture to be associated with a geometric object, richer and more granular than a simple attribute associated in the model, allowing the verification of uniqueness and correctness of the data. The results of the research confirm the feasibility of the proposed method.

8. CONCLUSION

This research work is part of a larger project that will involve the relationship of the information of economic objects to the information of geometric objects. Specifically, the research shows how, in the AEC sector, it is essential to perform a verification of the associated information during the cost estimation phase for a correct management of cost data within construction projects. The research studies and experiments the application of a semi-automated method of verification of the cost data to ensure uniqueness and consistency of the information. This will allow to quickly and effectively verify if the cost information present in the project is consistent with what is stated within the geometric model.

Despite the many advantages that this application can provide, some limitations have been found in the proposed method including:

- standardisation of information and identification of requirements that the model must have (if the model does not follow the specified requirements, it is not possible to carry out cost verification); it is not possible to test the method on any IFC model received;
- need for detailed analysis of the information in the IFC data model for a clear understanding of the geometric object; it is not possible to identify the geometric objects from the class attributes alone (Name, description, TypeEnum, ecc.) but it is necessary to deepen the relationships that the same creates with other entities (*IfcMaterial*, *IfcPropertySet*, ecc.). A practical example is found among the objects lean concrete and slab foundation; they are both *IfcSlab*.BASESLAB and one of the ways to differentiate them is to analyze the LoadBearing single value (True or False) in the Pset_SlabCommon.

Although the method has been applied to a specific case study in the structural field, the methodology can be applied for several case studies. Future developments should include testing it in different areas and models for construction and large-scale application to verify its reliability. In addition, an application with user-friendly interface must be developed to ensure easier use of the tool.

SEMANTIC WEB BASED INTEGRATION BETWEEN BIM COST AND GEOMETRIC DOMAINS

Jacopo Cassandro & Claudio Mirarchi & Alberto Pavan
Polytechnic of Milan, Italy

Andrea Zamborlini & Carlo Zanchetta
University of Padua, Italy

ABSTRACT: *In the architecture, engineering, construction, and facilities management (AEC/FM) industry methodologies are needed to ensure the interoperability of data and effective management of information from different sources. Integration of the cost domain and cost estimation within the Building Information Model (BIM) in the AEC/FM sector is still an unresolved problem and one of the most critical tasks due to the lack of a standardised cost domain, especially in the tendering phase.*

To ensure interoperability between cost data and geometric data, this research aims to address this gap by analyzing methods of converting cost data into Linked Building Data, thereby defining a cost domain in the Semantic Web, by collecting them into a graph database. This allows for structuring a cost domain, translating an IFC based structure previously developed by the research group, visualizing it using a graph system, and connecting it to the BIM geometric domain. Furthermore, it is possible to extend the cost ontology previously identified in the IFC model and facilitate the queries and analysis of cost data currently fragmented and based on unstructured data.

The results show how Semantic Web technology can be used to improve data interoperability, develop a cost ontology, and join both cost data and BIM models.

KEYWORDS: *Semantic Web, Linked Building Data, IfcOWL, cost ontology, IFC, RDF, graph system.*

1. INTRODUCTION

The construction process is complex, dynamic and requires numerous interactions between the different actors involved. The sharing of different information, including information on the amount of physical components of the building, the planning plan, and the consumption of resources and costs is essential for accurate time and cost management.

Nowadays, in the Architecture, Engineering, and Construction (AEC) industry, the standard format used for information exchange is the Industry Foundation Classes (IFC), a neutral and open ISO standard by buildingSMART. Currently, the most recent IFC scheme is IFC4 ADD2 and contains about 1200 classes. BIM software developers can implement an exporter to convert respectively their native BIM format to the neutral IFC format.

Despite the clear advantages of data interoperability, which would otherwise only be feasible in proprietary BIM software, the IFC data model still has some limitations (Pauwels & Terkaj, 2016). These include, for example, the impossibility of extending it in a user-friendly way, the difficulty of developing applications with this template, due to the complexity of the schema expressed in EXPRESS format (Krijnen & Beetz, 2018), or the impossibility of relating data between the IFC file and other cloud historicized files. The IFC scheme is used as an interoperable format for sharing information, with the aim of being a supplier-independent exchange format, but not a fully integrated and comprehensive description of a project. This leads to an immense untapped potential of data in the AEC industry (Krijnen & Beetz, 2018). In comparison, the Semantic Web (SW) uses the Resource Description Framework (RDF) triple schema to store data and ontologies to enhance the semantic structure to make information machine-readable (Berners-Lee et al., 2001). It may also contain multiple ontologies, a formal and explicit specification of a shared conceptualisation (Gruber, 1993), covering specific areas not included in the IFC scheme (Rasmussen et al., 2017) and enabling the visualization and improvement of the interoperability of the IFC information model.

In order to overcome these limitations, this research is focused on the potential of SW. This research focuses on the conversion of the architecture of cost items, assumed and implemented in the IFC data model in a previous study carried out by the research group (Cassandro et al., 2023), to RDF using the emerging Linked Building Data

(LBD) modular ontologies as proposed by the W3C LBD CG (Bonduel et al., 2018). To validate what has been done in the previous study, the IFC-to-LBD converter presented by Bonduel et al. (2018) has been used. Information from IFC building models is extracted and transformed into Abox RDF graphs suited for usage in Linked Data applications.

The graph system will contain the relevant information of both the geometric model and the cost architecture with the related properties. Data translation within the SW will allow to query the model, associate the two different domains studied (geometric and cost) within a single environment, and view cost data and related architectures.

This paper develops following these steps. First, a detailed analysis of the literature to deepen the themes on the SW. Secondly, the identification of the conversion tools available to date for the transition from IFC to RDF and the subsequent validation and analysis of the results within a graph database. Finally, the conclusions and future works will be set out.

2. BACKGROUND

2.1 Literature review

The first research on the application of the SW in the AEC Industries dates back to the early 2000s; since then, their use has spread to more and more areas of the industry, producing interesting results in terms of number of publications and significance of results. Beetz et al. (2015) and Pauwels et al. (2017) analysed the reasons for the spread of SW in the AEC industry, identifying three main reasons: (1) Interoperability, (2) Liking across domains and (3) Logical inference and proofs.

The possibility of improving the Interoperability (1) relies on the SW structure which provides a way to store information in a computer-understandable manner, making possible the comprehension of the information involved in the process both by a human being and a machine.

The linking across domain (2) relies on the opportunity to create a unique web of linked data with information from all the different areas of the AEC process, (e.g. GIS, costs, energy, facility management, and so on).

The third motivation is the logical inference and proofs (3), which relies on the OWL language used for the semantic meaning. Correct use of the language offers the opportunity to infer more information from the original input, improving the web and allowing us to do more complex queries.

As we previously said, the usage of SW in the AEC involves different areas of the industry; a review of some of the most significant utilisations is reported below.

H. Abanda et al. (2011) proposed a SW based decision support system, which helps the government to speed up and automate the bureaucratic processes. This approach shows how SW could be a powerful ally for the PA to manage all the applications for a licence. In Karan et al. (2015) the SW is used to overcome heterogeneity problems, which came from the traditional methods of heterogeneous data sharing, generating IFC from semantic web query results. The IFC structure lends itself to a translation in linked data, which is why Zhao et al. (2020) suggested a method for IFC data merging based on miming the IFC structure with nodes and edges. The IFC graphs are merged and then restored in the starting files, implementing the information. Merging information through SW can be done not only using the same type of input, like different IFC files; in fact, Malinverni et al. (2022) used an approach that merges information from GIS and BIM models, producing an enriched model that has many benefits for the entire project life cycle. Also, the safety issues are affected using SW, and Zhang et al. (2015) developed a prototype of a new approach to organize, store, and re-use construction safety knowledge to produce a framework that supports automated job hazard analysis in BIM. Also, the safety issues are affected using SW, and Zhang et al. (2015) demonstrated a prototype of a new approach to organize, store, and re-use construction safety knowledge to produce a framework that supports automated job hazard analysis in BIM.

The damage and degradation analysis can also be positively affected by linked data and an interesting example is reported by Jung et al. (2021); they discussed an automatic approach to infer the causes of concrete cracks starting from information about pattern, location, and penetration status. The possibility to express human thinking and make a logical inference by machines thanks to ontologies can remove the issue of complex qualitative analysis during the process of identifying the cause of a crack.

The most meaningful domain analysed for this paper is 5D planning, for which can be found different approaches.

F. H. Abanda et al. (2011) developed an ontology-based technology in modelling information about labour costs that aims to facilitate decision-making among building developers in Cameroon; Vakaj et al. (2023) proposed a new domain ontology called Offsite Housing Ontology to support cost estimation about resources, products, and production processes. A further reference for cost estimation is Fürstenberg et al. (2021); they studied how semantic web technology can support BIM-based automated cost estimation and the related challenges, focused on Norwegian road projects.

The need to find ways of translating IFC into ontologies led to different approaches. The first interesting attempts can be found in Beetz et al. (2005), where two different approaches convert the EXPRESS schema of an IFC into an ontology in OWL notation: one using an intermediate step with an XSLT file between the XML file and the OWL, and a second which derives the OWL notation directly from the original EXPRESS schema format of the IFC. After that the approach evolved, leading to Beetz et al. (2009) which presented a semi-automatic way of lifting EXPRESS schemas into ontologies. Pauwels et al. (2015) analysed the correct ways to translate EXPRESS language into OWL. Hoang and Torma (2015) present the IFC2LD converter, a Java application with a Web interface, for converting IFC schemas into OWL2 ontologies and IFC data into RDF graphs aligned with the ontologies. Pauwels and Deursen (2015) present their online RDF to IFC conversion service, which converts an IFC into RDF triples. Continuing chronologically, Ismail et al. (2017) show a workflow for the automatic transformation of IFC into an object graph database; this method is based on a dynamic EXPRESS parser and a web script console that creates a meta graph inside Neo4j. Bonduel et al. (2018) developed a conversion of IFC to RDF using W3C Linked Building Data modular ontologies. The graphs are structured with three types of ontologies: BOT (building topology), PRODUCT (classification of building elements), and PROPS (building-related properties); the result is a more user-friendly graph than the ifcOWL Abox graphs.

2.2 Cost definition in IFC domains focus on IfcCostItem

Nowadays cost items are associated as attributes to geometric entities. However, to correctly return the analysis and economic evaluation processes, it is necessary to have cost architectures configured as more complex systems than a simple attribute associated with a geometric object. The IFC standard, through the cost class (*IfcCostItem*), offers the possibility of structuring a cost data model.

IfcCostItem is a non-geometric entity, a subclass of *IfcControl*, within IFC. *IfcCostItem* describes a cost or financial value with descriptive information that describes its context (BuildingSMART, 2022). It represents the cost of assets and services, the execution of works by a process, lifecycle cost, cost estimates, budgets, and more in the IFC standard.

IfcCostItem is characterized by its own attributes (PredefinedType, CostQuantites, and CostValue) and others inherited. An *IfcCostItem* has the possibility to instantiate one or more cost values (*IfcCostValue*). Other key features are that every single *IfcCostItem* can be nested to create cost assemblies through the *IfcRelNests* report, can be assigned to an *IfcProduct* through the *IfcRelAssignsToControl* report, may have an associated product through the *IfcRelAssignsToProduct* report or a resource through the *IfcRelAssignsToResource* report.

2.3 IfcOWL and Linked Building data (LBD)

In recent years, the area of cross-domain linking has received increasing attention. This area aims to combine data from various sources with construction data, management of information based on ontology, and analysis of the performance of buildings (Pauwels, Krijnen, et al., 2017). According to W3C, the Web Ontology Language (OWL) is a language designed to represent complex knowledge about objects, relationships between objects, and groups of objects in a way that can be exploited by computers (*IfcOWL - BuildingSMART Technical*, 2023.). BuildingSMART has developed the IfcOWL ontology based on these definitions, providing an OWL representation of the Industry Foundation Classes (IFC) schema, maintaining the same status as the Express schema. OWL concepts (OWL - Semantic Web Standards, 2023) can be used to construct RDF graphs, called OWL ontologies (Pauwels & Terkaj, 2016), enabling easy linking between the building data and material data, cost data, GIS data, and so forth. However, due to the complex structure of the IFC data model, the ifcOWL representation of geometric data is difficult to manage (Pauwels et al., 2017a).

Achieving interoperability between domains is the main purpose of the Linked Building Data (LBD) Community Group in the World Wide Web Consortium (W3C) (*The Linked Building Data Community Group*, 2021). LBD allows for storing construction data sources separately and processing them through digital and computer systems (Curry et al., 2013). This results in a set of data that can be utilized and interconnected. Expandability is a key aspect of AEC where most projects are fragmented, complex, and diverse. Using the LBD different ontologies can be mapped and enhanced each other, facilitating a more comprehensive and integrated approach to handling diverse data sources and formats within the AEC industry.

3. RESEARCH AIM & METHODOLOGY

The research aims to verify the effective possibility of associating the new cost domain with the geometric one through the SW. This will allow to relate different domains within the same environment to improve data sharing and interoperability. In addition, it will be possible to manage cost items no longer as simple attributes attached to a geometric object, but as real cost architectures, more complex, ensuring in the future also the ability to verify and validate the associated data.

The first study to examine the possibility of structuring a cost domain using Industry Foundation Classes (IFC) has already been addressed in Cassandro et al. (2023). In this work, based on the assumptions and limitations of previous research in Cassandro et al. (2023), has been translated the ontology previously developed in the Linked Building Data (LBD) format. This will allow us to relate the cost domain to the existing domains (in the specific case the geometric domain); in fact, SW technology is well-suited to link knowledge stored in different domains (Beetz et al., 2015; Pauwels, Zhang, et al., 2017).

The methodology adopted is characterized by the following steps presented in Figure 1:

1. Study of the State of the Art of the current practices and research connected to SW and graph database;
2. Analysis of IFC entities (*IfcCostItem* identified in the standard to manage the cost information) and how to translate it into LBD;
3. Translation of cost ontology, developed in Cassandro et al. (2023) from IFC to LBD through a tool developed by Bonduel et al. (2018);
4. Information validation in a graph database such as Neo4j;
5. Results of experimental research

A way to represent cost information by using SW was formulated, developed, and validated. This could provide the basis for the information exchange resources among information systems for the more user-friendly query of data and linking different domains. The next sections describe the mechanisms used to implement and test the method.

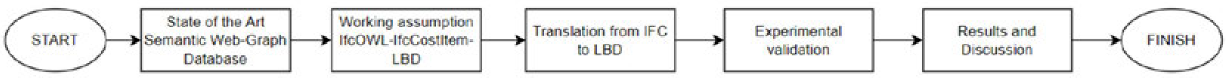

Fig. 1: Research Methodology

4. RESULTS

In this research, the case study is the same as that analysed by Cassandro et al. (2023). This allows to fully understand the differences between the methodologies adopted and to compare the results obtained during the two research. The case study is a wall composed of six layers; each layer corresponds to a different cost item within the regional price list (Lombardy Region) which must therefore be associated with the related geometric object, see Figure 2. These cost items have already been structured within the IFC data model.

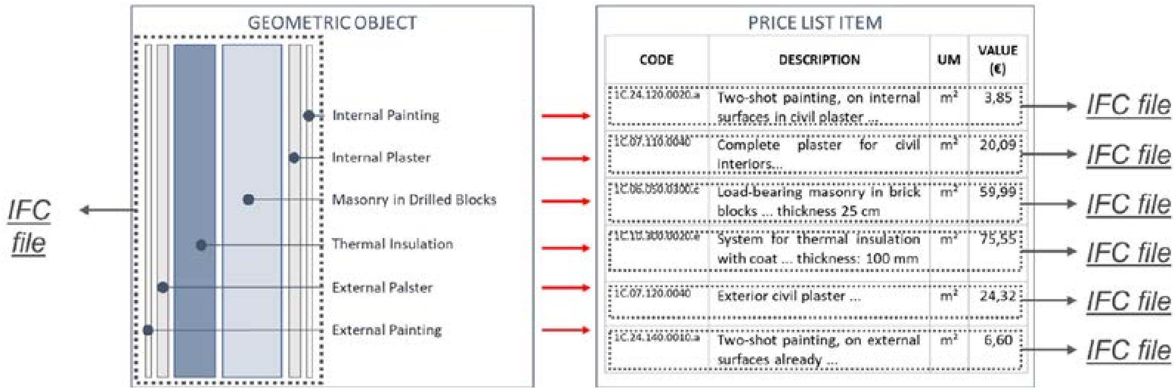

Fig. 2: Example layers of masonry and relative price items

Then the individual IFC files were converted into RDF format using the tool "IFCtoLBD[1]" developed by Jyrki Oraskari and Mathias Bonduel. This tool allows to convert an IFC file to a Turtle file described using BOT and optionally PRODUCT, PROPS, and GeoSPARQL (Bonduel et al., 2018).

The correct export specifications have been set thanks to Bonduel et al. (2018). For the correct output, it is necessary to activate the PROPS module of the ontology structure, which includes three levels of complexity. For the case study, Level 3 was selected (i.e., the most complete level). Thereby, the Blank node option was activated, which decreased the file size, exported RDF, and improved the readability. The output is a Terse RDF Triple Language (Turtle); a format made to express RDF data. This format uses triples made by subject, predicate, and object to represent information.

At this point the new file in Turtle format is loaded inside a graph database (in this specific case Neo4j is used); in this way, you can view the information and links between these (Figure 3). As visible from Figure 3 every entity is associated with a series of intrinsic attributes of the same one. IFC information is intrinsically interconnected and can naturally be represented by graphs. Figure 3 shows the IFC file for a painting cost item at the top and the corresponding data representation in a graph system at the bottom (nodes and edges). As it is visible, the graph representation is more intuitive in revealing the relationships between instances than the text based IFC.

Translating the IFC data model into a graphical system can lead to a simplified representation of the construction information and its relationships, as well as improving data query.

The developed methodology relies on an IFC, which contains both the geometrical information and cost information, inserted into the file using the appropriate classes previously studied in Cassandro et al. (2023). The creation and compilation of *IfcCostItem* classes has been implemented in Python using IfcOpenShell, as shown in Cassandro et al. (2023).

The conversion from IFC to an LBD was carried out using a tool developed by Bonduel et al. (2018). The correct exporter setting has been set after several attempts to get the type of LBD needed. Figure 4 shows all the cost item files, in RDF format, imported into the graph database and related to the geometric object (wall system). After that, the latter was also imported and displayed, visible in Figure 5.

The Neo4j graph database has been used to visualize the data. The Neosemantics plugin (n10s) was used to load RDF data and its associated vocabularies, including OWL, RDFS, SKOS, and others, into Neo4j. This plugin extends Neo4j's capabilities to work with semantic data in RDF format, allowing users to import, store, query, and analyze RDF data within the Neo4j graph database. It facilitates the integration of RDF-based knowledge graphs and linked data into Neo4j, enabling more comprehensive and semantic data modeling and analysis.

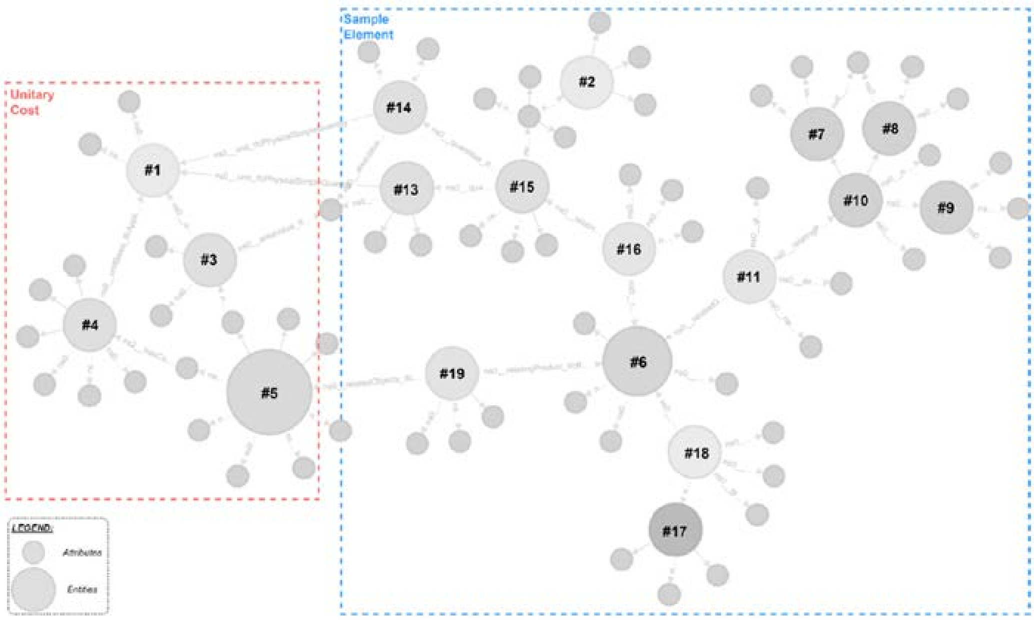

Fig. 3: Comparison between cost items in IFC format and RDF format

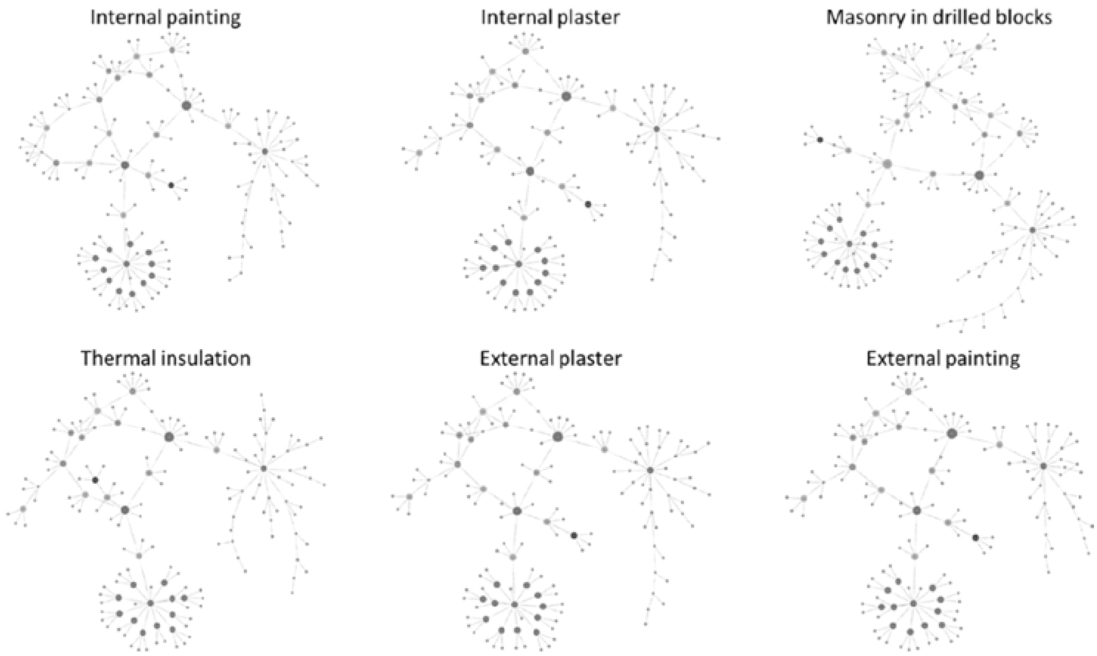

Fig. 4: Representation in the graph system of the six different cost items starting from IFC files

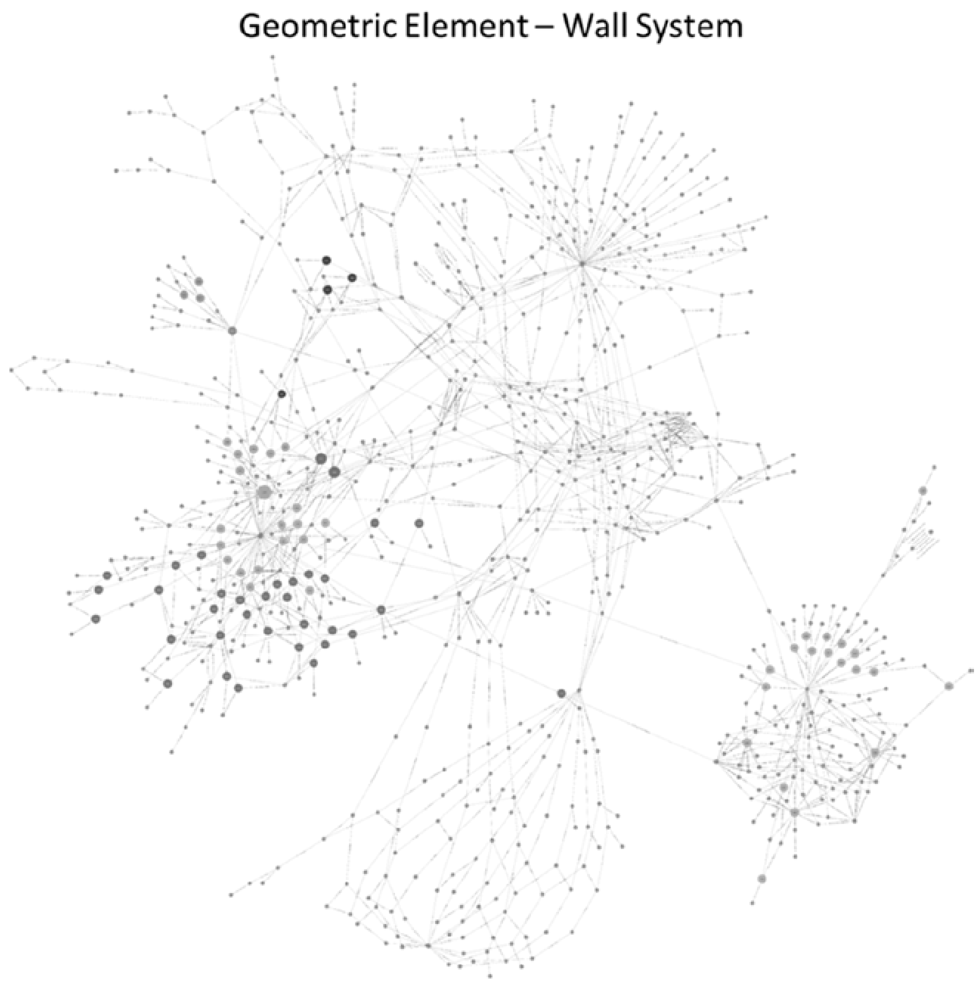

Fig. 5: Representation in the graph system of the geometric object (wall system) starting from IFC files

Through the Cypher script language, it was possible to work with the different Turtle format files available. Cypher is a declarative query language created specifically for working with graphs and interacting with the Neo4j database. Cypher queries are very expressive and readable and allow operations such as creating, editing, and querying data within the Neo4j database.

The first step was to load the data of the different files (Figure 6 - Script 1, Script 2). Subsequently, the data files were queried, and two node-entities were identified: *IfcCostItem (*Figure 6 – Script 3) which gathers all the architectural data related to individual cost items (within the cost domain) and *IfcElement* (Figure 7 - Script 7) which represents the geometric domain to which the cost item must be associated.

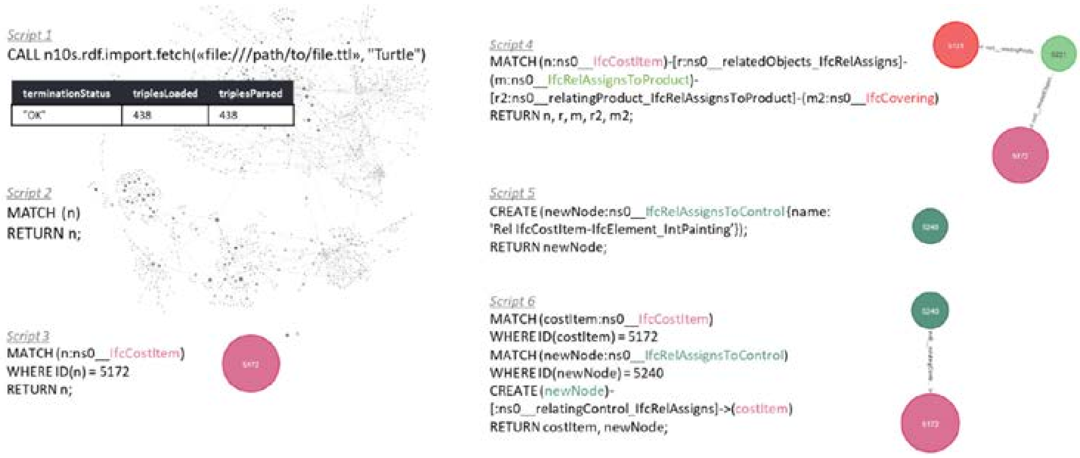

Fig. 6: First script sequence for *IfcCostItem-IfcCovering* connection (cost-layer painting)

Finally, the relationship between the two nodes-entities contained in the two domains has been created (Figure 7 – Script 9). As we can see in Figure 7, the two entities belonging to the two different domains (costs and geometry) have been connected using the logic intrinsic to the IFC data model. A node ("5240 - *IfcRelAssignsToControl*") has been created that corresponds to the exact IFC entity that ensures the connection between geometric entities and cost entities. This has led to the connection of the two different domains (cost and geometry).

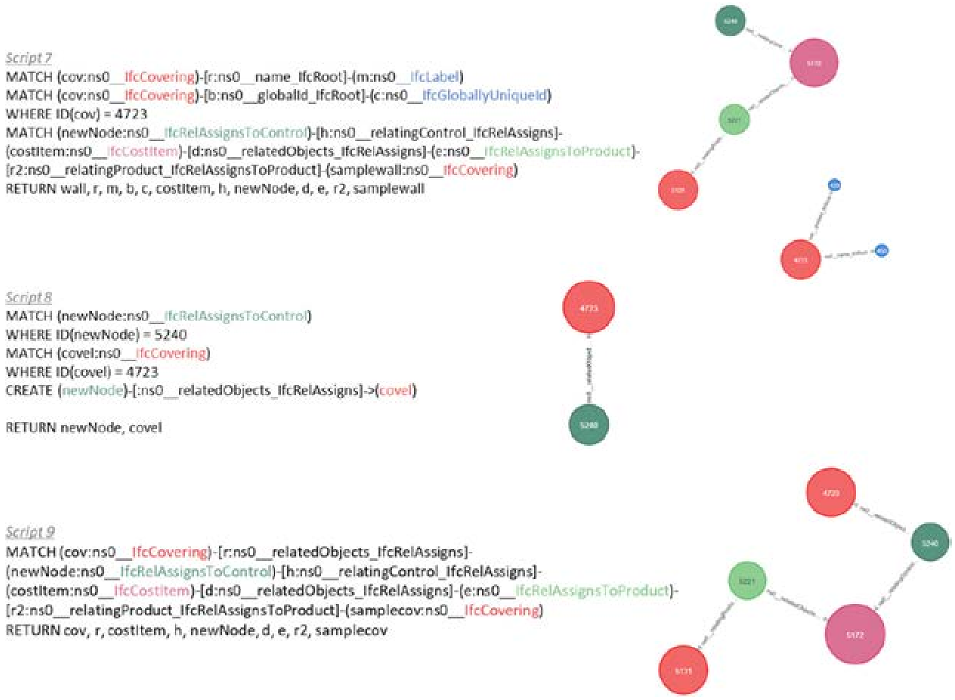

Fig. 7: Second script sequence for *IfcCostItem*-*IfcCovering* connection (cost-layer painting)

This procedure has been replicated for the remaining cost items to associate with the respective geometric objects to obtain a new system to graph containing the data of the geometric domain and the cost domain. Figure 8 shows the final output and a zoom on the association of the cost of the layer of internal painting (IfcCostItem_InternalPainting) to its geometric object (*IfcCovering*).

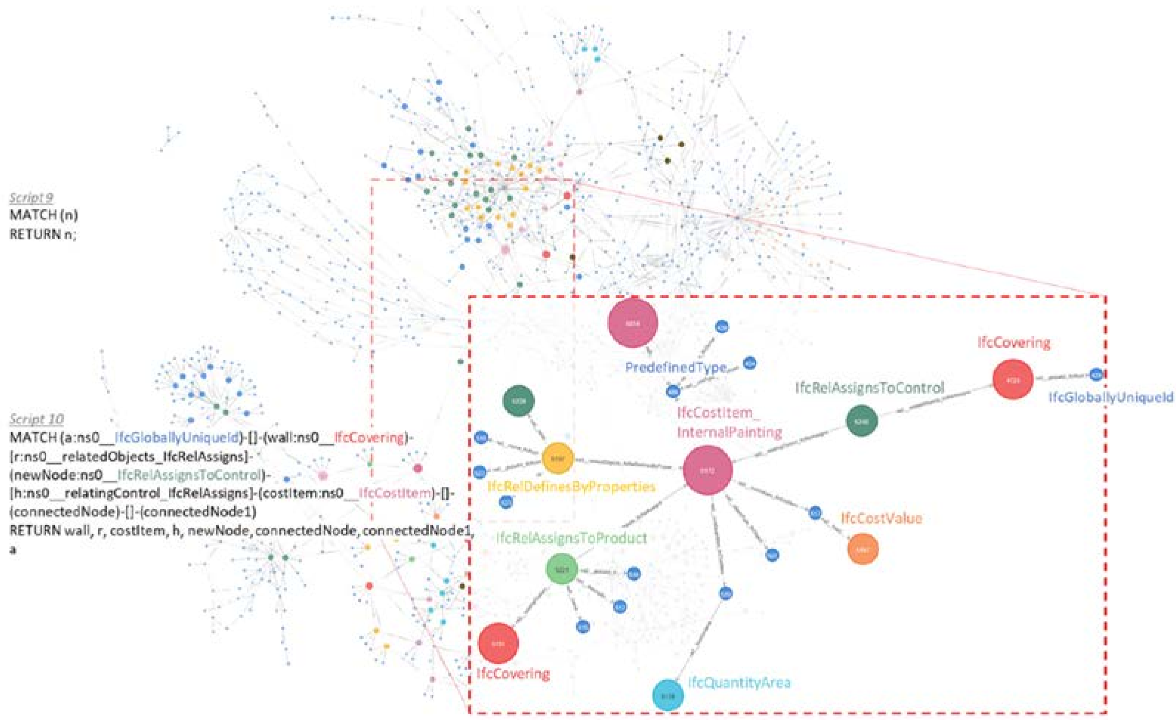

Fig. 8: Final output and zoom on the association of the cost to its geometric object (*IfcCovering*)

5. DISCUSSION

The study seeks to optimize and make the data of the cost items more user-friendly. Currently, these are displayed only as informational inputs, lines of code, or even simple attributes. The aim of the research is to focus on a subject of great interest and still cause numerous legal disputes. In the research, the possibilities and the limitations of the proposed method are highlighted based on the association of different domains within a graphic system. This would allow you to link different data from files even in different formats. This study presented how price elements can be instantiated as a graph and how their visualization allows us to better understand the logic of connection and relationship between entities. It has been studied the possibility of visualizing a new domain of cost for the price list of the Lombardy Region based on a graphical system to standardize and regulate the prices and the relative information.

Converting the IFC data model into a graph system can bring many advantages (Pauwels, Zhang, et al., 2017), (Zhu et al., 2022). The main reasons why converting IFC to a graph is an objective to be pursued are:

- a simplified representation of construction information (Silvescu & Caragea, 2019);
- clearer object relationships (Figure9);
- improved data integration and interoperability (Rodriguez & Neubauer, 2010), (Mazairac & Beetz, 2013);
- improved query and processing information (Pérez et al., 2010).

However, even if this methodology makes the data more visually intuitive, due to the limitations of the current tools available, it is not yet possible to convert the information in the IFC data model into RDF in a simplified way. A further limitation is due to the use of a programming language to query, create, and associate data belonging to different domains. This causes problems in a sector, the AEC, which is only beginning in recent years to interface with these new technologies.

This research has led to technological attempts made through the writing first in IfcOpenShell of individual cost items and then in RDF format for their association to the geometric domain and their simplified visualization; in this way, it is not necessary to understand the logic behind the IFC data model. The achievement of results that are real, effective, and scalable confirms the scalability of the method as it can also be implemented for other list items.

6. CONCLUSION

The results show how SW technology can be used to show and relate the cost domain for construction projects to different domains, such as the geometric domain. Starting from the IFC data model, the cost domain has been translated into LBD ontology thanks to the IFCtoLBD converter developed by Bonduel et al. (2018). In fact, due to the complex structure of the IFC data model, the LBD representation makes it easier for stakeholders to visualize and manage the data contained in the models. The IFCtoLBD converter developed by JURI uses the smallest BOT, PRODUCT, and PROPS ontologies to better separate and represent data (Bonduel et al., 2018).

In this study, the proposed architecture for the new cost domain, developed and validated by Cassandro et al. (2023), can be easily visualized within the graphical database. As a result, individual cost items and related information become readily accessible in the graphical database. Moreover, these elements can be queried individually, associated with their corresponding geometric objects, or even extended by creating new nodes and relationships.

During the study, several limitations were identified. Firstly, the complexity of data in the AEC industry can be more difficult due to the variety of information involved, demanding a deep understanding to integrate data into LBD format. Secondly, the AEC domain includes numerous standards and ontologies, which makes it difficult to ensure compliance with all relevant standards (e.g., IFC) when integrating data into LBD. Finally, interoperability remains a concern as not all software platforms are equipped to handle LBD, posing difficulties in achieving seamless data integration and interoperability across different platforms.

For future work, it is essential to prototype and extend the concepts explored in this study. In addition, the development of an extension for the converter to improve data translation should be considered.

ONTOLOGY-BASED CONSTRUCTION INSPECTION PLANNING: A CASE STUDY OF THERMAL BUILDING INSULATION

Sebastian Seiß, Markus Boden & Prof. Jürgen Melzner
Bauhaus-University Weimar, Germany

Yuan Zheng
Aalto University, Finland

Thibaut Delval & Rayan El Chamaa
Centre Scientifique et Technique du Bâtiment, France

ABSTRACT**:** *Poor construction quality is one of the most significant challenges for the construction industry. However, failures can be avoided or minimized by inspections based on detailed quality inspection plans as a part of quality assurance. Therefore, structured and project-specific planning of inspection plans is required to provide inspectors with the right information.*

Nevertheless, inspection planning is mainly manual, dependent on the individual's experience and high level of effort. As a result, inspection planning is often neglected and limited to providing general checklists that often lack semantically rich descriptions and are unspecific concerning individual project requirements. Furthermore, proper planning of inspections requires multiple information sources, such as building design, schedules, contractual and supplier guidelines, and standards, all of which must be provided or linked via an information model. Current research lacks an adequate formalized knowledge model to provide the knowledge-driven inspection planning process with the necessary domain knowledge to support inspection planning with heterogeneous information defined in isolated systems.

Therefore, this paper extends the Ontology for Construction Quality Assurance (OCQA) with the OCQA-Thermal Insulation (OCQA-TI) to formalize thermal insulation inspection planning knowledge. The OCQA offers a new linked data model that provides explicit knowledge of quality inspection planning. The development of the OCQA-TI follows the Linked Open Terms (LOT) methodology and is implemented using the Web Ontology Language (OWL).

The proposed ontology is evaluated using various approaches, including automatic consistency checking, answering competency questions, and criteria-based evaluation. The results indicate that the OCQA-TI can provide inspectors with relevant inspection planning knowledge and integrate various related information streams, thus providing a more comprehensive and efficient approach to insulation inspection planning. The functionality of OCQA-TI enables the fulfillment of increased sustainability and energy efficiency requirements by providing insulation inspection knowledge.

1. INTRODUCTION

Construction faces a significant quality problem, evidenced by an analysis by the German insurance company VHV showing that the total cost of reported damage claims has risen for years (Böhmer et al., 2022). A study by BauInfoConsult (2022) concurred, assuming a defective cost share of 12.8% of the industry turnover. With a total construction industry turnover of 143 billion euros in 2020 issued by the German Construction Industry Federation, the study extrapolates error costs of approximately 18.3 billion euros (BauInfoConsult, 2022).

Research and practice approaches have primarily focused on defect management yet have often neglected proactive defect prevention through inspection planning (Seiß, 2022). However, proactive inspection planning could avoid many errors and save costs. The VHV Report shows that approximately 58% of the causes of damage can be traced to avoidable execution and assembly errors as well as interface and communication problems. In addition, inadequate construction supervision accounts for approximately 7% of the causes of damage (Böhmer et al., 2022). Thus, a proactive, construction-accompanying quality assurance approach can address approximately 65% of all causes of damage.

Currently, energy efficiency and building sustainability requirements are increasing significantly worldwide. The

European Union has set targets for the construction and real estate industry's energy future. Climate neutrality in the building sector is to be achieved by 2050. Hence, new buildings must be constructed to the zero-emissions standard as early as 2028 (European Parliament, 2023). In the specific domain of insulation, quality assurance is particularly important. Insulation is crucial to buildings' energy efficiency, thermal resistance, and interior comfort since poor insulation installation and use can lead to heat loss, thermal bridges, moisture problems, and an overall decline in a building's energy performance (Sassine, 2013).

National policies were implemented after the oil shocks of the 1970s and the subsequent energy crisis to meet the requirements of stricter insulation and energy efficiency regulations. These policies led to adopting standards in France, such as the "*Documents Techniques Unifiés*" and the RT 2012 and RE2020 rules, regulating the materials used and their installation methods while quantifying buildings' losses, gains, and energy needs. However, the practical application of these rules has sometimes been questionable due to negligence or ignorance. Hence, it is difficult for a conventional inspection to identify potential defects since the insulation materials are always covered with various finishing elements (Antoine Szeflinski, 2007).

Non-destructive testing plays a crucial role in addressing these issues, allowing for precise recognition of construction phases, authentic elements, original and restoration materials, construction techniques, deterioration, durability, and structural strength. These are essential for assessing the energy and environmental performance of the building envelope. Visual tests, thermographic tests, sonic and ultrasonic tests, thermal flux measurements, and microclimate analyses are used in energy audits to obtain accurate results (LUCCHI, 2011). Notably, thermal insulation implementation inspections often focus on performance after completing the construction work. Nonetheless, this approach has a major drawback: a delay in detecting implementation defects. While waiting for performance inspections, quality problems can develop and become more difficult and costly to correct.

Therefore, considering corresponding inspection plans to guarantee the quality of finishing trades such as thermal insulation and meet the expanding quality requirements is necessary. However, quality assurance in the building industry concentrates on shell construction trades (Berner et al., 2015), while finishing trades often cause increased costs due to defects. In analyzing the BSB's quality inspections during construction, damage to thermal insulation accounts for a comparatively high 10.7% of total damage (Böhmer et al., 2020). France's heat and climate protection ordinance has led to a steady increase in the proportion of thermal insulation measures (Böhmer et al., 2020). Sales of External Thermal Insulation Composite Systems (ETICSs) have also steadily risen in Germany since 2018 (Statista, 2023). In parallel, the number of defects caused by ETICS has also increased. For example, building projects with ETICS are often affected by defects such as cracking, moisture penetration, and delamination (Böhmer et al., 2020).

Hence, introducing inspections of thermal insulation implementation throughout the construction process would be beneficial in addressing this problem (Zhong, 2012). This approach would allow for early defect detection and correction, implementation quality improvement, and optimal energy performance assurance in buildings from completion. Thus, exploring automation solutions to evaluate inspections would be imperative to bridge the gap between regulatory standards and on-site inspections. However, to our knowledge, there is still a lack of a structured and computable representation for formalizing the thermal installation regulatory standards. Meanwhile, the interoperability between standards and the on-site inspection information also remains. Ontology is known as a formal specification of the domain knowledge, which has been widely explored in the construction domain to facilitate knowledge management and information integration issues (Pauwels et al. 2017). But an ontology that is adequate to represent specific domain knowledge of the thermal installation quality inspection is still missing. Therefore, in this research, we aim to extend the Ontology for Construction Quality Assurance (OCQA) for involving the specific domain knowledge for the thermal installation inspection process. The proposed ontology aims to formalize thermal insulation inspection planning knowledge and link the on-site inspection information to achieve an automated evaluation of the thermal insulation evaluation. Inspections related to thermal insulation require the integration of data from various and heterogeneous sources, and the choice of technologies associated with ontologies was made to provide a framework for aligning and connecting disparate knowledge.

This paper is structured as follows. Sections 1 and 2 provide a general review of quality assurance and thermal insulation. Section 3 reviews the work on ontologies related to general inspection planning, while Section 4 describes the methodology used to develop the proposed ontology. Next, Section 5 discusses the specifications of OCQA-Thermal Insulation (OCQA-TI) ontology, while Section 6 provides a methodological conceptualization and implementation, which is evaluated using an example in Section 7. Finally, Section 8 discusses the limitations and contributions of the research and provides conclusions.

2. BACKGROUND

2.1 Quality Assurance and Inspection in Construction

Presently, there is a greater focus on comprehensive quality inspections and defect management to satisfy contractors in their construction projects until the client's final acceptance. However, despite these efforts, many gaps and discrepancies are still identified near the project's end. The issues are related to a lack of on-site personnel for managing quality and defects, an overwhelming workload to meet deadlines, non-unified checklists with much manual paperwork, poor communication among different project stakeholders, and a complex and labor-intensive interior finishing process. These problems require additional work to rectify the defects, often leading to project delays (Young S. Kim, 2008). When defects are detected after acceptance, the contractor has claims, so for executing companies, the expense of eliminating defects is worth avoiding defective work at all costs. Moreover, the services of the subcontractors must be checked for defects. Indeed, when a subcontractor's defect is unrecognized before the execution and leads to a defective overall performance, it results in a renewed execution (Langen & Schiffers, 2005).

Currently, construction projects have become increasingly complex. Hence, the more complex the construction projects and processes, the greater the quality risks and the relevance of undistributed information and communication processes in the planning and construction process (Böhmer et al., 2022), often leading to avoidable errors. In addition, decisions regarding quality inspections, including construction activities not to overlook and tasks to inspect, the quality data to be collected and verified, and the acceptance criteria for quality, are evaluated on-site by inspectors based on their previous experiences, which can vary from one inspector to another (Tan, 2010). This variation may arise for several reasons, such as a lack or absence of knowledge concerning regulations or feeling overwhelmed by the amount of regulatory text referenced for applicable provisions during quality inspections. As a result, manual verification of construction quality compliance has been a time-consuming and error-prone task (C. Eastman, 2009).

Therefore, construction inspectors require assistance with planning inspections to effectively define inspection objectives, explore various options, and efficiently allocate inspection resources. Thus, the inspection planning process can be divided into four steps (Lin, 2018) used to specify inspections by answering key inspection planning questions (DIN9001, VDI2619). First, the necessity of inspecting a characteristic (what?) is determined, and the associated inspection objects are defined. Second, the inspection time (when?), frequency (how many?), and scope (how much?) are determined. The third step defines the inspection procedure (how should the inspection be conducted?) and equipment (what materials are required for the inspection?), which must be simultaneously conducted since they are interdependent. This step also includes the inspection location (where is the inspection?) and the inspector (who is inspecting?). Finally, the fourth step determines the recording, management, and evaluation of the collected inspection data (Lin, 2018).

Furthermore, the agreed quality must be clarified as a building requirement to assess the objective quality and secure the success of construction work. In Germany, this clarification results from the general contractual conditions, the performance specifications, and the technical contractual conditions, according to §1 Para. 2 VOB/B. The construction target and, thus, the quality requirements of each construction project vary according to the project-specific performance specifications and contract components. A minimum set of requirements is ensured in German construction law in §1 para. 1 VOB/B by the obligatory agreement on the provisions of VOB/C, the General Technical Terms of Contract for Construction Work (*VOB*, 2016).

Moreover, verification in the form of testing activities is necessary per DIN EN ISO 9000 to ensure the quality of construction projects. Therefore, meeting the specified requirements should be verified using objective proof (ISO 9000:2015). In the construction industry, these inspection activities are conducted with structural acceptances divided into the following types: internal acceptance (according to the quality management plan) and acceptance under public law. Hence, a defect exists if the executed construction work deviates negatively from the contractual construction target (Berner et al., 2015).

2.2 Semantic Web and Ontologies

Data in the construction industry is generated in isolated systems and exchanged using various file formats, often with an insufficiently described relationship. The semantic web and associated linked data concept offers technical standards for a comprehensive, machine-readable exchange of heterogeneous information (Beetz et al., 2021). In a semantic web context, ontologies describe a shared conceptualization of a specified knowledge domain in a community of users. Therefore, using semantic web technologies, an ontology represents a part of the real world in a semantic model (Synak et al. 2009).

The foundational semantic web language is the Resource Description Framework (RDF), and its data structure is organized in triplicate, consisting of a subject, predicate, and object. The subjects and objects are depicted as nodes, while predicates are represented as edges connecting these nodes. As such, these RDF structures are often referred to as triplestores or RDF stores (Hitzler et al., 2008). These RDF structures are characterized by directed and labeled graphs (Herman 2004).

The capabilities of the RDF are further enhanced by additional languages and schemas, such as the Resource Description Framework Schema (RDF-S) and the Ontology Web Language (OWL). For instance, RDF-S broadens the scope of the RDF schema by introducing classes and defining properties. In comparison, the OWL utilizes RDF-F to represent ontologies and extends the model by establishing constraints among classes, properties, and entities (Allemang et al., 2020).

Typically, ontology knowledge provided by semantic web technologies is divided into two main components: an assertion box (A-box) and a terminology box (T-box). In some semantic web applications leveraging a specific rule language, an additional component, a rule box (R-box), is included. The T-box holds intentional knowledge or the terminology outlining a specific domain using a database schema-like vocabulary that incorporates classes, properties, and relations. The T-box's concepts remain constant and do not vary over time. In contrast, the A-box manages the facts tied to the terminology terms introduced by the T-box. In this way, the A-box instantiates the predefined classes and conceptual model with real-world individuals. It encompasses extensional knowledge about specific situations likely to change over time (Baader et al. 2007; Baader et al. 2017; Pauwels et al. 2017).

3. ONTOLOGY WORKS RELATED TO INSPECTION PLANNING

As we step into a new era of digital transformation in various sectors, there has been a surge of research and development efforts in the field of ontologies. Some have been particularly related to construction and inspection planning. Thus, this section aims to provide a comprehensive literature review starting with general ontology work in the construction domain and ontologies used in inspection planning.

Recently, ontologies have become increasingly relevant in the AEC sector, addressing challenges like data integration and knowledge management (Pauwels et al. 2017). Various ontologies have been created in the construction field, including the generic e-COGNOS (El-Diraby et al. 2011) and IC-PRO-Onto (El-Gohary et al. 2010). These ontologies, while comprehensive, lack a detailed representation of construction inspection, necessitating further expansion for accurate inspection representation. Therefore, further development resulted in Digital Construction Ontologies (DiCon) by Zheng et al. (2021), defining broader construction workflow-related entities and successfully integrating data from diverse systems. Beyond construction, ontologies such as IFCOWL (Pauwels 2016) and the Building Topology Ontology (BOT) by Rasmussen et al. (2020) have offered valuable semantic structures for building information modeling and topological concepts, respectively.

In the realm of construction execution, ontologies have made significant strides in addressing issues such as construction data integration and knowledge management. Therefore, this section focuses on ontologies specifically tailored to construction quality inspection. Zhong et al. (2012a, 2012b) introduced the CQIEOntology for quality management. This ontology primarily focuses on quality compliance checking while supporting inspection planning in an ancillary manner. The ontology expresses complex constraints usually found in quality regulations using the Semantic Web Rule Language (SWRL). This ontology-based approach enhances the construction quality inspection process by integrating these regulations within the construction process.

Martinez (2019) proposed an alternative method involving SPARQL queries to retrieve quality regulations based on the construction object and materials used, as specified in the ontology. Although the study primarily focused on predefined checklists, it overlooked the planning and preparation of quality inspections. The research aimed to primarily explore offsite manufacturing processes related to drywall steel frames.

Lastly, Xu (2019, 2021) developed the Highway Construction Inspection Ontology (HCIOntology), formulating inspections based on pay items and specifications defined by the Indiana Department of Transportation. The user interface allows users to select predefined check items based on to-be-inspected pay items, supported by a risk matrix. These check items contain various fixed characteristics of inspections, such as frequencies, objectives, checking conditions, and training documents.

The review demonstrated that ontologies are viable for formalizing construction domain knowledge. However, it also indicated insufficient effort is spent integrating diverse information sources and making inspection planning knowledge of multiple domains (e.g., trades) available. Additionally, the inspections are inadequately described and undefined in light of the shared terminologies provided by ISO 9000, ISO 9001, and DIN 55350. Research has also neglected inspection planning for finishing trades, specifically the thermal insulation trade. Therefore, this research paper aims to 1) prove the reliability of OCQA for multiple trades, 2) provide knowledge for inspection planning of the thermal insulation trade, and 3) integrate heterogeneous information defined in isolated systems related to thermal insulation inspection planning.

4. METHODOLOGY

Concerning OCQA, a hybrid approach was adopted based on the Linked Open Terms (LOT) methodology developed by Poveda et al. (2022). LOT was designed as an industry-oriented ontology development methodology more related to practical engineering cases than others and has been well evaluated through practical use. Furthermore, the activities in applying LOT are described in detail and documented on GitHub (Poveda-Villalón et al., 2022). The detailed process of the ontology's development methodology is illustrated in Figure 1. The process is divided into four phases: 1) specification, 2) implementation, 3) publication, and 4) maintenance.

The specification phase defines the ontology's scope, purpose, use cases, users, and requirements (Fernández-López, M. et al., 1997). Throughout the entire ontology engineering process, knowledge acquisition remains an ongoing and iterative process. Thus, a conceptualization is created, incorporating existing ontologies and encoding by building upon the specification. Subsequently, the developed ontology is evaluated to ensure its effectiveness.

Various evaluation methods are employed to assess the developed ontology. Following the evaluation phase, the ontology is documented using a Hypertext Markup Language (HTML) sheet. For wider accessibility, the ontology is published on GitHub, enabling a broad range of users and developers to access and reuse it.

GitHub is a valuable platform for ontology maintenance, facilitating collaboration and version control based on a repository (GitHub, 2020). It ensures the ontology remains up-to-date and well-maintained for its users and stakeholders. Thus, the following sections present the process steps of specification, implementation, and publication.

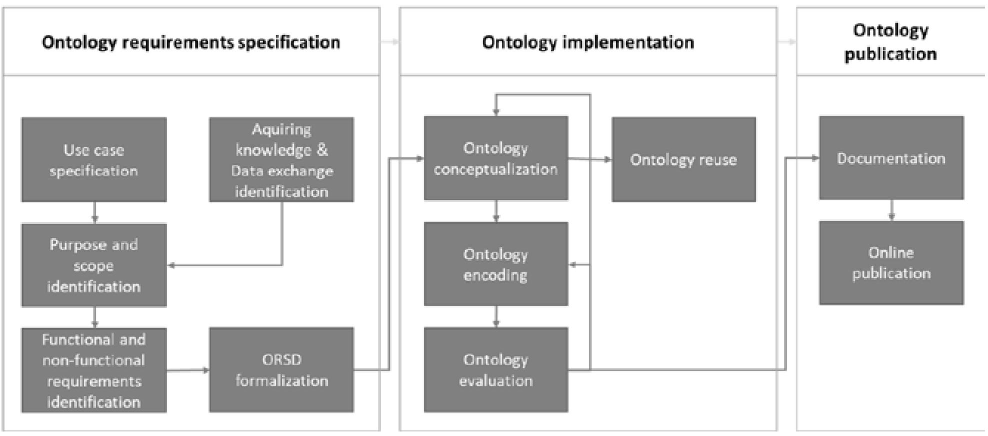

Fig. 1: Ontology development methodology according to Poveda-Villalón et al. (2022)

5. SPECIFICATION

This specification aims to create a formal document in natural language, utilizing competency questions (CQs) as the fundamental requirements (Fernández-López, M. et al., 1997). These CQs are derived from predefined use cases, aligning with the purpose and scope of the respective ontology. The resulting specification document is available on GitHub (Poveda-Villalón et al., 2022). The subsequent discussion formalizes the specification process steps.

Purpose: The ontology aims to formalize inspection plans for the domain of thermal insulation and related information of required domains, providing a shared representation of insulation inspection planning knowledge that specifies the terminology, semantics, and relations of inspection planning in the domain of thermal insulation. The terminology is defined according to DIN 55350:2021 and ISO 9000. Therefore, the purposes of the ontology can be summarized as follows:

1) providing a vocabulary for describing inspection plans and inspections for thermal insulation,
2) supporting manual inspection planning by providing detailed inspection planning knowledge,
3) supporting quality assurance decisions, and
4) strengthening the quality awareness of the staff.

Scope: OCQA-TI mainly focuses on representing the implementation of thermal insulation to ensure its proper installation and performance in new buildings and renovation. It provides structured knowledge on the optimal ways to install thermal insulation depending on the product and technique used while describing the necessary inspections, tests, equipment, and norms required to ensure its quality. Critically, our research focuses exclusively on process planning and the quality assurance of thermal insulation installation.

Use cases: The intended use cases of the ontology can be summarized as follows:

1) information retrieval by using queries,
2) heterogeneous data integration from isolated software solutions,
3) inspection planning support by querying inspection planning knowledge, and
4) inspection plan validation by reasoning.

End users: End users are project managers and management teams responsible for construction supervision, including inspectors, object planners, and building owners, depending on the project organization. In addition, the contractors can use the test plans provided for internal quality assurance. Notably, the users described do not use the ontology directly but interact with it via a software application. The ontology represents a substructure (backend) of software and is only used directly by developers (backend/substructure). Developers program software applications based on the ontology and store the data from heterogeneous sources in the ontology. End users use the ontology via an interface (superstructure or frontend) that ensures user-friendly operation (frontend/superstructure). For this purpose, users are provided with predefined queries for information or inspection planning knowledge retrieval.

Non-functional requirements (NFRs): NFRs pertain to how a system should perform, behave, and operate rather than focusing on what it should accomplish. In the field of construction ontologies, various studies have outlined NFRs, which can be summarized as follows: 1) coverage/sufficiency, 2) consistency, 3) usability, 4) extendibility/reusability, and 5) clarity and conciseness (Costin, A. and Eastman, C., 2017; Zhou et al., 2016; El-Gohary and El-Diraby, 2010; Zheng et al., 2021). These defined NFRs serve as evaluation criteria addressed through various evaluation methods.

Functional requirements (FRs): FRs are CQs aligned with the predefined use case of information retrieval. Table 1 provides a comprehensive list of the CQs that the proposed ontology aims to address based on questions for inspection planning from mechanical engineering that have been extended (Linß, 2018; Marxer et al., 2021).

Table 1: CQs related to the use case information retrieval.

Information retrieval
1. What are the characteristics being inspected?
2. What are the related entities of an inspection?
a. Where is the inspection location?
b. Who is responsible for the inspection?
c. What is the norm related to the inspection?
d. What equipment is required for the inspection?
3. What are the precedent and subsequent inspections?
4. What procedures are required for the inspection?
5. When is the start and end date of the inspection?

6. ONTOLOGY CONCEPTUALIZATION AND IMPLEMENTATION

6.1 Introducing the Ontology for Construction Quality Assurance (OCQA)

The basis for this work is the OCQA ontology (Seiß, 2022), designed to provide information about quality inspections in construction to support inspection planning. The main entities of the OCQA are the inspection, inspection plan, and regulations. The OCQA has a modular structure and can be supplemented as desired with inspection knowledge from different trades. Therefore, the OCQA-TI is designed as a trade-specific extension of the OCQA ontology. In addition, the Digital Construction Ontology (DiCon), with its previously described concepts for construction workflow, including agents, processes, and equipment, is integrated into the OCQA, extending the DiCon with detailed knowledge about inspection plans (Seiß, 2022).

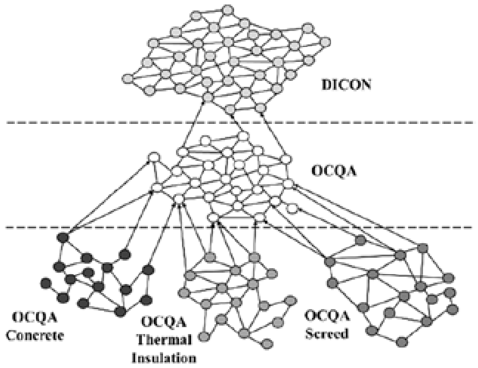

Fig.2: OCQA-TI as an extension of the OCQA

The integration among the various ontologies is depicted in Figure 2 and is achieved through hard reuse via owl:imports. This approach allows the complete and unaltered reuse of the imported ontology (Poveda-Villalón et al., 2022). The OCQA ontology also includes trade-specific modules catering to task-specific inspection planning. For instance, the OCQA-screed extension encompasses all inspections related to the screed trade. The OCQA-TI will be developed as a trade-specific extension of the OCQA.

6.2 OCQA – Thermal Insulation (OCQA-TI)

This section overviews the OCQA-TI and the associated ontologies in detail. Therefore, the classes, relations, and properties needed to describe inspections related to the domain of thermal insulation appear in Figure 3. The top of Figure 3 illustrates the DiCon ontology and the main classes used as a basis to define the OCQA. The OCQA provides the general terminology to describe inspections, which the OCQA-TI will use to specify inspections for the trade of thermal insulation.

Representing all aspects of the thermal insulation inspection was essential to conduct it, including the actual inspections, the corresponding inspection plan, inspection equipment, personnel involved, inspection procedures, and inspection regulations through specific classes within the DiCon and OCQA ontologies, defined as subclasses of the DiCon ontology. The *ocqa:Inspection* class is a specialized subclass of *dicp:Activity* class, highlighting its unique role in the context of activities defined by DiCon.

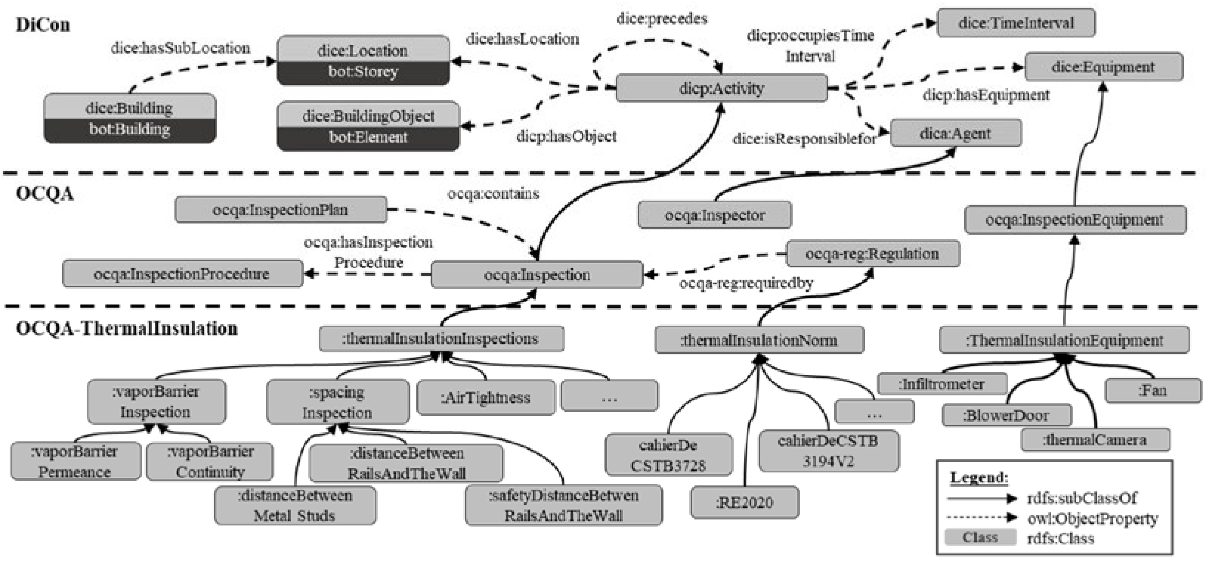

Fig. 3: Overview of classes, relations, and data properties of OCQA-TI and aligned ontologies.

The OCQA-TI is an ontology extension that enhances and refines the OCQA ontology, building on the DiCon ontology's foundational concepts. Within the OCQA-TI, the *:ThermalInsulationInspection* class represents various types of thermal insulation inspections like *:SpacingInspection*, *:AirTightnessInspection*, and *:VapourBarrierInspection* and is connected to the *ocqa:Inspection* class in the OCQA, signifying their specific role within the scope of quality inspections. Moreover, the *Inspection* class links to the *ocqa:InspectionPlan* class through the object property *ocqa:contains*, establishing a relationship between inspections and their inclusion in inspection plans. Additionally, *the ocqa:hasInspectionProcedure* object property connects the *ocqa:Inspection* class to the ocqa:InspectionProcedure class, specifying the procedures associated with each inspection. The *:ThermalInsulationNorm* class in the OCQA-TI, encompassing norms relevant to each thermal insulation inspection like RE2020, cahierDeCSTB3728, and cahierDeCSTB3194_V2 is introduced by the object property *ocqa-reg:requiredby,* which link this class to the *ocqa-regulation:Regulation* class.

Furthermore, the *:ThermalInspectionEquipement* class is introduced to describe the equipment required for thermal insulation inspections like *:ThermalCamera*, Infiltrometer, and *:BlowerDoor* and is directly linked to the *ocqa:InspectionEquipement* class in OCQA, which, in turn, is connected to the *dice:Equipment* class in the DiCon ontology, establishing a hierarchy of equipment concepts. Through these interconnected classes and object properties, the ontologies provide a comprehensive framework for managing and understanding thermal insulation inspections in the construction industry, utilizing construction quality assurance and workflows.

7. ONTOLOGY EVALUATION

The ontology evaluation is essential to check whether the developed ontology meets all the predefined requirements in the specification process (Fernández-López, M. et al., 1997). Different evaluation methods can be used to check compliance with different criteria (Zheng et al., 2021; El-Gohary and El-Diraby, 2010). This research evaluates the proposed OCQA-TI by automated consistency checking, CQs, and a task-based evaluation.

7.1 Automated Consistency Checking

Automated consistency checking aims to assess the developed ontology's consistency, guaranteeing no logical conflicts or inconsistencies. This process is achieved with description logic (DL) reasoners to assess the logical coherence of the ontology and maintain its integrity by ensuring there are no contradictions. Regarding the OCQA-TI, the automated consistency checking was conducted within the Protégé environment using the built-in Pellet reasoner. The automated consistency checking results showed that the OCQA-TI is consistent and coherent.

7.2 Answering the CQs and Task-Based Evaluation

We obtained practical inspection data from a residential building project about air tightness inspections, which are essential to ensure the condition of the air permeability before proceeding with the installation of thermal insulation. The assessment involved of implementing blower door tests while utilizing an infiltrometer as the specialized equipment to measure the value of the air permeability. The blower door tests were aligned with the stipulated guidelines of the RE2020 regulations, in which an air permeability constraint requires the measured value should be less than 0.6m3/(h.m3) for individual building types and 1m3/(h.m3) for residential building types.

The above example data was mapped and instantiated to OCQA-TI for two evaluation tasks. First, we used the instance data for answering the specified CQs. For the OCQA-TI, a SPARQL query was conducted to retrieve the target information of the thermal insulation inspection task to answer the example-specified CQs adapted from ontology CQs defined previously to check the coverage of the ontology. The CQs and results appear in Table 2. The results show that the OCQA-TI can retrieve accurate inspection information to answer the CQs, proving that OCQA-TI satisfies the ontology coverage criteria.

Second, based on the obtained data, we conducted a task-based evaluation to assess the usability of the proposed OCQA-TI ontology to solve a particular task. In this case, we conducted a use case to check if the measured air permeability values satisfied the RE2020 constraint. A SPARQL was conducted to identify the location where the air permeability value did not fit the constraint to provide the site manager with useful information to support awareness of the site condition and take actions to solve issues that occurred to ensure the upcoming tasks. The SPARQL query and result appear in Table 3. The result shows that the air permeability value in Zone B was 1.2, exceeding the maximum value in RE2020. Thus, the site manager should consider reducing the air permeability in Zone B to ensure the following insulation installation work. In summary of the task-based evaluation, the OCQA-TI can be used to check the inspection with the compliance of constraints from the norms.

Table 2: Specified CQs and answers based on the task of the blower door test.

Information retrieval	Answer
1. What are the characteristics being inspected by inspection :*Test001*?	*:AirPermeability _7832-3783-173*
2. What are related entities of an inspection?	
a. Where is the location of an inspection?	*:ZoneA*
b. Who is responsible for the inspection?	*:Inspector_XYZ*
c. What is the norm related to the inspection?	*:RE2020*
d. What equipment is required for an inspection?	*:NQ80YU64K*
3. What are following/precedence inspections of an inspection?	:*Test002*
4. Which procedure is required for an inspection?	*:BlowerDoorTest*
5. When is the start and end date of the inspection?	Start: *:04072023-1* End: *:04072023-2*

Table 3: SPARQL query and the result of air permeability constraint checking.

SPARQL query

```
SELECT ?test ?location ?value ?characteristic
WHERE {
  ?inspection a ocqa:Inspection .
  ?inspection ocqa:hasSubInspection ?test .
  ?test dicp:hasLocation ?location .
  ?location :hasAirPermeability ?characteristic .
  ?characteristic ocqa:hasAssignedCharacteristicValue ?AssignedCV .
  ?AssignedCV :maxvalue ?maxvalue .
  ?characteristic ocqa:hasActualCharacteristicValue ?ActualCV .
  ?ActualCV :value ?value .
  FILTER (?value > ?maxvalue)
}
```

Result illustrated in GraphDB

	test	location	value	characteristic
1	:Test002	:ZoneB	"1.2"^^xsd:double	:AirPermeability_7832-3783-174

8. CONCLUSION

In conclusion, poor construction quality remains a significant challenge in the construction industry, leading to increased costs and avoidable damage. Therefore, this paper proposed an innovative solution by developing the OCQA-TI. This ontology extension was designed to tackle the complexities of inspection planning and evaluation in thermal insulation and enhance the overall quality assurance process.

The research successfully extended the OCQA to incorporate thermal insulation, allowing for the description of insulation inspections and finishing trades. By bridging the gap between required and actual inspections on construction sites, the ontology provided proper knowledge, semantics, and terminology specific to thermal insulation, supporting inspectors and project teams in making informed decisions during an inspection. Additionally, the ontology facilitated gathering and integrating heterogeneous data from various software applications, promoting the traceability of information between systems. It also offered a practical solution for handling conflicting product guidelines, allowing references to guidelines instead of norms, thereby ensuring dual compliance with specific product requirements and regulatory norms.

This ontology development is expected to significantly improve construction site quality by enabling proactive defect prevention and enhancing the efficiency of inspection planning. With comprehensive and project-specific inspection plans readily available, construction teams can reduce the impact of work by better adhering to the inspection plans and rectifying any issues promptly. However, while the OCQA-TI ontology presents a valuable contribution, no ontology can be considered the definitive or best solution. As construction practices, regulations, and technologies evolve, continual improvement and updating of the ontology will be necessary to maintain its effectiveness.

Admittedly, there are several limitations of this study which are summarized as follows. First, the proposed ontology-based approach of thermal insulation inspection planning relies on the construction domain knowledge such as norms, standards, and production codes, which may be different in different regions or countries. For example, in this research, we adopt RE2020 to model the constraints, which is the French regulation that may not be applied to other countries. Therefore, to improve the usage of OCQA-TI globally, further efforts are needed to collect more international domain knowledge into the ontology. However, it is difficult to achieve by a single research team. Thus, in the future, we are aiming to provide a shared knowledge platform based on the OCQA-TI to collect more comprehensive knowledge for inspection by interaction and collaboration of users in different countries. Second, ontology needs to be continuously updated and maintained corresponding to changes of the domain knowledge and accommodating new inspection procedures, equipment, and reference values. Third, the ontology has not been fully applied or utilized on construction sites. Therefore, future research may expand the ontology to cover additional construction trades, enabling a comprehensive and interconnected quality assurance framework for various construction activities. Moreover, investigating automated inspection planning for the OCQA-TI using rule languages or other advanced technologies could further enhance the ontology's usability and efficiency. Additionally, there is the challenge of testing these technologies on a construction site in a real-world context, while also considering the socio-economic implications for construction workers and inspectors.

Overall, the OCQA-TI ontology offers a knowledge-driven approach to thermal insulation inspection planning, promoting enhanced information retrieval and data integration while supporting quality assurance decisions. By enabling early defect detection and addressing implementation issues, the ontology contributes to improved energy efficiency, interior comfort, and reduced building maintenance costs. As the construction industry continues to evolve, adopting such knowledge-driven approaches is crucial for ensuring safer, more durable, and energy-efficient buildings in the future.

AN AUTOMATED FRAMEWORK FOR ENSURING INFORMATION CONSISTENCY IN PRICE LIST TENDERING DOCUMENT

Chiara Gatto, Maryam Gholamzadehmir, Marta Zampogna, Claudio Mirarchi & Alberto Pavan
Polytechnic of Milan, Italy

ABSTRACT: *Effective cost estimation for tendering plays a critical role in the building construction process, enabling efficient investment management and ensuring successful execution of the construction phase. Traditional cost estimation procedure involves manual information processing to extract and match technical data from textual description construction resources. This activity requires practitioner deep experience and manual effort, often resulting in errors and, in the worst scenario, judicial disputes.*

In response to the increasing demand for structured information and automated processes, this study addresses the need for Public Administrations to achieve better control over the data contained in public tendering documents provided to practitioners. To fulfill this objective, a framework is proposed to automatically retrieve information from these documents, serving as a support tool to map items within the documents, highlight missing data, and critical semantic ambiguity.

The designed framework aims to develop a tool for automatically identifying similarities between work items and their corresponding elementary resource items in Price List tendering documents. By leveraging the information retrieval NLP technique of cosine similarity through TF-IDF, a methodology was developed to support and facilitate practitioners' activities. Finally, the framework was tested on four case studies extracted from Lombardy Regional Italian price list documents showing that the resulting support tool is able to automate the analysis process and efficiently reveal inconsistency. The model successfully extracted and correctly matched the elementary resource to the corresponding work query in 75% of the cases where the elementary resource was present in the list. Additionally, the model proved to be a valuable tool in helping practitioners identify missing resources.

KEYWORDS: *Automated cost estimation, Information retrieval, Text similarity, NLP, Tendering document, Public Administrations*

1. INTRODUCTION

Cost estimation plays a pivotal role in effective decision-making within construction project management. Numerous studies underscore its significance (M.E.Sepasgozar et al., 2021). However, traditional construction cost estimation often involves multiple manual processes, with limited automation, resulting in time-consuming efforts and susceptibility to human errors (Akanbi & Zhang, 2021). Despite the increasing use of BIM approaches, information exchange in AEC industry is still mainly based on the production of paper-based documents. These documents are often written in natural language, conveying knowledge through unstructured or semi-structured data. Natural language is by nature unstructured, and it is therefore difficult to be digitally managed. Manually data extracting can lead to discrepancies and inaccuracies in information, thereby posing financial risks, project delays, potential failure, and in the worst case scenario to judicial disputes (Jafari et al., 2021a). These issues impact the effectiveness of the projects along with the credibility/reputation of the stakeholders. Moreover, the gap between traditional document-based (i.e., semi-structured and unstructured) and model-based information can lead to information loss and inconsistency. (Opitz et al., 2014). Thus, effective data management turns out to be essential to the overarching project strategy.

Public administrations play a key role in the construction process, especially in the context of public procurement where they assume the role of contracting authorities. These entities encounter a large daily influx of data, much of which needs to be made accessible to external stakeholders. Among these diverse datasets, a significant portion consists of unstructured textual information. Consequently, there is a need for these administrations to enhance their data management capabilities.

Effectively addressing these challenges necessitates the adoption of a methodology capable of efficiently handling and structuring the considerable volume of semi-structured and unstructured data for tasks such as cost and time estimation. Within this framework, data pre-processing emerges as a fundamental phase, acknowledged for its role as the most time-intensive aspect of text classification.

Chiara Gatto, Maryam Gholamzadehmir, Marta Zampogna, Claudio Mirarchi, Alberto Pavan, *An Automated Framework for Ensuring Information Consistency in Price List Tendering Document,* pp. 837-847, DOI 10.36253/979-12-215-0289-3.83

To address the aforementioned issues, and to meet the growing demand for public administrations and practitioners to convert textual information into digital formats, this research proposes a methodology to develop a procedure for checking information consistency within price list tendering. This is achieved through the application of Natural Language Processing (NLP) techniques, ensuring the coherence of information within the document. The methodology focuses on confirming the alignment between work descriptions and the employed elemental resources. The proposed research activity follows the prior study focused on automating the process of structuring data from textual documents (Gatto et al., 2023). Specifically, this research shifts the focus on responding to the public administration's need to assess the consistency of information within the regional price list before structuring and subsequently providing it to the user, by verifying the correspondence between the textual information related to the construction works and the textual information of the respective elementary resources involved.

To minimize semantic ambiguity and enhance machine comprehension without human intervention, data in textual documents can be handled using NLP, which has demonstrated its efficacy in supporting human activity (Zabin et al., 2022). In this direction, (Tang et al., 2022a) developed NLP and rule-based algorithms to automate the information extraction from work descriptions in building construction. They integrated different algorithms such as Hidden Markov model and improved the accuracy by 89% compared to other common named entity recognition algorithms. However, despite the wide application of NLP in different construction fields, the application of these techniques in the pre-design phase is still a research gap in the literature (Locatelli et al., 2022). Data pre-processing of unstructured data is known as the most time-consuming phase of text classification in the whole process (Munková et al., 2013).

This research is organized as follows: The initial section, "State of the Art," presents the research background. Following that, the "Research Methodology" and "Framework Development" sections detail the study's approach and implementation. The subsequent segments, "Testing Framework" and "Results and Discussion," demonstrate the practical application of the framework and its evaluation. Ultimately, the "Conclusion" section encapsulates the key findings from the study.

2. STATE OF THE ART

Manual extraction of reporting requirements from extensive construction documents can lead to time and cost underestimations. In this direction, the application of NLP techniques has been increasingly adopted in the AEC sector to manage the information contained in documents ((Jafari et al., 2021b); (J. Zhang et al., 2020)). NLP is mainly applied in four scenarios of information extraction, document organization, expert systems, and automated compliance checking (Wu et al., 2022).

Recently, NLP has been used in the construction industry to facilitate cost estimation through document management (Tang et al., 2022b). To automate extracting information from construction regulatory documents, a study has been developed by applying a semantic rule-based NLP approach for a text recognition algorithm based on semantic analysis (J. Zhang & El-Gohary, 2016). In a later study, an automated framework was developed using NLP and machine learning techniques to automatically recognize and prioritize important contract terms, enabling managers to quickly and fully understand contract agreements (Hassan & Le, 2020). Furthermore, a model that automatically identifies the most relevant pairs of provisions from various specifications using semantic text similarity was developed (Moon et al., 2021). This assists practitioners by reducing the effort to complete tasks that involve written documents, enhancing the objectivity of outcomes, and minimizing human errors.

In the construction industry, dealing with inconsistent information, semi-structured and unstructured data in price list documents is an ongoing challenge. The causes of these issues often include human errors during data entry, outdated price lists, and issues with the software tools used for creating BIM models and price lists (Cha & Lee, 2018). These issues can cause inaccurate cost estimates, budget overruns, delays in project timelines, and disagreements between project stakeholders.

Concerning the inconsistency and ambiguity checking, a recent research activity has been performed using the support vector machine (SVM) supervised learning model methodology, leading to an automated method for detecting ambiguity in building requirements, which can then be reviewed and interpreted by domain experts to support the automated compliance checking process (Z. Zhang & Ma, 2023). In another work, the authors proposed an uncertain knowledge graph-based method to eliminate potential conflicts and acquire the 'most likely scenarios' by integrating multiple representations of building information (Xie et al., 2023).

Document classification is crucial in the process of digitizing and structuring information. Text data pre-processing serves as a foundational step for this process (Lee & Yi, 2017). Text classification as part of NLP, involves the automated categorization of text. This task can be accomplished using two main approaches: rule-based techniques and Machine Learning (ML) algorithms.

The conversion of textual information into digital formats is necessary for the building tendering process. The digitalization process not only enhances the accessibility and usability of the information but also opens up new scenarios for data analysis and decision-making. Application of advanced technologies such as NLP and machine learning, can automate the structure of price lists and show similarities between products and their corresponding resource items. This can help practitioners improve the consistency of information in documents.

2.1 Research gaps and challenges

As the construction industry continues to embrace digital transformation, the application of NLP has emerged as a promising area of research. NLP has the potential to revolutionize various aspects of construction, from project management to BIM. However, the integration of NLP into the construction sector faces some challenges that are explained in this section to highlight future research interests in this field.

(Ding et al., 2022) provided a review of the NLP-related research articles in the construction field and they pointed out related challenges such as data accessibility/monopoly to develop the intelligent agent and data diversity from various devices, such as text, images, sensors, and audio, presenting a challenge in developing comprehensive models with higher performance. Additionally, they mentioned that achieving full automation and high-level reasoning requires advanced extraction and understanding of models because NLP models can struggle with understanding the complex technical context in construction.

Another challenge is achieving semantic interoperability between BIM and NLP in the construction industry. The use of ontology as a bridging tool is a potential solution to address this gap, yet this area remains underexplored (Locatelli et al., 2021).

2.2 Tendering documents

Tender documents serve as a communication tool between the project owner and potential contractors, outlining project specifications, execution conditions, and the rights and obligations of all parties. The clarity of these documents is important to avoid financial disputes. The type of tender documents depends on the procurement method and contract type, and typically include drawings, specifications, and bills of quantities (Cunningham, 2015).

The quality of tender documentation can significantly impact on the procedure, alongside other factors like contract content and tender management. Despite the challenges, contractors must carefully prepare their bids to increase their chances of securing the contract (Leśniak & Janowiec, 2020).

Construction projects, seen as transient businesses, require careful project management, particularly during the tendering process. This process, which involves numerous variables and substantial resources, is influenced by factors such as the financial stability of contractors, offered price, delivery timeline, experience, environmental considerations, and personnel qualifications (Naji et al., 2022).

The Public Italian Contracts Code, art.23 D.lgs 18 Aprile 2016, n.50, imposes on each Italian region to annually provide a price list that contracting authorities have to use for setting the project cost base for tenders. Therefore, each region provides practitioners with a price list containing work items and their respective cost (Sdino & Rosasco, 2021). The tool mainly stores data associated with construction activities, including their unit prices. This resource assists practitioners in generating estimated metric calculations. Additionally, to ensure more transparency in the composition of the price of construction works, the price list provides a catalog of elemental resources involved in the latter. Therefore, there must be a full correspondence between works and elemental resources, otherwise inconsistency arises. Considering the need for annual updates, the price list is subjected to periodical revisions, consisting in the unit prices update, the addition of new work and elementary resource items or removal of outdated entries.

Information is conveyed by the tool in verbal form: sentences composed by words and syntax delivering knowledge. Since each item is written in natural language and because the document doesn’t follow a standard in providing information, a lack of homogeneity has been recorded between each item phrase structure and information typology transmitted. Public Administrations therefore are looking for tools to help them structure high amount of data.

3. RESEARCH METHODOLOGY

The methodological approach employed in the presented study is explained in this section and summarized as depicted in Figure 1Figure 1 Methodology chapter. Firstly, the development of the study starts by listening to the needs of public administrations in the AEC sector, who have been engaged to comprehend the challenges they face in managing information during public tendering processes. Following the prior study focused on automating the process of structuring data from textual documents (Gatto et al., 2023), a need emerged from public administrations to incorporate a preliminary step to assess the consistency of information within the regional price list before structuring and subsequently providing it to the user. The subsequent step was to explore the state of the art, aiming to delve into tools and methodologies applied for automating the management of unstructured data. This was followed by the development of a framework, leveraging information retrieval NLP techniques. Specifically textual similarity recognition based on cosine similarity using TF-IDF, was selected to build a tool designed to aid public administrations in establishing associations among essential resources within a construction project, thereby highlighting any gaps that may exist. This technique has proved to be valuable and effective within the domain of text similarity and in this study it is applied in the specific field of cost estimation, focusing on price list documents. Finally, the framework was tested in a practical case study to assess its effectiveness.

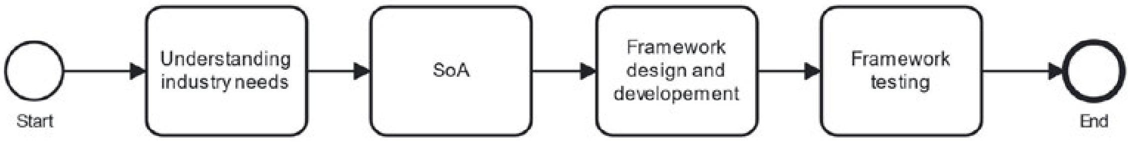

Figure 1 Methodology chapter.

4. FRAMEWORK DEVELOPMENT

This section presents the design and development process of the framework, as synthesized in Figure 2. The objective of this phase is to develop a comprehensive procedure for checking information consistency within price list tendering documents using Natural Language Processing (NLP) techniques, specifically aimed at verifying the correspondence between the textual information related to the construction works and the textual information of the respective elementary resources involved. The primary goal of public administrations is to provide users with a tool that ensures utmost clarity, free from semantic ambiguities and inconsistencies during the crucial phase of estimating construction costs.

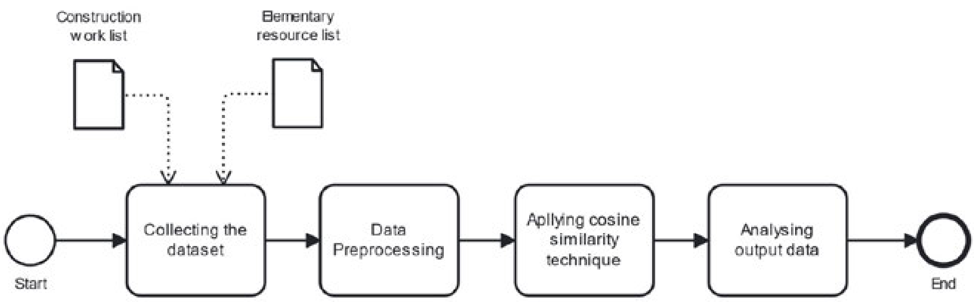

Figure 2 Framework flowchart.

By leveraging NLP technique, this framework allows the public administration to speed up the process of addressing elementary resource item to the work items where it is involved, thus helping with the detection of missing information and inconsistencies, ensuring the accuracy and reliability of how the data is presented to the user. The parameterization of information through NLP techniques empowers public administrations with greater control over the textual dataset, facilitating easier data manipulation and analysis. Furthermore, this process seeks to address the longstanding issue of ambiguity that often arises from cost item descriptions, ensuring a higher level of accuracy and precision in subsequent analyses and decision-making processes.

The developed framework mainly consists of four stages.

The first step in the process involves collecting the dataset, which comprises both the list of completed works and the corresponding list of elementary resources involved. The work's textual descriptions typically explicitly state the elementary resources utilized in the activity, allowing practitioners to identify them accurately. Once the dataset is assembled, it undergoes a pre-processing phase to ensure the correct execution of the subsequent steps.

Since the description of the elementary resources is expected to be contained in the description of the works, the cosine similarity technique using TF-IDF is chosen for the development of this framework. This measures the similarity between two vectors, A and B, by calculating their dot product and dividing it by the product of their magnitudes as:

$$(|A||B| * \cos(\alpha))/(|A||B|)$$

The resulting value ranges between 0 and 1, where 0 indicates no match (completely dissimilar vectors), and 1 represents complete similarity (vectors pointing in the same direction). This metric is widely used in text analysis to measure document similarity. TF-IDF is primarily concerned with determining the importance of words within individual documents and in literature is commonly used for tasks like information retrieval and document ranking, and in text. Alternatively, the utilization of cosine similarity through Word2Vec is centered around capturing semantic meanings. This is achieved by representing each word as a dense vector within a continuous space. Notably, certain studies have suggested that for text similarity, TF-IDF often outperforms the other method, highlighting its effectiveness (Sitikhu et al., 2019).

Once the dataset has been collected and the NLP technique to be used identified, the next step is to vectorize the list of elementary resources dataset and query them with the respective work descriptions, with the aim of deriving the elementary resource item associations. The cosine similarity technique allows to rank the list of elementary resources based on their similarity to the work descriptions, with the most similar resources being assigned with higher score similarity value.

After obtaining a ranked list of elementary resources associated with each work description, building construction cost estimation practitioners were involved to validate the accuracy and effectiveness of the output results. They carefully reviewed the output and assessed whether the correctness of the output with a higher score rate. The expert validation process not only serves as a critical quality control measure but also provides valuable insights and feedback, enhancing the overall robustness and practical applicability of the framework.

5. TESTING FRAMEWORK

In this section, the testing process of the framework is presented, with the aim of assessing its capability to accurately determine the appropriate elementary resource for each work item. The evaluation was conducted using four sample case studies extracted from the Lombardy Region Price List document (January 2023 version). The objective was to verify the framework's ability to assign the correct elementary resource to four specific types of works: masonry clay block, masonry concrete block, tile floor, and thermal insulation work.

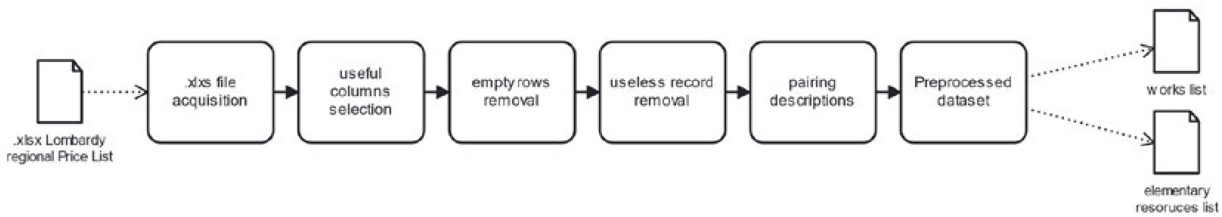

Figure 3 Preprocessing flowchart.

To ensure effective vectorization and handling of relevant information, dataset pre-processing plays a crucial role. The steps undertaken during this phase are depicted in Figure 3. As explained later, the pre-processing is focused on isolating and extracting the pertinent textual data; however, it does not involve further cleaning, such as removing stop words or those that appear with high or limited frequency in the text. The objective is to retain the essential context and meaningful information while preparing the data for vectorization and subsequent analysis.

Data was acquired from a single spreadsheet. where the knowledge organization follows a semi-structured format as shown in Figure 3, consisting of seven columns in the following order: item ID code, textual description, unit of measurement, unit price, percentage of labor incidence, percentage of material incidence, and percentage of equipment incidence.

CODICE	DESCRIZIONE	U.M.	P.U.	% Inc. M.O.	% Inc. MAT	% Inc. ATT
1C.06.100	MURATURE FACCIA A VISTA	NaN	NaN	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN
1C.06.100.0050	Muratura faccia a vista con mattoni pieni tipo ...	NaN	NaN	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN
1C.06.100.0050.a	- con mattoni 25 x 12 x 5.5 cm, spessore 12 cm	m²	98,31	33,90	41,38	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN
1C.06.100.0050.b	- con mattoni 25 x 5.5 x 5.5 cm (bastonetto), ...	m²	88,99	36,52	40,52	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN
1C.06.100.0100	Muratura faccia a vista con mattoni semipieni ...	NaN	NaN	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN

Figure 4 Raw dataset.

The raw dataset is characterized by many rows with null records, therefore, after the acquisition of the Lombardy Regional Price List document, the first step performed for cleaning the dataset is the removal of empty rows. Subsequently, only the useful columns have been selected, containing the ID code information and textual description of items.

Moreover, the hierarchy knowledge of information, such as chapters and sub-chapters, is provided by the price list tool by code length. The shorter the code, the higher is the hierarchical level of information; conversely, the longer the code, the deeper is the hierarchical level of information transmitted. In Figure 4, the first record characterized by the code "1C.06.100" represents the chapter referring to the exposed brick wall works, while the records with longer codes are the specific work activity within the masonry chapter. For the achievement of the objectives set within this paper, the data type to work with belongs to the last hierarchical level, where data are conveyed with the highest level of detail through textual items description. Work and elementary resource descriptions which a unit price is associated with are characterized by a code length higher than 13 digits.

Since elementary resources could be described at both single code and parent-child code levels, the last pre-processing step involved pairing the child entries with their respective parent entries, ensuring the framework's accuracy in resource assessment, as shown in Figure 5, where the process of pairing items description is shown.

By following these steps, we ensured that only relevant and properly organized data were used in the testing process, further validating the framework's effectiveness in elementary resource allocation for construction works.

The following stage consists of the cosine similarity technique application. Scikit-learn library have been used for

```

Figure 5 From left to right, the process of pairing child entries with their respective parent entries.

this purpose importing in a Google Colab notebook the *TfidfVectorizer* class and using the function *cosine_similarity*.

Descriptions from the elementary resource list are converted from textual to numerical representation through TF-IDF feature extraction action, obtaining a sparse matrix. This process effectively maps the vocabulary of the dataset's domain knowledge. As a result, each phrase in the dataset is transformed into a vector within the TF-IDF feature space, representing its unique characteristics in relation to the entire corpus of documents.

Later, the same process is repeated for a single description query, which comes from the works list. This query is transformed into a TF-IDF feature vector using the *TfidfVectorizer* that was fitted on the product descriptions.

Finally, the *cosine_similarity* function calculates the similarity between the query and all records (product descriptions) in the product list. This provides a similarity score for each elementary resource within the list with respect to the query. The products characterized by the most similar description to the query are retrieved by sorting the similarity scores in descending order, from the highest to the lowest value. For this study, it was decided to recall only the first 5 products, leaving out the later ones.

In the table below it is shown an example of the framework, by querying the list of products with the “1C.06.050.0100” work, whose description is “Semi solid masonry wall, 8 x 12 x 24 cm, with cement mortar, including the charge for the formation of shoulders, vaults, corners, pilasters, internal worktops”. The first elementary resource returned by the proposed methodology is the correct characterizing product of the enquired work. The overall proposed framework exploits cosine similarity through TF-IDF techniques for retrieving products in the Price List document. Those are ranked based on their similarity scores, allowing the user to identify the most relevant matches for the query.

The framework is tested on four samples. Each sample represents a different domain (masonry clay blocks, masonry concrete blocks, tile floors, and thermal insulations) with unique terminologies and sentence structures. By testing the developed methodology on a diverse dataset, it is possible to assess its scalability on different knowledge subdomain.

The last step of the framework requires the evaluation of the output, performed by practitioners, who assesses the correctness of the first output, characterized by the highest score rate.

Table 1 Framework output, queried with “1C.06.050.0100” work.

Score rate	ID code	description
0.50	MC.06.050.0040.a	Semi-solid bricks:- semisolid brick 8 x 12 x 24 cm
0.43	MC.06.050.0040.b	Semi-solid bricks:- semisolid brick 8 x 24 x 24 cm
0.38	MC.06.050.0040.e	Semi-solid bricks:- double UNI semi-solid brick 24 x 12 x 12 cm

0.33	MC.06.050.0015	Solid bricks 25 x 12 x 5.5 cm complying with UNI EN 771-1 and the Minimum Environmental Criteria set forth in the Decree of June 23, 2022 of the Ministry of Ecological Transition, for the construction of load-bearing masonry according to NTC 2018, thermal conductivity (λ) according to UNI 1745 of dry brick 0.431 W/mK

6. RESULTS AND DISCUSSION

In this section, a preliminary phase of analysis and discussion of the analyzed dataset is presented. This approach allows us to have a more comprehensive view of the results obtained before delving into further discussions.

6.1 Dataset preliminary analysis

A preliminary analysis was performed in order to provide a better description and visualization of the four selected dataset. Table *1* collects some significant data on which the evaluations are performed. It provides the size of the tested sample, both for works and elementary resources, for the subdomain knowledge analyzed (Clay brick wall, concrete brick wall, tiles, and thermal insulation). Furthermore, it provides the description with major, minor, and average number of words per work and elemental resource. A delta is also given to highlight the differences between works and elemental resources.

As it is possible to see from the table below, a homogeneous number of 40 work items have been analyzed for each test campaign. The related number of elementary resources varies according to the type of knowledge subdomain, ranging from a minimum of 33 to a maximum of 64 items.

Concerning the analysis of textual descriptions, the number of words in them was investigated. The clay Brick Wall campaign is characterized by 50.8 average words per work item. and 30.7 average words per elementary resource item, registering a delta of 20.1 words. Among the test campaigns, the Concrete Brick Wall campaign stood out with the longest descriptions, averaging 123.9 words per work item. In contrast, the Elementary Resources campaign displayed a mean word size of 59.9, exhibiting the largest word delta between the two.

The Thermal Insulation test campaign also featured lengthy descriptions. In this case, the average word count for both elementary resources and jobs was quite similar. On the other hand, the Tile Floors knowledge subdomain had the shortest textual descriptions for both elementary works and resources; moreover, the average length of the descriptions for works and elementary resources nearly matched, resulting in an almost zero delta.

Based on this overview, it is evident that there are differences among the various knowledge subdomains. Specifically, the Concrete Brick Wall subdomain requires a greater number of words to convey information. Additionally, the descriptions of works within this subdomain offer more extensive information compared to their corresponding elementary resources. Conversely, the Tile Floor subdomain necessitates fewer details in its descriptions, with both works and elementary resources providing relatively concise information. These differences highlight the varying informational needs and content richness across the different knowledge subdomains.

Table 2 Preliminary dataset analysis. W: work items; ER: elementary resource items.

	Clay brick wall			**Concrete brick wall**			**Tile floor**			**Thermal insulation**		
	W	ER	Δ	W	ER	Δ	W	ER	Δ	W	ER	Δ
.n° of items	*40*	*33*	*7*	*40*	*50*	*-10*	*40*	*59*	*-19*	*40*	*64*	*-24*
Max length	*105*	*89*	*16*	*140*	*121*	*19*	*82*	*94*	*-12*	*150*	*121*	*29*
Mean length	*50.8*	*30.7*	*20.1*	*123.9*	*59.9*	*64*	*46.3*	*46.5*	*-0.2*	*85.6*	*98.1*	*12.5*
Min length	*13*	*10*	*3*	*54*	*28*	*26*	*10*	*10*	*0*	*49*	*33*	*16*

6.2 Discussing framework result

Table 4 in this paragraph presents the results obtained, by displaying in the first row the number of times the model successfully assigned the elementary resource to the work query. Conversely, in the second row, the table shows the number of times when the model was unable to assess the correct output. The last row provides the number of missing elementary resource items. According to the domain of knowledge, different outcomes were achieved.

The poorest results were recorded for the Concrete Brick Wall and Clay Brick Wall domains. Also, as previously shown in table 3, these domains exhibited a substantial delta between the number of words between works and elementary resources, indicating that the works conveyed more information than the descriptions of elementary resources. For the Clay Brick Wall sample, 19 tests over 40 provided incorrect output, being 47.5% of the total tests; however, practitioners verified that in the 57.8% of incorrect outputs, the elementary resource is missing in the price list. Concerning the Concrete Brick Wall sample, 26 tests over 40 provided incorrect output. being 65% of the total tests.

Furthermore, it was observed that in certain instances, standardizing works and elementary resources resulted in a shift from negative to positive outcomes. Table 3 shows the output of the work query “Load-bearing masonry made of hollow core brick blocks, thermo-acoustic, with cement mortar, including formation of vaults, pilasters, corners; with:- simple blocks 13 x 30 x 19 cm, thickness 13”. The model does not return the correct elementary resource as the first output, but rather as the third ranked output. Just by equalizing the lexicon from "block" to "blocks", like the other items are, the similarity score of the correct output turns from 0.37 to 0.44, with a higher score.

Table 3 Framework output, queried with "1C.06.050.0300.b" work.

Score rate	ID code	description
0.39	MC.06.100.0010.b	Thermal insulation blocks, 45% drilling:- interlocking blocks, 30 x 25 x 19 cm
0.39	MC.06.100.0010.a	Thermal insulation blocks, 45% drilling:- interlocking blocks, 25 x 30 x 19 cm
0.37	MC.06.100.0010.c	Thermal insulation blocks, 45% drilling:- simple block, 13 x 30 x 19 cm

Conversely, Tile Floor and Thermal Insulation domains exhibited a larger number of positive outcomes, registering respectively 35 and 37 correct output tests out of 40, 87.5% and 92.5% respectively. In these cases, unlike previous tests, the descriptions of works and elementary resources had a smaller word delta. For Thermal Insulation, practitioners verified that in 67% of the negative outcomes, the correct data was indeed missing from the elementary resources list.

Table 4 Testing framework results.

	Clay brick wall	Concrete brick wall	Tile floor	Thermal insulation
correct	*21*	*17*	*35*	*37*
incorrect	*19*	*26*	*5*	*3*
Missing ER	*11*	*0*	*0*	*2*

7. CONCLUSION

The research presented in this study contributes to the empowerment of public administrations in effectively managing data from Price List Documents, aligning with the growing necessity to transition textual information into structured and machine-readable formats. Building upon the investigation conducted in the research titled (Gatto et al., 2023), this study introduces a methodology capable of extracting elementary resource information from a price list document and linking it to the corresponding construction work using cosine similarity NLP techniques.

The model successfully extracted and correctly matched the elementary resource to the corresponding work query in 75% of the cases where the elementary resource was present in the list. Additionally, the model proved to be a valuable tool in supporting practitioners in identifying missing resources. A limitation associated with this approach is its reliance on retrieving explicitly mentioned information from the text. Indeed, it cannot derive implicit information.

The study also highlighted that due to the lack of standardization in conveying information, the machine encountered ambiguity in interpreting the text. It emphasized the importance of adopting a more standardized approach to delivering information, making it more understandable not only to machines but also to humans.

It is important to note that the developed framework does not replace human activity but rather acts as a supporting tool. Human verification and validation of the model's outputs are essential.

Given the success of this framework, future developments aim to extend its application to broader contexts, with a focus on extracting cost information from various textual documents, including technical specifications and price list documents, and linking them to verify the consistency of cost information with the data contained in BIM models.

ENHANCING INTERACTIONS IN AUGMENTED REALITY FOR CONSTRUCTION SITES: INTRODUCING THE ARCHI ONTOLOGY

Karim Farghaly, Khalid Amin, Grant Mills & Duncan Wilson

The Bartlett School of Sustainable Construction, University College London

ABSTRACT: *Augmented reality (AR) systems offer new possibilities for enhancing how people interact with information and their environment in the construction sector. However, traditional software-driven approaches to AR system design have limitations in creating intuitive user experiences. This research presents a new user-centric framework and ontology for BIM-AR system development focused on human needs and perspectives. The BIM-AR Framework consists of a 5-step circular hybrid process with the user at the center. To enable knowledge sharing, the Augmented Reality Computer-Human Interaction (ARCHI) ontology was developed using Protégé based on established design principles. Initial validation indicates the framework's potential for improved AR system design, but further expert review and case studies are needed. The ontology also requires additional refinement and linkage to open data. This pioneering research lays the groundwork for next-generation AR systems that emphasize usability by taking a human-focused approach. With rigorous validation and evolution, the framework and ontology could transform AR technology development to create more purpose-driven and adopted solutions. This research represents a paradigm shift to user-centric AR system design that has significant potential to improve how augmented reality enhances construction project management.*

KEYWORDS: *Augmented Reality, Building Information Modeling, BIM, Linked Data, Ontology, Human Computer Interaction.*

1. INTRODUCTION

Augmented reality (AR) refers to technology that overlays digital information and objects onto the real-world environment in real-time (Azuma et al., 2001). This is achieved by supplementing the user's view with computer-generated input such as text, images, video, audio, and GPS data. In recent years, AR has emerged as a transformative technology with a diverse range of applications across industries like healthcare, education, manufacturing, and construction. Within the construction industry, AR is being explored as a means to enhance on-site work processes and information visualization. By overlaying 3D models, assembly instructions, or other data directly onto physical construction sites, AR enables workers to intuitively interact with digital information in context (Rankohi & Waugh, 2013). Specific applications include visualizing building designs and underground infrastructure, annotating issues for repair, remotely guiding workers through assembly tasks, and detecting risks or errors in construction (Behzadan & Kamat, 2009). AR and Building Information Modelling (BIM) can reduce workspace clutter, improve information communication, and integrate digital tools directly into the work environment (Um et al., 2023).

However, there are several challenges to widespread AR adoption in construction. Current AR solutions are often provider-specific proprietary platforms that lack interoperability (Um et al., 2023; X. Wang et al., 2013). This makes integrating AR into existing construction workflows difficult, as data may not transfer seamlessly between different vendor tools. Additionally, much AR research has focused on novel visualization techniques rather than task-based, user-centric design (Amin, Mills, & Wilson, 2023; Behzadan & Kamat, 2009). As a result, usability and practical utility for on-site workers requires further improvement. To drive end-user acceptance, AR solutions need to tie tightly to actual construction tasks and processes, with UX design centered around user needs (Rankohi & Waugh, 2013). Realizing AR's full potential in construction will require developing flexible and standardized AR platforms that can be tailored to diverse use cases. Rather than one-size-fits-all vendor products, open AR ecosystems are needed where components can be mixed and matched (K. Wang et al., 2023; X. Wang et al., 2013). Tying these tools directly to construction workflows and end-user requirements will be key. With improved integration and usability, AR can transition from isolated proofs-of-concept to transformative mainstream applications in construction.

2. BACKGROUND

In recent years, AR has emerged as a potentially transformative technology for the architecture, engineering, and construction (AEC) industry. By superimposing digital models, data, and instructions directly onto physical

construction sites and assets, AR enables more intuitive visualization and interaction with information in context. Researchers have explored AR applications across the construction lifecycle, including design visualization, construction planning, progress monitoring, quality inspection, maintenance, and safety training (K. Wang et al., 2023). One major area of research has been integrating AR with Building Information Modeling (BIM) to extend the utility of virtual BIM models to physical construction settings. BIM refers to digital 3D models of buildings containing rich parametric data on components and systems. Linking geo-located BIM models with AR allows contextually relevant on-site visualization and interaction with model data (Amin, Mills, & Wilson, 2023). This has been posited to improve communication, decision-making, work planning, quality control, and collaboration between on-site and off-site teams during construction and operations (Elshafey et al., 2020).

However, studies note that widespread field adoption of BIM-AR remains limited, especially in developing countries, due to technical and organizational challenges (Sidani et al., 2021). Major technical barriers include issues with accurate and stable registration of virtual content with the physical environment. This is impacted by factors like lighting, network connectivity, and occlusion (X. Wang et al., 2013). Developing flexible AR platforms that can leverage different positioning techniques based on context has been identified as important. Organizational challenges also exist around integrating AR into construction workflows and aligning it with user requirements (Amin, Mills, Wilson, et al., 2023). In particular, research gaps remain around understanding user needs and perspectives for on-site AR applications. As Amin, Mills & Wilson (2023) discuss, much AR research has focused on novel visualization techniques rather than task-based, user-centric design. However, usability and practical utility requires aligning AR tightly with actual construction tasks and end-user workflows. Wang & Dunston (2006) and K. Wang et al. (2023) similarly argue there has been insufficient investigation of user-centered factors that influence the effectiveness of AR for on-site construction tasks. These include aspects like UI design, functionality, and ergonomics based on workers' processes and needs.

Overall, studies emphasize that realizing the potential of BIM-AR in construction requires moving from proofs-of-concept to solutions tailored to end-users' requirements and field workflows. This entails research on AR applications within the context of specific construction tasks, roles, and information needs. A user-driven approach can help identify high-impact areas where AR adds value for field personnel and integrate AR seamlessly into existing construction practices and project delivery processes. Bridging these research gaps around user-centered design and task-based workflows will be key to driving user acceptance and widespread adoption of BIM-AR on construction projects. In the following section we will discuss the current practice of the implementation of BIM-AR solutions.

3. BIM-AR CURRENT PRACTICE

The typical process of developing and implementing BIM-AR solutions tends to follow a linear path (Figure 1), rather than a circular user-centric approach. Researchers/Project Managers often identify a potential construction application area for BIM-AR visualization, such as design review or progress tracking, based on technical feasibility rather than validated user needs (Amin, Mills, & Wilson, 2023). Developers then select AR hardware and software components to prototype, focusing on demonstrating novel visualization capabilities more than usability (X. Wang & Dunston, 2006). A pilot study is conducted to test the BIM-AR prototype in a lab or limited field setting, with evaluation criteria tending to be technical performance metrics rather than workflow integration or user-centered design (Sepasgozar et al., 2016). If feasible, the prototype may be deployed in a real construction project to showcase a “proof of concept”, but these deployments often function as stand-alone tools disconnected from broader workflows and BIM processes. User feedback is collected informally, if at all, and BIM-AR solutions are not co-designed with end users or iteratively refined based on their input and task needs. Outcomes focus on the technical aspects and visualization capabilities, rather than productivity, quality, or other construction industry benefits. Consequently, BIM-AR prototypes frequently stall at the proof-of-concept stage without translation into commercial solutions or best practices (K. Wang et al., 2023). In summary, the current linear BIM-AR development process does not start with identifying user requirements or aligning systems tightly to construction workflows. Collaboration with industry stakeholders occurs late, if at all, which limits the real-world utility and adoption of BIM-AR innovations. A more circular, participatory design approach is needed, where end user perspectives drive the development and evaluation of BIM-AR solutions for construction.

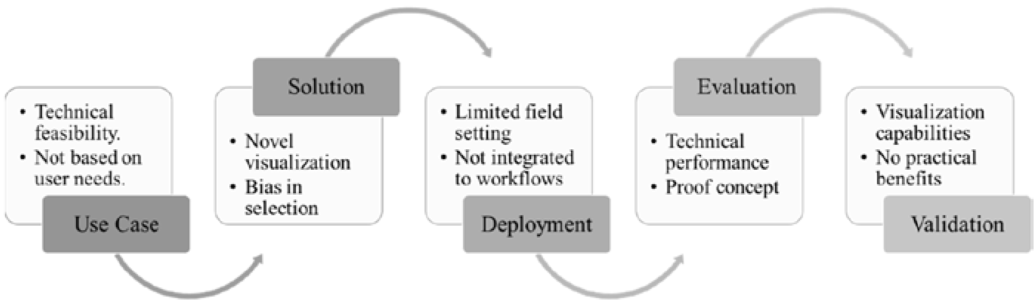

Figure 1: The current practice of BIM-AR solutions and research

4. PLUG&PLAY BIM-AR SOLUTION

A more circular approach for the effective implementation of BIM-AR solutions in the construction industry is proposed. As mentioned before, the current linear process of BIM-AR development has limitations, as it does not sufficiently incorporate end user requirements or align solutions with real-world workflows. To address this, we suggest a participatory, iterative process, Augmented Reality Computer-Human Interaction (ARCHI), that centers end user perspectives for (Figure 2):

- Cultivate Use Case - The starting point should be identifying a practical use case cultivated by end users. This includes details on the application area, project phase, location, and key stakeholders who would benefit from the BIM-AR implementation. Example use cases could be design coordination, construction planning, or facilities maintenance.
- Identify Requirements - With a target use case, multidisciplinary workshops with stakeholders are held to determine functional and information requirements. User requirements capture necessary features and workflows to efficiently accomplish tasks using BIM-AR. This entails understanding objectives, processes, pain points, and needs. Information requirements outline graphical and non-graphical data inputs from integrated systems like BIM to achieve the user requirements.
- Map to Key Functions - The user and information requirements are then mapped to key BIM-AR functions needed to fulfill the use case. As Amin, Mills & Wilson (2023) proposed, these functions include positioning, visualization, interaction, collaboration, automation, and integration. Not all functions are necessary; the focus is on those critical for the specific use.
- Select Solution - With key functions defined, the project team surveys potential AR devices, software platforms, and components to meet the requirements. Table 1 provides an overview of current BIM-AR solutions and capabilities. The goal is finding flexible tools to fulfill the required key functions.
- Implement with Users - BIM-AR experts collaborate with end users to implement the selected solution in the construction project context. Workshop sessions ensure it aligns properly with real-world workflows while addressing information needs. Agile development principles can help adapt the system based on user feedback.
- Assess Against Use case and Requirements - Once deployed, structured assessments evaluate the BIM-AR solution against the original functional and information requirements. Metrics quantify performance, usability, and impact on productivity, quality, safety, etc. User surveys also provide qualitative feedback on enhancements.

By applying this circular approach, BIM-AR solutions are driven by end user and project requirements rather than technical novelty. The focus is on integrating AR seamlessly into existing construction practices to solve real problems. Continuous assessment and improvement further refine the system over time and across projects. With BIM-AR tools tightly aligned to use cases and stakeholder needs, user adoption and benefits can expand markedly. This practical, participatory implementation process is key to unlocking the true potential of BIM-AR in construction.

5. ARCHI ONTOLOGY

To achieve the proposed framework, it is crucial to identify and capture all the key information needed for effective implementation. In this section, we introduce the ARCHI ontology which identifies all the important aspects to be captured. For developing a domain or upper ontology, it is essential to follow a set of defined recommendations and ordered steps (Farghaly et al., 2023). The process of the development of an ontology consists of seven main steps (Noy & McGuinness, 2001). The first step is to define the covered domain and the scope. As mentioned before, this research concentrates on the aspects related to BIM-AR solution implementation and presents the different tasks needed for that. The second step is to consider reusing existing ontologies. Several classifications and taxonomies have been taken in consideration as ontologies in this research such as PVICAT (Amin, Mills, & Wilson, 2023) for the key functions, Human Computer Interaction (HCI) ontology (Costa et al., 2022) for the user and solution classes. The third step is to enumerate important terms in the ontology. In this step, terms are extracted to form a list of concepts (classes, relationships, and slots) from the data schema regardless of any overlap between the concepts they represent. The names of the selected terms have to follow a specific strategy as specified in define resources-naming strategy task. In this stage, all the classes and their related instances are identified. The fourth step is to define the classes and develop the class hierarchy. Several approaches can be used for developing a class hierarchy: namely, top-down, bottom-up and combination. Most of the ontologies are developed based on the top-down approach, which starts from an abstraction of a domain and continues to a concrete level. However, it has been argued that the bottom-up approach is more effective as domain modeling is based on raw and evidential data instead of theoretical conceptualization. In this research, the top-down approach is used for the reusable ontologies and concepts, while the bottom-up approach is selected for the development of the new ontologies. For example, the PVICAT was utilized to identify the classes of the key function classes. The researchers used that to develop instances for each class (Table 2). The instances were identified through the engagement of the researchers in two projects where BIM-AR are implemented. The fifth step is to define the properties of classes (slots); while the sixth step is to define the facets of the slots. The values of slots are described in different facets such as: value type, allowed values, cardinality, and other facet features. The value type facet can be described in different value types, such as string, number, Boolean and enumerated. The allowed value facets define the range of slot, and the cardinality facets define how many values the slot can have. In this research, the string value type is used for defining most of the slots for the classes' properties. Finally, the seventh step is to create the instance of classes in the hierarchy. The last three steps are ongoing part of this research. Several interviews and workshops will be conducted with end users to identify the instances especially for both the use case and requirement ontology.

The ARCHI ontology was initially modelled collaboratively using diagram.net, enabling researchers to visualize and connect classes and relationships. The resulting UML diagram was exported and converted to an OWL ontology using the Chowlk tool. This OWL file was then imported into Protégé for further refinement. Protégé provides a platform to construct domain models and knowledge-based systems by enabling the creation of classes, properties, and individuals. To develop a robust ontology of knowledge for the BIM-AR framework, certain design principles and best practices were followed. As highlighted by Hlomani and Stacey (2014), the ontology requires precise conceptualization of the domain knowledge through iterative refinement of definitions. Furthermore, Gruber's (1995) criteria of clarity, coherence, extendibility, minimal encoding bias, and minimal ontological commitment were adhered to ensure a well-founded ontology. By leveraging Protégé and adhering to established guidelines, the ARCHI ontology codifies the concepts and semantics required to represent the knowledge and relationships underlying the BIM-AR framework.

The ARCHI ontology consists of 5 key classes that characterize the problem space from different perspectives: Use Case, Requirements, Key Functions, Solutions, and Users (Figure 3). The Use Case class captures details about the context and goals of implementing AR into a BIM workflow. This includes the phase of integration such as design, construction planning, active construction, handover, or operations. It also covers specific applications and objectives, such as visualizing design models on-site, evaluating construction progress, or providing digital overlays for facility maintenance. Additionally, it describes the physical environment where AR will be utilized, for example a construction site or design office. The Requirements class contains the functional and non-functional needs that emerge based on parameters defined in the Use Case. For instance, a construction site application may require ruggedized hardware to withstand harsh conditions. Or an operations use case may require integration with existing facility management software platforms. Also, it covers the information requirements related to the information needed for the 3D models provided by the BIM systems. Based on each use case, we can define a Model View Definitions (MVD). Requirements provide a link between goals and necessary capabilities. The Key Functions class draws from the taxonomy of augmented reality capabilities synthesized by Amin et al (2023). It contains main categories of AR functionality. Each class also has associated instances as shown in Table 2. This provides a standardized vocabulary to describe AR features. The Solutions class characterizes the software, hardware, and other technological components of existing AR platforms. This includes parameters like software packages and versions, types of display hardware, interface modalities, tracking methods, input devices, and capabilities for data output or export. Lastly, the User class models the human users of the AR system. Both solution and user classes leverage existing ontologies related to human-computer interaction to fully define user-solution side factors. These 5 classes provide a structured foundation for evaluating and selecting optimal AR solutions. Use Cases define goals, Requirements outline needed capabilities, Key Functions provide a vocabulary of AR features, Solutions characterize technologies, and Users represent the human perspective. By mapping Use Cases to Requirements and Key Functions, then matching those to candidate Solutions while considering Users, the ontology enables principled assessment of how well a given AR platform suits a particular BIM use case need. This facilitates both targeted selection of existing tools and identification of areas requiring new solutions.

In summary, ontology-based modeling of the BIM-AR solution space can enable richer representations of end user perspectives, workflows, requirements, and project contexts. This knowledge base can then drive the circular participatory framework by connecting BIM-AR capabilities directly to construction practices and stakeholder needs. Additional research is underway on ARCHI's formal ontology development and its applications for guiding successful BIM-AR adoption.

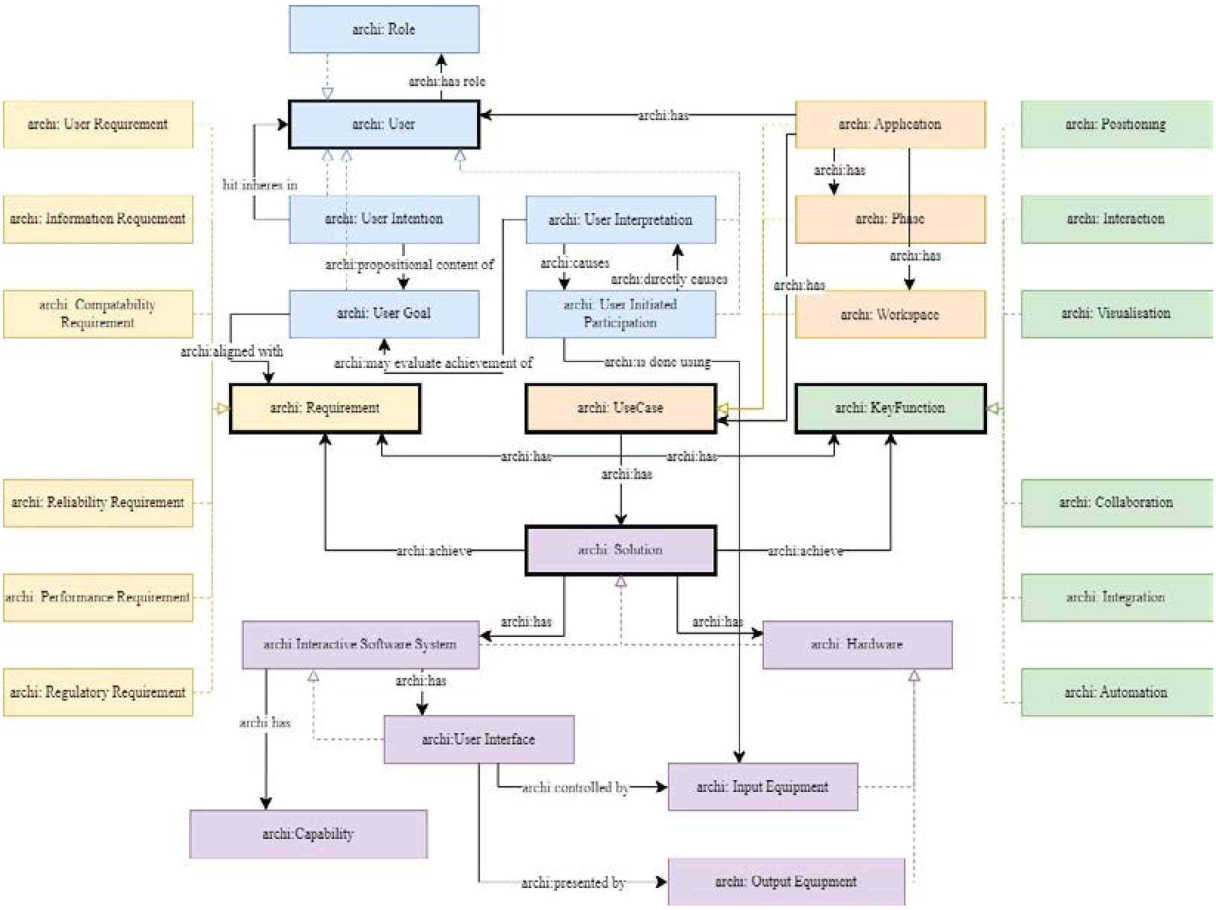

Figure 3: The main classes and relationships of ARCHI ontology.

Table 2: Key function classes and their instances and mapped solution capabilities

Key Function Class	Key Function Instances	Capabilities for the Key Function Instances
Positioning	Marker-based	Scan Marker
Positioning	Natural Feature-based	Scan Natural Feature
Positioning	Object-based	Scan Object
Positioning	Manual Mapping	Map Coordinates
Interaction	Modify	Move, Rotate, Resize, Delete
Interaction	Retrieve Information	Read, Download
Interaction	Store Information	Capture Image, Capture Video
Interaction	Add Information	Comment, Markup
Visualisation	Digital-Digital Inspection	Identify Clash, Identify Defect
Visualisation	Visibility Customization	Show, Change Color, Change Appearance
Collaboration	Issue communication	Upload Image, Upload Video, Stream
Automation	Visual Inspection	Class detection, defect detection
Automation	Report Generation	Progress report, clash report, defect report
Integration	Production and Programme control	Real-time integration with other systems
Integration	Presentation of external datasets	Real-time integration with weather and others
Integration	Improve/Extend existing function	API capabilities to extend functions

6. CONCLUSIONS

The BIM-AR Framework and ontology presented in this research offers a novel user-centric approach for designing and deploying augmented reality systems. Rather than taking a software-driven approach focused on tools like Unity, this framework emphasizes human-centered design with a focus on AR content. The core of this approach is a 5-step circular hybrid process that continuously evolves based on user needs and perspectives. To facilitate the sharing of information between process stages, the ARCHI ontology was developed to capture key data points and relationships. This human-focused approach represents a paradigm shift from traditional AR design methodologies. By putting the user at the center and iterating based on their requirements, the framework enables the development of more intuitive and purpose-driven AR applications. The ARCHI ontology also plays a key role by codifying knowledge to prevent information loss across the design lifecycle. Overall, the framework aims to create a more seamless AR experience by enhancing the symbiotic relationship between user and technology.

While initial expert review and case studies demonstrate the potential of this BIM-AR approach, further validation is required. Future work should concentrate on gathering additional use cases across different domains to refine the framework. More robust testing and evaluation of the ontology is also needed to ensure it adequately captures the necessary design knowledge. Extending the current ontologies with linked open data could also strengthen the knowledge-sharing capabilities. With further development and validation, this human-centric methodology could provide a new paradigm for AR system design that leads to more adopted and usable AR solutions.

This research presents a promising user-focused approach to AR design, moving away from software-centric methodologies. The BIM-AR Framework and ARCHI ontology provide an integrated solution to put human needs at the forefront. While more work is required, this pioneer research lays the foundations for next-generation AR systems that emphasize the human perspective over tools. With rigorous validation and evolution, this framework can enable AR developers to create more intuitive and purpose-driven applications that deliver value in various real-world contexts. The user-centric future envisioned by this research has the potential to transform augmented reality technology and cement its place as an integral part of how people interact with information and their environment.

A REVIEW OF COMPUTER VISION-BASED PROGRESS MONITORING FOR EFFECTIVE DECISION MAKING

Roy Lan & Tulio Sulbaran, Ph.D.
The University of Texas at San Antonio. San Antonio, TX

ABSTRACT: *Construction Progress Monitoring (CPM) is a significant aspect of project management aimed to align planned design with the actual construction on site, the process ensures that the project is well within the control of the stakeholders involved and ensures the project is completed complying with the construction documents, on time, and within budget. Despite how central progress monitoring is to attaining project success and advances in technology, the progress monitoring is majorly implemented manually, which requires manual retrieving and processing of site data to compare with the planned design. This manual process is both time-consuming and prone to errors. Automating the task of progress monitoring involving real-time data acquisition and timely information retrieval can assist the project managers for effective decision making to the successful delivery of the project. Thus, the objective of this research was to assess the impact of computer vision (CV) – based progress monitoring as a driver for effective decision-making in project management. A qualitative methodology was implemented for this research using Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) to review and analyze studies on the application of computer vision (CV). The study reviews studies of CV based CPM process, highlighting its benefits against the traditional method of progress and the limitation to its adoption. Research findings from this paper provide an increased understanding and have a broader scope on the application of computer vision-based progress monitoring.*

KEYWORDS: Computer Vision, Construction progress monitoring, Decision-making, Project management

1. INTRODUCTION

Progress monitoring involves the processes required in tracking, evaluating and organizing the performance of a project, and identifying areas where modification needs to be implemented (PMOK, 2017). In the development phase of construction projects, site activities are tracked by the project manager using progress monitoring methods (Qureshi et al., 2022). Progress monitoring of a construction project is essential to the successful delivery of the project, this is because it entails recognizing the disparities between the planned design and the ongoing construction. As most tasks are interdependent, frequent inspections assist managers to detect anomalies early, avoid potential delays, and decide when to take remedial action (Reja et al., 2022). The progress monitoring phase is regarded as a complex task, it requires efficiency as it provides the essential inputs to the managers on site for prompt and informed decisions. This process, when done effectively helps to prevent cost and schedule overruns and improve the retrieval, management and processing of site data (Kopsida et al., 2015). According to Hanet et al. (2016), the limitations in manual and other conventional data acquisition procedures in progress monitoring cause more than 53% of construction projects to fall behind schedule and more than 66% of them to fall short financially.

The traditional method of progress monitoring of construction projects involves manual retrieving of data, information processing, documentation, and reporting on the project status. However, this method is time-consuming, information obtained are prone to human errors, and often report obsolete information which impedes effective decision-making from stakeholders (Rehman et al., 2022). To improve this, the process can be made effective through automation. Technologies exist for the automation of progress monitoring; with focus on retrieving data from the site, some of which include unmanned aerial vehicle (UAV), geographic information system (GIS), virtual reality (VR), augmented reality (AR), radio frequency identification (RFID), and global positioning systems (GPS). However, computer vision technology can be consolidated with these technologies to be implemented for progress monitoring. Computer vision (CV) is similar to the human vision, but utilizes machine learning algorithms or deep learning models in analyzing, predicting and making useful interpretation from data inputs which could be images or videos (Paneru & Jeelani, 2021).

For the automation of construction progress monitoring, a noticeable amount of research has been carried out. An overview study conducted by Ekanayake et al., (2021) on the application of computer vision-based interior construction progress monitoring. The study categorized the challenges that hinder the successful implementation of CV based interior construction project monitoring (CPM) into indoor objects, lighting condition and movements of the camera used. However, the study mostly focused on challenges for interior use. McCabe et al., (2017) also

Roy Lan, Tulio Sulbaran, *A Review of Computer Vision-Based Progress Monitoring for Effective Decision Making,* pp. 856-864, DOI 10.36253/979-12-215-0289-3.85

investigated on indoor CV-based CPM, their study identified the challenges encountered using UAV's. for automated data retrieval. A related study by Kopsida et al., (2015) categorized the different stages involved in the automation process in terms of technology used and assessed, time efficiency, accuracy, cost and mobility. Most of the studies highlighted the need to overcome challenges for the successful implementation of a CV-based CPM. The objective of this study is to assess the impact of CV– based CPM as a driver for effective decision-making in project management. Investigating how this technology can improve decision making, by revealing its current level of adoption identifying the benefits, and the limitation involved to its application.

2. METHODOLOGY/APPROACH

For this study, a systematic review was conducted. This type of review involves identifying all relevant literature that is pertinent to the review question, critically evaluating identified literature and summarizing the findings (Gough et al,.2012). It helps to answer an important question or identify areas of importance relevant to the research question (Harris et al., 2014). The review begins by posing a research question, identifying relevant studies, critically evaluation of the studies, data collection, analyzing and structuring of the data, summarizing the evidence and reporting findings from the study (Khan et al., 2003). While the systematic review approach has been predominately used to conduct research in the medical field (Munn et al., 2018). It has been used several times in the field of construction management; for a review of sustainable construction management (Araújo et al., 2020), a review of the concept of buildability as it relates to construction management (Osuizugbo et al., 2022), and a review of the inter-relationship building information modeling (BIM) and safety in construction (Martínez-Aires et al., 2018). This is because the output from this type of review is usually comprehensive and exhaustive requiring an explicit methodology and helps present output in a structured sequence (Shamseer et al., 2015)

This systematic review was conducted using the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) which include four stages: Identification, Screening, Eligibility, and Includes (as shown in Figure 1). The databases sources used were Scopus, Web of Science (WOS) and Civil Engineering Database from the American Society of Civil Engineering (ASCE). Google Scholar was also used for the search of relevant studies. Keywords used in the databases for search include, "Computer vision" and "construction progress monitoring," as well as "Computer vision-based construction progress monitoring." For relevant extant literature, the search range was from the year 2005 upward. Duplicate files, and records having a different language from English that could not be translated were also excluded. Also, some papers had a methodological approach that did not align with the objective of this study, such papers were screened out. After screening and eligibility criteria the total number of papers evaluated and appraised for this study were 47.

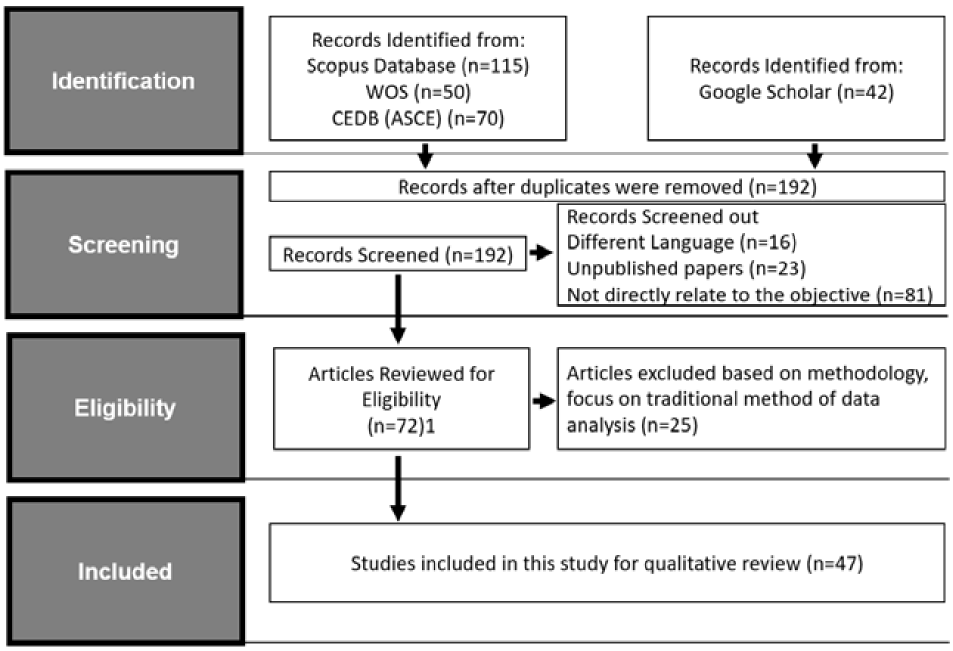

Fig. 1: Flowchart showing the systematic review process using PRISMA.

3. ANALYSIS AND RESULTS

3.1 Description of subprocesses of CV-based CPM process

In recent times, the application of CV-based CPM in project management has gained traction as the advantages it possesses has been observed to aid stakeholders for an effective decision-making process in the lifetime of a project (Braun et al., 2020). Different studies categorized the sub processes involved in CV-based CPM. The categories include, data acquisition, information retrieval, progress estimation, and output visualization (Kopsida & Vela, 2015; Rehman et al., 2022). Data acquisition and 3D reconstruction, as-planned & as-built modelling and progress monitoring (Reja et al., 2022). This review categorizes the process into three data acquisition, information retrieval and progress monitoring and visualization as shown in Figure 2. Each of the subprocess is summarized based on review of extant literature. The sequence is such that the data obtained automatically is analyzed to retrieve germane information such that there can be a systematic comparison between the as-planned and the as-built structure, and the disparities are made known in a comprehensible pattern. This section reviews the subprocesses associated with CV-based CPM.

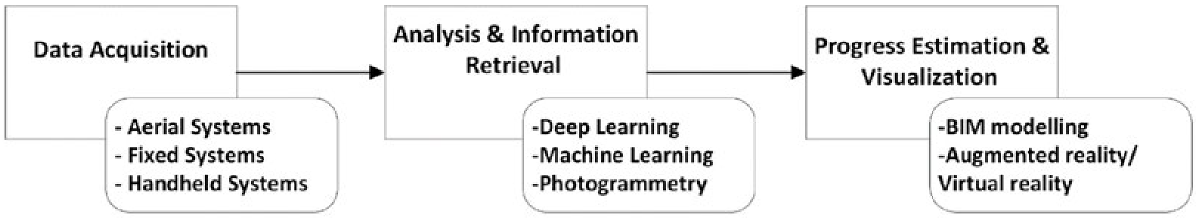

Fig. 2: Subprocesses of the CV based CPM.

3.2 Data Acquisition

Data format for automated progress monitoring include but not limited to two-dimensional (2D) or three-dimensional (3D) images, from cameras and depth cameras respectively (Omar & Nehdi, 2016). Videos obtained from videos cameras which could be fixed or mobile with the aid of technologies such as unmanned aerial vehicles (UAV), or unmanned ground vehicle (UGV). Also, a point cloud which involves tiny points which could be plotted for relevance in a 3D space or surface that can be sourced from 3D laser scanners like light detection and ranging (LIDAR) (Paneru & Jeelani, 2021a).

The construction site is known to be very dynamic in nature, consisting of various activities occurring most times intermittently (Ibrahim et al., 2009). Thus, the need to have a comprehensive overview that can be augmented by using digital images and videos in monitoring construction progress requiring little expertise because of the simplicity in its application. Table 1. Shows a summary of the data acquisition subprocess indicating the method of acquisition, devices utilized in this method, the benefits and the limitations to its use.

Table 1: Computer Vision Data Acquisition

Acquisition method	Devices	Benefits	Limits	Ref.
Aerial systems	UAV's integrated with sensors	- Provides a detailed coverage of site - Maneuvers complex areas which are difficult to manually navigate. - Can be integrated with sensors like cameras and laser scanners	- Requires expertise and certification to operate - It could be expensive depending on the specification - Precision when use is required	(D. Kim et al., 2019; McCabe et al., 2017)
Fixed Sytems	Surveillance cameras	- Provides stability for more clarity in data input obtained - Adequate for sustained period of data acquisition	- Restricted to one angle of view. - Not efficient for comprehensive coverage	(Benyeogor et al., 2020)

Handeld systems	Mobile cameras, tablets, smartphones	- Portable and handy making it comfortable for use - Provides flexibility in use, no restriction in getting elevations and angles - Best for use in getting up-close data for clarity	- Requires multiple takes to cover the entirety of construction space - Data obtained is subject to the users bias and accessibility.	(Jeon et al., 2006; Mahami, Nasirzadeh, Ahmadabadian, et al., 2019)

3.3 Information Retrieval & Analysis

The data retrieved in form of images and videos needs to be analyzed in order to obtain useful information, which will be vital for progress estimation (next sub-process). Some of the commonly used methods includes traditional machine learning technique which includes support vector machines, Hough transform, artificial neural network and deep learning techniques using deep convolution neural networks (CNN). Zhu et al., (2010) proposed a novel technique using Hough Transform Technique to analyze 373 images of large-scale concrete columns for inspection of surfaces to detect defects, the technique when evaluated performed well with a high precision of 89.7% and recall of 84.3%. Kim et al., (2013) presented a method for measuring construction progress based on information included in 4D building information modelling (BIM) and 3D data, the data was classified using support vector machines (SVM) classifier, the SVM model was trained using a labelled 3D data. Because the initial as-built statuses of some components may be inaccurate as a result of an incomplete 3D data set, a two-stage revision was performed. The first stage was based on the sequence of activity execution and the second stage was based on the connectivity between components. Both the sequence of activity execution and the connectivity between components were stored in the BIM. The final as-built statuses produced by this process may be used to determine actual finish dates and to measure actual construction progress. The accuracy of the proposed method was validated using an incomplete set of 3D data acquired on an actual construction site achieving 99% precision rate on the second revision. Additionally, Wang et al., (2021) proposed a vision-based framework for monitoring precast walls during construction, using convolution neural networks (CNN) based computer vision method including Mask R-CNN and DeepSORT to realize object detection, instance segmentation and multiple objects tracking on the dataset obtained from surveillance cameras. The output from the study confirmed the detection rates of CNNs are fast compared to other techniques, this agrees with studies from (Paneru & Jeelani, 2021b; Sultana et al., 2018). Other relevant analytical methods include, Simultaneous Localization and Mapping (SLAM) (Kim et al., 2018), Structure From Motion (SFM) (Mahami et al., 2019),) Histogram Oriented Gradients (HOG) (Memarzadeh et al., 2012 ,and Laplacian of Gaussian (LoG) (Hui & Brilakis, 2013). Table 2. Shows a summary of the information retrieval and analysis subprocess indicating the analytical method, models utilized in the method, the benefits and the limitations to its use.

Table 2: Information Retrieval & Analysis.

Analytical method	Model	Benefits	Limitations	Ref
Traditional Machine Learning	HOG, LoG, SURF, Hough transform, SVM	- Can handle large data - Reliable and high accuracy when trained with balanced dataset.	- Requires large dataset - Requires preprocessing and feature extraction of data	(Zhu et al., 2010)
Deep learning	Mask R-CNN, DeepSORT	- Models can learn patterns from data in high speed - Models trained usually have accuracy - Requires no manual feature extraction or engineering	- Requires high end hardware for processing. - Requires large dataset fir better analysis,	(Z. Wang et al., 2021)
Photogrammetry	SFM, SLAM	- Usually cost effective in comparison with laser scanners - Flexibility of use on construction sites	- Long processing time - Requires hardware with	(Kim et al., 2018)

3.4 Progress Estimation & Visualization

This subprocess makes use of the information retrieved by analyzing the information retrieved. This process is usually a comparison between the as-planned model and the as-built model. The comparison is also known as registration as identified from various literature (Kopsida & Vela, 2015; Rehman et al., 2022). The output is significant for project controls as it gives an update on the project schedule; if the project is on schedule or behind schedule by showing the extent of construction which has been put in place on site (Reja et al., 2022). The result of this comparison is necessary in identifying the successive steps which the stakeholders can take in order to meet the project's objective. The concept of building information modelling (BIM) is very prominent in this subprocess, as the format of the as-planned model can be presented in the four-dimensions 4D BIM model for comparison. After the comparison process, a matching process to see the disparity between the observed and the planned is conducted. The use of voxels, object matching, and probabilistic model have been used to detect progress. This progress is visualized using technologies which enable immersion such as Augmented reality and virtual reality (Ahmed, 2019). Several studies have identified the use of AR and VR as better visualization tools for progress monitoring (Omar & Nehdi, 2016; Rohani et al., 2014). In a case study, Meža et al., (2015) conducted a survey comparing AR with traditional visualization techniques like Gantt charts, AR ranked highest in "understandability of project documentation in monitoring of construction" and "usability of project documentation in monitoring of construction". Wang et al., (2013) proposed a framework for integrating BIM with AR; the platform which is able to couple BIM and AR so that information about 'as-built and as-planned progress' as well as 'current and future progress' can be obtained and presented visually. Comprehensively, consolidated studies have identified AR and VR technologies to be ideal visualization techniques in progress monitoring, as they have shown to facilitate understanding of construction progress estimation.

3.5 Cost and Time-factor of Traditional and Computer Vision-based Progress Monitoring

In project management, cost and time are very significant factors that are used in defining the success of the project, and mangers are constantly seeking ways to optimize cost, be on schedule and to meet standard requirements of a construction project (Chan et al., 2004; Luong et al., 2021). They are also very important criteria which managers and stakeholders consider during decision-making in construction. Hence, it is imperative to include these parameters for the comparison of CV-based CPM and traditional progress monitoring. The cost of setting up a CV based CPM is relative depending on the devices used in each subprocess. In comparison to the traditional method which requires no automation or negligible technology, is perceived as an expensive process. Expenses including purchase of equipment, software, maintenance cost, technical support personnel and the training of users (Omar & Nehdi, 2016). Additionally, numerous researches have shown that CV based CPM is a time-saving and efficient process (Golparvar-Fard et al., 2009; C. Kim et al., 2013). In a case study conducted by Braun et al., (2020), using deep learning technique with sfm-based data consisting of categorized images of formwork, scaffolding and columns, a real time comparison between the as-planned and as-built, to detect progress of site activities was achieved in real time. When evaluated, the method produced a high precision of 90% in detection rate, enormously saving time in the process.

3.6 Comparison between Traditional progress monitoring and CV based CPM

In this section, the CV-based CPM was compared with the traditional progress monitoring using relevant indices which can assist stakeholders when making decision on both methods. Table 4 shows summary was obtained from the systematic review of literature on the application of both methods.

Table 4. Summary of the comparison between CV-based CPM and Traditional progress monitoring

Evaluation Criteria	CV-based CPM	Traditional Progress Monitoring
Data Acquisition	Reliable and timely	Depends on the sense of judgement of the personnel executing the task
Information retrieval & Analysis	Requires expertise from the personnel performing the analysis, mistakes can be spotted and quickly	Requires more of human input, personnel involved in the process needs to be properly trained to avoid errors, which will lead to impact on the project.
Progress monitoring & visualization	The use of BIM/virtual reality/augmented reality gives a sense of realism and immersive and provides sturdy detail of the project.	Doesn't provide the realism and immersion that CV based CPM provides. Output might be difficult to interpret.
Cost	Process can be expensive, especially cost of hardware, software and training	Cost relatively cheaper when compared to CV based CPM

Time	Generally, saves time, notable for efficiency in site management.	Time consuming process

3.7 Limitations to the application of CV-based CPM

Despite the benefits which CV based CPM process offers to stakeholders to enable effective decision making, there still exist some barriers which leads to the hesitation to its adoption. Some of these limitation include; lack of technical expertise on software and hardware, adverse weather conditions, occlusions, specifications of data acquisition device. These limitations were grouped into three which include, environmental factors, technical factors and human factors.

Environmental factors are the barriers within the site location which prevent successful application of CV-based CPM. This includes, the impact of weather, for automating the data acquisition subprocess. The impact of the weather isn't negligible as adverse weather condition distorts the quality of the image which inadvertently leads to poor analysis of the input (Omar & Nehdi, 2016). Poor lightning condition is also significant in the processing of input data. Hamledari et al., (2017) proposed a framework that automatically detects components of an interior partitions using 2D images, their study inferred on the significance and impact of good lightning in order to achieve good results on the detection of site objects. Other environmental factors include, air quality, site condition, due to varying activities, certain sites may be too clustered leading to data acquisition device hindered view of the entirety of work site space.

Technical factors include the factors related to the technology implemented in each of the subprocess. Some are, the specification of data acquisition devices, image and video capturing devices, knowledge on the appropriate devices for the type of data required. Also, for the information retrieval, knowing the proper analysis on the data can be challenging, certain techniques require a lot of data to be trained in order to give a desired output (Moragane et al., 2022). Aerial systems like the UAVs require certifications, and a level of technical knowledge to operate, this can be challenging especially if it's a small-scale project involved.

Human factors are largely critical to the successful implementation of CV-based CPM. Barriers such as privacy issues, and reduced creativity from workers due to the displeasure caused by the feeling of being monitored (Ibrahim et al., 2009; Moragane et al., 2022). Despite this method being an automated process, certain subprocesses require the input of personnel in order to operate. For example, at the information retrieval subprocess, the technical know-how of the personnel executing the task is significant and as such requires requisite training (Paneru & Jeelani, 2021a).

3.8 Intellectual Merit / Broader Impact

The intellectual merit of this work is how it reviews CV based CPM, highlighting on the process involved, developing an evaluation criterion to compare CV-based CPM with the traditional monitoring process, also identifying limitation to its application in project management. The broad impact of this work is will yield an increase understanding of CV based CPM by as an alternative to the traditional monitoring process, as its current level of adoption is still at its nascent stage. A simple holistic understanding of the process by stakeholders can assist in a more informed decision towards project monitoring in project management.

3.9 Conclusion

In project management, construction progress monitoring is a very significant process in achieving a successful project delivery. However, most projects still undergo the traditional manual progress monitoring process. The process has been identified to be time consuming, error prone and subject to the bias and technical know-how of the personnel involved in the process, and this concern leads to the need to automate the process. The objective of the paper was to assess the impact of CV based CPM as an effective decision making tool by highlighting key subprocesses involved in the process, including listing an evaluation criteria for comparing the CV based CPM with the traditional manual monitoring process, and to identify barriers to its adoption as a project monitoring tool in project management. A systematic review was conducted, to evaluate literature relating to the topic. Databases from Scopus, WOS, ASCE and Google scholar were sources of data for the review, PRISMA analysis was used in screening all the papers in order to ascertain relevant literature for this study.

The outcome of this study gave a concise description of subprocesses associated with CV based CPM process. Images and videos are currently the most utilized data in this process and this is most common because of its ease of accessibility and availability of processing systems. Aerial systems which include the use of drones and augmented reality googles show great potential as an effective data acquisition device. Deep learning technique using CNN due to its speed in detection can be integrated with aerial systems for an effective monitoring system with real time output. Lastly, the study highlighted limitations for the applications of CV based CPM and categorized these as human environmental and technical factors, and the review identified technical factors to be a significant factor among others. In short, this study is important because it provides a simple holistic understanding of the process thus aiding stakeholders with accurate knowledge for decision-making towards CV based CPM in construction project management.

ABSTRACT: *The construction industry stands to greatly benefit from the technological advancements in deep learning and computer vision, which can automate time-consuming tasks such as quality control. In this paper, we introduce a framework that incorporates two advanced tools - the Visual Quality Control (VQC) tool and the Digital Twin visualization with Augmented Reality (DigiTAR) tool - to perform semi-automated visual quality control in the construction site during the execution phase of the project. The VQC tool is a backend service that detects potential defects on images captured on-site using the Mask R-CNN algorithm trained on annotated images of concrete and railway defects. The surveyor, aided by the Augmented Reality (AR) technology through the DigiTAR tool, can in-situ confirm/reject the detected defects and propose remedial actions. All the quality control results are recorded in the relevant BIM model and can be viewed on-site overlaid on the physical construction elements. This solution offers a semi-automated visual inspection that can speed up and simplify the quality control process, especially in case of large linear infrastructures, illustrating the added value of AR-based applications in Digital Twins.*

KEYWORDS: *BIM, Augmented Reality, AR in Construction, Deep Learning, Computer Vision, Visual Inspection, Digital Twins*

1. INTRODUCTION

A prominent challenge in the construction industry is the ability to swiftly and seamlessly adapt to changes. To address this issue, an effective approach involves harnessing the power of computer-aided tools that can replace time-consuming activities. By integrating such tools into construction processes, valuable time and effort are saved, leading to significant cost reductions. By introducing digitalized processes to handle repetitive and labor-intensive tasks, construction projects can enhance their adaptability and responsiveness to changes. This allows teams to allocate their resources more efficiently, enabling them to focus on more critical aspects of the project. Furthermore, the digitalization of manual processes and the use of machine learning algorithms facilitate faster decision-making and reduce the likelihood of errors, as they can process vast amounts of data accurately and consistently. The increased accuracy and efficiency provided by these tools contribute to improved project outcomes and overall productivity.

This study introduces a semi-automated approach for visual quality control during the execution phase of construction projects. The proposed framework leverages recent technological advancements in deep learning and computer vision. It is designed to incorporate two essential components: the Visual Quality Control (VQC) tool and the Digital Twin visualization with Augmented Reality (DigiTAR) tool. The VQC tool serves as a backend service; it incorporates a deep learning network trained to detect concrete and railway defects in construction site images. The DigiTAR tool harnesses the power of AR technology to provide a unique visualization experience of the BIM model. Through DigiTAR, users can immerse themselves in the construction site and witness the 3D Building Information Modeling (BIM) model in real-time, where the digital BIM model components are overlaid onto the physical components. DigiTAR is responsible for visualizing the VQC results on-site. This means that key stakeholders, such as the project manager and quality manager of the construction project, can conveniently review and confirm these results firsthand. Their confirmation of these VQC results is pivotal, as it determines whether additional remedial works are assigned to the components identified in the VQC data. By having access to such crucial data on-site, decision-making processes can be expedited, and effective collaboration among stakeholders is further enhanced.

The novelty of the proposed approach in comparison to other existing solutions is that it simultaneously allows: (1) a collaborative inspection of construction sites (different inspectors, both in-situ and asynchronously); (2) different types of annotations (texts, strokes, images, 3D models); (3) geolocated annotations (related to specific

Apostolia Gounaridou, Evangelia Pantraki, Vasileios Dimitriadis, Athanasios Tsakiris, Dimosthenis Ioannidis, Dimitrios Tzovaras, *Semi-Automated Visual Quality Control Inspection During Construction or Renovation of Railways Using Deep Learning Techniques and Augmented Reality Visualization,* pp. 865-876, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.86

elements of the virtual BIM model); (4) the monitoring and editing of registered annotations; and (5) the in-situ visualization of both the designed and the actual state of the building by means of the AR technology. By incorporating these novel features, the proposed approach significantly improves the inspection process, fosters collaboration among stakeholders, and ensures higher-quality construction outcomes. This comprehensive and innovative approach addresses critical challenges faced in the construction industry, promoting efficiency and excellence throughout the project lifecycle.

The rest of the paper is structured as follows. In Section 2, related work is surveyed, focusing on: i) visual inspection methods of railways using deep learning techniques and ii) AR approaches for on-site construction inspection. In Section 3 we present the bundle of the quality control tools in detail, addressing its design and technological and implementation issues. Section 4 provides the results of the evaluation process and a case study demonstration example of utilizing the proposed framework in a real environment. Finally, the conclusion section summarizes the main findings.

2. RELATED WORK

In this section, the relevant literature review is presented. Firstly, we focus on the automated inspection of construction sites using mainly deep learning techniques. Secondly, research approaches concerning the construction sites inspection with the use of AR technology are briefly presented.

2.1 Visual inspection using deep learning techniques

In recent years, deep-learning algorithms have shown remarkable performance in image object recognition and Convolutional Neural Networks (CNNs) have attracted wide attention as an effective recognition method. CNNs have been applied successfully to detect structural damages. Many studies have been conducted focusing on binary classification issues, such as crack detection (Brien et al., 2023), including additional estimations regarding the depth of the crack (Laxman et al., 2023) or the width of the crack (Meng et al., 2023). In addition, multiple surveys have been focused on crack detection and segmentation (Attard et al., 2019; X. Xu et al., 2022), corrosion detection (Atha & Jahanshahi, 2018; Papamarkou et al., 2021), bughole detection (F. Wei et al., 2019), and multi-damage detection (Cha et al., 2018; Kumar et al., 2021).

Focusing on railways inspection, most of the studies examine the defects on the railway track lines due to the long-term pressure from train operations and direct exposure to the natural environment, which have a direct impact on the safety of train operations (Cao et al., 2020; Guo et al., 2021; Liang et al., 2019; Zhang, Liang, et al., 2021). In (Gan et al., 2017), an automatic inspection system for rail surface discrete defects due to fatigue was created and tested, extending the literature review with the Rail Surface Discrete Defects (RSDD) dataset. The Rail-5k dataset (Zhang, Yu, et al., 2021) includes the thirteen most common types of rail defects and is considered a benchmark dataset for rail surface and fastener defects. In (Zheng et al., 2021), a multi object detection method based on deep CNN is proposed, achieving a non-destructive detection of rail surface and fastener defects. In this method, rails and fasteners on the railway track images are firstly localized by YOLOv5. Then, surface defects of the rail are detected and segmented based on Mask R-CNN (He et al., 2017), while a ResNet framework is used to classify the state of the fasteners. In (X. Wei et al., 2019), the authors compare different methods for fastener defect detection and recognition, concluding that with the Faster R-CNN the fastener positioning and recognition can be carried out simultaneously. (Y. Xu et al., 2021) proposed a novel method for tunnel defect inspection (such as leakage and spalling) based on the Mask R-CNN. The network was modified appropriately (extra feature pyramid network and edge detection branch) to achieve a higher accuracy in tunnel defect detection and segmentation. (Xue & Li, 2018) proposed a fully convolutional network (FCN) model for automatic classification and detection of tunnel lining defects (such as leakage, crack, and segment joint). The authors compare their proposed method with traditional convolutional networks (such as VGG) and Faster R-CNN, concluding that the proposed model is very fast and efficient. In (Xue et al., 2020), a deep learning-based model for automatic calculation of the water leakage areas of a shield tunnel surface is proposed. Optimization measurements, such as data augmentation, transfer learning, and cascade strategy, were adopted to improve the performance of the original model.

In conclusion, many of the existing studies focus on concrete surfaces and tackle the issue of binary classification (e.g., crack/non-crack). To the best of our knowledge, studies that concern multiclass classification and detection focus mostly on long-term concrete defects. In addition, they mainly refer to bridge or rail track deterioration and defect detection.

2.2 AR for construction inspection

In (García-Pereira et al., 2020) an AR-based tool is developed for the inspection of prefabricated buildings. The tool has been evaluated positively, as it allows collaborative inspection, supports multi-type, geolocated annotations, and in-situ augmented reality visualizations. (Chi et al., 2022) present a method, which combines AR and laser-scanning technologies to provide intuitive and accurate rebar inspection. The as-built (point clouds) and as-planned data are compared to provide discrepancy information for the inspectors. With the AR, the user is able to visualize the rebar inspection outputs and provide rework instructions. (Zhou et al., 2017) propose an AR-based method to rapidly inspect segment displacement during tunneling construction. The quality inspector is able to overlay the baseline model, which is established according to the quality standard, onto the real structure and measure the differences between them. In (Kwon et al., 2014), a defect management system for reinforced concrete work is presented, utilizing BIM, image-matching, and AR. The authors developed two separate applications: an image-matching system for quality inspection without visiting the construction site (by comparing the 2D images from the BIM model with the real on-site images) and a mobile AR application for workers and managers to detect dimension errors/omissions on-site, in order to save time and reduce rework costs.

The proposed framework combines the automated image-based visual inspection, powered by advanced deep learning techniques, with AR on-site visualization and confirmation of the QC outputs. The scope is to provide an efficient solution that not only saves time, but also prevents chained construction error and reduces the need for costly reworks during the construction phase.

3. MATERIALS AND METHODS

The work presented in this paper is developed as part of the COnstruction phase diGItal Twin mOdel (COGITO) project (*COGITO Project*, n.d.). The COGITO project offers, among others, a bundle of tools for conducting a semi-automated visual quality control during the construction phase of large linear infrastructures (especially railways) aiming at minimizing the effort and the time usually needed for on-site visual inspection.

Within COGITO, an image-based inspection system is developed, complemented with AR visualization and interaction. Firstly, as-built data (2D images) are acquired on-site using various capturing devices, such as smartphones, cameras, and AR devices. Secondly, the acquired images are processed (e.g., cropping, resizing) by a dedicated Visual Data Pre-processing tool. At this point, each processed image is linked to a specific QC task and to the respective BIM elements depicted in the image. In the third step, the data are forwarded for the automated visual quality control. Since each image is linked to a specific element of the BIM model, the quality control results and the detected defects are also linked to elements of the BIM model (fourth step). Therefore, the inspector is able to visualize and confirm the QC results on-site using AR with each QC result pinned on the corresponding BIM element (fifth step). The inspector can either confirm or reject each detected defect and propose a rework or a mitigation work, if needed (sixth step). Finally, workers perform the proposed remedial works (seventh step). Since the defects, as well as the proposed reworks, are recorded to the BIM model, the defect management is facilitated, resulting in cost and time savings during the construction phase. The overview of the COGITO Visual QC framework is presented in Figure 1.

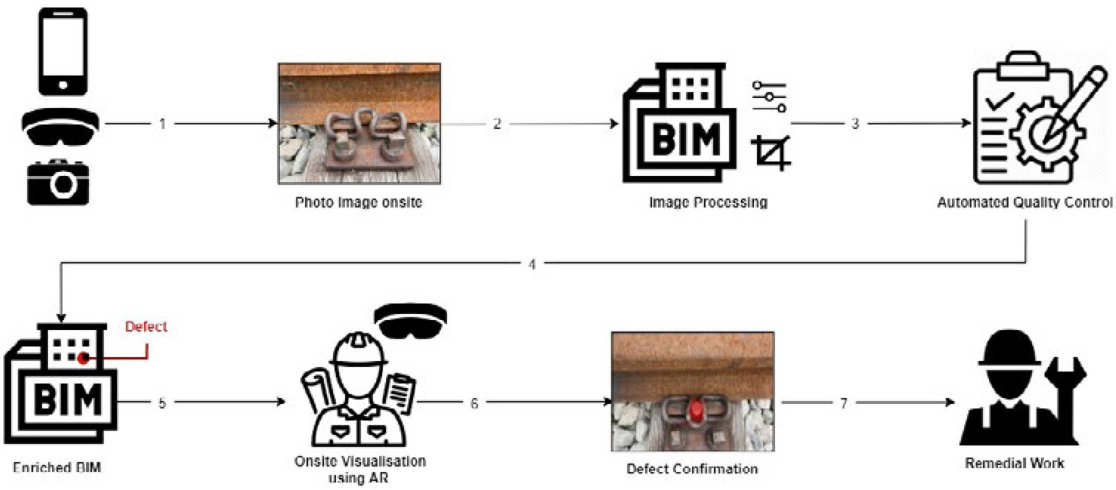

Figure 1: COGITO QC workflow

3.1 On-site Data Acquisition

Since it is necessary to capture images or videos of specific new as-built elements, various means of data acquisition can be utilized, such as cameras, mobile phones, drones and/or AR glasses (*Microsoft HoloLens2*, n.d.). Regardless of the means used for this purpose, some generic guidelines should be followed during this procedure, in order to achieve successful automated quality control and optimize the quality of the obtained results. More specifically, the images should be approximately 1000 x 1000 pixels, without spray markers or other signs that may affect negatively the QC results. They also need to be close shot and clear (not too generic or blurry) and the lighting conditions should be appropriate to ensure that the desired element is visible in the image. In case of video, the captured video will be automatically converted into a panorama image during the data processing phase. However, the video duration should be approximately five seconds (less than eight seconds) in order to generate an appropriate panorama image. In addition, a straightforward path should be followed while capturing. It is recommended to avoid rotating, shifting, sliding back or maneuvering. Finally, all the conditions for image capturing (close shot and clear, sufficient lighting conditions, without spray markers) should be also applied in case of video capturing.

3.2 Visual Data Pre-processing

After the on-site data capturing, the images need to be prepared and uploaded for the automated quality control. Within the COGITO project, this can be achieved both via a Pre-Processing Desktop application or the DigiTAR application in-situ, if the images are captured with a mobile phone or with HoloLens 2, respectively. The images should be linked to a specific QC task and BIM element before processing. The image processing includes filter application, such as modifying the contrast or the brightness of the photo and resizing or cropping it to focus on the region of interest. The aim of preprocessing is to prepare the image for the automated quality control. In case of uploading a video, a respective panorama image is generated automatically and the user is able to process it in a similar way to the normal images. Once all the desired data (images and videos) have been processed and related to a QC task, they are forwarded for the automated quality control. In Figure 2, the COGITO visual data pre-processing workflow is depicted.

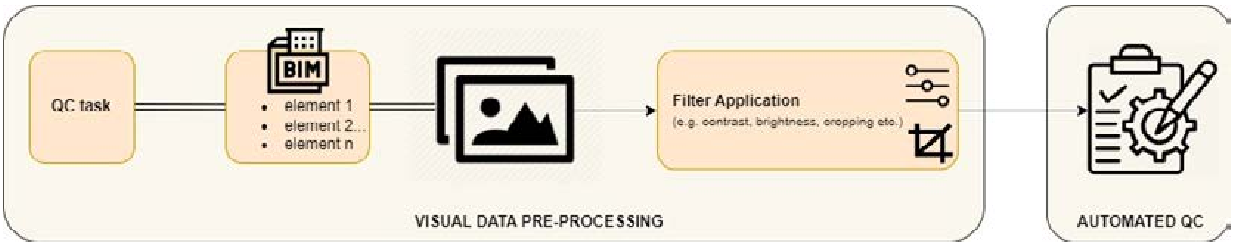

Figure 2: COGITO Visual Data Pre-Processing workflow

3.3 Automated Quality Control

The preprocessed visual data are forwarded for the automated quality control. Since the scope of the COGITO solution is to perform an automated quality control during the construction phase of new large linear infrastructures (especially railways), the VQC tool has been specifically designed to serve this purpose and the chosen defect classes for the algorithms are tailored to address construction-related issues, rather than covering defects attributed to aging of materials. Based on the deep learning algorithms employed, the VQC tool is able to detect defects, which are likely to occur during the railway construction, on concrete and steel elements. More specifically, in case of concrete surfaces, the system is able to detect cracks or honeycomb defects, while in case of railway steel elements, it detects missing clamps, missing screws, and missing screw nuts. The defect detection includes both the object detection and semantic segmentation. The goal of object detection is to classify individual defects and localize them using a bounding box and the goal of semantic segmentation is to distinguish the defects at the pixel level.

3.3.1 Dataset Preparation

For the concrete case, a dataset with concrete cracks and honeycomb images was built. The images have been combined from (*Crack Segmentation Dataset*, n.d.) and (*Concrete Crack Segmentation Dataset*, n.d.). Furthermore, additional data (with high resolution and image size) captured by Unmanned Aerial Vehicles (UAVs) were used. The original large UAVs images were divided into several smaller images using a Python script. For the steel case, a dataset was built using images collected from an above ground railway construction site in Munich. The images depict three types of defects that can occur during the railway placement: missing clamp, missing screw, and missing screw nut. The data were resized to be consistent and have fixed dimensions (i.e., 1024 x 1024 pixels). Since the scope of the project is the automated quality control in railways, underground areas are likely to exist. Therefore, an offline data augmentation was performed to the images, in order to reduce the brightness and simulate the tunnel lighting conditions. For the concrete dataset, 1970 images were used in total to train the model for detecting the two aforementioned types of concrete defects. The ratio of the training and validation sets was almost 4:1; the training and validation sets comprise 1544 and 426 images, respectively. For the steel dataset, 2195 images were used in total to train the model for detecting the railway joint defects. The ratio of the training and validation sets was almost 5:1; the training and validation sets comprise 1720 and 493 images, respectively. The annotation of the dataset is an important and fundamental step. The image label tool LabelMe (Russell et al., 2008) was used to label the masks of the objects in both cases (concrete and steel elements).

3.3.2 Transfer Learning Implementation

The VQC tool is designed to detect defects on concrete surfaces and in steel railway elements. For this purpose, two different models (for concrete and steel case, respectively) have been trained using the Matterport's implementation of Mask R-CNN for TensorFlow2.0 (Abdulla, 2017). Mask R-CNN is an extension to the original Faster R-CNN, by adding a branch for predicting segmentation masks on each Region of Interest (RoI) using an FCN, in parallel with the existing branch for classification and bounding box regression (He et al., 2017). Therefore, Mask R-CNN not only outputs a class label and a bounding box, but also a binary mask for each detected object. The network was trained with a learning rate of 0.001, momentum of 0.90, and weight decay of 0.0001. ResNet50 was used as a backbone architecture. The IMG_SIZE and the TRAIN_ROIS_PER_IMAGE parameters were set to 512 and to 80, respectively. The RPN_ANCHOR_SCALES parameter was set to (16, 32, 64, 128, 256). The value of MAX_GT_INSTANCES and DETECTION_MAX_INSTANCES parameters were set in both cases to 5. Since a transfer learning technique was applied, the COCO dataset was used to pre-train the network and initialize its weights. Finally, only the head layers were re-trained and fine-tuned on the appropriate datasets.

The configuration of system environment was Python 3.8, Keras 2.4.3, TensorFlow 2.4.1, CUDA 11.0, and CUDNN 8.0.5 on a computer with a NVIDIA GeForce RTX 3080 GPU and a Core i7-10700 @2.9GHz CPU, with 32 GB RAM memory.

3.4 AR Visualization

The QC results obtained by the automatic visual quality control are visualized on-site with the DigiTAR tool, in order to be confirmed by the relevant stakeholders, such as the project manager and the quality manager of the construction project. Based on their decision, additional remedial works can be assigned to the components included in the VQC results. In addition, the DigiTAR tool enables the AR visualization of the BIM models. The user is able to view the 3D BIM model on-site, i.e., view the 3D BIM elements overlaying the physical elements. The workflow of the QC results confirmation process within DigiTAR is depicted in Figure 3. DigiTAR is developed using the Unity 3D Game Engine and is specifically optimized to operate on (*Microsoft HoloLens2*, n.d.) devices. In Section 3.4.1, the BIM model visualization functionality of the DigiTAR tool is described in detail, while the registration process of the BIM model is described in Section 3.4.2. Details for the visualization of the relevant QC results and the data acquisition functionality of DigiTAR are enclosed in Sections 3.4.3 and 3.4.4, respectively.

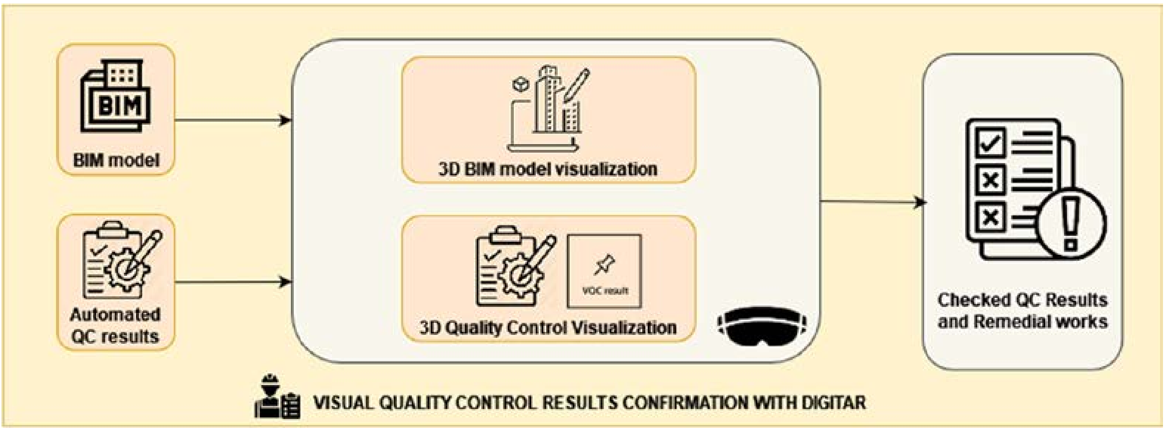

Figure 3: DigiTAR BIM model visualization and QC results confirmation workflow

3.4.1 BIM model visualization

BIM model visualization is a key functionality of the DigiTAR tool. To enable this functionality, DigiTAR requires as input the BIM model of the construction site in an Industry Foundation Classes (IFC) format. Additionally, the tool needs the 3D geometry representation of the BIM model. The geometry representation of the BIM model is achieved through the transformation of the IFC file to a file format supported by the Unity Game Engine, such as the OBJ file format.

The IFC parsing process in DigiTAR involves importing the IFC and OBJ files, extracting the IFC data, and mapping those data to the 3D model. This process is handled by custom C# classes based on the Xbim library (Lockley et al., 2017). The IFC parsing process is implemented by recursively querying and retrieving data from the IFC file for the elements of the IFC file using the IFC Schema. A GameObject is generated for each IFC element and parent/child relationships are established based on the hierarchical relationships of the elements in the IFC file. Upon completion of the IFC parsing, the result is a hierarchical structure, where each GameObject has its own IFC properties extracted in a dedicated C# class.

3.4.2 BIM model registration

After visualizing the BIM model, the next crucial step in the DigiTAR tool is registration, which involves aligning the 3D model of the construction site to the actual site. Within DigiTAR, registration relies on image targets using the Vuforia SDK (*Vuforia Engine*, n.d.). An image target is an image that the application running on HoloLens will detect and track. This image will be the link between the static 3D world (BIM model) and the real world.

The image target is printed and positioned at a location in the real world, ensuring that it is accessible to the person wearing the HoloLens. At the same time, an identical image is placed in exactly the same spot in the 3D BIM model. To enable the detection of the image target, the user uses speech command "Scan for marker". This way, the data captured by the HoloLens sensors and cameras are utilized by DigiTAR for image target detection. More specifically, features are extracted from the HoloLens camera stream and are compared to the reference features already extracted from the image target. In the context of pattern recognition, the features that are extracted in advance from the image target constitute the pattern that the algorithm searches across the continuous flow of data streams. When the person wearing the HoloLens looks at the image target, the features extracted from the data stream of HoloLens are matched to the pattern of features belonging to the image target. Therefore, the image target is detected and registration is performed.

After successful registration of the 3D BIM model and in order to maintain it, the registered 3D BIM model is continuously tracked. In the DigiTAR application, the registration of the 3D BIM model is tracked using spatial anchors; spatial anchors represent important points in the world that the HoloLens coordinate system keeps track of over time. The registered 3D BIM model can be set as a spatial anchor using the dedicated in DigiTAR speech command "Anchor model". This way, the next time the user opens the DigiTAR application, the 3D BIM model is loaded aligned to the real world without the need to repeat the registration process.

3.4.3 QC results visualization

The QC results are visualized using 3D QC tags that are pinned on the elements of the BIM model that are included in the QC result. The QC tags are displayed in Figure 4. To visually notify the user, the color of the tag is indicative of the relevant QC results: green if no defect has been detected, red if all QC results have detected defects, and orange if the QC results include both detected defects and no defects.

Figure 4: Visual Quality Control tags are pinned on the involved elements

Firstly, the QC tag is placed on the center of the element's bound. When an element with a QC gets in the user's field of view, the QC tag dynamically changes its position and rotation while staying on the surface of the 3D element. More specifically, the position of the QC tag is dynamically adjusted to the user's height, while the rotation of the QC tag is dynamically adjusted so that the QC tag is displayed vertically in front of the user. A view of a 3D BIM model with pinned QC tags is depicted in Figure 5. Moreover, if the user selects (using the Hand ray gesture on HoloLens[1]) a 3D element that has a pinned QC tag, the QC tag follows the movement of the user's hand, while staying on the surface of the 3D element. An illustration of this feature is depicted in Figure 6. If the user performs the air tap gesture[2] on a QC tag, the related VQC results are displayed using dedicated AR menus, as described subsequently in Section 4.2.

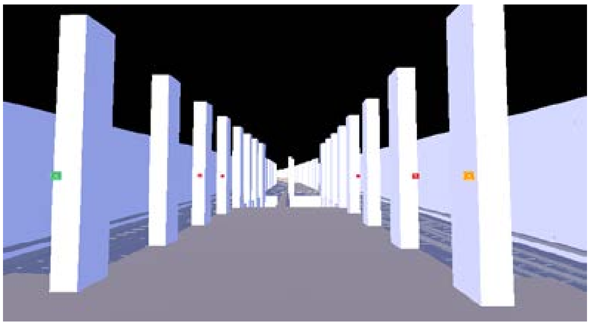

Figure 5: View of the 3D BIM model with QC tags

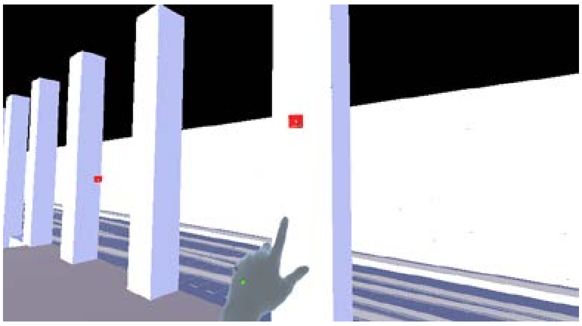

Figure 6: When selected, the QC tag follows the movement of the user's hand

3.4.4 Data acquisition and pre-processing

DigiTAR acts as a data acquisition tool for gathering images on-site to be used for automated quality control. This functionality is implemented in DigiTAR using a hand-attached menu[3]. When the user selects the dedicated "Capture Image" button, an asynchronous process is initiated to assess the HoloLens camera stream for photo capturing.

When the user looks at what they want to capture and say "Capture image", a photo is captured. The photo is saved in a folder of the HoloLens device. This folder, exclusively created by DigiTAR, stores only the images captured within the tool. This segregation is essential since these photos are accompanied by important metadata, including the capture time and the user's position and orientation at the time of capture. The alignment of the 3D BIM model with the real world, achieved through the registration process and spatial anchoring, enables precise association of the captured images with their corresponding locations in the BIM model.

After capturing the images, users can perform pre-processing on them before uploading them to be utilized by the automated quality control system. For this purpose, DigiTAR establishes direct communication with the backend of the Visual Data Pre-processing module. This seamless integration streamlines the process of preparing the captured images for subsequent quality control analysis, ultimately enhancing the efficiency and accuracy of the entire construction quality management process.

4. RESULTS AND DISCUSSION

The first subsection presents and analyses the evaluation process of the trained Mask R-CNN for defect detection. In the second subsection, a use case of the overall quality control process is presented, endowed with the in-situ results' visualization and confirmation via the DigiTAR application.

4.1 Automated Quality Control Evaluation

The performance of the two models (concrete and steel case) was evaluated using the mean Average Precision (mAP), since this metric is often used to evaluate object detection models. Precision is the percentage of correct positive predictions for overall predictions. Specifically, mAP is the mean value of average precision (AP) for each object class (Guo et al., 2021). The concrete model and the railway model were evaluated for 20 and 10 epochs respectively. The mAP for the concrete model reached the value of 0.87, while the mAP for the railway defects was calculated 0.95. Figure 7 shows the ground truth and the respective predictions of the proposed models for some typical examples. For each example, the generated images contain the label prediction, the confidence level, and the respective mask. The label prediction indicates the identified defect type detected by the model. The confidence level represents the model's level of certainty or confidence in its prediction. The mask displayed in

the images highlights the specific region or area where the defect has been identified. This visual representation allows for a clear understanding of the location and extent of the detected defect within the image.

a) original images

b) predictions

Figure 7: Original images (a) and predictions (b) for crack, honeycomb, missing clamp, missing screw, and missing screw nut.

4.2 Use Case Demonstration

The case study is focused on a railway line across Munich, Germany. The old line had to be replaced with a new one. During the reconstruction phase, the site was checked for cracks, honeycombs and rail defects, such as missing clamps, missing screws, and screw nuts.

Regarding the AR visualization, the IFC and the OBJ files for the railway site were parsed within DigiTAR using the BIM model visualization process, which is described in Section 3.4.1. The registration process, that is described in Section 3.4.2, was conducted using a strategically positioned image target within the construction zone. Precise measurements in meters, obtained from the IFC file, guided the accurate placement of the image target on-site. After the registration process was completed, the 3D BIM model became aligned with the actual construction site. This alignment allowed for accurate integration of the digital model with the real-world environment. An on-site 3D BIM model visualization using DigiTAR is illustrated in Figure 8. Figure 9 illustrates the successful visualization of the QC outcomes on HoloLens 2 using DigiTAR.

Figure 8: Screenshot of the 3D BIM model, as visualized on-site with DigiTAR

Figure 9: Screenshot of QC tags visualized on-site with DigiTAR

The surveyor captured images of the new elements using the DigiTAR tool following the procedure described in Section 3.4.4. Also, the surveyor processed the images on-site and uploaded them for automatic quality control. Utilizing the power of the VQC tool, the uploaded images underwent comprehensive assessment, generating valuable results. These results were then promoted to the DigiTAR tool for on-site inspection and confirmation. By performing the air tap gesture on a QC tag, an overview of the related Visual QC results was displayed to the surveyor, as depicted in Figure 10.

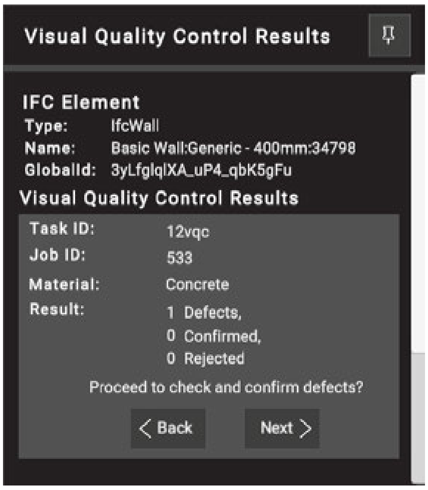

Figure 10: Overview visualization of the Visual QC results for a specific element

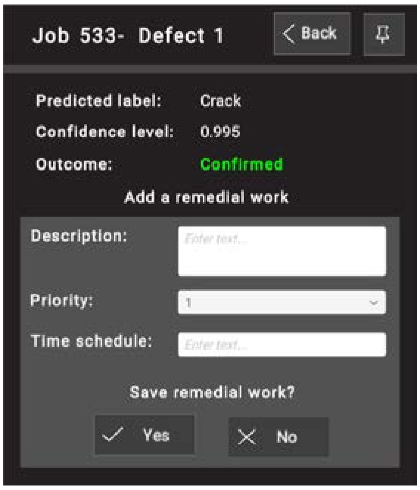

Figure 11: Menu to add remedial work to a QC result

By selecting the “Next” button in the menu in Figure 10, the surveyor could view details for the detected defect, as can be seen in Figure 12. The annotated image, the label of the detected defect and the confidence level were displayed (left figure in Figure 12). By selecting the “Original image” button, the surveyor could switch to viewing the original image that was sent for automatic visual quality control (right figure in Figure 12).

Upon confirming a detected defect, the surveyor was presented with the option to add a remedial work for the identified issue. The user-friendly menu to add a remedial work, as depicted in Figure 11, facilitated this process within the DigiTAR tool. To input the necessary information for the remedial work, the surveyor simply selected the relevant input fields on the menu. Upon selection, the HoloLens system keyboard was activated, allowing the user to type using hand gestures, making the data input intuitive and efficient.

The ability to process the remedial work in real-time within DigiTAR provided valuable advantages. It allowed for immediate consideration of mitigation measures and enabled rapid decision-making to address the identified defect effectively. This dynamic workflow streamlined the process of adding remedial works and contributed to enhanced project management and quality control.

5. CONCLUSIONS AND FUTURE WORK

Embracing automation in the construction industry leads to improvements in the adaptability of the project and paves the way for greater innovation and advancement. As technology continues to evolve, leveraging automatic tools becomes a crucial aspect of staying competitive in the ever-changing construction landscape.

This study presents a framework for semi-automated visual quality control inspection in construction sites during the execution phase of the project. The framework incorporates two tools; the Visual Quality Control (VQC) tool and the Digital Twin visualization with Augmented Reality (DigiTAR) tool. The first tool incorporates a deep learning network trained to detect concrete and railway defects and serves as a backend service for automatic visual quality control on images captured at construction sites. The second tool leverages AR technology to display the visual quality control results on-site. The surveyors can inspect the detected defects in-situ and confirm or reject them. They are also prompted to add remedial works, if needed. DigiTAR displays the 3D BIM model of the construction site, i.e., the model is visualized to overlay the actual site, allowing construction professionals to interact with the BIM model in a dynamic and realistic manner using AR technology. This critical functionality enhances the overall understanding and visualization of the construction site, promoting better decision-making and coordination throughout the project lifecycle.

By combining automated quality control (performed by the VQC tool) with DigiTAR's intuitive interface and augmented reality capabilities, the surveyors gain real-time access to the quality control outcomes. This facilitates decision-making and enables prompt confirmation of the results, ensuring the construction project adheres to the highest quality standards. The seamless flow of data and information between the automatic quality control system and the DigiTAR tool enhances efficiency and accuracy, ultimately contributing to the successful execution of the construction project. The proposed framework aims to demonstrate how the synergy between cutting-edge technology and user-friendly interfaces can create a powerful asset for construction professionals in ensuring top-notch project outcomes. Future efforts will be dedicated to improving and expanding the model's training to encompass a wider range of defects. This endeavor aims to enhance the model's accuracy and efficiency in detecting various types of issues within the construction site. Additionally, the image acquisition procedure could be automatized and significantly improved utilizing drones and construction site inspection robots (such as Spot robots that are used for automated laser scanning), since our framework has been developed to support this functionality. Finally, there is a plan to equip the model with the capability to detect defects on video streams and empower DigiTAR to also display the video captures. This enhancement will enable real-time monitoring and analysis of ongoing construction activities, empowering construction professionals to address potential issues as they arise.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Union’s Horizon 2020 Research and Innovation Programme through COGITO project under Grant Agreement No. 958310. Special thanks to Olympia Odos and to Rhomberg Sersa Rail Group for providing UAV images of concrete defects and images of railway steel defects, respectively. Special thanks to Rhomberg Sersa Rail Group, and especially Katharina Leer, for their valuable participation in the use case demonstration.

A COMPARATIVE STUDY OF DEEP LEARNING MODELS FOR SYMBOL DETECTION IN TECHNICAL DRAWINGS

Benedikt Faltin, Damaris Gann & Markus König
Ruhr University Bochum, Germany

ABSTRACT: *Symbols are a universal way to convey complex information in technical drawings since they can represent a wide range of elements, including components, materials, or relationships, in a concise and space-saving manner. Therefore, to enable a digital and automatic interpretation of pixel-based drawings, accurate detection of symbols is a crucial step. To enhance the efficiency of the digitization process, current research focuses on automating this symbol detection using deep learning models. However, the ever-increasing repertoire of model architectures poses a challenge for researchers and practitioners alike in retaining an overview of the latest advancements and selecting the most suitable model architecture for their respective use cases. To provide guidance, this contribution conducts a comparative study of prevalent and state-of-the-art model architectures for the task of symbol detection in pixel-based construction drawings. Therefore, this study evaluates six different object detection model architectures, including YOLOv5, YOLOv7, YOLOv8, Swin-Transformer, ConvNeXt, and Faster-RCNN. These models are trained and tested on two distinct datasets from the bridge and residential building domains, both representing substantial sub-sectors of the construction industry. Furthermore, the models are evaluated based on five criteria, i.e., detection accuracy, robustness to data scarcity, training time, inference time, and model size. In summary, our comparative study highlights the performance and capabilities of different deep learning models for symbol detection in construction drawings. Through the comprehensive evaluation and practical insights, this research facilitates the advancement of automated symbol detection by showing the strengths and weaknesses of the model architectures, thus providing users with valuable guidance in choosing the most appropriate model for their real-world applications.*

KEYWORDS: *Computer Vision, Technical Drawings, Symbol Detection, Comparative Study*

1. INTRODUCTION

Symbols pose an efficient and space-saving way of conveying complex information, enabling understanding across languages due to their standardized appearance. They find application in diverse contexts, such as street signs (Gudigar et al., 2016), maps (Huang et al., 2023), or technical drawings (Elyan et al., 2020b). For instance, in construction drawings symbols can represent architectural components, plumbing fixtures, elevation markings, and more, making accurate identification of the symbols essential for understanding the entire drawing. The importance of precise symbol detection becomes even more apparent when algorithms are used to understand the technical drawings automatically, e.g., for their digitization. Therefore, research has focused on developing effective and accurate algorithms for locating and classifying symbols in technical drawings. Ah-Soon (1998) proposed to adapt Messmer's algorithm for symbol recognition in architectural drawings using graph matching. The drawing is first vectorized, followed by the extraction and merging of geometric features for each symbol, and clustering similar symbols by type. In a separate work, Adam et al. (2000) developed an orientation and scale invariant method for recognizing symbols in technical documents. Their algorithm is based on the Fourier-Mellin transform, which extracts features used to label the symbols through a classifier.

Most of this research focuses on traditional image analysis techniques, such as vectorization and feature engineering. However, with the advent of efficient deep learning approaches, such as convolutional neural networks (CNN), the research community's interest has shifted to use such models for localizing and classifying symbols in technical drawings. Ziran and Marinai (2018) leverages the object detection networks Faster R-CNN and Single Shot Detector (SSD) to detect symbols representing objects such as furniture, doors, and windows in architectural floor plans. In the context of piping and instrumentation diagrams (P&IDs), Mani et al. (2020) develops a custom CNN to classify components in the P&IDs. The proposed network is trained to classify patches cropped from the overall drawing into three classes: tag symbol, component symbol, or no symbol. When the network detects a symbol within a patch, the corresponding detection is projected back onto the original drawing. In a different approach for P&IDs, Elyan et al. (2020a) employs the YOLO architecture for symbol detection. Additionally, the authors propose a method based on generative adversarial networks to mitigate the issue of class imbalance in technical drawings. Class imbalance occurs when the number of instances per symbol class shows significant variation. A novel approach to enhance symbol detection by inferring the symbol orientation is

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)

introduced by Faltin et al. (2023b). The authors leverage human pose detection networks, specifically Mask R-CNN and YOLOv7Pose, to achieve accurate symbol pose estimation in construction drawings.

While the proposed approaches already utilize several different detection models, the overall field of object detection has experienced rapid growth, leading to the emergence of numerous model architectures (Zaidi et al., 2022). Researchers and industry practitioners alike face the difficult task of selecting the most appropriate architecture for their specific applications. This becomes especially difficult when other critical requirements such as training time, inference time, or model size must be considered in addition to detection accuracy. For instance, in real-time applications, faster inference time may be prioritized, while in resource-constrained environments, smaller model sizes may be important. Therefore, researchers and practitioners need to conduct thorough evaluations of the various object detection models to make an informed decision.

Previous research has compared different model architectures for different applications to aid in model selection. However, to the best of the authors' knowledge, there is no study that directly compares detection models for symbol detection in pixel-based drawings. Nevertheless, related publications have conducted comparison studies in various other domains. For instance, Brößner et al. (2022) compares nnUNet with the transformer-based Swin-UNet for bone segmentation in ultrasound images, finding that both networks are similarly applicable to the task. In another study, Wang et al. (2023) conducts a comparison for different backbones such as ResNet, Swin, and ViTAEv2, by pre-training them on a large dataset of satellite images to later test them on different down-stream tasks, such as image segmentation or object detection. The authors discover that the transformer-based models show competitive results compared with the CNN models. In particular, ViTAEv2 achieves the highest performance on the different tasks. Moutik et al. (2023) compares several models based on CNNs, transformers, and hybrid approaches, to recognize human actions in video data. This study concludes that the CNN- and transformer-based models perform similarly, both with their strengths and weaknesses, but overall, the hybrid methods achieve the best results.

Our research contributes to this broad research area by providing a comprehensive analysis of state-of-the-art object detection models and evaluating them based on several criteria for symbol detection in construction drawings. The remainder of the paper is structured as follows: Section 2 presents the methodological design of the comparative study conducted and details of the datasets used. Subsequently, in Section 3, we present and discuss the results of our comparative study, shedding light on the performance of different detection models. Finally, Section 4 summarizes the results and provides possible directions for further research in this area.

2. METHODOLOGY

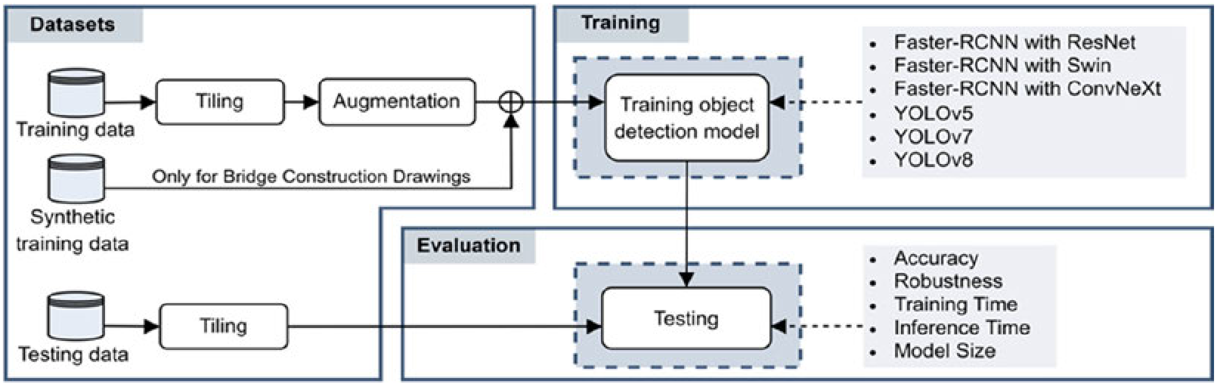

Fig. 1: Overview of the methodology used in the comparative study.

The structure of this comparative study is shown in Fig. 1. Real data is collected and annotated to train and test the selected models. In addition, synthetic data is generated to extend the dataset. The models are trained with a combination of real and synthetic data, while only real data is used for testing. Section 2.1 provides a detailed description of the datasets. The comparison includes six different network architectures: YOLOv5 (Jocher et al., 2022), YOLOv7 (Wang et al., 2022), YOLOv8 (Jocher et al., 2023), and Faster R-CNN (Ren et al., 2017) with three different backbones namely ResNet (He et al., 2016), Swin (Liu et al., 2021), and ConvNeXt (Liu et al., 2022). A brief introduction to the compared network architectures is presented in Section 2.2. In order to comprehensively assess the models, they are evaluated with respect to five criteria, i.e., accuracy, robustness, training time, inference time, and model size, which are explained in detail in Section 2.3.

2.1 Datasets

To obtain a meaningful comparison, the models are trained and tested on two distinct datasets representing different sub-sectors of the construction industry: bridge construction drawings and floor plans. The *bridge*-dataset comprises 15 real construction drawings with approximately 10.000 x 6.000 pixels dimensions. To make the large dimensions of the drawings manageable for the models, tiling is used to divide the drawings into patches. The drawings contain three types of symbols: section symbols, elevation markers, and dimension symbols (cf. Fig. 2). The size of these symbols varies from 20 to 300 pixels, which is relatively small compared to the overall size of the drawing. Consequently, the models must be able to produce meaningful feature representations even for small objects. To investigate this, the study explores different patch sizes to examine the influence of the symbol-to-image size ratio. Therefore, three patch sizes are considered: 256 pixels, 512 pixels, and 1024 pixels. This results in three data subsets named *bridge_256*, *bridge_512*, and *bridge_1024*, containing 2120, 1185, and 543 patches, respectively.

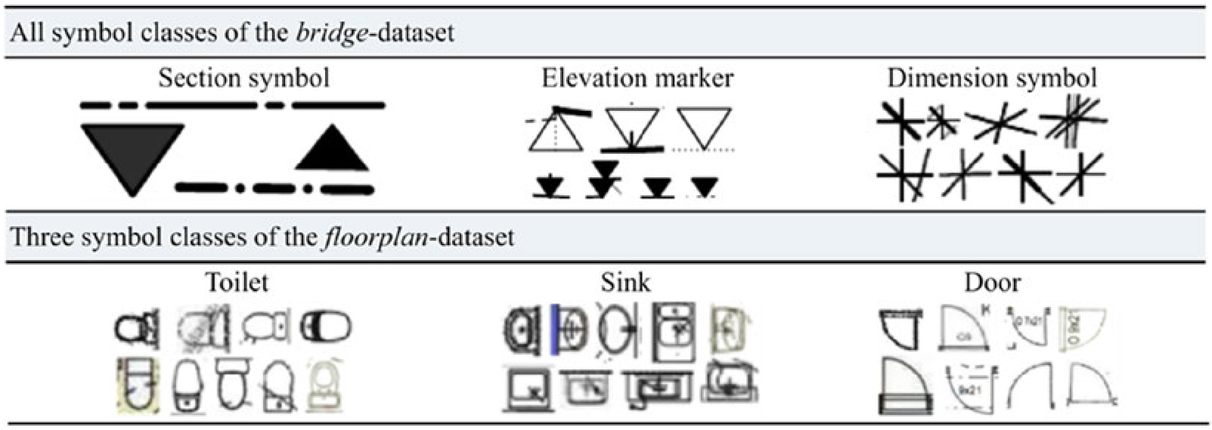

Fig. 2: Example illustration of some representative symbols selected from the datasets.

Since the number of patches is still quite limited, additional synthetic data is generated based on the procedure introduced by Faltin et al. (2022a). Lastly, to investigate the influence of the quantity of training data on the model's performance for the *bridge*-dataset, a reduced data subset called *bridge_1024_red* is created, which comprises only 10% of the original data subset *bridge_1024*. Table 1 gives an overview of the composition of all datasets.

Table 1: Overview of the composition of the data subsets. Synthetic data is only used for training and validation.

	No. training images	No. synthetic training images	No. validation images	No. synthetic validation images	No. testing images
bridge_256	5611	1500	993	250	316
bridge_512	3179	1500	544	250	192
bridge_1024	1477	1500	250	250	94
bridge_1024_red	130	170	25	25	94
floorplan_1024	10294	0	1800	0	750

On the other hand, the *floorplan*-dataset consists of 5000 fully annotated floor plans of residential buildings sourced from the CubiCasa-dataset (Kalervo et al., 2019). The majority of the drawings in this dataset are similarly sized ranging between 500 and 2000 pixels, therefore they are resized uniformly to 1024 pixels (*floorplan_1024*). The drawings distinguish eight different symbol classes: window, door, electrical appliance, toilet, sink, sauna bench, fireplace, and bathtub. Fig. 2 illustrates the high intra-class variation among these symbols, which requires effective generalization of the object detection models to handle the diverse styles.

2.2 Object Detection Models

In this study three single-stage detection models, namely YOLOv5, YOLOv7, and YOLOv8 are compared with three two-stage detection models. Each two-stage model modifies the Faster R-CNN architecture by replacing the backbone while keeping the region proposal network and detection head unaltered. The selected backbones are ResNet, ConvNeXt, and Swin. In this section, a short overview of the different architectures is given.

The YOLO model series is known for its high detection performance and fast inference speed. Both YOLOv7 and YOLOv8 are extensions of YOLOv5 but incorporate different ideas such as anchorless detection and different convolutional blocks to enhance the base model's performance.

In comparison, ResNet is a well-established CNN-based image classification network commonly used as the backbone architecture for Faster R-CNN. On the other hand, the Swin backbone is a transformer-based architecture, building upon the concept of the visual transformer introduced by Dosovitskiy et al. (2020). Swin addresses the challenges of adapting transformers to the image domain by employing a hierarchical architecture with shifting attention windows. Lastly, ConvNeXt progressively modernizes the basic ResNet architecture by incorporating key components of visual transformers into the CNN-based architecture.

For each of the chosen model architectures, the base size and the smallest version, referred to as tiny, are compared. This investigates whether equivalent results can be obtained with smaller model sizes. In general, larger models can extract more meaningful features due to their increased complexity, allowing them to handle challenging tasks while, in contrast, making them prone to overfit. The smallest versions are ResNet-50, Swin-Tiny, ConvNeXt-Tiny, YOLOv5n, YOLOv7-tiny, and YOLOv8n, while the base-versions are ResNet-101, Swin-Base, ConvNeXt-Base, YOLOv5m, YOLOv7, and YOLOv8m.

2.3 Evaluation

To provide a comprehensive overview of the strengths and weaknesses of each model, they are evaluated based on five criteria: accuracy, robustness, training time, inference time, and model size. A detailed explanation of each criterium is given in the remainder of this section:

2.3.1 Accuracy

Accuracy measures the model's ability to correctly locate and classify the symbols within the drawing. To assess the accuracy the standard metric of mean average precision (mAP) as defined by Padilla et al. (2021) is utilized, as it considers the precision and recall, evaluated at certain levels of intersection over union (IoU). While the precision indicates the proportion of accurate predictions made by the model among all the predictions, the recall denotes the proportion of correct predictions compared to the total number of ground-truth boxes available. Lastly, the IoU quantifies the overlap between a prediction and the ground-truth bounding box, measuring the model's localization accuracy.

2.3.2 Robustness

Obtaining and annotating extensive training data is time-consuming, resulting in data scarcity in many cases. Hence, it is highly desirable to have a robust object detection network, which means it performs reasonably well even with limited training data. The model is trained with 90% reduced training data to evaluate robustness. After training, the network's performance is tested with the full test dataset using the mAP metric. This enables an estimate of the accuracy decrease when training data is significantly limited.

2.3.3 Training time

Training time measures the physical time required for the model to reach a plateau, indicating that no further improvement is expected. This is particularly important in applications with limited computational resources or where the model is regularly retrained. While the training time may vary depending on the hardware used, in this study all models are trained on the same GPU to ensure comparability.

2.3.4 Inference Time

The inference time quantifies how long it takes for the model to make a single prediction, making it a vital metric for real-time applications.

2.3.5 Model size

Model size describes the memory requirements of the model and is a crucial factor that directly affects various aspects of model performance. Smaller models usually have a smaller number of parameters, leading to shorter inference times. However, extremely small models may not have the necessary complexity to handle the given task effectively. Therefore, it is important to carefully select the appropriate model size to achieve optimal performance.

3. RESULTS & DISCUSSION

To perform the comparative study, the models are trained by running three Nvidia A100-SXM4-40GB GPUs. The two-level networks are available pre-trained solely on the ImageNet-1K dataset, which is a subset of the larger ImageNet dataset (Deng et al., 2009). Conversely, the YOLO models are available pre-trained exclusively on the MS COCO dataset (Lin et al., 2014). The AdamW (Loshchilov & Hutter, 2017) optimizer is employed with a batch size of 64 and an initial learning rate of 0.0001 for backpropagation. The maximum number of epochs is set to 400, but early stopping is utilized to prevent overfitting. In order to increase the overall quantity and diversity of the training data, data augmentation techniques such as flipping, rotation, scale, or translation are utilized for all data subsets. The results are presented and discussed in the following sections based on the different evaluation criteria.

3.1 Results for Accuracy

Table 2 shows the results of the comparative study focusing on symbol recognition accuracy. To evaluate the symbol detection performance with the mAP metric, an IoU threshold of 0.5 (mAP@0.50) is appropriate for most use cases. Nevertheless, the more stringent mAP@0.50:0.95 is also used in this study to evaluate the models more comprehensively. For the bridge dataset, ConvNeXt-B achieves the highest mAP@0.50 score of 0.996 on 512 x 512 pixel patches, closely followed by ResNet-101, Swin-T, and Swin-B, all obtaining a score of 0.992 on 1024 x 1024 pixel patches. This suggests that the symbol-to-image size ratio is not critical, as the models accurately detect smaller symbols even on larger patches. But on the contrary, performance generally declines with smaller patch sizes, with the lowest results observed on 256 x 256 pixel patches. This demonstrates the importance of context, as the models must consider each symbol's surrounding space to locate and classify it properly. This is consistent with the observations of Lim et al. (2019), who similarly emphasized the importance of context when dealing with small objects.

Table 2: Performance results of the detection models on the *bridge*- and *floorplan*-dataset. The bold fonts indicate the best results for the respective data subset, while the asterisk indicates the best results for the specific dataset.

	Bridge-dataset						*Floorplan*-dataset	
	256 x 256 Pixel		512 x 512 Pixel		1024 x 1024 Pixel		1024 x 1024 Pixel	
	$mAP_{0.50}^{IoU}$	$mAP_{0.50:0.95}^{IoU}$	$mAP_{0.50}^{IoU}$	$mAP_{0.50:0.95}^{IoU}$	$mAP_{0.50}^{IoU}$	$mAP_{0.50:0.95}^{IoU}$	$mAP_{0.50}^{IoU}$	$mAP_{0.50:0.95}^{IoU}$
ResNet-50	0.912	0.739	0.973	0.815	0.986	0.833	0.771	0.492
ResNet-101	0.927	0.743	0.980	0.827	**0.992**	0.830	0.776	0.485
Swin-T	0.945	0.769	0.961	0.801	**0.992**	0.846	0.789	0.517
Swin-B	**0.950**	0.742	0.978	0.834	**0.992**	0.847	0.799	0.518
ConvNeXt-T	0.934	0.763	0.992	0.862	0.991	0.855	0.795	0.527
ConvNeXt-B	0.934	0.786	***0.996**	0.864	0.991	0.862	0.806	0.524
YOLOv5n	0.884	0.578	0.868	0.615	0.912	0.645	0.649	0.379
YOLOv5m	0.886	0.704	0.951	0.799	0.973	0.838	0.761	0.510
YOLOv7-tiny	0.884	0.648	0.924	0.675	0.949	0.686	0.763	0.474
YOLOv7	0.934	0.705	0.956	0.786	0.967	0.748	***0.816**	0.551
YOLOv8n	0.921	0.715	0.890	0.705	0.965	0.794	0.717	0.454
YOLOv8m	0.938	0.814	0.965	0.854	0.982	0.891	0.805	0.570

Regarding mAP@0.50:0.95, ConvNeXt-B still achieves the best results with 0.864. Conversely, YOLOv5n is the weakest performer in both mAP@0.50 and mAP@0.50:0.95, likely due to its lower model complexity affecting its ability to handle the complex symbol detection task.

For the *floorplan*-dataset, YOLOv7 leads by a significant margin (0.816), followed by ConvNeXt-B (0.806) and YOLOv8m (0.805). However, when considering mAP@0.50:0.95, YOLOv8m outperforms YOLOv7 with a notable gap. The general accuracy on the floor plans is lower compared to that of the bridge drawings. This discrepancy may be due to a larger number of symbol classes or a wider variety of symbol styles in the *floorplan*-dataset.

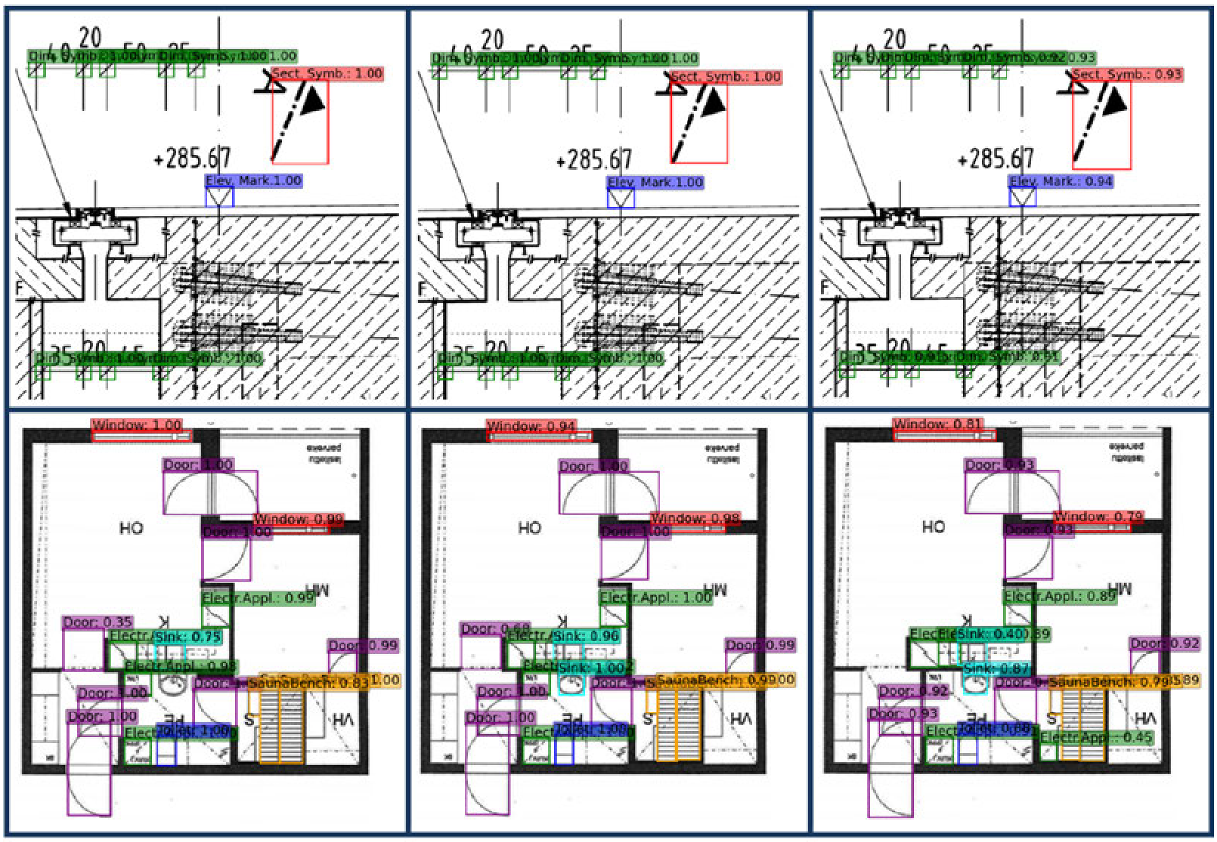

Fig. 3: Predictions of the base models of Swin (left), ConvNeXt (center), and YOLOv8 (right) on a patch from the *bridge*-dataset (top) and the *floorplan*-dataset (bottom).

Overall, larger and newer models perform better when accuracy matters. However, no significant difference in detection accuracy is seen between transformer-based and modern CNN-based networks. Despite that, the YOLO models tend to achieve lower mAP values than the two-stage models. This might be due to the YOLO model's smaller size. One exception is the YOLOv8m model, which achieves the highest values of all YOLO models and sometimes even outperforms the two-stage models.

3.2 Results for Robustness

The results for the reduced training dataset are presented in Table 3. While ConvNeXt-B shows the highest mAP score on the full training dataset, its performance declined by 25% when trained on the reduced dataset. It is also noteworthy that YOLOv5n, which already performed the worst, showed the largest decrease with 51%. On the other hand, YOLOv7 is quite robust to reduced training data, showing an 18% drop with mAP@0.50:0.95 score of 0.614. It is followed by the second most robust network ResNet-101 with a decrease of 26%.

3.3 Results for Training Time, Inference Time & Model Size

Table 3 shows the training time, inference time, and model size of the compared object recognition networks. Among them, YOLOv8n has the shortest training time with 0.51 hours on average, while still achieving promising results, as shown in Table 2. On the other hand, the transformer-based Swin-B network requires the longest training time. This is probably due to the computationally intensive attention mechanism used by the Swin network. In terms of inference time, the YOLO models demonstrate superior performance compared with the two-stage models. Specifically, YOLOv7-tiny achieves the fastest inference time, averaging 1.6 milliseconds per image, followed by YOLOv7 with 6.4 milliseconds per image. Surprisingly, despite its smaller network size, YOLOv5n does not display the fastest inference time. It is worth noting that even the largest network, ConvNeXt-B, has a relatively small memory requirement of 400 MB.

Table 3: Performance results on the reduced *bridge*-dataset as well as training time, inference time, and model size. The bold fonts indicate the best results for the respective column.

	bridge_1024_red				
	$mAP_{0.50}^{IoU}$	Performance decrease	Training time in hrs. averaged	Inference in ms/img on 1024 x 1024 pixels	Model size in MB
ResNet-50	0.590	-31%	2.58	52.9	157.97
ResNet-101	0.611	-26%	3.21	55.3	230.62
Swin-T	0.635	-25%	5.19	70.4	170.95
Swin-B	0.602	-29%	7.52	109.9	397.56
ConvNeXt-T	0.633	-26%	4.20	64.5	171.88
ConvNeXt-B	0.645	-25%	5.51	104.2	400.27
YOLOv5n	0.319	-51%	0.82	12.9	**7.12**
YOLOv5m	0.541	-35%	2.67	17.8	80.77
YOLOv7-tiny	0.491	-28%	1.12	**1.6**	22.94
YOLOv7	**0.614**	**-18%**	3.15	6.4	139.21
YOLOv8n	0.570	-28%	**0.51**	12.9	11.49
YOLOv8m	0.672	-25%	2.49	18.3	98.65

In summary, it is important to find a balance between model size and accuracy. Smaller models may perform worse and models that are too large may overfit on the training data. Therefore, when choosing an appropriate model size, an optimal trade-off between model complexity and performance must be made based on the specific requirements of the application.

4. CONCLUSION

This paper provides a comprehensive comparison of six object detection models employed for the task of symbol detection in pixel-based construction drawings. The evaluated models include YOLOv5, YOLOv7, YOLOv8, and Faster R-CNN, equipped with three different backbones, i.e., ResNet, Swin, and ConvNeXt. For each architecture the smallest and baseline model size are employed, resulting in a total of twelve compared models. The evaluation is conducted along five key criteria, namely accuracy, robustness, training time, inference time, and model size. This offers valuable insights to guide the selection of appropriate models for diverse use cases and their specific requirements. The models are trained and tested on bridge construction drawings as well as floor plans representing two common sub-sectors of the construction industry.

Among the evaluated models, ConvNeXt shows the highest accuracy in the *bridge*-dataset, which makes it the best choice for detecting small symbols with low variance. On the other hand, when a high variance of symbol style is present, YOLOv7 or YOLOv8 are more suitable choices. Notably, YOLOv7 also proves robust when trained with reduced data, therefore making it superior to YOLOv8. Overall, the YOLO models generally have lower training and inference times, which can be directly linked to their smaller model size. Overall, the more recent models, including YOLOv8, Swin, and ConvNeXt, show comparably high accuracy, suggesting that significant improvements in the future will be limited. Nevertheless, promising research directions such as self-supervised learning (Jaiswal et al., 2021) and active learning (Schmidt et al., 2020) are expected to advance training efficiency by reducing the amount of training data required or the manual annotation effort. Moreover, expanding upon the proposal by Elyan et al. (2020a) for generating synthetic data through deep learning models, employing new methods such as stable diffusion (Rombach et al., 2022), could improve detection results even more, mitigating the scarcity of real data.

The results of our study provide valuable insights for the future development of symbol detection research, enabling further exploration of model performance on other technical drawing types, such as P&IDs. Investigating hybrid models that combine transformer- and CNN-based architectures represents another promising direction for future research.

5. ACKNOWLEDGMENTS

This research is being conducted as part of the BIMKIT project, which is funded by the German Federal Ministry of Economics and Climate Protection. Furthermore, we would like to thank Lisa Freiin von Rössing for her valuable contributions to this study.

TOPOLOGICAL RELATIONSHIP MODELLING FOR INDUSTRIAL FACILITY DIGITISATION USING GRAPH NEURAL NETWORKS

Haritha Jayasinghe & Ioannis Brilakis
Department of Engineering, University of Cambridge, United Kingdom

ABSTRACT: There is rising demand for automated digital twin construction based on point cloud scans, especially in the domain of industrial facilities. Yet, current automation approaches focus almost exclusively on geometric modelling. The output of these methods is a disjoint cluster of individual elements, while element relationships are ignored. This research demonstrates the feasibility of adopting Graph Neural Networks (GNN) for automated detection of connectivity relationships between elements in industrial facility scans. We propose a novel method which represents elements and relationships as graph nodes and edges respectively. Element geometry is encoded into graph node features. This allows relationship inference to be modelled as a graph link prediction task. We thereby demonstrate that connectivity relationships can be learned from existing design files, without requiring domain specific, hand-coded rules, or manual annotations. Preliminary results show that our method performs successfully on a synthetic point cloud testset generated from design files with a 0.64 F1 score. We further demonstrate that the method adapts to occluded real-world scans. The method can be further extended with the introduction of more descriptive node features. Additionally, we present tools for relationship annotation and visualisation to aid relationship detection.

KEYWORDS: *BIM, Digital twin, GNN, machine learning*

1. INTRODUCTION

Ageing industrial facilities often lack essential documentation, resulting in sub-optimal maintenance and breakdowns. Digital twins remedy this and assist in the operation and maintenance of industrial facilities. However, generating twins for existing facilities is a laborious and time-intensive process that outweighs the perceived benefits offered by the twins. (Agapaki et al., 2018). While this has resulted in significant interest in automation, current approaches merely segment elements and model their geometry. However, industrial facilities are composed of a vast number of interconnected elements of various categories; thus, the identification of their connectivity relationships is a crucial, yet challenging step in the digitisation process.

The prevalent methodology for constructing geometric DTs from existing facilities, known as "Scan-to-BIM" (Tang et al., 2010) consists of the following steps: (1) raw data collection, (2) data preparation, (3) geometric modelling, and (4) semantic enrichment of the model. The focus of this paper is the final step.

Semantic enrichment' refers to the incorporation of various forms of additional information into a digital twin to enhance its value. Some common examples are element relationships, material information, damages to elements, and code compliance information. There are various types of 'element relationships' within industrial facilities. Tang et al (Tang et al., 2010) identifies three commonly found relationship types. Namely, topological relationships (e.g., a pipe being connected to an elbow), aggregation relationships (e.g., a pipe being within the HVAC (Heating, Ventilation and Air Conditioning) system) and containment relationships (e.g., a window belonging to a wall). This paper focuses on topological relationships.

Topological relationships between various elements of a facility are a key component of its documentation. For instance, when diagnosing faults within building systems (Tang et al., 2010), carrying out maintenance tasks, or checking for code compliance (Bloch & Sacks, 2020), topological relationships must be identified in advance. They are also crucial when analysing sub-systems within a plant, which assists maintenance and monitoring.

A variety of industry tools such as Trimble RealWorks, Leica Cyclone, ClearEdge3D EdgeWise are used in the DT construction process. Currently, element relationships modelling between elements is largely a manual process with industry tools providing limited automation. Tools such as EdgeWise can connect adjacent pipes, but not other piping elements. AVEVA E3D and PointSense offer the ability to derive pipe branches but require user guidance through point picking. A feature comparison of popular tools is given in table 1 (Son et al., 2015). The requirement of manual guidance throughout the modelling process is one of the primary pitfalls of current software solutions, necessitating significant expert labour.

Elbow	NA	NA	FA
Tees	NA	NA	FA

This paper proposes a novel method for automatically identifying topological relationships between elements within industrial facility models using GNNs. We demonstrate our model's performance both on synthetic and real-word data. Furthermore, we present tools for relationship visualisation and annotation to aid in the relationship detection process. Crucially, this research demonstrates the applicability of graph inference for element relationship inference in BIM.

2. BACKGROUND

Current literature on industrial facility DT construction predominantly encompasses the first three steps of the Scan-to-BIM process. Annotated point cloud datasets such as CLOI contains elements from classes such as Channels, Valves, I-beams, Flanges, Elbows, Cylinders and Angles (Agapaki et al., 2019). A prominent instance segmentation method utilizes CLOI-NET, a modified PointNet++ based neural network to identify element point clusters using the above dataset. This achieves 73.2% mean precision and 71.1% mean recall over all classes. However, results for more complex shapes such as flanges are considerably lower, especially in the presence of occlusions. Another approach proposes ResPoint++, which uses an encoder-decoder structure trained on I-Beams, R-Beams, pumps, pipes, and tanks (Yin et al., 2021). Xie et al proposes PipeNet for modelling straight pipes via centreline prediction (Xie et al., 2023). Once element point clusters are retrieved, they are geometrically modelled with approaches such as CAD model matching (Agapaki & Brilakis, 2022). However, the final semantic segmentation step, particularly in the form of relationship inference is yet unsolved, in industrial facilities as well as in other domains. Moreover, scan datasets with annotated relationships currently do not exist.

Traditionally, element relationships are defined with various data schemas such as IFC. However, graph representations of IFC models have recently become prominent due to their ability to query information more effectively. In a graph representation, each element is represented by a graph node. Relationships between elements are depicted by edges. Graphs are well suited for the representation of building information as both spatial and non-spatial information can be stored as node or edge properties within a graph (Ismail et al., 2018).

Previous attempts at automated detection of element relationships rely on hard coded rules. Nguyen et al. proposes an algorithmic approach to inferring relationships such as adjacency, containment, intersection, and connectivity from CAD models of elements (Nguyen et al., 2005). This requires complete CAD models without occlusions and is constrained by many assumptions. Another approach infers connecting tees and elbows based on pipe centrelines to predict pipelines (Oh & Kwang, 2021). Hard coded rules are unique to their domain. Thus, these approaches cannot scale to various domains, and are limited to a few common scenarios. To our knowledge, no published work exists that attempts to derive relationship information between various elements a laser scan.

Such a task would require an understanding of the nature of element relationships within an environment. For instance, the existence of a pipe and an elbow in proximity and in alignment suggests that the two elements are linked. There is a diverse and non-exhaustive set of such instances where relationships can be inferred, especially in the presence of occlusions and barriers such as walls. Furthermore, these vary between domains; the types of relationships in a bridge are vastly different from those in an industrial facility. Thus, rule-based approaches to relationship inference tend to perform poorly. We posit that a method of automatically learning the nature of relationships in a particular domain is better suited for this use case. In particular, we focus on GNNs, which are geometric deep learning approaches capable of learning directly from graphs.

GNN architectures can be split into spatial and spectral GNNs. Spatial GNNs such as GraphSAGE (Hamilton et al., 2017) and Graph attention Networks (GAN) (Veličković et al., 2017) create vector embeddings of graph nodes and aggregate features of adjacent nodes. In contrast, spectral GNNs such as Graph Convolution Networks (GCN)

(Kipf & Welling, 2016) are based on graph message passing. Other influencing factors include size of the graph and type of task. Tasks can be broadly categorized into three types: node classification, link prediction and graph classification. The choice of architecture for a particular task is influenced by a variety of factors. For instance, GraphSAGE and GCN are by default suited for graphs without edge features. Furthermore, they both behave as inductive frameworks, allowing them to scale to nodes that are unseen during the training process. However, inductive frameworks are unable to perform prediction on a completely edgeless new node, as information cannot be propagated in the absence of edges. Methods such as Edgeless-GNN (Shin et al., 2021) address this shortcoming by introducing pseudo edges based on similarities in node features. These edges ensure message propagation to new nodes.

There are very few applications of GNNs in the buildings domain. Buruzs et al. and Wang et al. both utilize graph representations of IFC models for the task of room type classification. They utilize a GCN and a modified version of GraphSAGE architecture respectively (Buruzs et al., 2022; Wang et al., 2022). They both model the task as a node classification problem and focus on indoor living spaces. Some of the edge features used within the graph representation include type of connection (e.g., Door vs wall) and material of connection (wooden vs metal door), while some of the node features include volume, height, oriented bounding box dimensions etc. The above methods demonstrate the suitability of graph learning in BIM.

The above findings demonstrate that we do not yet know how to automatically detect relationships between industrial facility elements. We merely know how to identify individual elements in isolation, but a digital twin should represent the connectivity and interactions of the system. The aim of this work is to address this gap in knowledge by answering the research questions; (a) Which strategy to utilize for automated inference of topological element relationships with high precision and recall? And (b) How to train an element relationship inference model in the absence of annotated relationship datasets?

3. PROPOSED SOLUTION

We propose a method for automated topological relationship detection between elements. The scope of this research is limited to cylinders, elbows, tees, and flanges. These elements account for a majority of the modelling workload (Agapaki et al., 2018).

Segmented element point clusters of existing industrial facilities are the input data source. These individual point clusters are extracted from a scan using an existing instance segmentation method such as CLOI-NET. Elements and their relationships are represented in the form of a graph. Each element is modelled as a graph node, and its geometric features and element class are encoded into a graph node feature vector. Relationships are represented by edges. Relationship detection is modelled as an edge prediction task and a GNN is trained for this purpose.

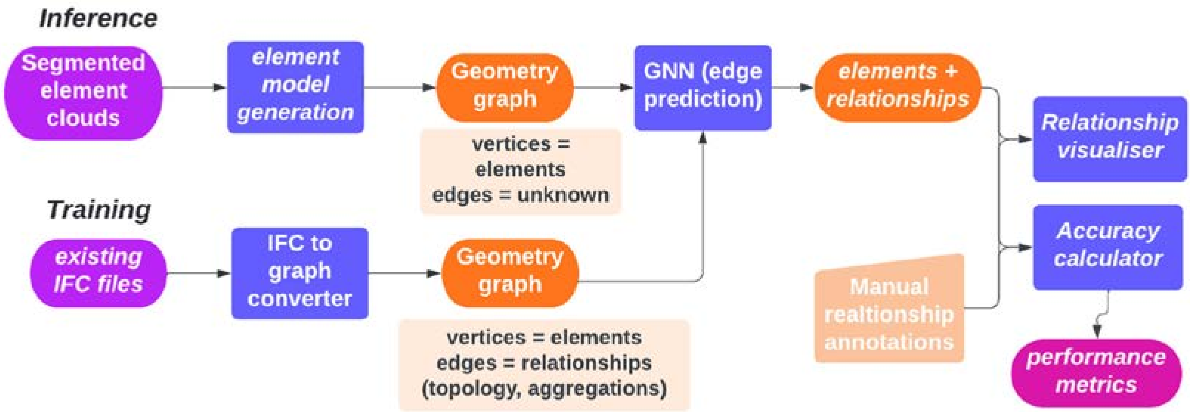

Figure 1. Overview of the proposed solution

Element geometry information is encoded into graph node features. These features are used by the GNN to learn the influence of element geometry on connectivity between elements. A more descriptive node feature provides additional information to the GNN. Possible features include: (a) minimum oriented bounding boxes (MOBB) of elements, (b) element-specific parameters such as axis, radius etc., (c) sampled subset of points, and (d) learned feature vectors. Oriented bounding boxes can be easily derived but are limited to crude information regarding element geometry and position. These are heavily affected by outliers and errors in instance segmentation. In contrast, element specific features are more difficult to extract from point clouds, but are more descriptive, especially for shapes such as elbows. They can represent geometries accurately with few parameters. Examples include element position (e.g., centre point), orientation (e.g., cylinder axis) and element geometry (e.g., radius, length). Element parameters of simpler shapes such as cylinders may be extracted using methods such as RANSAC, but more complex shapes such as elbows can prove challenging. Yet another approach would be to encode the element point cluster into a feature vector. Such an encoding may be generated automatically by using a deep learning approach such as PointNet (Qi et al., 2016) and would theoretically be capable of robustly representing the element.

Manual annotation of a relationship dataset to train the GNN would require a significant amount of time and labour. Thus, we generate training data from design files which contain element relationship information. In terms of GNN architecture, we opt for GraphSAGE, as it is (a) capable of inductive learning, (b) suited for link prediction, (c) scales linearly in the number of graph edges and (d) has been successfully utilised for previous BIM applications (Wang et al. 2022).

4. RESEARCH METHODOLOGY

This research is designed upon the assumption that topological relationships between elements can be inferred from their geometric features, and that the nature of such relationships can be learned by a neural network. We further assume that the data loss from compressing point cloud instances to node features does not significantly affect the ability of a GNN to identify element relationships.

The dataset used for training is composed of design files for an offshore Liquid Natural Gas hub in NavisWorks format. The subset utilized for experimentation comprises of two sub sections of the site containing around 37,000 elements with around 31,000 unique topological relationships (Figure 2). Element relationships were extracted using a python script through the NavisPythonShell plug-in and geometries were extracted by the NavisTools plug-in.

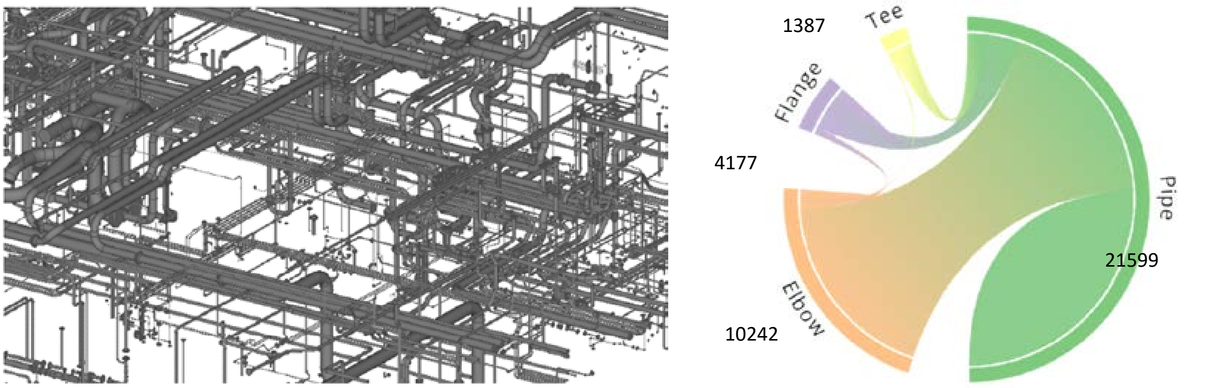

Figure 2. A subsection of the input dataset (left) and element relationship frequencies (right).

Out of the proposed node feature representations, we test the bounding box and sampled subset of points strategies. The relative simplicity of these methods provides a starting point for assessing the feasibility of our solution. For the bounding box representation, we calculate the principal axis vector, centre-point, and dimensions of the minimum oriented bounding box. For the latter representation, we randomly sample 100, 500, and 1000 points for each element (Figure 3).

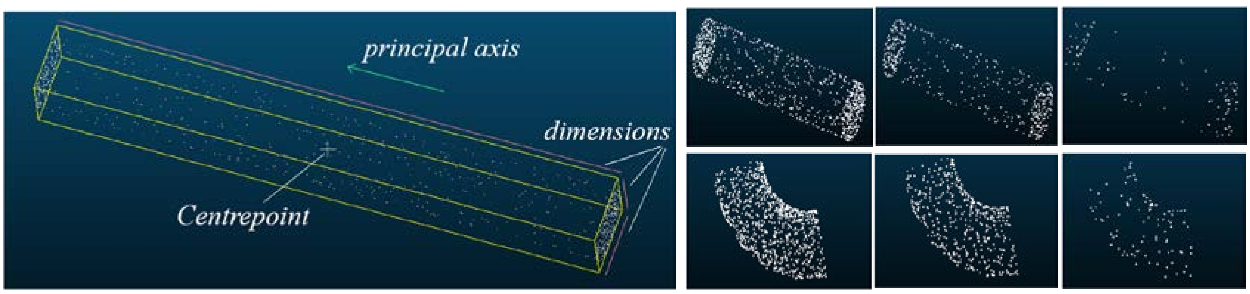

Figure 3. Node features derived from bounding box (left) and Element points sampled at 1000, 500, and 100 points (right)

We experimentally determine that node features derived from bounding box geometry provide best results. Our graph representation consists of a graph whose nodes represent individual elements, and whose edges denote topological relationships between the elements. Each node is represented by a feature vector consisting of the above bounding box parameters. Specifically, the principal axis is represented by a 3D unit vector, and centre point and dimensions are also represented by 3D vectors. The class label of the element is appended to the feature vector using a one-hot encoding.

The link prediction GNN and graph dataset were implemented using PyTorch and Deep Graph Library. The training/validation set consisted of around 20,000 elements and 17,000 topological relationships. 10% of this set was reserved for validation. Furthermore, a separate, disjoint section of the design file dataset was used as a test-set, ensuring that the trained model scales to unseen graphs. The test-set comprised of around 17,000 elements and 15,000 relationships. For training, we generate a positive graph containing all edges in the training set, and a negative graph containing the inverse of those edges. As each element could potentially be connected to every other element, the negative graph contains an exponentially large number of edges. Therefore, we sample a subset of edges to create a balanced training set. The sampling is performed dynamically during training to include all potential negative edges. Furthermore, we restrict our search to potential edges between elements within a pre-defined range and generate pseudo edges based on physical proximity between elements.

Our proposed GNN is based on the GraphSAGE architecture and contains 2 GraphSAGE layers for node feature aggregation, as well as a 2-layer Multi-Layer Perceptron (MLP) for edge feature computation. The node features act as input for the 1st layer of the GNN. In a single layer, features of each nodes' neighbours are aggregated using mean aggregation, and combined with its previous features and a trainable weight vector. Next, edge features are computed to calculate probability of a link. We evaluate two prominent edge feature predictors, namely dot product and MLP, and determine that an MLP with two layers and a Rectified Linear Unit (ReLU) activation function yields best results. The model is trained using Binary Cross Entropy loss.

5. RESULTS AND DISCUSSION

Performance comparisons of hyperparameters are given in table 2. Training losses failed to converge when training with sampled points as node features. Thus, all results listed in the table utilize bounding box parameters and element class label as node features. All models were trained for 500 epochs, with Adam optimizer and a learning rate of 0.01.

Overall, the system achieves a recall of 0.88, precision of 0.51 and F1 score of 0.64 on the test-set at 0.5 classification threshold. A breakdown of model performance on relationships between various element types is given in table 3. The drop in both precision and recall is primarily due to errors in pipe-pipe relationships, stemming from disjoint piping elements.

Table 2. Performance comparisons between various hyperparameters on validation set

	Precision	Recall	F1 score	AUC-ROC
Node representation update method (with MLP – 2 layers)				
1 SageGRAPH layer	0.967	0.771	0.858	0.879
2 SageGRAPH layers	0.980	0.738	0.842	0.967
3 SageGRAPH layers	0.976	0.737	0.840	0.924
Edge feature computation method (with SageGRAPH – 2 layers)				
Dot product	0.700	0.955	0.806	0.900
1 MLP layer	0.486	0.677	0.566	0.451
3 MLP layers	0.937	0.736	0.825	0.855

We also test model adaptability to real world data by testing on a manually annotated subset of the CLOI dataset containing flanges, elbows and pipes. Tees were excluded due to their low prevalence. The dataset contains around 600 relationships between around 1100 elements. We develop a new relationship annotation and visualisation tool based on LabelCloud, an open-source point cloud bounding box annotation tool (Sager et al., 2021) for this purpose. The model achieves a recall of 0.99, precision of 0.75 and F1 score of 0.85 on this dataset. The higher performance is a result of the dataset being less complex than the design dataset with less densely packed elements.

Table 3. Recall and precision by element type, in design file (top) and CLOI (bottom) testsets

Precision	Flange	Elbow	Tee	Pipe
Flange	0.74	0.94	0.88	0.93
Elbow		0.89	0.60	0.96
Tee			0.94	0.71
Pipe				0.24

Recall	Flange	Elbow	Tee	Pipe
Flange	1.0	0.98	1.0	0.97
Elbow		0.97	0.97	0.94
Tee			1.0	0.94
Pipe				0.76

Precision (CLOI)	Flange	Elbow	Pipe
Flange	0.25	0.93	0.85
Elbow		0.14	0.92
Pipe			0.70

Recall (CLOI)	Flange	Elbow	Pipe
Flange	1.0	1.0	1.0
Elbow		1.0	0.98
Pipe			1.0

Additionally, we visualise results by programmatically generating cylindrical elements at connection points to denote topographical relationships (Figure 4). Most false positives and false negatives occur on elements with smaller radii. In particular, the model predicts false edges on small parallel pipes. Parallel pipes connected via two elbows are another cause of false positives. The model is also more likely to miss relationships in densely packed regions. Notably, errors are more prevalent among smaller connecting elements such as tees. This may be attributed to shortcomings of the node feature representation. Unlike pipes, smaller elements such as tees or elements do not have an unambiguous principal axis. Therefore, a bounding box representation may be inadequate to represent their geometry. Switching to more descriptive features such as element parameters may prove to be a valuable avenue for future work. Visual analysis of CLOI dataset results (figure 5) demonstrates that errors are primarily false positives mainly caused by noisy point clusters. This is explained by the high sensitivity of the bounding box representation to noisy points.

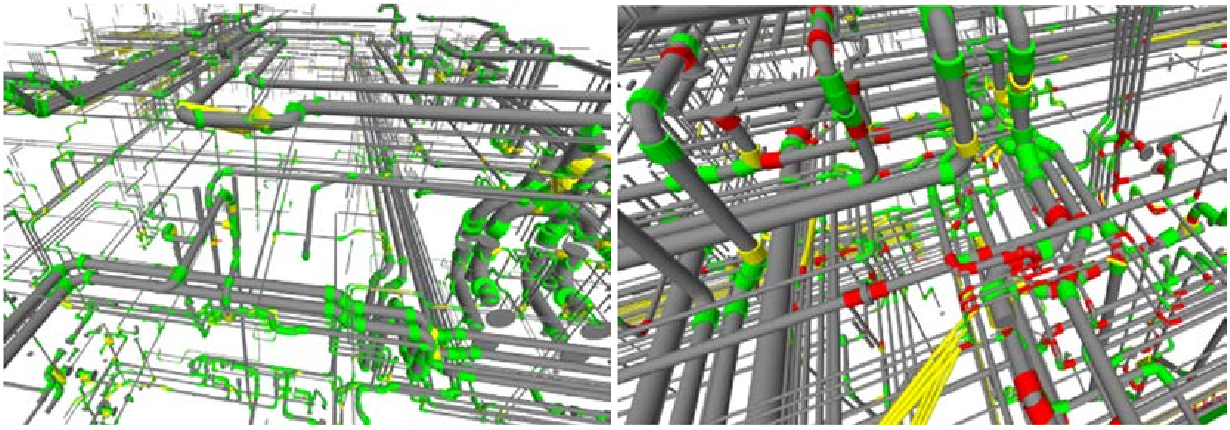

Figure 4. Model predictions (left), and failure cases (right) on design file testset and predictions on CLOI dataset (bottom) (True positive=Green, False positive=Yellow, False negative=Red)

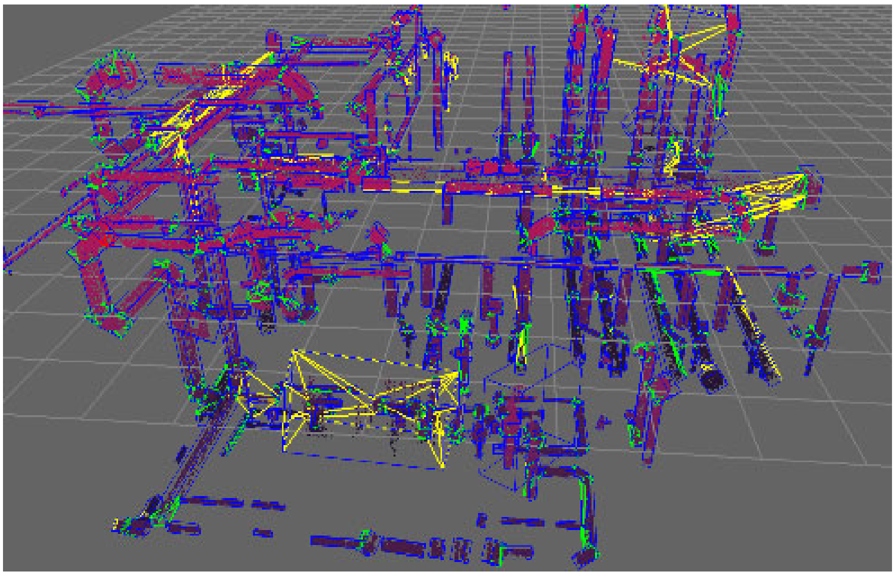

Figure 5. predictions on CLOI dataset. Edges are denoted by lines between edges of element bounding boxes (True positive=Green, False positive=Yellow, False negative=Red)

6. CONCLUSION

We propose a novel method for automatically identifying topological relationships between elements within industrial facility models using GNNs. Specifically, this research is the first to accomplish this task without a rule-based approach. While significant improvements are required to match the precision and recall of human annotators, our method demonstrates the feasibility of automated relationship inference, and can be used as guidance for annotators. Many failure cases are caused by limitations of the bounding box node representation. These include sensitivity to noisy points and inability to represent geometry of smaller elements accurately in densely packed areas. Thus, there is significant potential for future improvement by substituting a more advanced representations such as element parameters or a learned feature representation. Another limitation of the proposed method is low performance in the presence of occluded points, which are common in large scale indoor scans.

The method can also be extended to detection of aggregation relationships such as facility subsystems. Furthermore, the inferred relationship information may also be utilised as additional context to improve instance segmentation performance. Crucially, in contrast with previous hand-coded approaches in various domains, this paper presents an automated alternative to relationship inference, which is crucial to the semantic enrichment step of the scan-to-BIM process. It is thus suited for more complex scenarios, and is easily adaptable to other domains, making digital twinning more accessible to previously unexplored infrastructure domains.

ACKGNOWLEDGEMENTS

This research has received funding from the Engineering and Physical Sciences Research Council (EPSRC), AVEVA Group Plc. and British Petroleum Plc. Design file and scan datasets used in this research were provided by British Petroleum Plc. and AVEVA Group Plc.

INDOOR TRAJECTORY RECONSTRUCTION USING BUILDING INFORMATION MODELING AND GRAPH NEURAL NETWORKS

Mingkai Li, Peter Kok-Yiu Wong, Cong Huang & Jack Chin-Pang Cheng
The Hong Kong University of Science and Technology, Hong Kong

ABSTRACT: *Trajectory reconstruction of pedestrian is of paramount importance to understand crowd dynamics and human movement pattern, which will provide insights to improve building design, facility management and route planning. Camera-based tracking methods have been widely explored with the rapid development of deep learning techniques. When moving to indoor environment, many challenges occur, including occlusions, complex environments and limited camera placement and coverage. Therefore, we propose a novel indoor trajectory reconstruction method using building information modeling (BIM) and graph neural network (GNN). A spatial graph representation is proposed for indoor environment to capture the spatial relationships of indoor areas and monitoring points. Closed circuit television (CCTV) system is integrated with BIM model through camera registration. Pedestrian simulation is conducted based on the BIM model to simulate the pedestrian movement in the considered indoor environment. The simulation results are embedded into the spatial graph for training of GNN. The indoor trajectory reconstruction is implemented as GNN conducts edge classification on the spatial graph.*

1. INTRODUCTION

Indoor trajectory reconstruction refers to the process of estimating the path or trajectory followed by a moving object or person within an indoor environment. This can be useful in various applications, such as indoor navigation, activity recognition, or monitoring systems. There are different approaches to indoor trajectory reconstruction, including sensor-based methods and computer vision (CV) techniques. Sensor-based methods rely on sensors, such as accelerometers, gyroscopes, magnetometers, or depth sensors, to track the movement of an object or person. The sensor data is processed using techniques like sensor fusion or Kalman filtering to estimate the trajectory (Patron-Perez et al. 2015). This approach is commonly used in devices like smartphones or wearable devices. Wi-Fi or Bluetooth signals can also be used to estimate the location of a device within an indoor environment (Traunmueller et al. 2018). By measuring the signal strength from different access points or beacons, it is possible to determine the approximate position of the device. Trajectory reconstruction can be achieved by tracking the device's movements over time using signal strength variations. However, as people pay more attention to privacy, these methods have become more controversial and inconvenient, since it requires pedestrians to actively upload signals. CV techniques can be employed to reconstruct trajectories using visual information captured by cameras or depth sensors (Wong et al. 2022). These methods may involve object detection, tracking, and motion estimation algorithms. For example, by tracking the position of a person in multiple frames of a video, it is possible to reconstruct their trajectory within the indoor environment. In this regard, CV techniques are more acceptable for public as it required less information exposure.

Person re-identification (ReID) is a CV task that involves identifying and tracking individuals across different cameras or video frames (Zheng et al. 2015). The goal of ReID is to match a person's identity across non-overlapping camera views or at different points in time within a video sequence. In scenarios such as closed circuit television (CCTV) systems, where multiple cameras are installed in an area, ReID can help track individuals as they move between camera views. It is particularly useful in crowded or complex environments where traditional tracking methods may fail due to occlusion or changes in appearance. ReID applies deep learning techniques such as convolutional neural networks (CNNs) to extract discriminative features from the person's appearance (Cheng et al. 2016), which are further compared among different individuals to match the same person's features while differentiating them from others. However, ReID performs differently indoors and outdoors, as they differ significantly in terms of lighting conditions, camera placement, and occlusion. Indoor environments often have controlled lighting and less occlusion of pedestrian, which can result in more consistent appearance of individuals, thereby ReID algorithms usually could achieve better performance. However, indoor cameras are often installed at fixed positions with controlled angles and have narrow fields of views and limited camera coverage due to the narrow space of indoor environment and occlusion of building elements. It is not realistic to install cameras to

cover all indoor space as it requires large investment and maintenance cost in CCTV system. Hence, other techniques are required to enable indoor trajectory reconstruction.

Building information modeling (BIM) is a powerful tool for building management and provides a common data environment to connect different platforms to support various applications (Song et al. 2022; Cheng et al. 2022). Integration of BIM and CV techniques has emerged as a hot topic in recent years and unlocks a lot of applications. For example, construction activities can be recognized and analyzed by CV algorithms, and the relevant information can be extracted and intergraded into BIM model to improve the construction progress monitoring (Deng et al. 2020; Braun et al. 2020). Furthermore, information about the building components can also be intergraded in the digital representation of the BIM model for automatic detection and identification (Troncoso-Pastoriza, et al. 2018).

Graph neural network (GNN) is a type of deep learning model that is specifically designed to operate on unstructured data that can be represented as graphs (Zhou et al. 2020). The key idea behind GNNs is to propagate information across the nodes and edges of a graph, allowing each node to gather and update information from its neighbors. GNNs have shown promising results in various domains, including social network analysis, molecular chemistry, recommendation systems, and CV tasks involving graphs or structured data (Wu et al. 2020). In recent years, GNNs have been applied to the building design and management. Nauata et al. (2020) applied GNN to generate house layout following given relational architecture. Cheng et al. (2022) leveraged GNN to conduct crowd prediction in the building. In this regard, GNN is a potential technique to assist the indoor trajectory reconstruction as the building layout can be represented as a graph and can be further processed by GNNs.

This paper proposed an indoor trajectory reconstruction method using BIM and GNN. A spatial graph is proposed to depict the indoor environment. Pedestrian simulation is conducted using the agent-based model established based on BIM model to enrich the spatial graph. The CCTV system is integrated with BIM model by camera registration, so that the information generated by CV algorithms based on the cameras' videos can be related to specific location in the BIM model. With the information from CCTV system, the spatial graph is then processed by a GNN to reconstruct the indoor trajectory of pedestrian. Section 2 introduces the methodology in details, while Section 3 provides an example to illustrate the proposed method.

2. METHODOLOGY

The proposed framework of indoor trajectory reconstruction is shown in Fig. 1. The BIM model is first used to establish a spatial graph to describe the spatial relationship among the indoor spaces including corridors and rooms. To be specific, the floor plan of the Revit model is analyzed by a Dynamo algorithm to identify the entrances, exits, intersections and dead ends. These points would be nodes in the graph and corridors connecting these nodes would be edges. Besides, DWG file is exported from BIM model and imported into a pedestrian simulation software called AnyLogic. The movement of pedestrian inside the building is simulated. The required time for a person to move from one point to others is recorded and embedded into the graph as edge attribute. The CCTV layouts are linked to the BIM model by camera registration so that the identification of some person in the field of view of one camera can provide information of the location of the person in the building. ReID algorithm is adopted to identify a specific person across several cameras. The series of timestamps and positions of one person will be passed to the spatial graph and possessed by a graph neural network to identify the trajectory of this person.

2.1 Integration of BIM and CCTV System

Cameras have been widely used in buildings for safety and efficiency surveillance. Especially with the integration of artificial intelligence and building BIM, many intelligent applications have emerged. To unlock the potential of CCTV-BIM integration, the first step is to localize the cameras in the considered environment, based on which the event or person identified in cameras can be linked to specific position in the BIM model.

2.1.1 Camera Registration with BIM

Camera registration, also known as camera pose estimation, is the process of relating the camera coordinates to the real-world coordinates of objects or scenes. Some previous studies leverage conformity of geometric primitives such as points, lines, and planes to determine the translation, rotation, and scale in reference to as-planned models or real world (Asadi et al. 2019). These methods usually require manual operation and rely on predefined viewpoint assumption including camera position and orientation (Lukins and Trucco 2007; Rebolj et al. 2008). Asadi et al. (2019) automated the registration process by performing an augmented monocular simultaneous localization and mapping and perspective detecting and matching between the image frames and their corresponding BIM views. Though automated methods are more efficient, manual approaches with low technical threshold are still common as the camera registration process is one-off for a scene as long as the cameras are fixed.

Fig. 2 shows an example of manual camera registration with BIM model. The position and rough orientation of the camera are provided, so that the objects such as doors and walls in the field of view (FOV) can be easily mapped to the building elements in the BIM model. Several characteristic points at the intersection line of wall and floor, such as corner points of walls, will be selected in the FOV, while their correspondences will be identified in the BIM model. The function for transforming the pixel coordinates in camera's FOV to global coordinates in the BIM model can further be established. For example, for the FOV in Fig.2, two characteristic points $C_1(C_1')$ and $C_2(C_2')$ are selected, for any point $C_p(x_p, y_p)$ in the FOV, its corresponding point C_p' can be determined by following equations.

$$x_p' = \frac{x_p - x_1}{x_2 - x_1}(x_2' - x_1') + x_1' \quad (1)$$

$$y_p' = \frac{y_p - y_1}{y_2 - y_1}(y_2' - y_1') + y_1' \quad (2)$$

The above equation can only be used for cameras with no distortion, otherwise some corrections are needed. When more than two characteristic points are identified, the coordinates can take the average of the calculation results of every pair of the points using the above equation. For a FOV where characteristic points could not be found, several markers with known global coordinates can be set on the floor, which can be easily identify in the camera's FOV to establish the transformation function.

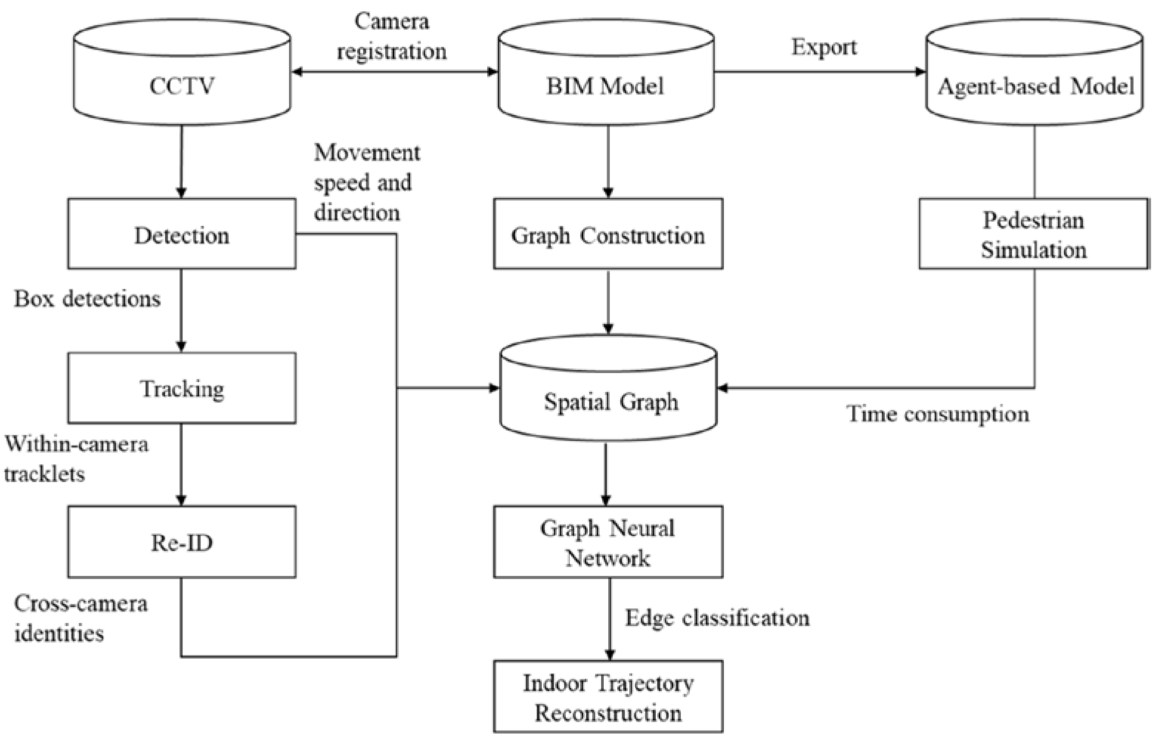

Fig. 1: Proposed framework of indoor trajectory reconstruction

Camera registration allows for accurate transformation between the real-world coordinates and the 2D coordinates in camera. It is crucial in multi-camera systems, where multiple cameras are used to capture a scene from different viewpoints. By accurately registering the cameras, it becomes possible to merge or fuse the information from different cameras and create a consistent and comprehensive representation of the scene. Overall, camera registration is a fundamental step in computer vision applications that involve cameras, enabling precise mapping between the real world and the image plane, and facilitating accurate measurements and analysis of the captured visual data.

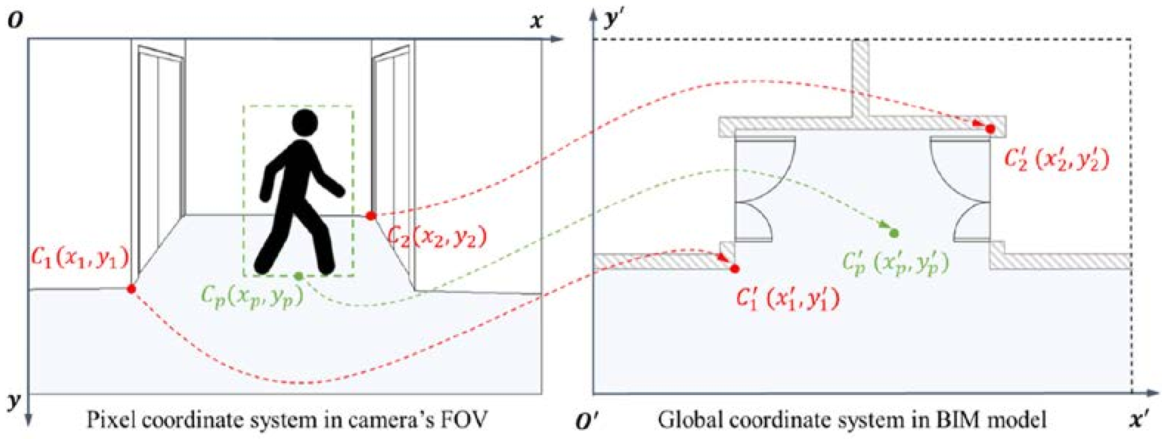

Fig. 2: Example of camera registration with BIM

2.1.2 Real-to-BIM

With camera registration, the information captured by CCTV system can be reflected into BIM. By adopting CV techniques, pedestrian can be detected with a bounding box. It is assumed that the midpoint of the bottom line of the bounding box can roughly represent the location of a person if the detection module in Section 2.3.1 reaches certain accuracy. Based on this, the movement direction of a person can be identified, which can be further matched with the directions of different branches of corridors to estimate the trajectory of the person. Besides, the speed of the person can be further calculated, as the movement distance of the person in real world can be achieved through transformation and the time consumed is also known.

As some cameras will be installed outside some rooms, the videos from cameras can be used to estimate whether a person has entered a room. Firstly, necessary information is extracted from BIM model using Dynamo, including door's dimension, door's location, and room's name. The location of a door is simplified as a segment AB on the 2D plane, while a person is abstracted as a point P. There are three cases based on the relative position of the line segment and the point, shown in Fig. 3. Based on this, we develop the algorithm to detect, when a person disappears from the video, the room he/she enters, or whether the person leaves, as shown in Fig. 4. For each point, we repeat such a process m times to collect the distances between this point and m line segments (doors), then regard the line segment that has the smallest distance as the final result. In other words, the closest door a person nears when he/she disappears is identified as the one the person enters.

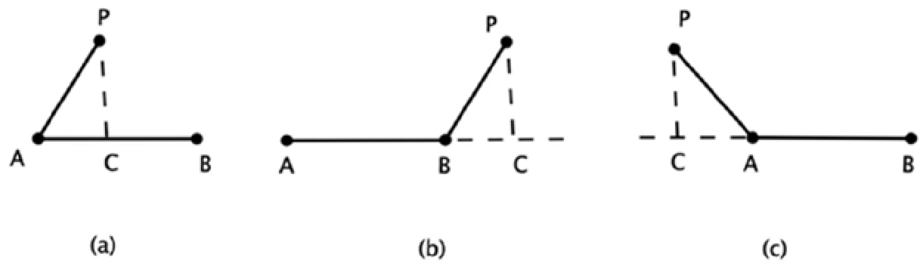

Fig. 3: Three cases for the shortest distance between a point and a line segment

2.2 Spatial Graph

Spatial graph is proposed to represent the indoor environment based on the BIM model. Besides, pedestrian simulation is conducted using agent-based model, which is derived from BIM model. The simulation results are then embedded in the spatial graph. With the information from CCTV system, the indoor trajectory can be reconstructed based on the spatial graph using GNN.

2.2.1 Graph Construction

Spatial graph is proposed by improving the medial axis transform (MAT) (Lee 2004) for indoor trajectory reconstruction. As shown in Fig. 5, MAT adds nodes at every turning point in the building, while spatial graph skips those nodes that are not fork, because the trajectory of pedestrian will not have multiple possibilities when passing through this kind of nodes. What these two methods have in common is that the edges in the both graphs represent sections of the corridor. Spatial graph includes several kinds of nodes: “entrance/exit” nodes (in green), “dead end” nodes (in dark green), “room” node (in orange), “fork” nodes (in red) and “camera” nodes (in blue). Dividing the nodes into different categories can depict the indoor environment more accurately and provide more information for GNN.

Algorithm 1: DETECT the room in which each person enters

Input: A person's coordinate P
A set of 2D vectors represent m doors $D = \{\overrightarrow{A_1B_1}, \overrightarrow{A_2B_2}, \dots, \overrightarrow{A_mB_m}\}$

$rid \leftarrow 0$
$dist \leftarrow \infty$
for $i \leftarrow 1$ *to* m **do**
  $C_i \leftarrow$ the projection point of P onto $\overrightarrow{A_iB_i}$
  $r \leftarrow (\overrightarrow{A_iP} \cdot \overrightarrow{A_iB_i}) \; / \; |\overrightarrow{A_iB_i}|^2$
  if $r \leq 0$ **then**
    $d \leftarrow |A_iP|$
  if $r \geq 1$ **then**
    $d \leftarrow |B_iP|$
  if $0 < r < 1$ **then**
    $d \leftarrow |C_iP|$
  if $d \leq dist$ **then**
    $rid \leftarrow j$
    $dist \leftarrow d$
$M_{rid} \leftarrow$ the midpoint of $A_{rid}B_{rid}$
if $|PM_{rid}| \geq k * |A_{rid}B_{rid}|$ **then**
  $r \leftarrow 0$
else

2.2.2 Pedestrian Simulation

To achieve more information for indoor trajectory reconstruction, pedestrian simulation is conducted to analyze the behavior and the time required for a person to reach a specific position in the considered environment. We adopt agent-based modeling (ABM) for pedestrian simulation. ABM has been widely applied to simulate the real-world operation, particularly pedestrian movement, traffic network and manufacturing chain. The three main elements in ABM are agents, their attributes as well as behavioral rules (Cheng and Gan, 2013). Each agent is an autonomous component having its attributes defined by user-input parameters, such as its size and moving speed. Every agent also behaves according to a set of decision rules, for example, approaching multiple places in a specified sequence. With these characteristics, every agent in an environment persistently interacts with each other, in pursuit of specific objectives.

There have been extensive case studies that were able to simulate human behaviors in various scenario. Said et al. (2012) modeled how occupants in a high-rise building react in case of emergency and find the quickest evacuation route. On the other hand, Liu et al. (2014) demonstrated the functionality of ABM in simulating typical pedestrian flow phenomenon, such as bidirectional flow in corridors and through bottlenecks. Their simulation result consisted of the flow rate, movement velocity and spatial density. Suggested by Seyfried et al. (2005), pedestrian flow is notably consistent with the fundamental traffic theory. This inspired us to analyze the speed-density-flow relationship for pedestrian movement, by adopting traffic flow theories.

One typical ABM engine is AnyLogic, which possesses excellent user-friendliness by allowing graphical drag-drop control and advanced Java codes. Moreover, it supports realistic visualization by either component markup or importing geometric models from external application. In this paper, the BIM model is imported to AnyLogic using DWG file as intermedia. Then the walls of the building can be generated automatically. By setting the source and target of pedestrian flow, the movement of pedestrian in the considered indoor environment can be simulated. Besides, we also added “line service” at the positions of fire doors (which are normally closed) to consider the time delay of passing the doors. The pedestrian queuing behavior and parameter setting are investigated by Kim. et al. (2013), which laid the foundation for establishing a robust framework for our project.

2.2.3 GNN-based Trajectory Reconstruction

With the pedestrian simulation based on ABM, the spatial graph can be further enriched with the time consumption information from one position to the other within the indoor environment. Each edge in the graph has two features: “time consumption” and “pass_or_not”. The former is a feature to indicate the time required for a person to reach a specific position from the other. The time is taken as the average value detected from the simulation. The latter is a binary-class feature showing whether a person has passed a specific path, which is represented by an edge. The movement direction mentioned in Section 2.1.2 is used to estimate the path that the person is most likely to travel through, which is achieved by matching the detected direction with the directions of different branched of corridors. Besides, each node will have 5 features: x-coordinate, y-coordinate, category, timestamp when a person is detected, and speed of detected person. “Category” refers to the categories of node according to Section 2.2.1. Speed of detected pedestrian relies on the camera registration and CV techniques to estimate the speed. For those nodes that no pedestrian pass, the value of this feature is set as 0. Base on this graph representation, the indoor trajectory reconstruction can be formulated as an edge classification task on graph, as shown in Fig. 6, aiming to divide all edges into those that pedestrians pass by and those that do not.

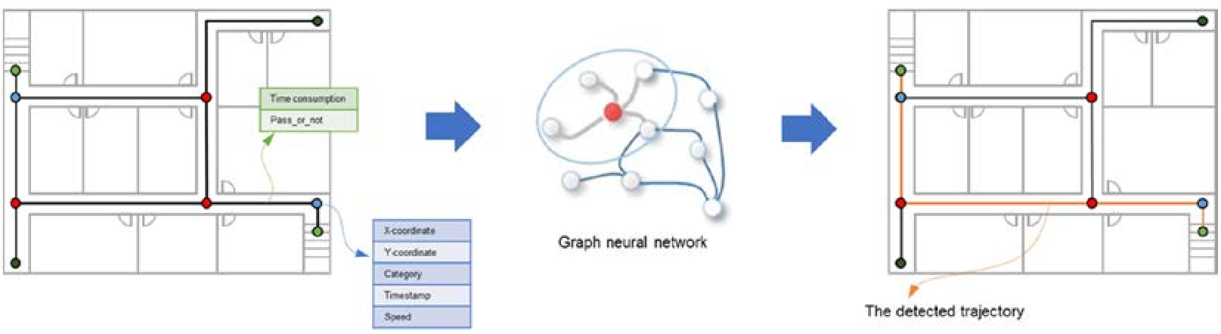

Fig. 6: Edge classification for indoor trajectory reconstruction

2.3 Multi-target Multi-Camera Tracking and Re-Identification

Given a query video, our method targets on detecting, tracking and identifying all people within this video, which is composed of three parts, a detecting module, a tracking module, and a ReID module. The whole framework is shown in Fig. 7.

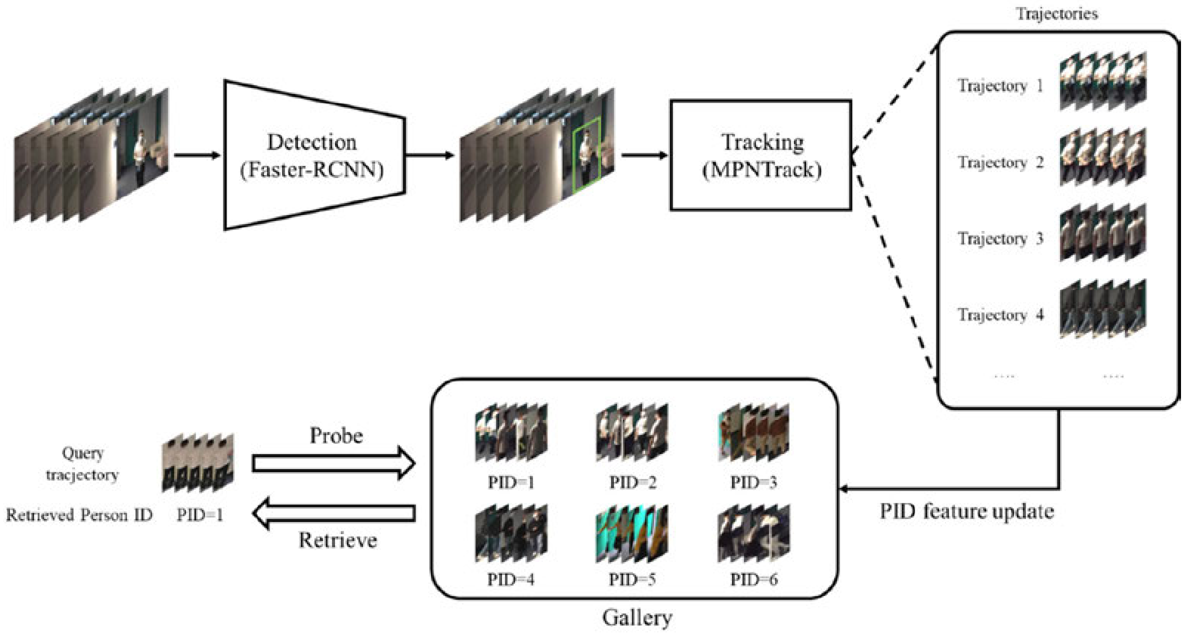

Fig. 7: The framework for multi-target multi-camera tracking and re-identification

2.3.1 Detection

For each frame in the query video, we first apply a Faster-RCNN (Ren et al. 2015) to detect all persons within this frame. In detail, given a frame, a CNN is applied to extract pixel-wise features, which are then sent to a region proposal network (RPN) to generate region-of-interest (RoI) which may contain a person. These regions are fed into another CNN classifier to determine whether they correspond to a person or not. Finally, a non-max-suppression (NMS) method is applied for redundancy removal. NMS first outputs the highest scoring box and then suppresses all overlapping boxes with that box, repeating this process until all boxes are processed.

2.3.2 Tracking

The tracking module works for aligning objects in later frames with those in previous frames. We use a GNN called MPNTrack (Braso and Leal-Taixe, 2020) to achieve this goal. To be specific, for positive predictions in each frame, we first apply a RoIAlign operation to extract their features. We then construct a graph. Features of positive predictions in each frame are treated as nodes, and all prediction pairs across frames form the edges within this graph. For each edge in this graph, we encode its feature as the deviation between the features of its two end nodes. These edge features are then passed through a multi-layer perceptron (MLP) for classification. If two end nodes of an edge correspond to the same person within two frames, we label it as one, otherwise zero. In this way, we associate predictions across frames, which predictions correspond to the same instance and which are not. Therefore, we derive appeared instances in the query video.

2.3.3 Re-ID

Finally, we deploy a Re-ID module to identify these instances. We first forge an instance gallery. Given the training videos, the detection and tracking module was first used to obtain different instances. We then randomly select n (n=10 in our experiments) instances for each person and store them in the instance gallery. We extract feature vector for each instance from the well-trained Re-ID model and use these feature vectors as the high-level semantic representations for persons. During testing, for different instances obtained from the query video, we treat them as probe, extract their feature vectors and retrieve their identifications stored in the instance gallery. Specifically, we compute the cosine distance between the queried feature vectors and all the stored feature vectors, and treat the person with the least feature distance as the output identification. The detailed structure is shown in Fig. 8.

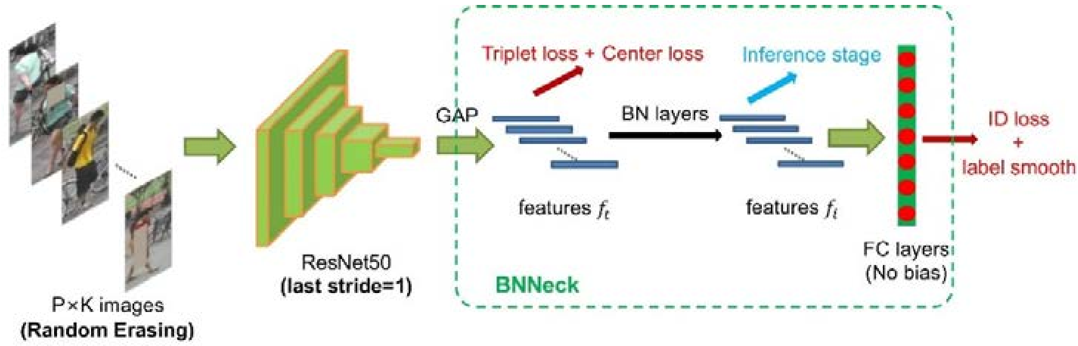

Fig. 8: The detailed structure of the Re-ID module (Luo et al. 2019)

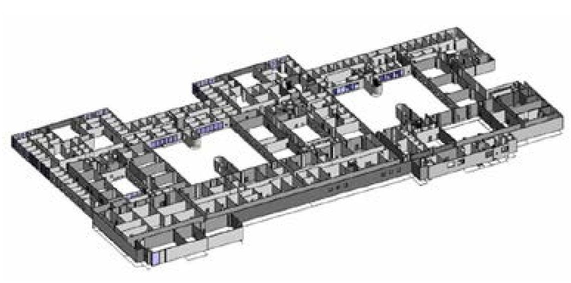
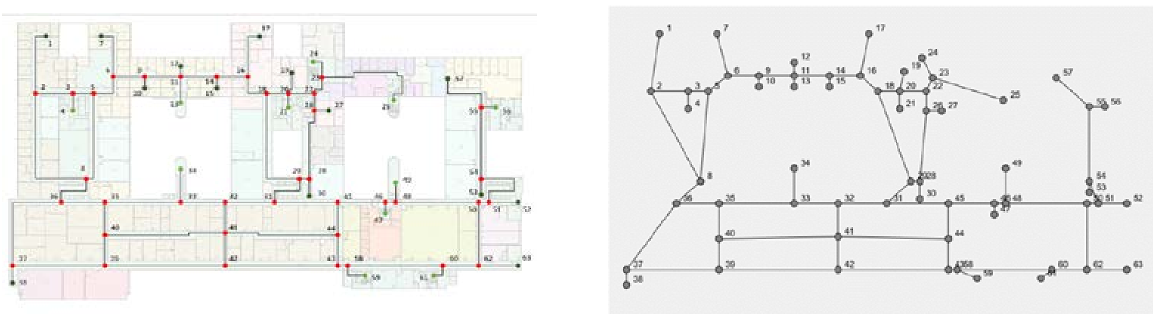
3. ILLUSTRATIVE EXAMPLE

We selected a part of the HKUST campus with more than 200 rooms to demonstrate the method proposed in this paper. Firstly, we developed a Dynamo program to derive the spatial graph based on the floor plan from the BIM model. Fig. 9 shows the process of graph construction. Then DWG file is exported to AnyLogic to support agent-based pedestrian simulation (as shown in Fig. 10) to enrich the spatial graph. Currently, the simulation model is established automatically based on the DWG file, though some manual adjustment is needed. The pedestrian flow logic is established manually, which could be automated with some further developed. We extracted the average time for pedestrian to reach a position from the other as the "time consumption" feature for the corresponding edge. Besides, by selecting different combinations of starting and end points, the movement of pedestrian in the building following designated paths can be simulated, the results can be further used to train the GNN.



(a) BIM model

(b) Floor plan



(c) Graph construction

(d) Spatial graph

Fig. 9: Graph construction based on BIM model

The CCTV system is integrated with the BIM model through camera registration, so that the information captured by cameras can be linked to the specific location in the BIM model as well as the spatial graph. In our experiment, we conduct camera registration manually for 6 cameras using characteristic points and Equation (1) and (2). With the ReID techniques, the same person appears in different cameras' POV can be identified. The ReID model is pre-trained on a public benchmark -- DukeMTMC-reID (Ristani et al., 2016), and got an accuracy of 100% for the

100 pedestrians we observed in the building. The high accuracy may result from the stable lighting condition and fewer pedestrian appearing in the FOV of each camera, compared to the outdoor environment.

Fig. 11 shows the feature maps and ReID process, while Fig. 12 provides an example of ReID results.

Fig. 10: Pedestrian simulation based on AnyLogic

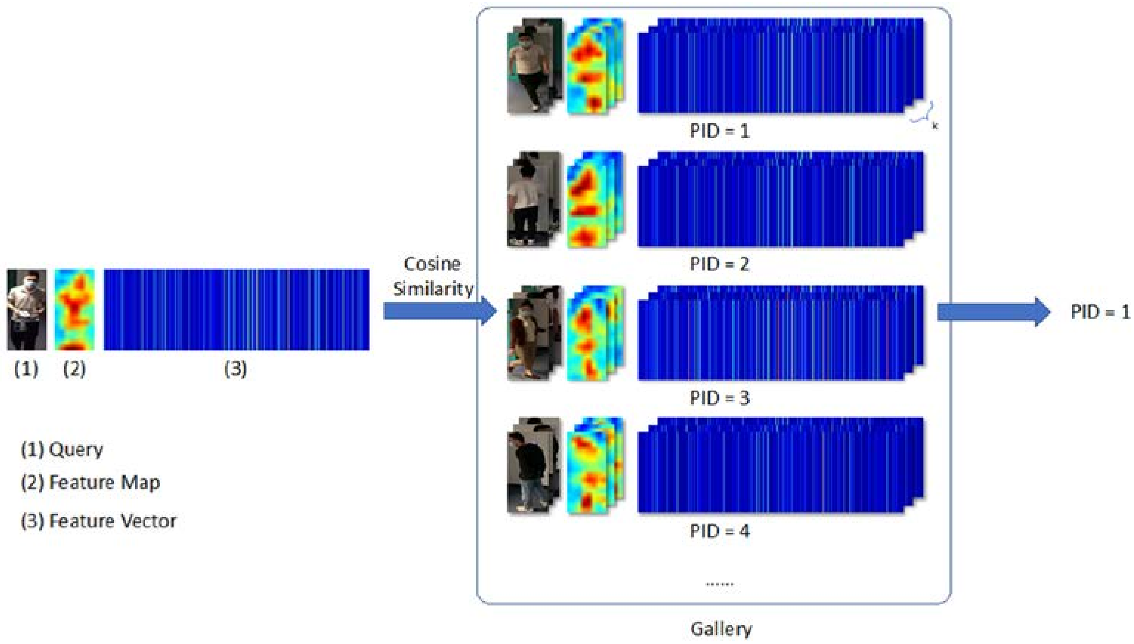

Fig. 11: Feature maps and Re-ID process

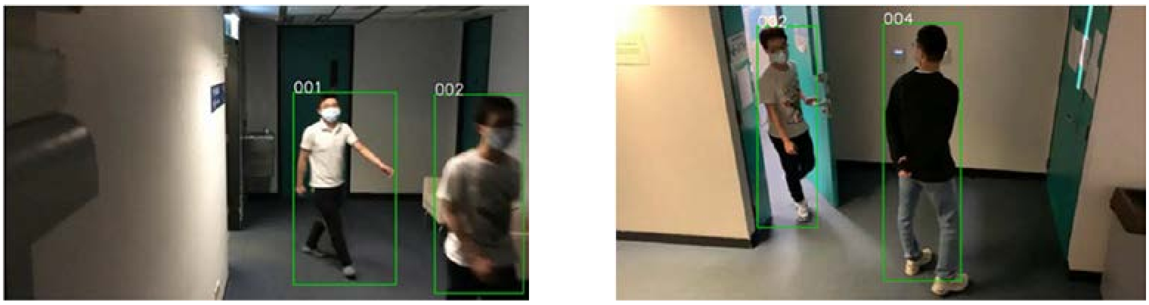

(a) Scene 1 (b) Scene 2

Fig. 12: Examples of the Re-ID results for the two cameras' videos

Information including ReID results as well as the direction and speed of the detected person were embedded into the graph and processed by GNN to make edge classification. The indoor trajectory can be reconstructed by classifying edges into 2 categories: those the person passed, and those did not. The GNN classification achieved 81.2% for the trajectories for the observed 100 pedestrians. We found that for some cases where pedestrians stopped during the process, GNN would produce some wrong classifications, since staying will affect the total time for a person to reach a specific location.

4. CONCLUSION AND DISCUSSION

This paper proposed an indoor trajectory reconstruction method integrating BIM and GNN. A spatial graph is proposed based on BIM to depict the connection of indoor spaces and integrate information captured by CCTV system. The CCTV system is related to the BIM model through camera registration. ABM-based pedestrian simulation is leveraged to simulate the movement of persons within the building, which provides more information to the spatial graph. Trajectory reconstruction is implemented using GNN, which works on spatial graph to aggregate information and classify edges. This study provides an automated approach to trace the pedestrian in the building, which could provide building managers with more insight in the indoor movement pattern and crowd distribution, and thereby could support a lot of smart applications such as indoor navigation, ambient-assisted facility management, precise product delivery, etc.

The proposed approach still has several limitations. For environments with a large number of rooms, the CCTV system usually cannot cover all the entrances of rooms due to limited number of cameras. In this scenario, for those rooms whose doors are not in the FOVs of cameras, we could not achieve the time of staying in the room for a detected person only using cameras, hence it may affect the GNN's performance on edge classification. Other techniques such as Internet of things could be explored to provide supplementary information for those positions that are not covered by cameras. Besides, optimization of camera layout can also be investigated to enlarge the coverage of camera and reduce blind areas. In addition, an automated camera registration method can also be included to improve the convenience of applying the proposed method.

IMAGE SEGMENTATION APPLIED TO URBAN SURFACE AND AERIAL CONSTRAINTS ANALYSIS

Marco Lorenzo Trani & Federica Madaschi
Politecnico di Milano, Milan, Italy

ABSTRACT: *The rapid progress of artificial intelligence (AI) has prompted the exploration of its potential applications in the construction industry, although at a slower rate. Since the starting point of a design is the analysis of the site's constraints, the purpose of the ongoing research is the application of artificial intelligence in risk assessment for site areas. The primary objective of this research project is to develop an interactive map that employs AI to identify potential surface and aerial interferences. This map aims to support planners, engineers, and architects during the site context analysis phase by providing real-time visualization of obstacles. The interactive map allows users to explore and analyze identified obstacles, enabling cluster markers and filtering of features. The results obtained from applying this approach in Milan, Italy, demonstrate its functionality and usability, highlighting the tool's ability to provide valuable information in both localized and citywide scenarios. Potential improvements such as size assessment and advanced marker generation are also being examined to enhance the management of surface and air interferences. The goal is to enhance the tool's functionality, accuracy, and planning efficiency in construction projects.*

1. INTRODUCTION

During the project execution phase, a multiplicity number of agents and situations may affect the organization and the functioning of a construction site in terms of time and costs of the project. Indeed, these elements of 'disorder' can cause activities outside the program with negative effects on the quality, work, and safety of workers. The presence of the yard can be also a potential operational problem as continuity, health, and safety must be ensured both within the yard and outside. Thus, both perspectives must therefore be studied bidirectionally, at the interface between the site and environment. In addition, potential problems that may arise in terms of the size and duration of the project must be carefully analyzed for the construction of the network and mobile infrastructure and mobile construction site.

The *operational criticalities* represent the construction process variables, not necessarily known a priori, which may cause difficulties or inability to perform planned works. The analysis of potential criticalities in construction projects helps to identify operational issues and anticipate additional costs or time needed to avoid surprises during the work. For this reason, developing a specific design analysis is fundamental to arriving at the execution phase with an informed attitude toward possible problem solving. Operational criticalities can be organized into five criticality classes related to different areas, adopted as:

- Surrounding situation: analysis of the several characteristics related to the construction site and its surrounding.
- Production: analysis of the relationship and the organization between functional-spatial design elements, technological-productive design elements, and the utilization of human/techniques/materials/resources which are crucial for efficient and cost-effective execution.
- Specific design elements: analysis of programming aspects of a project which may be left incomplete for a conscious choice caused by specific difficulties in obtaining useful data to improve the design.
- Health and safety of the site: evaluation of how preventive and protective equipment, organizational measures, and training can affect the time and cost.
- Contingencies: analysis of those situations outside the construction site which may occur without generating surprise.

The risk assessment is a crucial step in evaluating and comparing design options, as any identified issues can be addressed during both the design and execution phases. It is important to investigate criticalities beforehand to address and solve them during the execution phase. This helps to quantify any increased costs and construction times. Writing an operational criticality report can support the validation of the design and contribute to client and designer awareness of any unresolved criticalities. It is important to update the document regularly throughout each design phase. This ensures that any critical issues that are identified during the first phase are addressed, and

Referee List (DOI: 10.36253/fup_referee_list)

Marco Lorenzo Trani, Federica Madaschi, *Image Segmentation Applied to Urban Surface and Aerial Constraints Analysis,* pp. 907-916, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.90

any new critical issues that arise in subsequent phases can be resolved with an improved level of detail. The question then arises of how to exploit existing models of artificial intelligence related to the analysis of images to create a support tool aimed at drafting the document on the identification and analysis of critical issues and its constant updating. Indeed, it may be applied during the different project phases: for example, when the site inspection has not yet been carried out, the analysis of images from Google Street View (GSV) of the area can help the designer to have a clearer idea of the context in which it will operate. Instead, if the analysis is carried out on the photographic survey of the site, also carried out at different times of the duration of the yard, it can help to keep the surrounding criticalities monitored. Some critical issues that may arise during the development of the work can be detected with greater precision and detail. Hence, this paper focuses on the operating criticalities relative to the surrounding situation of a yard. The project presented aims to create an interactive map through simple and easy-access implements. It wants to demonstrate how using an artificial intelligence model for image segmentation applied to input images from GSV, is possible to create an interactive map that accurately provides the position of possible criticalities. A tool of this type, although of simple structure, can be very useful to designers, architects, or engineers during an inspection. It can become a support from which to draw a list of elements to be evaluated once they arrive at the site, because obviously, it is not possible to avoid this activity.

2. LITERATURE REVIEW

The development of an interactive tool supported by artificial intelligence, that provides a constantly updated view of the critical issues due to the context can be a basis for the implementation of further improvements to better support designers and engineers. The dynamic nature of the map must be able to allow the continuous updating of the input data, ensuring a greater precision than the static maps provided by the geographic information systems (GIS) (D. Farkas et al., 2016) which may contain inaccuracies or outdated information, regarding the positioning of services and sub-services.

The contextualization of the intervention plays a crucial role in construction projects. It involves a thorough study of the site, its surroundings, and the internal factors that directly impact the time, cost, and feasibility of individual operations. In today's construction industry, where companies often face significant pressure to meet strict time and budget targets, insufficient evaluation and consideration of surrounding constraints can result in an unsafe and accident-prone workplace (E. Rahnemay et al., 2017). Addressing these challenges, the integration of artificial intelligence with Building Information Modeling (BIM) has gained prominence in recent years (Y. Pan et al., 2022). This integration offers the potential to handle the vast amounts of complex and uncertain data present in construction projects more reliably and efficiently.

2.1 The Dense Prediction Transformers Model

Fully convolutional networks are the prototypical architecture for dense prediction (Long et al., n.d.; Sermanet et al., 2013). Dense prediction, a foundational challenge in computer vision, entails leveraging input images to generate intricate output structures such as semantic segmentation, depth estimation, and object detection through learning (Liu, 2021).

Convolutions are linear operators with a restricted receptive field, which requires sequential stacking in deep architectures to attain a comprehensive context and substantial representational capacity due to the limited receptive field and expressivity of individual convolutions. The image segmentation model used for the development of the tool in this paper was developed by Ranftl et al., who introduced Dense Prediction Transformer (DPT). DPT is an architecture for dense prediction tasks that adopts an encoder-decoder design, where the encoder utilizes a transformer as its fundamental computational building block. Notably, the authors employed the vision transformer (ViT) proposed by Dosovitskiy et al..

Thus, this model introduces a distinct architecture that replaces the conventional convolutional neural network. The main advantage of the vision transformer lies in its ability to generate a consistent and high-resolution global receptive field at each stage. Unlike the traditional convolutional approach, which examines individual windows gradually, transformers possess a unique mathematical architecture that establishes relationships between each neuron or zone in an image and each other. As a result, transformers show a relational nature, considering the entire image simultaneously in each position. This attribute facilitates the generation of predictions that are more refined and globally consistent than fully convolutional networks.

3. SURROUNDING SITUATIONS

The surrounding situations class is crucial as thoroughly examines the variety of factors that are closely related to the construction site and its surroundings. These factors can have a significant impact on work time and cost, influence the construction site's layout, and how materials are stored, handled, and manufactured (Marco Lorenzo Trani, 2012).

Speaking of yard contextualization, are numerous categories of operating criticalities to analyze and report in the analysis of criticalities document. Indeed, within it, problems deriving from site location in an urban fabric, hydrogeological characteristics of the site, subsurface constraints and due to the sub-services, aerial and surface constraints, also analysis of the environmental impact of the yard and the interference it may have with other nearby activities, are reported. Therefore, based on the categories of objects that the DPT model can recognize, seven elements have been identified on which to base the realization of the model (buildings, trees, plants, signboards, streetlights, skyscrapers, and poles), representative of certain categories just mentioned, going to focus the attention on localization in the territorial context, surface features, surface features, aerial restriction, and interferences with other activities.

The first mentioned controls the general access conditions to the construction site which may represent a potential operation criticality. For example, where the primary road is restricted, uneven, or overcrowded, it may be imperative to carry out extra measures to enhance the current road infrastructure or build new infrastructure to satisfy requirements. In case of temporary unavailability of the usual routes, the absence of alternative routes can further think hard about the planning of certain supplies to reduce the risk of a failed delivery or of lack of construction site-free spaces. The presence of road constraints for example represents a potential operational criticality in relation to the need to acquire dispensations or permissions from the public body. If the usual routes are temporarily unavailable and there is no alternative, it's important to carefully consider the planning of supplies to minimize the risk of failed deliveries or lack of space at a construction site. Road constraints, such as the need for dispensations or permissions from public bodies, can also create operational challenges. In the project developed this translates into the realization of the street network for the area under examination based on driveways, to provide an analysis of the critical issues concerning the main roads.

The technological-architectural, urban, and naturalistic preexistences represent a source of potential criticality, for example, the presence of a cantilever roof that, because of its height, doesn't allow the site access. As part of the project, the surface features were considered in the analyzed area by identifying the nearby buildings. Evaluation of neighboring buildings, in addition to influencing the height development of the yard, may also determine the choice of specific workings to avoid damage to elements not belonging to the site.

The presence of plants, trees, or poles in the area can pose a significant challenge to the safe and efficient operation of construction activities. This includes both aerial and mechanized handling, as well as the installation of temporary structures like scaffolds. Therefore, the aerial restriction analysis is important to ensure that these obstructions do not hinder the proper functioning of the construction site and that cranes can rotate freely at night without interfering with nearby buildings.

Lastly, the construction site's proximity to other productive activities can be a potential operational issue since the continuity, healthiness, and safety of both subjects must be ensured. If the site involves public services, the protection of service users is also considered in the critical analysis. Both perspectives need to be investigated in the interface between the construction site and the environment. The healthiness or hazardous elements generated from the environment to the site must be evaluated concerning the anthropic use of the environmental system. Additionally, potential issues that may arise in terms of the project's size and duration must be carefully analyzed for the construction of network infrastructure and mobile yards.

4. THE PROJECT

The purpose of the presented project is to identify potential surface and aerial interferences that may affect the area where a construction or civil yard is expected to open. To achieve this, an interactive map was created using the Python library "*folium*" to pinpoint the exact location of these obstacles. Python code was used to generate a street network for an interactive map using Google's OpenStreetMap. Users could choose to create the network for an entire city or a portion by entering coordinates or neighborhood names. The Lambrate and Città Studi neighborhoods in Milan were analyzed for this paper project. By incorporating the street network into the code, geographic coordinates were established that allowed downloading images from Google Street View. To ensure that ample data was gathered for identifying constraints, the network points were settled to be downloaded at a consistent distance of 25 meters.

In Figure 1, the road network generated is shown. Figure 2, with the orange points, shows the 2625 points identified for the analysis: each of them is characterized by an ID which is associated with the longitude and latitude of the position where it is located. After which, the corresponding images through GSV were downloaded. It’s important to note that there isn't a direct correspondence between points and images, as GSV provides multiple frames from different angles. This feature worked to benefit the project, as it allowed to detect possible interferences with greater accuracy.

Fig. 1: Milan neighborhoods street network

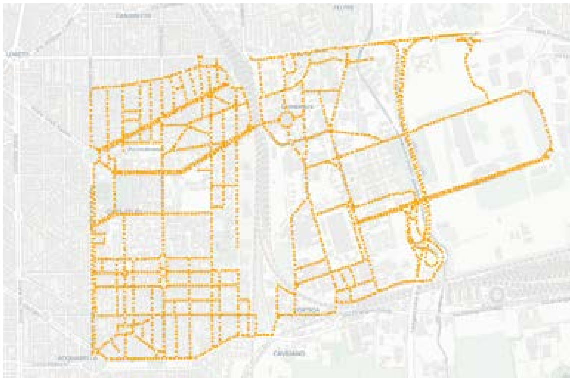

Fig. 2: 2625 street network points arrangement

Once the images were downloaded the DPT Model was utilized to analyze them. Rather than using object detection, image segmentation was chosen in the tool for obstacle identification due to its approach. It processes of classifying each pixel of the image into a class or label that identifies the occupied area of the object that can be recognized by the algorithm. This model proved to be highly effective in recognizing a wide range of possible obstacles, even in urban environments with numerous overlapping elements, limited image quality, or small obstacle sizes. In Figure three, how the process works it shown. The first row displays the input data in the form of images from GSV. Meanwhile, the second row showcases the model's image segmentation results. By utilizing pixel classification based on the labels integrated into the model, the reconverted objects like machines, poles, and bicycles can be identified in the images.

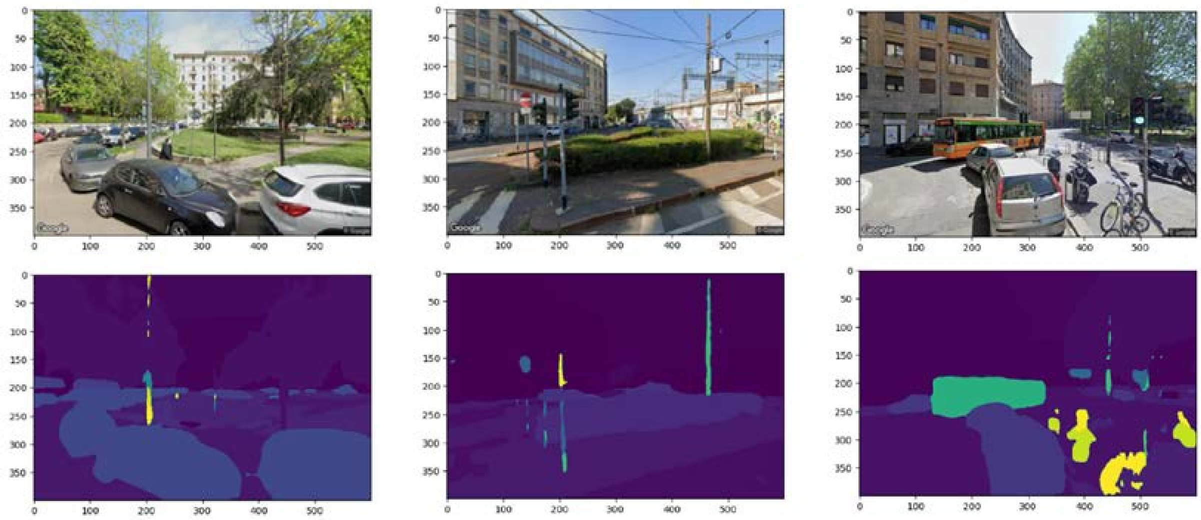

Fig. 3: Example of images segmented by the model

The model was trained to recognize over a hundred objects and use a filtering command to store outcomes for the most relevant constraint elements, including buildings, trees, plants, signboards, streetlights, skyscrapers, and poles a new CSV file with results was created.

After conducting Image Segmentation, the focus shifted toward visualizing the identified constraints. Upon counting the objects, it was observed that there were over 10,000 potential constraints that were recognized. The table below categorizes and counts these constraints.

Table 1: Number of elements recognized from 10500 images analyzed by Image Segmentation Model

Element	Building.	Tree	Plant	Signboard	Streetlight	Skyscraper	Pole	Total
Total	1882	1868	1563	1749	1655	4	1499	10220

Using the Folium library, constraint indicators have been configured with precise geographical coordinates from the road network generated previously: the code iterates each element of the CSV file containing the data related to the project. For each obstacle a marker has been generated that has been assigned a color based on a color dictionary for quick and easy identification. Included is the option to select markers, which displays a popup with specific information such as object name, image segmentation result, latitude and longitude coordinates, and reference image. Additionally, is possible to have multiple markers linked to the same image input. This is due to the fact that the image segmentation was done on the same input, resulting in different outcomes for the two objects. The reason for this is that during analysis, the model searches for all the elements it was trained for, as shown in Figure 3. Therefore, having the same references within the popup is not an indication of an error.

Let's examine the output tools in detail, focusing on their key features and assessing the advantages and disadvantages of the chosen representatives. The main difference between them lies in the type of marker used. The first tool employs *CircleMarkers* to indicate obstacles, while the second uses *ClusterMarker*.

To identify the position of obstacles in the studied area, the first tool created uses CircleMarkers for each element. These markers are color-coded based on the results obtained, allowing for a visual representation of the data. All the obstacles identified in Table 1 are displayed on the final map, thanks to the code implementation. Figure 4 depicts how the output appears to a user who has zoomed in on a specific area.

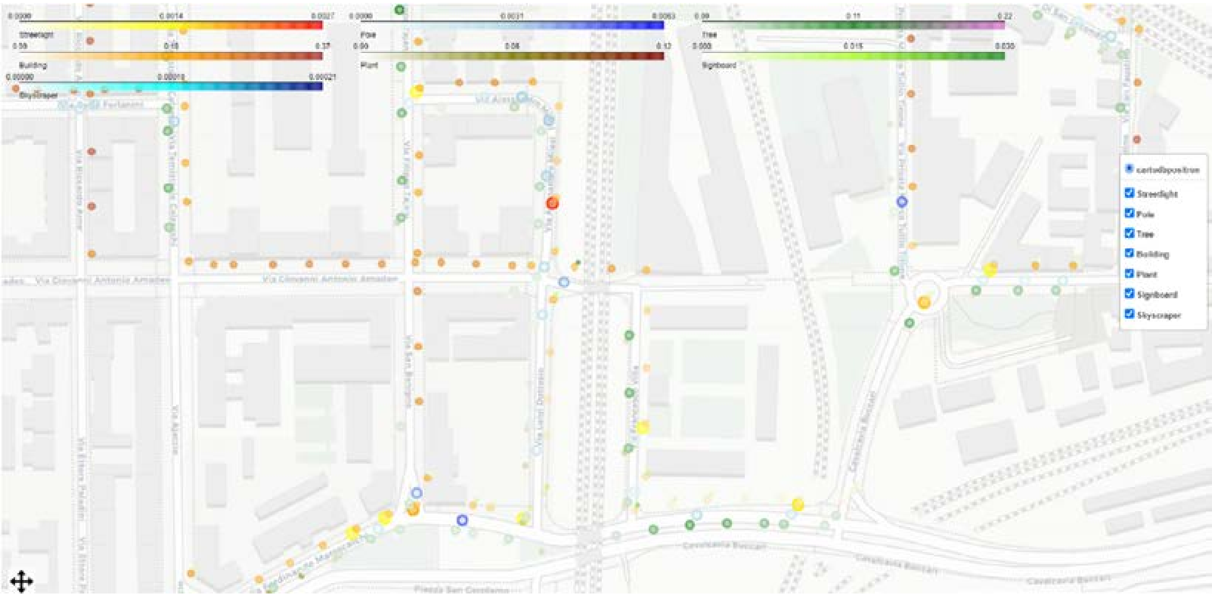

Fig. 4: *CircleMarkers* output map, zoom in is applied

To facilitate the reading of the position of markers, two solutions have been adopted. The first is general, inserted inside the code as a constraint for the positioning of the various indicators according to the reference category. In fact, an offset in the generation conditions within the map was made so that there was not a total overlap that prevented the display. Instead, the second solution concerns the possibility of managing the layers on which the markers have been inserted. Figure 4 shows that points with the same coordinates are slightly separated from each other. However, the exact location can be determined by selecting the marker of interest for the popup display. Different size radii were used to distinguish between the various markers, with their size gradually decreasing. To display or hide a marker, simply select it from the drop-down menu located on the left side of the map.

The second map proposed shows surface and air constraints via *ClusterMarker*. These markers are sued to clearly showcase clusters of data that are focused on a specific point while also indicating the number of elements in a micro zone. This is achieved by displaying circular markers that contain a numerical value within the area it covers.

By adjusting the map zoom, the markers can be enlarged or reduced. The groupings are distinguished by their color: green indicates a few markers, while red indicates a large number. In Figure 5 a visual representation of the second type of output is reported.

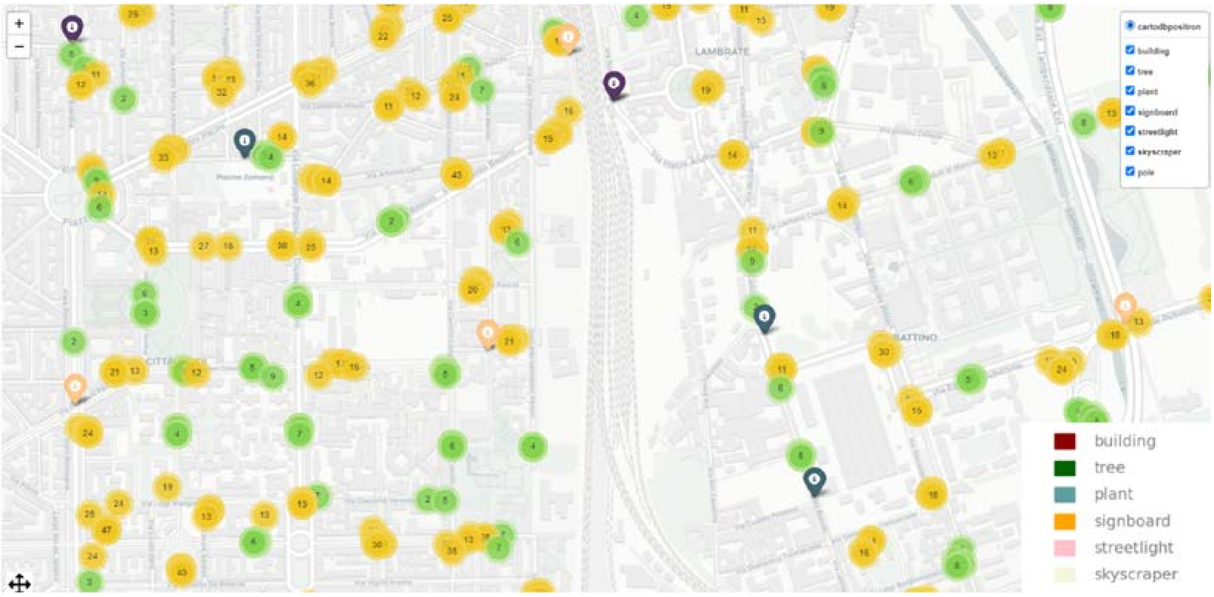

Fig. 5: *ClusterMarker* output map

This second output exhibits the same characteristics as the *CircleMarker version* but with distinct functions and interpretations. For instance, the filter option is always incorporated to allow for data selection, but instead of concealing layers, it directly hides the obstacle category. Moreover, the legend, located at the bottom right, no longer changes color scale based on outcomes, but rather on the classification of constraints, assigning a specific color to each. Figure 6 illustrates a zoom-in on the map to see more clearly the markers. However, when multiple groups appear at the same location, it can be challenging to get in an immediate overview of constraint positions. It is necessary to click on the specific interest group to view it. Moreover, there may be overlaps between groups associated with different categories and various *ClusterMarkers*, which can make the results less clear and immediate. Figure 6 demonstrates also how a popup appears when a marker is selected.

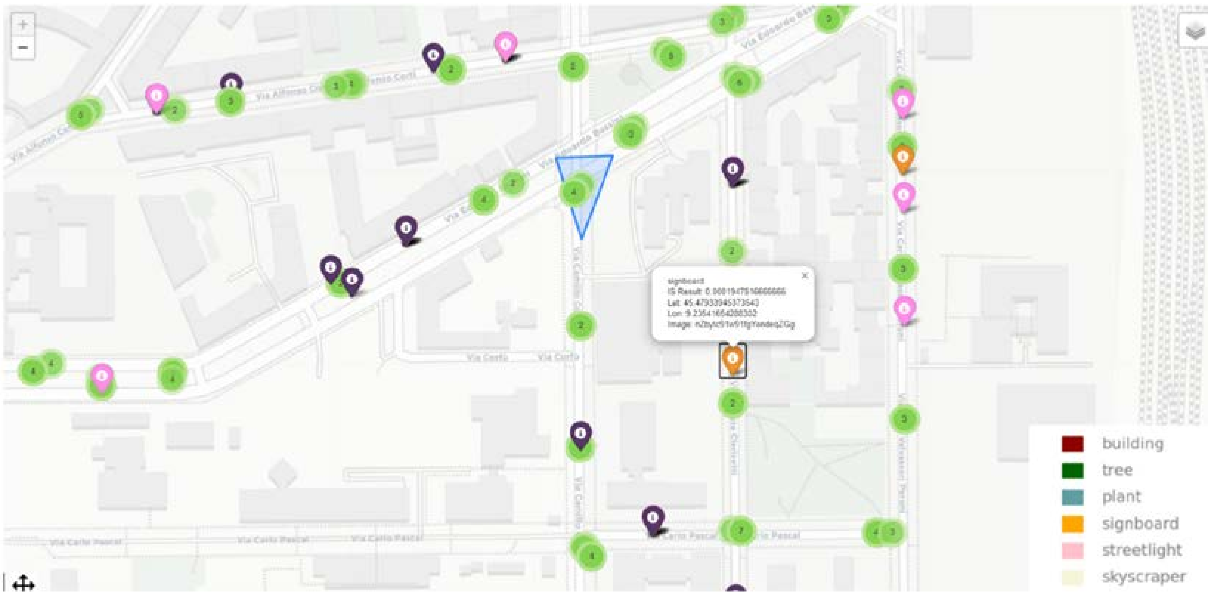

Fig. 6: *ClusterMarker* output map, zoom in and popup are applied

5. TOOLS APPLICATION AND VALIDATION

An application case was used to perform a thorough analysis of the tools' operation. In this case, the focus was on analyzing the criticality of the intervention that needs to be carried out at the junction of via Carlo Pascal and via Celeste Clericetti. Figure 6 depicts the map of the area before results from the analysis were included. The blue rectangle represents the intervention's position, while the red circle marks the specific area to be analyzed.

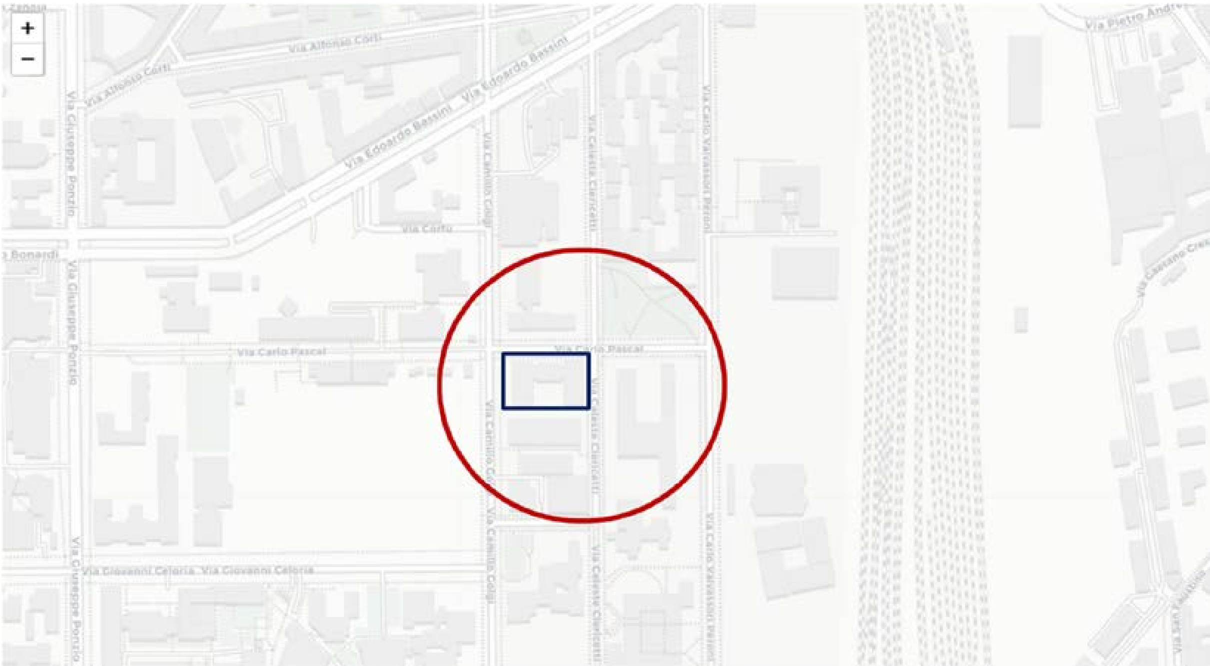

Fig. 7: Identification of the location of the assumed construction site and the area to be analyzed

To identify critical points, Figures 8 and 9 were analyzed, which report the output results obtained using the developed tools.

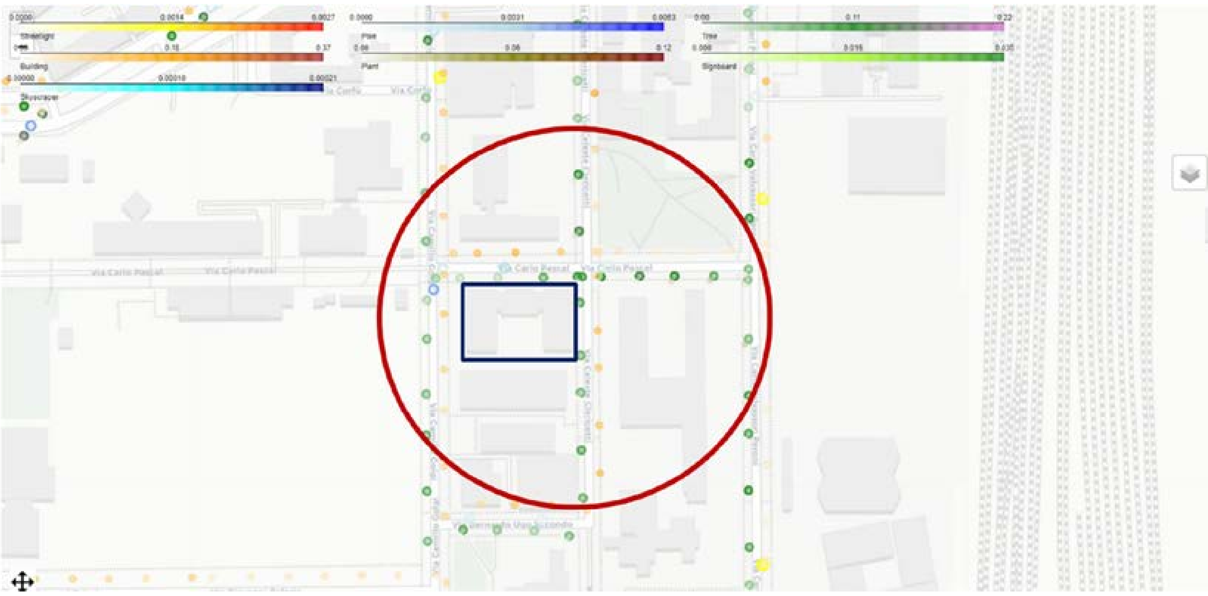

Fig. 8: Operational criticalities from tool Output 1

In Figure 8, there is a depiction of the constraints located near the intersection that has been identified as the area of analysis. The main issues that may arise are related to the presence of trees and buildings, which could potentially cause problems during future air handling procedures. Despite this, the arrangement of markers appears to be tidy and easily discernible, although this could be due to the high zoom used on the area and the existence of only two primary categories of elements.

In contrast, Figure 9 displays the outcomes obtained by utilizing tool number 2. Upon comparing these results with the previous image, it becomes apparent that reading the results, in this case, is neither rapid nor straightforward. The presence of numerous *ClusterMarkers* in one location hinders readability as one must open them to view specific locations. Additionally, this grouping only applies to Markers that belong to the same category. As shown in the figure, when multiple elements that belong to different categories overlap, their groupings also overlap. This can make it difficult to read the results when using the map at a higher zoom level than what is shown in the figure.

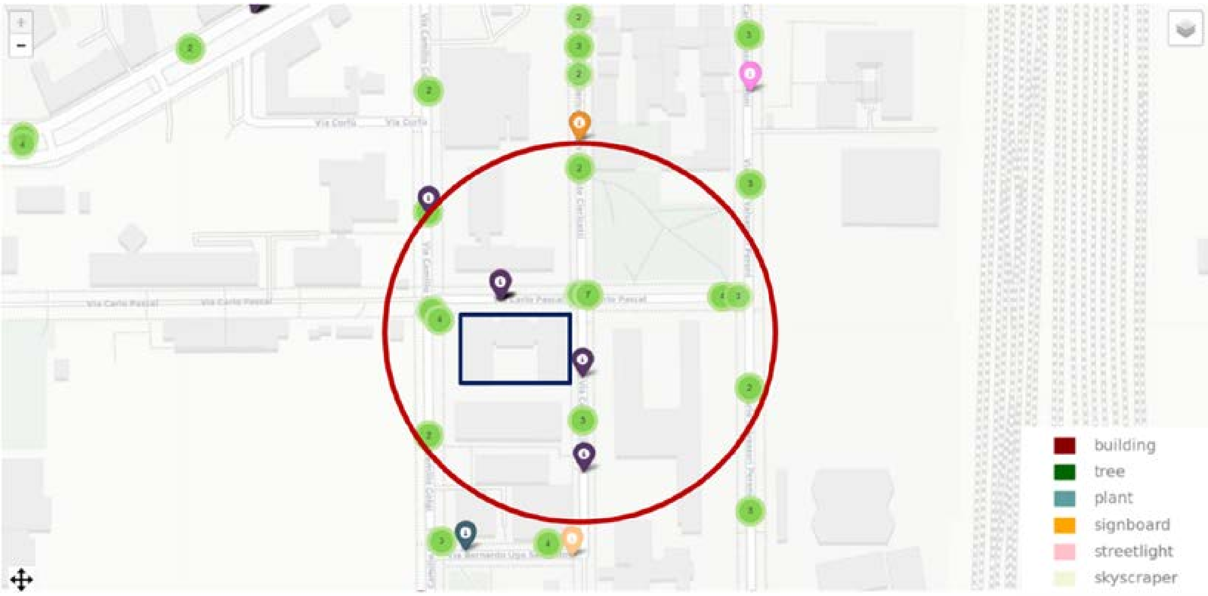

Fig. 9: Operational criticalities from tool output2

Although with the respective problems, identifying critical points in the area was relatively easy. Table 2 clearly shows the number of obstacles that could potentially cause issues during the operational phases of the future construction site. It is evident that the main obstacles are the buildings and trees adjacent to the area being analyzed, as previously mentioned.

Table 2: Number of elements recognized in the analyzed area

Element	Building.	Tree	Plant	Signboard	Streetlight	Skyscraper	Pole	Total
Total	23	32	6	0	3	0	8	69

Therefore, the proposed project has achieved its objective of reliably identifying objects and their positioning on the map with good results while acknowledging operational limits. However, it is important to note that the clear display of obstacle placement seen previously may not always be guaranteed. The first tool requires the application of a filter to provide a clear view of individual obstacles, although improvements have been planned for the overall view. On the other hand, the instrument with *ClusterMarkers* may have poor readability due to the overlap of different object groupings at the same point.

Typically, to assess potential risks in a particular environment, images are analyzed to identify any potential obstacles. Hence, it's crucial to study how the model segmented the images and locate these obstacles on output maps. The proposed code provides visual support for this analysis. Two of the images extracted by GSV for the analysis of Via Carlo Pascal (Figure 10) are shown below. Normally the designer would identify and manually report the possible obstacles, such as the presence of trees for air handling, or car parking in case the occupation of public land was necessary. Analyzing images through the image segmentation model, this procedure becomes assisted and facilitated. Comparing the original with the results obtained and shown in Figure 10, it is possible to see how elements such as cars, trees, sidewalks, and poles are recognized and marked distinctly. The classification of image pixels according to the elements for which the model has been trained can therefore be of fundamental help where the overlapping of objects makes it difficult to recognize them.

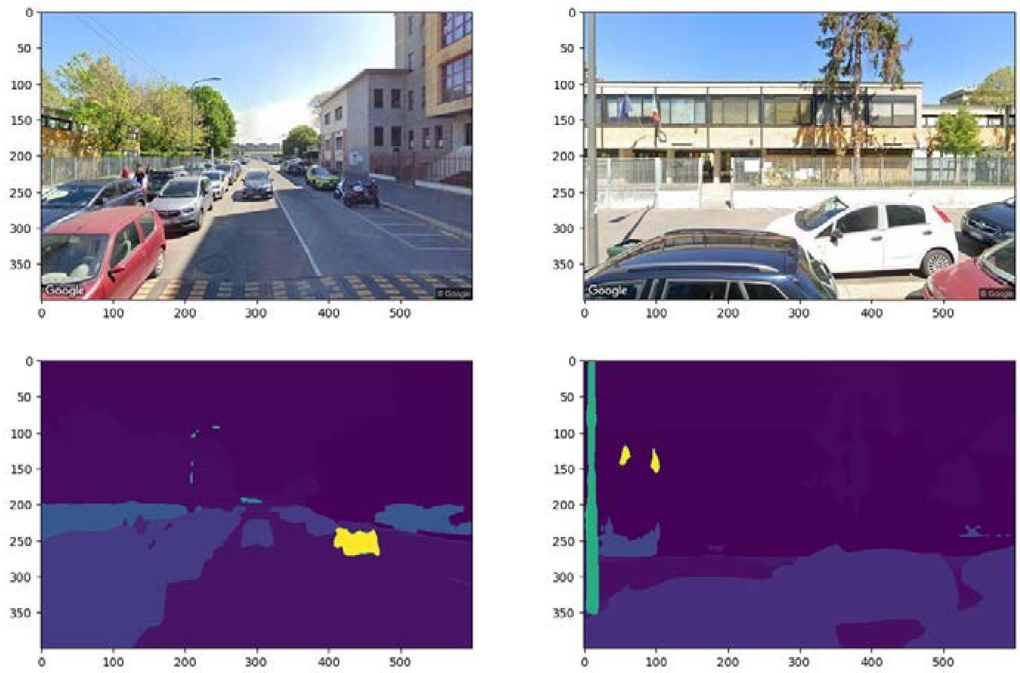

Fig. 10: Image segmentation results for the street analyzed in the example

However, by exploiting this type of approach for the analysis of criticalities, two fundamental limits can be identified, one technical and one "operational". The technical limit concerns the elements for which the model used has been trained. Indeed, there are about 150 objects that it can recognize, and not all of them are useful results for the purpose of this research. The solution to this limitation could be solved by developing a model trained to recognize a list of specific objects, related to the sector. Clearly, the realization is not immediate because in-depth knowledge of this type is beyond our competence.

The "operational" limit consists in not being able to rely entirely on the instrument. The validity of the results in terms of object recognition and positioning according to geographical coordinates has been obtained and demonstrated with excellent results. However, it should be remembered that an analysis carried out by this tool does not completely replace an analysis conducted directly by the designer. As stated above, the tool wants to be a support to ensure greater accuracy in the assessment of criticalities, but it is good to remember the existence of a margin of imprecision that only human experience can fill.

6. POSSIBLE IMPLEMENTATIONS AND CONCLUSIONS

The improvement and further development of the tool could lead to higher output quality and the implementation of additional functionalities. One of these functionalities could involve classifying objects based on their height and identifying them within the map as either aerial or surface constraints.

By adopting this classification approach and changing the output type, it would be possible to develop a tool that neglects the classification of objects according to their category of belonging. The recognized elements would still be positioned on the map based on their geographic coordinates; however, the color scale representing them would be based on the evaluation of their heights. Assuming to give the possibility to the user enters the reference value beyond which a constraint is considered aerial, the chromatic scale could then be defined based on this input that would represent the central value.

Nevertheless, regardless of the approach adopted for the development of such a tool, the utilization of artificial intelligence models, like the one employed in this study, has proven to be a proactive way to identify potential difficulties related to construction site organization and planning operations. However, it is essential to recognize that the images used as input, sourced from Google Street View (GSV), may have limitations in terms of quality and detail. Therefore, it is plausible to consider that the effectiveness and accuracy of the tool could be optimized by employing photographic surveys executed with appropriate instrumentation. This integration would enable the tool to provide more detailed and precise results concerning the construction site context, facilitating better analysis and identification of critical areas. In addition to the possibility of employing specific and higher-quality photographic surveys, considering the development of a dedicated AI model for this purpose could further enhance the capability to identify and address challenges inherent in construction site organization, offering a tailored solution for this domain.

In conclusion, adopting these measures would provide designers with a more sophisticated and efficient tool to navigate the complexities of construction sites, reducing the risk of errors or unforeseen complications, and enhancing overall decision-making in construction planning and management.

ABSTRACT: *This paper suggests the potential application of generative artificial intelligence-based image generation technology in the field of architecture, for early phase shape planning, using the styles of renowned architects. The study employed the following approaches: 1) Intensive image generation based on the styles of 20 architects to test the AI's recognition ability and image quality. 2) Additional training was conducted for architects with low recognition rates to construct an enhanced learning model in the quality of image generation. 3) In addition to generating architectural visualization images using existing architects' design styles, alternative styles were proposed through design combinations, aiming to concretize ambiguous idea communication in the early stages of design and enhance its efficiency. The study sheds light on the future prospects of applying this generative AI model in the field of architecture.*

KEYWORDS: *Design Style of Architects, Generative AI, Image Generation, Fine-tuning*

1. INTRODUCTION

In the field of architecture, visualization plays a crucial role in comprehending and evaluating complex design alternatives and spatial qualities [Greenberg, 1974]. Especially in the early design stages, it allows clear expression of design ideas and spatial concepts, enabling the identification and resolution of potential issues and facilitating effective communication among stakeholders [Akin, 1978]. Ultimately, early-stage visualization defines the design direction, enhances collaboration, efficiency, and leads to better outcomes. However, creating high-quality visualization images, particularly during the abstract design phases, remains challenging. While advancements in 3D modeling and rendering have improved the realism of visualizations, the process still demands time and specialized skills [Fonseca, 2017]. Currently, the emergence of AI and machine learning-based image generation models offers the ability to create images from text in a short timeframe. Applying this technology in the field of architecture has the potential to expedite the design process and foster creative design solutions.

Building upon this, our research focuses on the feasibility of generating architectural visualizations using AI-based image generation method. In Chapter 3, we tested the performance of the image generation AI model based on architects' styles, and in Chapter 4, we conducted additional training based on the test results. Finally, Chapter 5 demonstrates the practical applications of the Image generation AI including trained model.

2. BACKGROUNDS

2.1 Architectural visualization generation methods

Architectural visualization has evolved significantly over the years, transitioning from traditional manual techniques to embrace the power of digital technology. Historically, architects relied on hand-drawn sketches, physical models, and paintings to communicate their design ideas [Kehir AI-Kodmany, 2001; Atilola et al., 2016]. These methods, though expressive, had limitations in terms of scale, precision, and the time-intensive nature of creation. As architecture moved into the digital era, Computer-Aided Design (CAD) emerged as a game-changer, enabling architects to produce accurate and editable digital representations of their designs [Chiu, 1995]. It marked the beginning of a transformative shift in architectural visualization, offering architects the ability to iterate rapidly, explore design alternatives, and create highly detailed virtual models.

As technology continued to advance, architectural visualization expanded its horizons to encompass photorealistic rendering, three-dimensional (3D) modeling, and immersive experiences [Koutamanis, 2000]. Sophisticated

Youngjin Yoo, Hyun Jeong, Youngchae Kim, Seung Hyun Cha and Jin-Kook Lee, *Generative Design Intuition from the Fine-Tuned Models of Named Architects' Style,* pp. 917-925, DOI 10.36253/979-12-215-0289-3.91

rendering software, bolstered by powerful Graphics Processing Units (GPUs), enabled architects to create high-fidelity visualizations that realistically conveyed materiality, lighting, and texture. 3D modeling provided a comprehensive understanding of spatial relationships [Eastman, 1999], offering architects the ability to manipulate and analyze their designs in a virtual environment [David et al., 2022]. This progress in technology not only increased the efficiency of the design process, ultimately leading to better-informed design decisions and more visually impactful presentations.

2.2 Image generation artificial intelligence (AI)

In 2014, Generative Adversarial Networks (GANs) emerged as a dominant paradigm for image generation research. GANs showcase their prowess by creating realistic images through competitive training involving a generator and a discriminator [Goodfellow et al., 2014]. As the stability of GAN training methods improved, the focus shifted towards generating images with specific attributes and refining the generated outputs [Karras et al., 2020]. These techniques have been applied to comprehend the information conveyed in architectural drawings, making it interpretable for computers. [Kim et al., 2019; Kim et al., 2020]

Since 2020, within the diverse landscape of image generation AI platforms, several notable options have emerged. Midjourney [Oppenlaender, 2022] specializes in style blending, empowering users to influence the fusion of multiple styles within the generated images. DALL-E 2 [Ramesh et al., 2022] creates images from textual descriptions, showcasing the potential to transform words into visuals, despite occasional inconsistencies. In contrast, Stable Diffusion [Rombach et al., 2022] leverages a diffusion model, ensuring stability during training and providing the capacity to manage image quality and intricacy. It shows immense promise in bridging the gap between abstract architectural concepts and their visual manifestation.

Among these, Stable Diffusion holds particular promise for architectural visualization research, given its ability to handle complex image transformations, align well with architectural subtleties, provide stability during training, and offer control over output quality and detail [Oppenlaender et al., 2023; Borji, 2023]. This positions Stable Diffusion as a potent tool to bridge the gap between architectural concepts and visual representation, redefining how architects approach their work and streamlining the creative process.

2.3 Potential for architectural visualization automation

There has been extensive research in image generation AI; however, its full potential for architectural visualization has yet to be realized. This research introduces a novel approach to architectural visualization using image generation AI models, emphasizing their transformative impact on this field. By harnessing advanced machine learning techniques, the study explores innovative methods to enhance architectural visualization, including text-to-image generation, which creates images from textual descriptions [Saharia et al., 2022]. This capability enables the generation of highly realistic images, making it a versatile tool with significant potential for various architectural visualization applications.

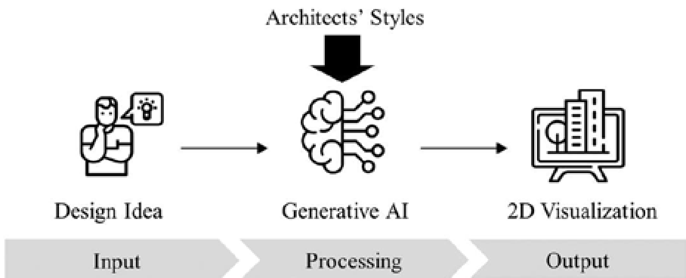

Fig. 1: Research approach: Image generation AI based architectural visualization

3. INTENSIVE TEST OF IMAGE GENERATION AI WITH ARCHITECTS' STYLE

3.1 Image generation test for architects' styles

Image generation artificial intelligence (AI), particularly Stable Diffusion (SD), involves two primary methods. The first method generates images from a text prompt, known as text-to-image generation. The second method, image-to-image generation, requires a seed image in addition to text prompts to generate images based on both inputs. In this paper, we focus primarily on text-to-image generation which generates images (Img_G) using the

"$generate()$" function, requiring a AI model (M), parameters ($Param$), and prompts (P_t).

$$generate(M, Param, P_t) = Img_G \tag{1}$$

$$Param = \{resolution, sampling\ method, sampling\ steps, CFG\ scale\} \tag{2}$$

$$P_t = \{SDP, RQP\} \tag{3}$$

The $Param$ consist of four components: $resolution$, determining the image size in pixel; $sampling\ method$, selecting method for image extracting from latent space; $sampling\ steps$, defining the number of extraction stages; and Classifier-free guidance scale ($CFG\ scale$), specifying the influence level of the prompt. The P_t consist of Scene Description Prompts (SDP), describing the target scene, visual composition, and graphic style, and Resolution Quality Prompts (RQP), adjusting the image's quality. Additionally, to prevent errors, each prompt composition includes negative prompts to specify what should be excluded. Table 1 provides example prompts corresponding to its composition.

Table 1: Prompt composition and its examples.

Composition of P_t	Positive Prompt example	Negative prompt example
Scene description prompts (SDP)	A residential house, professional photograph, photorealistic rendering, deep depth of field, high-key lighting, two-point perspective, etc.	Commercial buildings, painting, sketch, bird's-eye view, isometric, portrait, cropped view, etc.
Resolution quality prompt (RQP)	realistic shadows, enhance-detail, v ray rendering, full HD, masterpiece, highly detailed, high quality, 8k, etc.	low quality, too much noise, normal quality, watermark, blurry textured, blurry, noise, faint, text, etc.

In this section, we tested the performance of the text-to-image method defined earlier for generating architectural visualization. We randomly selected 20 architects who have received architectural awards or have had significant international influence, and generated images reflecting their styles. While additional descriptive keywords could enhance image quality by further delineating each architect's features, we excluded them for a clearer assessment of the default model's architect's style recognition capabilities. Instead, we used only the prompt "Architect's name-inspired residential house" and prompts associated with photorealistic rendering, commonly used in architectural visualization. We generated approximately 100 to 150 images for each architect in a local PC environment, with a resolution of 1024 by 512 pixels. The generated results are summarized in Figure 2.

None style "A residential house" | Low Recognition "Renzo Piano-inspired residential house" | High Recognition "Frank Gehry-inspired residential house"

Fig. 2: Result of text-to-image generation test

3.2 Findings and ongoing inquiry in image generation AI

The generated results were assessed based on three criteria for their alignment with P_t. This assessment encompassed: (1) Style fidelity, which measures the accuracy of depicting the design characteristics of architects, (2) Domain fidelity, which verifies the representation of unique features for residential houses, and (3) Image quality, assessing the extent to which the photorealistic style rendering prompt was reflected in terms of graphic style, composition, and resolution.

The image generation test results indicated that the current SD model achieved a high level of domain fidelity and overall image quality. However, it exhibited low recognition for specific architects' styles, regardless of their prominence, resulting in lower quality and less detailed images of generic Western-style residential houses without any corresponding style features. As a result, the need for further additional training of the existing image generation model to address these limitations in recognizing certain architects' styles became evident. Motivated by this necessity, we conducted additional training, specifically targeting Architects' design styles, as depicted in Figure 3.

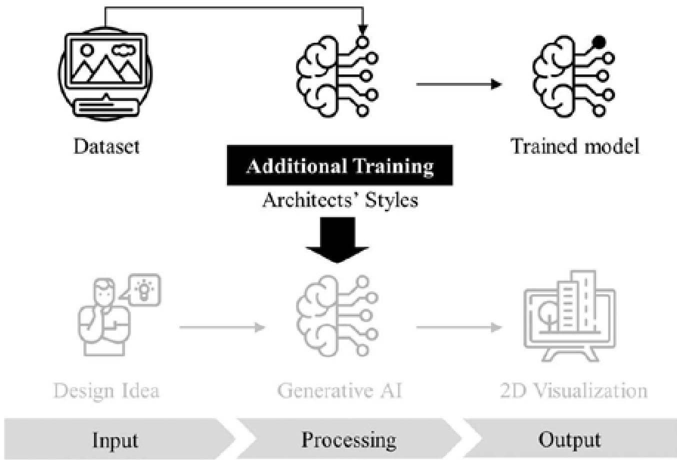

Fig. 3: Research Overview: Additional training for architects' styles

4. ADDITIONAL TRAINING FOR ARCHITECTS' STYLES

4.1 Additional training and data preparation

If the majority of generated images (Img_G) do not match the target image group (Img_t), it is required to replace the current model (M) with an alternative model (M'). This replacement can involve either substituting the model or enhancing it through further training. In this chapter, Low Rank-Adaptation (LoRA) approach [Hu et al., 2021] is employed for additional training, aiming to improve the recognition of specific architects' styles and to generate images that appropriately belong to the Img_t. The target model (M_t) is developed using the "$train()$" operator, based on the base model (M), hyperparameters ($Hyperparam$) and a target training dataset (D_t).

$$Most\ of\ Img_G \notin Img_t \Rightarrow M' \rightarrow M \quad (4)$$

$$train(M,\ Hyperparam,\ D_t) = M_t \in M' \quad (5)$$

Hyperparameters play a significant role in both the model's learning process and the subsequent performance of the M_t. We specifically focused on three crucial hyperparameters: the training batch size (BS_t), the number of epochs ($epoch$), and the learning rate (α). At the same time, the effectiveness of additional training relies on a high-quality dataset (D_t) containing image data (Img_D) along with corresponding annotation text files (Txt_D).

$$Hyperparam = \{BS_t, epoch, \alpha\} \quad (6)$$

$$D_t = \{Img_{D1}, Txt_{D1}, \dots, Img_{Dn}, Txt_{Dn}\} \quad (7)$$

The additional training process, as depicted in Figure 4, involves two essential steps: (1) dataset preparation [Abdallah et al, 2017] and (2) training [Hu et al., 2021]. During the dataset preparation phase, meticulous training data collection is required to ensure alignment with P_t. Preprocessing phase aids in removing unnecessary content that might disrupt the training process. It is crucial to ensure content quality of training data, and the correspondence between Img_D and Txt_D. Following this, the Txt_D is paired with the respective Img_D, and the prepared D_t is then trained using the specified $Hyperparam$.

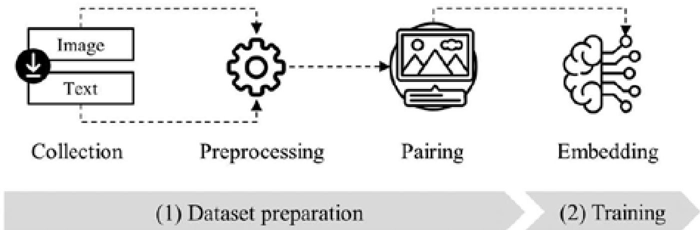

Fig. 4: Additional training process

4.2 Additional training of existing model with architects' styles

In this chapter, we provided additional training to architects who received low or no recognition in the image generation test discussed in Chapter 3. We conducted a few-shot learning using the previously defined training approach. By incorporating the trained LoRA model (M_t) into the image generation function, the possibility that generated images ($Img_{G'}$) closely resemble the designated Img_t is notably improved compared to the previous results. When utilizing M_t, in addition to M, it is crucial to input the application weight (W), a value ranging from 0 to 1, where 0 represents 0% and 1 represents 100%.

$$generate(M' \vee M(M_t, W),\ Param,\ P_t) = Img_{G'} \tag{8}$$

We compared the performance of the default model (M) with the trained model (M_t) by generating images with both. The image generation process followed equation (8), and the parameters (Param) and prompts (P_t) used for image generation remained consistent with those used in Chapter 3. As shown in Figure 5, the existing model had very low recognition rates for certain architects, so even with a full weight, the specific features of those styles were not represented. However, when using the trained model, these features are correctly displayed, and their application is proportional to the weight. The additional training allows us a wider range of style options that the original model could not achieve.

Default model 1.0 "SANAA-inspired residential house" | Trained model 0.5 "SANAA-inspired residential house" | Trained model 1.0 "SANAA-inspired residential house"

Fig. 5: Additional training results: SANAA style

5. DEMONSTRATIONS

Our investigation revealed that AI-driven image generation rapidly produces high-quality architectural visualizations from text prompts, empowering architects to easily create reference images and visualizations from the start of the design process. This chapter demonstrates the practicality of Image Generation AI, particularly Stable Diffusion, across various architectural styles. The three applications include: (1) building additional training models for desired architects' styles, (2) generating architectural visualizations applying an individual architect's style, and (3) generating style alternatives by combining more than two styles.

5.1 Implementation of different styles through additional training

In this scenario, we employ image generation AI to incorporate diverse architects' styles, providing users with desired visualization outcomes through additional training. In this chapter, we conducted additional training following the process outlined in Figure 4, targeting five architects with very low recognition rates, aiming to enhance the model's level of detail. To ensure high-quality training images, we sourced project photographs from reputable sources, such as Architects' official websites, focusing on full facades in 1-point or 2-point perspective. Preprocessing involved image resizing and the removal of excessive information. Text data was constructed for each image, extracting from interviews with architects, expert analyses, and prior research about their styles. Each target style was trained with 15-25 datasets in average, with hyperparameters {1, 100, 0.0001}, and it took 8-15 minutes per each training.

The resulting model files, incorporated into the existing model, produce architectural exterior images closely mirroring architects' design styles, even when data is limited. In this chapter, we generated five M_t files, each representing the styles of different architects, capable of producing high-quality images comparable to those shown in table 2 of chapter 5.2.

5.2 Visualization of design alternatives from text prompts

This scenario describes how we acquired a diverse set of creative reference images representing different architects' design styles. In this chapter, we applied the M_t developed in the previous chapter to M in order to generate architectural visualizations based on the styles of 20 selected architects, using the same prompts as those used in the image generation test in chapter 3.1. We generated approximately 100 to 150 images for each architect based on equations (1) and (8), with the parameters {(1024, 512), Euler α, 20, 7}. These images, as demonstrated in Table 2, accurately reflect not only their respective styles but also maintain the essential characteristics of residential buildings, even for architects with little prior experience in residential projects. These generated outputs provide a rich source of diverse and concrete ideas and inspirations right from the initial stages of architectural design, streamlining communication and facilitating the design process.

Table 2: Resume of generated visualizations from text prompts

Input prompt	Output		Descriptive Keywords
I.M. Pei-inspired residential house, Photorealistic rendering prompt set			Modernist, minimalist, geometric, cultural fusion, monumental, symmetrical, glass and steel, iconic, etc.
Renzo Piano-inspired residential house, Photorealistic rendering prompt set			Lightness, Transparency, industrial materials, fluidity, civic and public focus, open spaces, etc.
Le Corbusier-inspired residential house, Photorealistic rendering prompt set			Modernism, functionalism, free façade, open floor plans, concrete, horizontal windows, etc.
SANAA-inspired residential house, Photorealistic rendering prompt set			Minimalist, subtle elegance, organic forms, conceptual simplicity, fine steel structure, white color, transparency, etc.
Shigeru Ban-inspired residential house, Photorealistic rendering prompt set			Sustainability, paper architecture, wooden modular structure, organic design, grid, organic forms, patterns, etc.
Frank Lloyd Wright-inspired residential house, Photorealistic rendering prompt set			Organic architecture, prairie style, horizontal lines, flat roofs, clerestory windows, cantilevered overhangs, etc.
Antoni Gaudi-inspired residential house, Photorealistic rendering prompt set			Curved lines, mosaic and tilework, nature-inspired design, whimsical details, unconventional forms, use of color, etc.
Mies van der Roe-inspired residential house, Photorealistic rendering prompt set			Minimalism, steel and glass, open floor plans, linear and geometric design, Bauhaus influence, international style, etc.

Ex) Photorealistic rendering prompt set = *Positive prompts:* professional photograph, photorealistic rendering, realistic, enhance-detail, v ray rendering, full HD, masterpiece, highly detailed, high quality, 8k, two-point perspective, exterior view, full shot, deep depth of field, f/22, 35mm, high-key lighting, natural lighting, realistic shadows; *Negative prompts:* low quality, bad proportion, awkward shadows, unrealistic lighting, pixelated textures, too much noise, unrealistic reflections, normal quality, watermark, bad perspective, confusing details, blurry textured, blurry, noise, cloudy, faint, text.

5.3 Combination between architects' styles

This scenario illustrates the creation of diverse image references by blending multiple architectural styles, resulting in novel and previously unseen styles. Users can expand their architectural image references using image generation AI by combining the styles of two or more architects. The P_t and $Param$ for these operations are the same as those in other image generation cases, except for the SDP (Scene Description Prompts), which is observable in Table 3. This setup allows for a comparison between the results of applying a single style and the application of multiple styles, facilitating an assessment of the progress of the operations.

Table 3: Example of combination of architects' styles using text-to-image method

Classification		Mono-style: SANAA style	Mono-style: Luis Barragan style	Multi-style: SANAA and Barragan
Input	Model	Trained model		
	Parameters	Resolution: 1024 × 512 / Sampling method: Euler a / Sampling steps: 20 / CFG scale: 7		
	Prompts	SANAA-inspired residential house, Photorealistic rendering prompt set	Luis Barragan-inspired residential house, Photorealistic rendering prompt set	SANAA and Luis Barragan-inspired residential house, Photorealistic rendering prompt set
Output				
Descriptive Keywords		Minimalist, elegance, sensitivity, fine steel structure, white color, simplicity, transparency, etc.	Minimalism, color, geometry, concrete, simplicity, play of light and shadow, etc.	Fine structures, colorful, rectilinear, concrete, simplicity, geometry, etc.

As shown in Table 3, the combination of two different styles is evident and noticeable. When the curvilinear style of SANAA is combined with the rectilinear style of Luis Barragan, the curvilinear aspect of SANAA becomes less pronounced. Additionally, the resulting style incorporates the color palette and materiality of Luis Barragan, along with SANAA's distinctive design feature of thin structures. These findings demonstrate that image generation AI can create new alternative styles based on existing ones, potentially generating a variety of additional alternatives.

6. CONCLUSION

This research marks the initial steps in exploring the potential of architectural visualization through image generation AI, with a specific focus on the Stable Diffusion model. The study underscores the significant impact of image generation AI, particularly in the field of architecture and its application in early-stage architectural visualization. Leveraging deep learning and image generation techniques, we trained the model to capture the distinctive styles of renowned architects, using this knowledge to visualize typical residential houses. Our testing revealed that while the default SD model generally produces high-quality architectural visualizations with domain fidelity, it does face limitations in recognizing the unique styles of architects. However, we demonstrated that these limitations can be improved through additional training, highlighting the powerful potential of image generation AI.

This approach plays a pivotal role in bridging the gap between abstract design concepts and tangible visual representations, empowering architects to effectively convey their creative ideas. Integrating AI technology into architectural visualization broadens creative possibilities, enabling architects to explore a diverse range of design alternatives. Looking ahead, further research is essential to develop comprehensive and refined methods for additional training, expanding beyond architects' styles to other targets. Additionally, the focus should be on enhancing the accessibility and utility of this technology by exploring other generation methods, such as image-to-image, and the development of user-friendly tools.

PLANNING ALTERNATIVE BUILDING FAÇADE DESIGNS USING IMAGE GENERATIVE AI AND LOCAL IDENTITY

Hayoung Jo, Sumin Chae, Su Hyung Choi & Jin-Kook Lee
Department of Interior Architecture and Built Environment, Yonsei University, Seoul, Korea.

ABSTRACT: *This paper describes an approach utilizing Generative AI to support diverse design alternatives for building facades based on the local identity. Extensive research is currently being conducted for exploring the applications of LLM-based generative AI models to diverse kinds of visualizations. By applying generative AI to facade design, the study aims to develop additional training models that generate alternative design options reflecting local identity, facilitating the acquisition of remodel design images from multiple texts and images. Building facades in cities and regions are essential for people's aesthetic perception and understanding of the local environment, enabling the recognition and differentiation of specific areas from others. Therefore, implementation method of the additional training model based on generative AI in this study, reflecting this, can be summarized as follows: 1) collection and pre-processing of image data using Street View, 2) pairing text data with image data, 3) conducting additional training and testing with various inputs, 4) proposing relevant application methods. This approach can be expected to enable efficient communication of design at an early stage of the architectural design process beyond traditional 3D modeling and rendering tools.*

KEYWORDS: *Building facade, Generative AI, Local identity, Design alternative, Additional Training Model*

1. INTRODUCTION

Recently, platforms such as 'Midjourney,' 'Dreamstudio AI,' and 'Stable Diffusion' have been developed and used alongside Large Language Model (LLM) based platforms like 'ChatGPT' (OpenAI, 2022) to generate images using Diffusion models. These platforms are provided in accessible forms for the public, and their interfaces and functionalities are consistently updated. These platforms are based on generative artificial intelligence, allowing users to easily create desired images creatively by providing prompts and adjusting settings. This generative AI-based image creation approach is not only applied in design and art fields but also in various other domains. It is also being employed in architecture, generating images of diverse buildings and spatial designs in various styles, contributing to applied research.

In this study, the aim is to apply the image generation capability of generative artificial intelligence to obtain facade images of buildings. Furthermore, this involves creating building images with regional design identities, aiming to establish an approach for more efficient utilization during the initial building planning and design stages (Relph, 1976). This approach focuses on commercial buildings, allowing for the swift acquisition of creatively designed facade images in the early architectural phases by adjusting the degree of regional identity incorporation.

The research follows the following methodology: Initially, to evaluate the effectiveness of the image generation model, a repetitive process of image generation was conducted, resulting in the creation of a substantial number of images for testing. Based on these results, it was evident that additional training of the basic generative AI model was necessary. Subsequent steps for this additional training were carried out as follows: 1) Constructing a training dataset, 2) Conducting additional training and generating model files, 3) Confirming and utilizing result images incorporating the additional training model files. This was executed in the form of additional training utilizing the Diffusion-based model. The additional training was built upon LoRA (LoRA: Low-Rank Adaptation of Large Language Models), and by adjusting hyperparameters, it was ensured that high-accuracy images were generated. Following this, the generated additional training model files were applied to generate and confirm result images, suggesting an approach to visualize these images in the early architectural stages.

2. BACKGROUND

2.1 Image Generative AI

Since 2020, diffusion process-based techniques have gained prominence in the arena of deep learning-driven image synthesis. These approaches iteratively update pixel values to progressively generate images (Ho, Jain, & Abbeel, 2020). Concurrently, scholars have immersed themselves in artificial intelligence models that facilitate the

FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Hayoung Jo, Sumin Chae, Su Hyung Choi, Jin-Kook Lee, *Planning Alternative Building Façade Designs Using Image Generative AI and Local Identity,* pp. 926-932, DOI 10.36253/979-12-215-0289-3.92

transformation of textual data into visual representations, marking significant progress in the domain of image generation (Ramesh, Dhariwal, Nichol, Cuy, & Chen, 2022; Saharia, Chan, Sawena, Li, Whang, Denton, … & Norouzi, 2022; Rombach, Blattmann, Lorenz, Esser, & Ommer, 2022).

While considerable scholarly inquiry has been devoted to deep learning-assisted image synthesis, its potential in the realm of architectural design visualization remains largely untapped (Kim, & Lee, 2020). This investigation introduces an innovative proposition for architectural design visualization, harnessing the capabilities of AI-driven image synthesis models and recognizing their transformative impact in the landscape of image generation. Through the application of these advanced machine learning techniques, this section aims to explore novel pathways to enhance architectural design visualization via AI-powered image training models.

With the advancement of the LLM model and the image synthesis technology, the feasibility of producing architectural visualization images based on provided textual input has become achievable. Termed as text-to-image synthesis, this process possesses the ability to generate highly realistic images, making it a versatile instrument for generating a diverse range of architectural visualization content. As AI technology continues its evolution, the role of text-to-image synthesis is expected to play a crucial role in the architectural domain. Consequently, the integration of AI-driven image synthesis enhances the potential for imaginative exploration beyond traditional methodologies.

2.2 New opportunities for Architectural Visualization

Architectural visualization, such as photorealistic images, plays a crucial role in enhancing communication within the field of architecture (Lee, Lee, Kim, & Kim, 2023). Firstly, photorealistic renderings transcend mere geometric massing, enabling architects to vividly convey their design intentions to clients. These images serve as intermediaries between architectural drawings and experiential aspects of architectural spaces by presenting architectural concepts in a reality-like manner (Kim, & Lee, 2022). Such visualizations facilitate shared understanding among stakeholders. Secondly, visualization empowers not only architectural professionals but also stakeholders, clients, and the public to grasp architectural visions that transcend architectural terminology and technical complexity. Visualized images like photorealistic renders enable individuals to comprehend the interaction between planned architectural attributes, ambiance, and the surrounding environment, enabling informed decision-making based on information. Transitioning from geometric massing to photorealistic render images allows for a more universal and comprehensive communication of intricate architectural concepts, thus promoting smoother communication.

In summary, integrating visualization images like photorealistic renderings into the architectural design process enables efficient communication in the early stages of architecture, induces information-based decision-making, and enhances creative design. While traditional architectural visualization relied on complex technical processes and necessitated GPUs and specialized hardware, leveraging generative AI, as discussed earlier, allows for obtaining numerous detailed visualization images effectively without the need for separate GPU renderers.

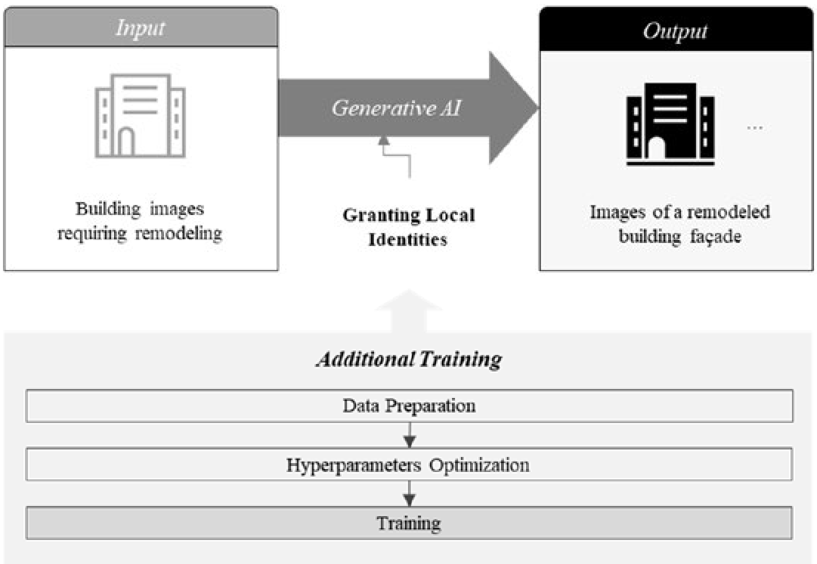

Fig. 1: Overview of the approach proposed in this study.

The following section examines the application of such generative artificial intelligence to architecture, exploring the potential of generating architectural images. This investigation, as outlined in the introduction, focuses on the design aspect of building facades within the realm of architectural elements (Kier, 1984). Specifically, this inquiry aims to determine the feasibility of effectively generating architectural visualization images by emphasizing regional identity as a pivotal design consideration within building facade design.

3. TEST ON BASIC IMAGE GENERATION MODELS

3.1 Test Generative AI Platforms

Various platforms are being developed using generative artificial intelligence to make it easily accessible for the public. These platforms utilize different interfaces and base models, resulting in a range of image generation platforms that cater to various user requirements such as freedom of generation, design style of images, sizes, and image quality. In this paper, we utilized the commonly used platforms 'Midjourney,' 'Dreamstudio AI,' and 'Playground AI' to understand their respective interfaces, directly engage with them, and explore their features and specific functionalities.

Among these three platforms, the latter two platforms, excluding 'Midjourney,' offer partial free usage for image generation, with subscriptions or purchases required for more extensive usage. Each interface provides common features including the option to select various image styles like 'Enhance,' 'Anime,' 'Photographic,' 'Comic book,' as well as the ability to create Positive and Negative prompts. All platforms also offer the functionality to adjust specific settings to generate images. Additionally, they provide an "Image-to-Image" feature wherein users can input desired images to generate text based on the images, resulting in the creation of different images. By utilizing these functionalities, one can quickly generate images tailored to specific requirements. For instance, when aiming to acquire building facade images as shown in Table 1, it becomes possible to generate images that incorporate more creative ideas. The following section will proceed with an examination of building facade image generation through detailed testing, utilizing prompts that encompass greater specificity and domain knowledge.

Table.1: Investigation of the interfaces of prominent platforms for image generation models and examples of generated images (The generated images from Midjourney and Dreamstudio AI are provided by openart (https://openart.ai/), while the examples generated by Playground AI are based on similar prompt-based approaches).

		Midjourney	**Dreamstudio AI**	**Playground AI**
Web Interface				
INPUT	Key Prompt		Building Façade Image	
OUTPUT	Generated Images			
3.2 Testing of Façade Image Generation Reflecting Local Design Identity

In this section, we aim to investigate whether it is possible to generate facade design images that reflect regional identity using generative artificial intelligence. To achieve this, we conducted image generation tests based on text prompts using the existing basic model grounded in Diffusion. The tests were divided into three main categories: facade images of buildings without region-specific text input, facade images of buildings reflecting Korean style, and facade design images of commercial buildings in Manhattan. The goal was to compare the generated images for these three categories. For each category, we utilized key prompts such as "Building Facade," "Building Façade reflects Korean style," and "Building Façade reflects Manhattan style." Additionally, we employed prompts to enhance image quality to generate results like those in Table. 2.

By utilizing the existing generative artificial intelligence-based model, it was observed that when region-related text prompts were input, corresponding images could generally be generated. However, this primarily resulted in localized images, and it was found that the generated facade design images did not exhibit diverse variations reflecting the unique images associated with each region. For instance, in the case of Korean facade images, predominantly images of buildings featuring traditional Eastern style hanok architecture were generated. Therefore, in the subsequent section, we proceed to construct a model through fine-tuning of the existing generative artificial intelligence model, aiming to determine if image generation with a focus on regional facade design identity can be achieved.

Table. 2: Example of generating building facade images with regional names using the basic generative AI model

No.	Key Prompts	Generated Images
1	Building Facade	
2	Building Façade reflects Korean style	3	Building Façade reflects Manhattan style	
4. CONSTRUCTION AND UTILIZATION APPROACHES OF THE ADDITIONAL TRAINING MODEL

4.1 Additional Training and Testing of Local Facade Design Identity Model

In this section, we aim to investigate the generation of facade design images that reflect regional identity by conducting additional training of a generative artificial intelligence model within the scope of the target region. Model construction utilized the Diffusion-based model implemented on the foundation of LLM (Large Language Model) for additional training. This additional training process can be summarized into three main stages: 1) Data Preparation, 2) Model Training, and 3) Image Testing and implementation. Data preparation involved pairing image and text data. For efficiency in image data collection, street-view functionality from portal sites API was employed, as described earlier. However, the distorted nature of 360-degree panorama images from street-view led to generating indistinct façade images, lowering image quality and accuracy. To address this, image preprocessing was conducted to correct distortions, resize images to a consistent size, and then pair them with text data to compile the dataset.

For model training, the LoRA (Low-Rank Adaptation of Large Language Models) approach was adopted to facilitate additional training of the Diffusion model (Hu, Shen, …& Chen, 2021). LoRA allows for rapid additional training of existing large-scale models within a short timeframe, without significant demands on GPU performance. Unlike other methods, LoRA generates relatively smaller additional training model files and offers the advantage of easily assessing style incorporation through adaptability changes in the model files. Thus, in this research, LoRA is employed to construct additional training models, optimizing hyperparameters to generate highly accurate images with minimal distortion. The optimization of hyperparameters, including adjustments to epochs, training batch size, and caption extensions, aims to enhance the accuracy and quality of the resulting images.

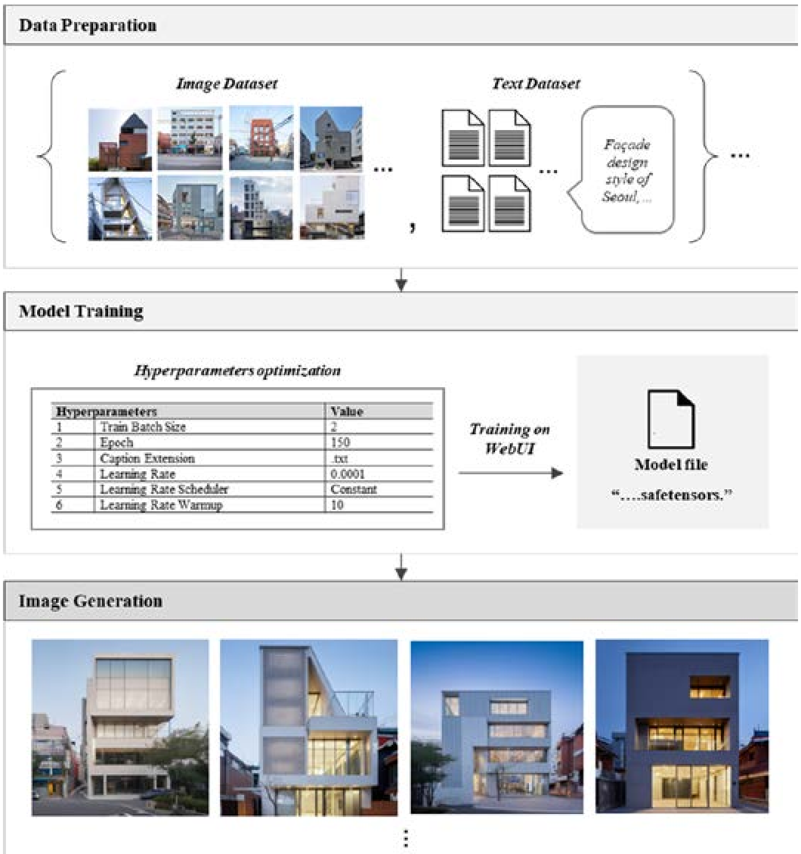

Fig. 2: Construction Process of the Additional Training Model

When conducting additional training using LoRA, model files with the extension ".safetensors" are generated. Inserting these generated model files into the model management folder of the Stable Diffusion Web-UI enables the models to function in the format of a text prompt, allowing the generation of desired images alongside the text data used for training. Furthermore, by adjusting the adaptability of the generated model files, a wide array of creative design images can be produced. Applying the additional training model file created using exterior images and text data of commercial buildings in the Seoul area, according to different weight values, results in images as shown in Table 3. When applying a weight of 0.1, images of buildings with views from different angles beyond the front facade are generated. As the weight approaches 1.0, images distinctly reflecting Seoul's facade design style are generated.

Table. 3: Test of Additional Training Models according to each weight

4.2 Utilization Approaches of the Additional Training Model File

In this section, we demonstrate one example of an approach that can be applied in the early stages of architecture using the constructed additional-trained model files. We validated the images that could be generated by applying the model files using actual facade images of buildings in Seoul. When applying this method and providing detailed prompts, it was observed that images reflecting Seoul's facade design style could be generated.

5. CONCLUSION

In the initial design stages of existing buildings, facade design plans have traditionally relied on manual efforts by designers and architects, or methods involving 3D modeling tools and high-performance GPU renderers. These methods have necessitated repetitive tasks to facilitate communication with clients. This study discusses an approach that leverages the recent advancements in generative artificial intelligence, which is being actively applied in related fields, to generate facade design alternatives using image generation AI. Within the context of this research, we propose an approach that enables quick confirmation of building facade design plans reflecting regional facade identity in the early design stages and the generation of numerous alternatives.

According to the approach proposed in this study, it was confirmed that utilizing image generation AI can rapidly confirm building facade design plans, incorporating regional facade identity, and produce a multitude of alternatives. This approach was demonstrated through applying Seoul's facade design style using actual building images to showcase its effectiveness. Consequently, exceptional visualization images were generated.

Although there may be limitations in this study, particularly in constructing a fine-tuned model focused on Seoul, it holds significance in its potential to create and explore more diverse and domain-specific models using this methodology. This opens the door for further application-oriented research, leveraging more specific characteristics and domain knowledge to refine the approach.

ABSTRACT: *Early failure detection and abnormal data reconstruction in sensor data provided by building ventilation control systems are critical for public health. Early detection of abnormal data can help prevent failures in crucial components of ventilation systems, which can result in a variety of issues, from energy wastage to catastrophic outcomes. However, conventional fault detection models ignore valuable features of dynamic fluctuations in indoor air quality (IAQ) measurements and early warning signals of faulty sensor data. This study introduces a hybrid framework for early failure detection and abnormal data reconstruction applying variance analysis and variational autoencoders (VAE) coupled with the long short-term memory network (VAE-LSTM). The periodicity and stable fluctuation of IAQ data are exploited by variance analysis to detect unusual variations before failure occurs. The IAQ dataset which is corrupted by introducing complete failure, bias failure and precision degradation fault is then used to verify the feasibility of the VAE-LSTM model. The results of variance analysis reveal that unusual behavior of the data can be detected as early as 12 hours before failure occurs. The reconstruction performance of the developed method is shown to be superior to other methods under different abnormal data scenarios.*

KEYWORDS: *Early failure detection, Abnormal data reconstruction, Variational autoencoder (VAE), Long short-term memory network (LSTM), Sustainable IAQ management*

1. INTRODUCTION

Indoor air quality (IAQ) in public buildings is regarded as a hot study topic as it has a big impact on human health. Recent research has shown a connection between indoor air pollutants, including CO_2, with health effects and academic performance (Szabados et al., 2022). According to the EPA's IAQ tools for schools (EPA, 2009), CO_2 concentrations in schools should adhere to the ASHRAE standard 62-2001 limit of 700 ppm over the outdoor concentration (just above 1000 ppm overall) for CO_2 concentrations. Besides various laws and regulations, there is a need for continuous monitoring of IAQ, which includes the installation of sensors to detect anomalous events that may have a detrimental impact on the IAQ. Sensors are generally placed on walls or ceilings to collect hourly levels of pollutants, such as CO_2, NO_2, and particulate matter (PM), which are small and aerodynamic. In addition, sensors can also collect relative humidity and temperature data. These monitoring sensors are important in the management of ventilation systems. Unfortunately, hardware sensors can encounter various issues, such as bias and precision degradation. In addition, they may experience data loss due to environmental or operability issues, which results in their measurements being unrealistic (Kim, Liu, Kim, & Yoo, 2014). When air quality is not monitored properly, it can lead to a decrease in IAQ levels. On the other hand, overestimation of the levels of pollutants can cause energy wastage. For these reasons, an effective method for early failure detection and reconstruction of faulty IAQ sensors can help increase the uptime of ventilation management.

Some investigations have used statistical methods for abnormal data reconstruction (Kasam, Lee, & Paredis, 2014; Ouyang, Zha, & Qin, 2017). Although statistical methods are easier to implement and work well when there are few abnormal data, their performance is constrained as the data complexity increases. Additionally, the majority of statistical techniques rely on linear assumptions, which are incompatible with nonlinear real-world situations. Traditional machine learning approaches can use the whole data set to understand the patterns of failure performance in order to solve this problem. Unfortunately, they require a lot of manually classified anomalies to learn a predictor from given observations (Wang, Feng, & Liu, 2021), and due to the failure of unanticipated patterns of learning, such methods have poor performance (Bu et al., 2018). The emergence of neural methods without labelled information that is capable of handling non-linear data is a major factor that has led to the increasing number of applications of deep learning in process monitoring.

Time series prediction using deep learning methods, especially the long short-term memory neural network (LSTM), has achieved significant achievements in recent years (X. Li et al., 2017; Qing & Niu, 2018; Su & Kuo, 2019). A hybrid convolutional neural network and long short-term memory model (CNN-LSTM) was used to impute missing values in time-series datasets for air-conditioning appliances (Hussain et al., 2022). The hybrid technique outperformed the CNN and LSTM variants in terms of performance. Ma et al. suggested a hybrid Bi-directional Imputation method using an LSTM model and Transfer Learning to fill the gaps in the energy consumption data (Ma et al., 2020). Transfer learning was utilized to prevent network saturation problems while the basic model was pre-trained on data from a comparable building. The performance demonstrated that the suggested architecture could successfully handle various scenarios with missing data, including continuous and random missing data. The developed strategy, however, was predicated on the prior assumption of source and target data collected on sufficiently similar buildings. In general, LSTMs are commonly used in a wide range of applications due to their ability to model non-linear dependencies. However, the prediction performance of LSTM can also be sensitive to the anomalies in the input due to its non-linear nature. Our proposed approach is to make sure that the input of the LSTM prediction network contains as little abnormal data as possible. Therefore, a method for abnormal detection and reconstruction in time series is necessary. However, existing abnormal detection methods require a lot of manually labelled abnormal observations. Some methods, which are based on unsupervised learning, are used for time-series abnormal detection to address these concerns by concentrating on normal patterns rather than anomalies (Breunig, Kriegel, Ng, & Sander, 2000; Cao, Nicolau, & McDermott, 2016; Erfani, Rajasegarar, Karunasekera, & Leckie, 2016). Unfortunately, due to the failure of unanticipated pattern learning, such discriminative modeling-based techniques still necessitate a significant number of normal observations and have low accuracy (Bu et al., 2018).

Traditional fault detection methods based on supervised learning require sufficient training data (D. Li, Zhou, Hu, & Spanos, 2016; Zhao, Li, Zhang, & Zhang, 2019). However, the amount of data is usually insufficient in reality, because it is difficult to get high-quality training data sets for each type of failure. Yan et al. proposed a semi-supervised fault detection method, which only uses a small amount of data to detect the failure of the air-conditioning unit (Yan, Zhong, Ji, & Huang, 2018). However, it is limited only when the same failure occurs again.

Recently, there has been a rise in deep generative modeling techniques that can be used for detecting anomalies. Autoencoder (AE) is a powerful deep learning technique that is appropriate for failure diagnosis with limited fault data since it can learn data features, avoiding the dependence on failure data (Zhang, Jiang, Zhan, & Yang, 2019). In addition, AE is a crucial tool of non-linear process monitoring as it can handle the encoding of input data and the extraction of features to provide meaningful representations of data in various applications, such as failure detection and data reconstruction. Variational autoencoder (VAE) technology has been shown to have benefits over conventional AE architecture. Both VAE and AE architectures can compress data from high-dimensional space to low-dimensional space (also known as latent space) and reconstruct complicated data. The main difference between VAE and regular AE architectures is that the former has a continuous latent space, allowing it to learn the distribution of data and reconstruct new information, which is crucial for process monitoring. However, as VAE is not a sequential model and cannot handle long-term dependencies in time series, it is possible to combine a sequential modeling approach such as LSTM models with VAE to solve this issue. Lin et al. proposed a hybrid VAE-LSTM model which can detect anomalies on multiple time scales (Lin et al., 2020). The VAE module forms local features on brief windows, while the LSTM module estimates the sequence's long-term correlation. However, if there is no abnormal data in the dataset, the hybrid VAE-LSTM model is not suitable as a means of prediction, as it will increase the computational complexity and cost. Thus, it is possible to make both the VAE-LSTM and the LSTM alone train independently and be exchanged if needed.

To effectively address the issue of sensor faults, a comprehensive framework with early fault detection and reconstruction techniques is required. However, the combination of fault data reconstruction and early failure detection is rarely reported. Previous publications have demonstrated that early failure detection has a variety of applications, including analysis of climate pattern change (Drake & Griffen, 2010; Rogers et al., 2018), credit risk diagnosis (Ali & Dağtekin, 2008; Lu, Shen, & Wei, 2013), and early failure detection of key system components (Lee, House, Park, & Kelly, 1996; Yu, Woradechjumroen, & Yu, 2014). As introduced earlier, the increasing popularity of VAE in fault detection also makes it a new approach in early fault detection. The ball screw degradation assessment method used in (Wen & Gao, 2018) is similar to the one used in the manufacturing industry. The assessment shows that the deterioration of a ball screw can be evaluated using the Variational Autoencoder Reconstruction Error (VAERE). Malfunctions in an air handling unit (AHU) were studied in (Mesa-Jiménez, Stokes, Yang, & Livina, 2021), in which the VAERE was used to reproduce the sudden change of temperature before the fault occurred. This is because VAE can model the underlying probability distribution of the input, especially when processing a time sequence with a typical periodic pattern. In the case of failure, the periodic characteristics of the time sequence will be destroyed. Therefore, the reconstruction error of the VAE can be used to observe the unusual behavior in the time series data. However, there are still issues that the existing literature does not address. Firstly, some studies adopt a reactive approach rather than a proactive approach. When a system fails, it often leads to service interruptions and necessitates engineers to temporarily shut down certain pieces of equipment in order to remedy the problem. Secondly, the probability of misjudgment of the failure diagnosis by a single indicator is high, and it is more scientifically correct to use multiple indicators for early warning. Therefore, it is necessary to develop an active multi-index method for early failure detection.

To solve the problem of sensor faults including fault detection and reconstruction, a sustainable and real-time IAQ monitoring framework is proposed, which mainly focuses on early failure detection, failure data reconstruction, and assessment of the impact of failure data on ventilation performance. Early fault detection mainly utilizes the periodic characteristics of IAQ time series data and conducts variance analysis on reconstruction errors to monitor early warning failure signals. The reconstruction model combines the VAE architecture and Long Short-Term Memory neural network (LSTM). The purpose of integrating the two structures in this study is to extract data features according to the dynamic characteristics and nonlinear dependence of IAQ data, so as to reconstruct abnormal data. The contributions of this study are described in detail as follows:

- A proactive early failure detection method is proposed for IAQ time series data. Taking advantage of the periodic and stationary fluctuation characteristics of IAQ data under normal operating conditions, the unstable behavior of the raw data before the failure is reproduced using variance analysis. The variance analysis is applied to the reconstruction error of VAE to check the fluctuation of IAQ data indicating where the failure has already occurred. Therefore, the engineers can find the potential failure and carry out maintenance, when necessary, before these failures actually happen.
- When an anomaly is detected, the reconstructed data using VAE-LSTM replaces the abnormal data. The restored data is then fed into the LSTM neural network to forecast the time series. Thus, both the hybrid VAE-LSTM and the LSTM may be learnt independently and replaced as needed. The VAE-LSTM is developed by using the normal IAQ measurement data. Given that IAQ often exhibits changing patterns over time, the time variable, Hour, is translated into one-hot encoders as conditional information. For example, the IAQ in a restaurant typically present dramatic differences during meal hours and non-meal hours, and the time variable Hour can be used to provide additional conditional information. Therefore, Hour, which can be written by one-hot encoding vectors, is supplied as an input to both the encoder and decoder to provide additional controls over the process of data generation.
- To verify the superiority of the proposed method over other neural approaches, different types of abnormal data are presented in the test dataset: the IAQ dataset is corrupted by introducing complete failure, bias failure and a precision degradation fault.

The rest of the work is organized as follows: Section 2 provides the dataset used, the method description, steps in network training and explanations of the validation performance analysis. Section 3 compares the performance of the proposed method to other methods. Section 4 discusses the conclusions and limitations.

2. MATERIAL AND METHODS

In this section, a framework for early failure detection and fault data reconstruction is designed based on VAE, as illustrated in Fig.1. Firstly, the variance analysis is applied to find the abnormal fluctuations of IAQ data before the failure occurs. Once the abnormal signal is detected, the proposed VAE-LSTM hybrid model is applied to reconstruct the abnormal data. To verify the superiority of the proposed reconstruction model, various scenarios of abnormal data are introduced into the test dataset. The remainder of this section illustrates the detailed procedures.

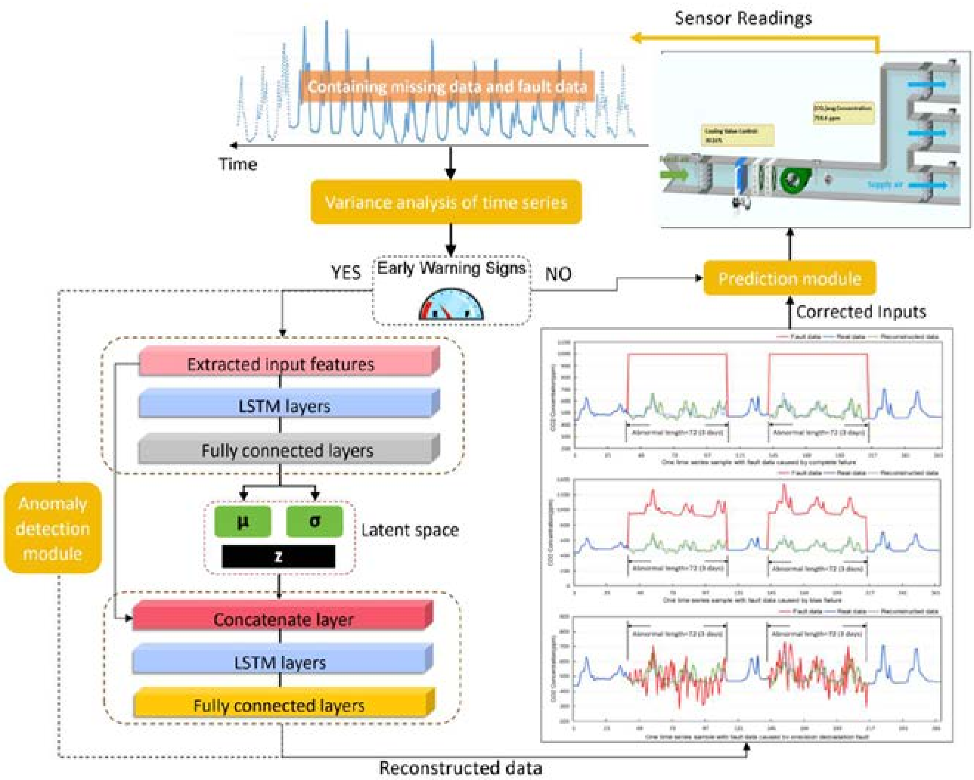

Fig. 1: Framework of this study

2.1 Data collection

The Facilities and Management Office of the Hong Kong University of Science and Technology (HKUST) provided the data used in this study. The dataset recorded IAQ data of various types of campus buildings, including canteens, library buildings, lab buildings, etc. Among them, the canteen exhibits large IAQ oscillations caused by obvious variations of pedestrian flow. Furthermore, during the peak dining hours of the canteen, pedestrian flow increases significantly, and indoor pollutants like CO_2 concentration can sometimes exceed the standard indoor concentration of 1000 ppm. This necessitates more precise ventilation management system control, and high-quality CO_2 sensor data are required for achieving this control. Therefore, we chose the CO_2 concentration of the canteen as an example to test the proposed methodology. The chosen time period included holidays, non-holidays, and the final exam period, which brings certain challenges for data analysis. In holidays, the behavior of occupants will be different from regular days, and the number of people during peak hours will be significantly reduced. These variations will affect the data patterns of indoor pollutants such as CO_2. Typical temporal models are hard to adapt, resulting in error-prone predictions. Therefore, external features need to be added to provide additional clues to the temporal model to maintain high prediction accuracy when dealing with changes in holidays and examination periods.

2.2 Early failure detection

In order to analyze the early warning signals of the sensor data generated by the ventilation management system and give the engineering maintenance personnel sufficient time to repair the failure, a fault detection technique, i.e., variance analysis, is applied to the reconstruction error of the VAE-LSTM model. The early warning indicator is applied to the time series with failures through a selected sliding window. The choice of sliding window length is a compromise between the time resolution and the clarity of transitional signal changes.

The variational autoencoder (VAE) is an algorithm for stochastic variational inference and learning using neural networks as the recognition model (Kingma & Welling, 2013). The reconstruction error of VAE can be calculated for abnormal detection. The idea underlying abnormal detection is that the VAE is not able to reconstruct unpredictable patterns or noise as well as it can regular data. Therefore, when x_i in a given time series i is reconstructed by VAE, the error between the output $\hat{x}_i$ and input of abnormal data is significantly larger. Variance is used to measure the degree of fluctuation of a set of data. Variance analysis is very straightforward to use and does not require specialized knowledge because it is a simple failure detection approach. The goal of this study is to integrate the reconstruction error based on VAE model with variance analysis to identify out-of-law abnormal fluctuations in IAQ data in advance, described as:

$$e_i = x_i - \hat{x}_i \quad (1)$$

$$\sigma_v^2 = \frac{\sum(e_i - \bar{e})^2}{n-1} \quad (2)$$

where n is the number of observations in a sample, σ_v^2 is the sample variance, e_i is the reconstruction error for each input, $\bar{e}$ is the mean value of all observations in the sample, and x_i and $\hat{x}_i$ are the actual and the reconstructed output, respectively. Therefore, the VAE indicator is derived from the reconstruction error, which is referred to as the variational autoencoder reconstruction error (VAERE).

2.3 Model development

For faulty data reconstruction and missing data imputation in ventilation control systems, a technique that can effectively handle complicated and failure data is required. This work benefits from combining the representation learning capabilities of deep generative models—in the form of variational autoencoders (VAEs)—with the temporal modeling capabilities of long short-term memory (LSTMs) to manage long-term time sequence data and generate accurate data based on intrinsic distributions. To train the proposed VAE-LSTM model without supervision, the dataset needs to be divided into a training set and a test set, with a continuous segment containing no anomalies serving as the training data and the remaining time series containing anomalies used for evaluation in the test set. Fig. 2 illustrates the architecture of the VAE-LSTM model.

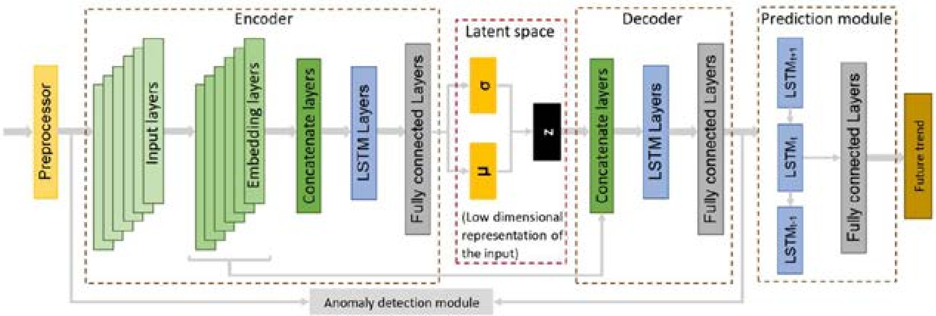

Fig. 2: The proposed VAE-LSTM architecture

The design process of the proposed model is as follows. Firstly, collect the IAQ training dataset without faulty and missing readings, and we introduce some fault data and missing intervals (with a fixed length and proportion) on the dataset to validate the model performance. In addition to sequences with faulty or missing data as the main input of the VAE-LSTM model, sequences of integers that encode the additional information provided as categorical features, such as month, weekday, hour, and holiday, serve as the second meaningful inputs. Due to the characteristics of buildings with significantly varying occupancy patterns at different hours, and to make the predictive model more concise, the variable Hour is taken as additional information for IAQ sequence reconstruction. The original IAQ data and the categorical feature which is transformed by the embedding operation are concatenated into the LSTM layer to capture the relationship between temporal features. The ReLU is selected as the activation function of the LSTM layer. The output of the LSTM goes through a dense layer with a non-linear activation function. It then generates a 2D output, just like every other encoder in a VAE architecture, which is used to approximate the mean and variance of the latent distribution. The decoder takes samples from the 2D latent distribution upsampling and then concatenates the generated sequence with the original categorical embedding sequence to provide more control over reconstructing the original IAQ sequence. LSTMs and dense layers with ReLU activations constitute the rest of the decoder structure. The training of VAE-LSTM adopts the early stopping training mechanism to minimize the combination of reconstruction loss and distribution loss. The patience was set as 10. Specifically, the training process will end if the model loss does not decrease after 10 iterations. Adam was chosen as the optimizer as it provides the best convergence (Kingma & Ba, 2014). The hyperparameters were chosen by fine-tuning the VAE-LSTM structure. The best hyperparameters were selected based on their performance in fault data reconstruction and missing data imputation.

The reconstructed sequence is utilised for time series prediction by the LSTM neural network after the abnormal data is replaced by the VAE-LSTM output. The prediction module consists of one layer of LSTM and one dense layer. Grid search is used to optimise the model architecture and hyperparameters. Input and output temporal dimensions are the same. Mean squared error (MSE) is used as the loss function throughout the training process, which was performed with 500 epochs, and the Adam optimizer with a learning rate of 0.001.

2.4 Validation scenarios

Since anomalous events are rare, it is usually not feasible to collect sufficient abnormal data for detailed characterization. Therefore, to assess the effectiveness of the proposed framework, we designed different types of abnormal scenarios with fixed lengths and proportions on the test set, with the key benefit of creating an arbitrary amount of abnormal data while using the original data as a ground truth. The downside of this procedure is that it may overfit the abnormal data or provide worse results for real anomalies. As a result, only real data is utilized to train the model, whereas anomalous data is solely used to evaluate it.

A detailed explanation of the abnormal scenarios is as follows. Anomalies such as gain and offset of sensor signals may arise due to incorrect calibration or mechanical wear over a period of time. We attempt to simulate three types of typical sensor faults: 1. Complete failure: the size is assumed to be twice the average concentration of the original data; 2. Bias failure: the size is assumed to be twice the original faulty data segment; and 3. Precision degradation fault: the size in the temporal dimension is taken as the average and standard deviation of the original data.

3. RESULTS AND DISCUSSION

We now employ the methodology described in Section 2 for the collected sensor data for analysis. Table 1 presents a statistical summary of the data in this study. Real faulty data are utilised to evaluate the effectiveness of variance analysis in early failure detection. Abnormal data scenarios are then introduced to evaluate the reconstruction and imputation performance of the proposed method against other approaches.

Table 1: The basic statistics of variables.

Attribute	Content
Variable	CO_2 concentration
Time period	From 2021/11/08 13:00 to 2022/02/19 22:00
Unit	ppm
Resolution	Hour
Mean	508.56
Minimum	412
Maximum	844.7
Standard Deviation	77.67

3.1 Early failure detection analysis in IAQ measurements

We applied variance analysis to analyze the failure of the CO_2 sensor in the indoor ventilation control system, which resulted in abnormal changes in CO_2 concentration up to 1000 ppm instantaneously. Therefore, the purpose of applying variance analysis in this study is to detect this anomaly before it occurs. Figure 3(a) shows one week of CO_2 data containing the failures, with an abnormally high CO_2 concentration.

The analysis results are shown in Figure 3, where the collected CO_2 data is presented together with the analysis results. For convenience, the variance on the Y-axis is represented on a logarithmic scale. We used different windows to obtain early failure signals, with a 14-hour window when applied to CO_2 data and a 23-hour window when applied to the reconstruction error. The choice of window size is based on the clarity of the provided signal. It is evident from the figure that the variance results for the normal data are periodic, while unexpected fluctuation patterns appear before the failure. When the variance is applied to the reconstruction error as shown in Figure 3(b), the failure signal is generated about 12 hours prior to the failure, and the reconstruction error gradually increases, which shows the unexpected fluctuation pattern before the failure. Therefore, early failure signals give time for the maintenance engineers to make the necessary adjustments and repairs before the failure actually occurs.

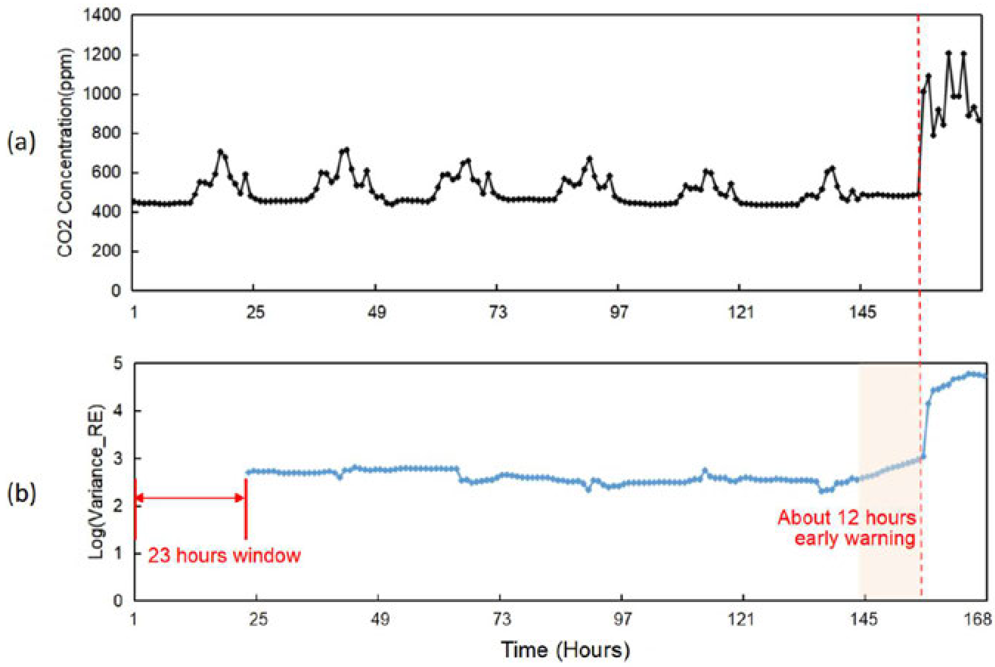

Fig. 3: Variance analysis of the CO_2 sensor failure.

3.2 Reconstruction performance of the IAQ measurements

As discussed in previous sections, three types of abnormal data scenarios are used to compare the performance of the proposed method to that of other approaches. Due to sensor ageing, damage, poor working environmental conditions, etc., a number of sensor failures may occur, with complete failure and bias failure being the most common. To evaluate the reconstruction performance of AE-based sensor faults, we introduced different kinds of faulty data in the test dataset. The magnitude size of each sensor failure is described in Section 2.4. The rate of fault data was set to 0.5, and the fault data lasting 3 days were randomly inserted into the test set. Figure 4 shows a section of CO_2 data containing fault data segments and the reconstructed results. Table 2 demonstrates the fault data reconstruction results of the AE-based model for different faulty data. Root mean square error (RMSE) and mean absolute error (MAE) are used as metrics to measure the capability of the AE-based model of reconstructing the fault data. The largest value of RMSE is 43.197 ppm calculated by the standard AE model. When the encoder and decoder structures are designed using LSTM, the reconstruction performance improves by up to 17%, which proves that LSTM can capture the nonlinear and autocorrelated relationships of CO_2 data. In addition, the reconstruction model based on VAE provides better capability for fault data reconstruction. This is because VAE can solve the problem of non-regularized latent space in the encoder and provide generation capability for the whole space. The encoder of AE produces the vectors in the latent space, while VAE outputs the distribution in the latent space for each input, adding a constraint on that distribution to convert it to a normal distribution, and this constraint guarantees that the latent space is regularized. As a result, the VAE-LSTM reconstruction accurately forces the faulty data to normality.

Table 2: Reconstruction performance of different approaches under different types of fault data.

Fault data reconstruction performance						
Reconstruction methods	Complete failure		Bias failure		Precision degradation fault	
	RMSE (ppm)	MAE (ppm)	RMSE (ppm)	MAE (ppm)	RMSE (ppm)	MAE (ppm)
AE	39.441	28.105	43.197	30.126	39.789	28.696
AE-LSTM	37.343	26.008	36.882	25.867	36.800	25.814
VAE-MLP	34.370	**24.111**	33.228	26.104	32.712	25.087
VAE-LSTM	**32.153**	24.508	**31.133**	**18.212**	**27.133**	**17.081**

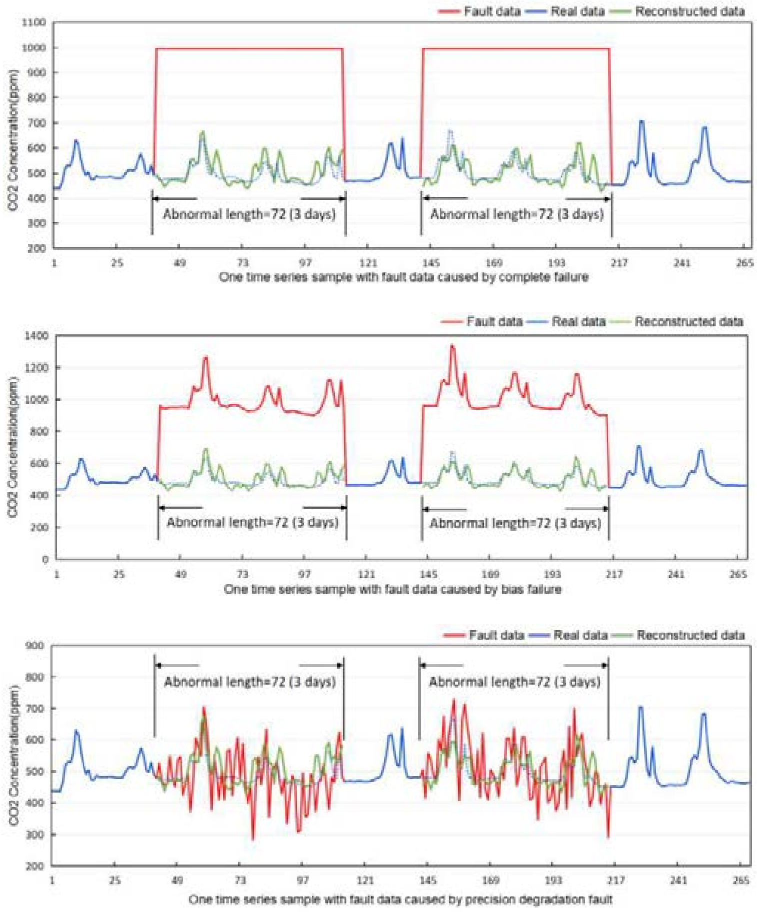

Fig. 4: Reconstruction performance of the VAE-LSTM model under interval-based fault scenarios

3.3 Discussion

This study presents a method to reconstruct IAQ data since abnormal data such as bias failure, complete failure, precision degradation fault often occur due to sensor malfunctions. One of the main contributions of this paper is the development of the VAE-based model for reconstructing various types of abnormal data, including LSTM configurations that properly depict indoor environmental patterns. The time series of CO_2 concentration, in particular, has periodic peaks and extremes, which is a complexity to consider when developing models employing LSTM. Furthermore, model training should be done offline to guarantee that the network has sufficiently learned the basic parameters in order to provide optimal learning performance for IAQ data and achieve accurate abnormal data reconstruction.

In addition to the reconstruction of indoor CO_2 data, the VAE-LSTM model developed can be generally applied to other tasks involving periodic abnormal data processing, such as indoor crowd and energy consumption. In fact, there is a link between indoor CO_2 concentration, indoor crowd, and energy consumption. CO_2 concentration can be generally used as a proxy indicator to assess whether indoor space is occupied and whether indoor crowd affects energy consumption. Our proposed VAE-LSTM approach encodes categorical features, such as months, weekdays, hours, and holidays into integer sequences as auxiliary information to capture the periodic patterns of time series data, and the original categorical sequences are connected to the generated sequences of the decoder to provide more control over the process of reconstructing and imputing the sequences. The flow pattern of a human crowd and fluctuations of energy demand have similarities with fluctuations in indoor CO_2, and both follow a cyclic pattern, so our proposed VAE-LSTM method can also be used to constitute a model for processing crowd and energy demand from abnormal data.

In contrast to other studies that only utilize VAE-based models for abnormal detection, this study incorporates variance analysis to detect non-periodic abnormal signals in IAQ data in advance, and early failure detection can prevent problems in critical parts of the Heating Ventilation and Air Conditioning (HVAC) system. For example, the case in this study is the indoor CO_2 concentrations at a university restaurant. When abnormal signals are detected using our proposed approach, the restaurant manager can contact engineers to check the system in time.

Even if part of the system facilities is shut down, the restaurant manager can prepare backup ventilating equipment in advance to ensure that the customers can enjoy their meal in a good indoor environment, especially during peak hours.

4. CONCLUSIONS

A neural approach, consisting of a variational autoencoder and long-short-term memory network (VAE-LSTM), was developed for early detection and reconstruction of malfunctioning sensors in HVAC systems in order to improve the reliability of the sensors in indoor environment control. Taking advantage of the periodicity and stable fluctuation characteristics of IAQ data, the results of variance analysis on reconstruction errors reveal that unusual behavior of the data can be detected as early as 12 hours before failure occurs. The abnormal data are then reconstructed using the developed VAE-LSTM model. The validation is carried out by introducing different types of abnormal data on the CO_2 sensor. The superiority of the VAE-LSTM was then illustrated by comparing the developed approach to other methods.

However, for an approach dealing with faulty sensors, an explanatory function of fault locations and causes should be provided to the on-site engineer in order to avoid time-consuming proactive repairs, and the knowledge-based method or expert rules can meet this requirement and capability. Therefore, in our future work, we will provide rational explanations for system failures by combining analytical-based, knowledge-based and data-driven approaches and apply them to fault detection and diagnosis of ventilation control systems, especially for large-scale building systems.

REFLECTING USERS' PHYSICAL CHARACTERISTICS IN SPATIAL VISUALIZATION

Sumin Chae, Hayoung Jo, Bomin Kim &Jin-kook Lee
Dept. of Interior Architecture & Built Environment, Yonsei University, Seoul, Republic of Korea

ABSTRACT: *This paper aims to quickly and precisely visualize remodeled design images based on image generation AI so that they can be used as alternative images in the early stages of design. In order to create a space image suitable for the user, the contents of the text are proceeded as follows. Bathrooms with many accidents in the space were selected as the target space, and users were designated as elderly people with many physical changes. Learning image data for additional training was self-generated according to the user's body characteristics, and the learning data focused on musculoskeletal aging among the body characteristics of elderly users. When the image was generated using additional training models, it was confirmed that a meaningful spatial image was created for musculoskeletal aging users, and it can be expected that the spatial image for spatial remodeling can be obtained quickly and accurately without the help of experts through subsequent studies to make it easier for general users.*

KEYWORDS: *Generative AI, Physical Characteristics, Elderly-friendly Bathroom, Detailed Modeling*

1. INTRODUCTION

This paper explores the integration of artificial intelligence (AI) technology into image generation during spatial remodeling and initial design phases. It aims to automate visualization for promoting safe space utilization by considering user's physical characteristics and to investigate various practical applications. Spatial visualization plays a crucial role in conveying design concepts and ideas visually to clients. However, generating visualizations for architectural spaces requires a significant amount of time and effort, and one alternative is to leverage image-generating artificial intelligence. By utilizing image-generating AI, detailed user input regarding spatial requirements can lead to the generation of corresponding space images.

To design safe spaces, it's essential to establish environments suitable for users and based on professional expertise, ensuring safety. However, this design process can incur costs such as labor expenses. Nonetheless, using generative AI allows for the efficient generation of trustworthy alternative space images by utilizing models trained on abundant data. Therefore, this study investigates an extended visualization approach in the field of architecture through image-generating AI. It focuses on generating a variety of personalized visualization alternatives for users, rather than presenting standardized alternatives.

2. BACKGROUND

2.1 Image Generation AI

The advancement of intelligent computing technology has brought about innovative changes in research methodologies and approaches within the field of architecture. Tools such as the architectural design assessment rule-checking system (Eastman, *et al*. 2009) and the spatial data-based building design review system (Lee, *et al*. 2012) have also been utilized. However, more recently, the rise of image-generating artificial intelligence (AI) technology has introduced significant transformations in the architectural realm. While previous studies primarily focused on the application of AI algorithms for predicting and optimizing architectural elements such as building appearance and interior composition, the present landscape is marked by image-generating AI technology providing fresh perspectives on visual representation and design in architecture. This influence extends not only to the architectural domain but also spans various other fields. For instance, within the medical sector, image-generating AI has been employed to analyze medical images and medical knowledge-based imagery (Kather, *et al*. 2022). Similarly, in the realm of arts, image-generating AI has found utility as a tool for creative artwork generation (Beyan, *et al*. 2023). This multifaceted application underscores the integration of image-generating AI across diverse domains, fostering ongoing research endeavors.

Furthermore, the focus of research has been directed towards leveraging artificial intelligence for performance optimization within the architectural context. Models powered by AI algorithms empower architects to experience energy efficiency within designs before the commencement of construction. This approach not only streamlines

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)

the design process but also contributes to sustainable and user-centric outcomes, fostering anticipations of substantial contributions. In essence, the amalgamation of AI technology with architecture is shaping novel research directions and enhancing both design methodologies and the conceptualization of architectural spaces.

2.2 Design of a space reflecting physical characteristics

Occupants continually modify and inhabit spaces to enhance comfort. Shifting demographics, family compositions, and evolving space roles often prompt interior modifications. Precision in incorporating users' physiological and psychological data into designs can significantly improve the quality of life by enhancing safety, usability, and independence (Demirbilek & Demirkan, 2004). For instance, designing spaces for individuals with disabilities necessitates collaboration between experts and users, ensuring their unique needs are met (Imrie, 2004). Similarly, creating spaces for children requires considerations such as play areas, noise control, and equipment tailored to their needs (Evans & Moch, 2003). Moreover, equipment scale within a space often deviates from conventional dimensions to harmonize with users' specific requirements. This departure from standardization not only influences the spatial arrangement but also distinctly shapes the manner in which objects are engaged within these environments.

Within this multifaceted framework, it becomes acutely clear that the alignment of spatial configurations and amenities with the diverse physiological attributes of users is an imperative. This thematic focus is central to the present study, which delves into the meticulous curation of spatial layouts and equipment, meticulously calibrated to resonate with the myriad physiological attributes presented by users. This comprehensive endeavor stands as the foundation for establishing environments centered around the user, thus aiding in improving the overall quality of life.

3. AI-BASED SPATIAL IMAGE GENERATION

3.1 AI-Based Image Generation Test

To enhance satisfaction and facilitate convenient usage of spaces, appropriate improvements are essential. To achieve these improvements, a clear understanding of the users of the space is crucial. Furthermore, it is necessary to incorporate the layout and facilities of the space based on the users' physical characteristics. To generate spatial images based on these physical characteristics and reflect the users' desired points of improvement, a focused test was conducted. We tested image generation using the text-to-image functionality of the AI platform named Stable Diffusion (SD), which utilizes a Diffusion model. This involves using a deep learning model to generate images based on natural language input (Zhang, *et al*. 2023). In order to utilize SD, relevant prompts need to be formulated for the desired images. These prompts are categorized into Positive Prompts and Negative Prompts. Positive Prompts are crafted to enhance space types and image quality, while Negative Prompts are designed to prevent image degradation or errors. The image generation test focused on residential bathroom spaces, which often experience numerous accidents. In this test, not only were typical bathroom images in Korea generated, but also images tailored to the physical characteristics of elderly users, in an effort to ascertain if these factors were being considered. For this purpose, the generation of bathroom images was performed using image generation AI, with specific attention to bathrooms in domestic settings, particularly bathrooms prone to accidents. To ensure the consideration of users' physical characteristics, bathroom images that catered to the needs and safety of elderly individuals were generated alongside conventional bathroom images.

Table 1 Generating images by text

Standard bathroom	
Positive prompt	A basic bathroom with a white porcelain toilet, a sink with a chrome faucet, and a standard bathtub with a showerhead. The walls are tiled with white rectangular tiles and the floor is covered with grey linoleum, Simple, clean, functional, standard, basic, minimalistic, bright lighting, plain, High resolution, sharp focus, realistic lighting, standard aspect ratio.
Negative prompt	Multiple layouts, avoid bright and clean elements, low quality, bad proportion, normal quality, watermark, bad perspective, confusing details, text, blurry

Musculoskeletal aging user bathroom	
Positive prompt	Musculoskeletal Aging, bathroom for the elderly, wall handrail attached, non-slip tile, perspective view, wide angle, Simple, clean, functional, standard, basic, minimalistic, bright lighting, plain, High resolution, sharp focus, realistic lighting, standard aspect ratio, standard.
Negative prompt	Multiple layouts, avoid bright and clean elements, low quality, bad proportion, normal quality, watermark, bad perspective, confusing details, text, blurry

3.2 Physical Characteristics-Based Training for Spatial Image Generation

Upon reviewing the generated images, it is evident that the spatial visualization capability is impressive; however, images are being generated without considering user conditions, required expertise, and specific situations. Observing the Korean-style bathroom images, the structure of a typical Korean apartment bathroom, including the sequence of toilet, sink, and shower booth/bathtub, is not reflected in the generated images. Instead, the images are generated with a focus on a single bathroom component, neglecting the holistic bathroom layout. In the case of elderly friendly bathroom images for older users, safety facilities should be reflected to prevent accidents when the elderly use the space. However, the generated image does not reflect the safety equipment properly, or, even if installed, the safety equipment is attached to a space other than the bathroom, generating a facility that is unsuitable for space conditions. Consequently, to utilize image-generating AI for generating

Elderly-friendly bathroom space images, an approach involving the addition of learned images that incorporate safety equipment in appropriate positions within the bathroom based on medical expertise and the physical characteristics of the elderly is required.

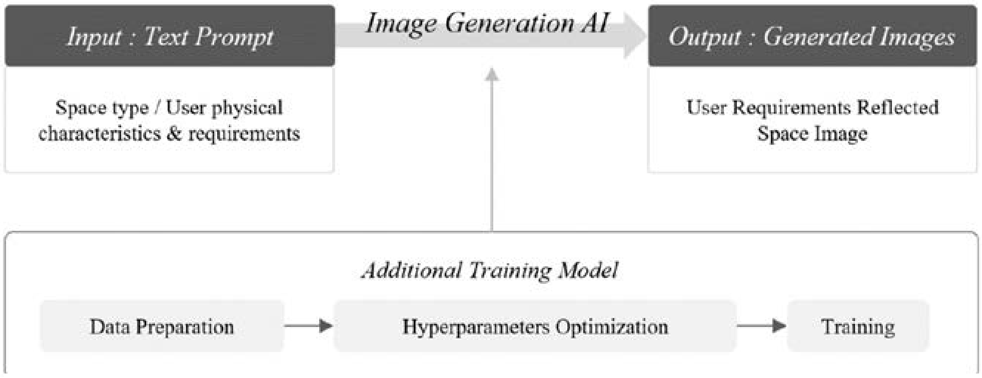

Figure 1 Summary of the configuration outlined in this study.

4. ADDITIONAL TRAINING FOR DESIGN COMPONENTS VISUALIZATION

4.1 Data preparation and Pre-processing

The datasets required for further training should comprise image files along with corresponding text descriptions. However, the available training images for Korean-style bathroom structures, obtainable from the current website, predominantly consist of wide-angle images to capture confined bathroom spaces. Consequently, even with additional training, the generated images might continue to emphasize wide angles or exhibit pronounced distortion. Furthermore, when considering bathrooms designed for elderly users, images depicting safety equipment installed by non-experts without professional knowledge outnumber those accounting for individualized physical characteristics. This discrepancy could potentially result in compromised safety and reliability. Therefore, the generation of image data conducive to effective learning is imperative.

Given this scenario, it becomes essential to independently generate image data specifically tailored to bathrooms for the elderly, considering their unique physical attributes. To accomplish this, a comprehensive exploration of

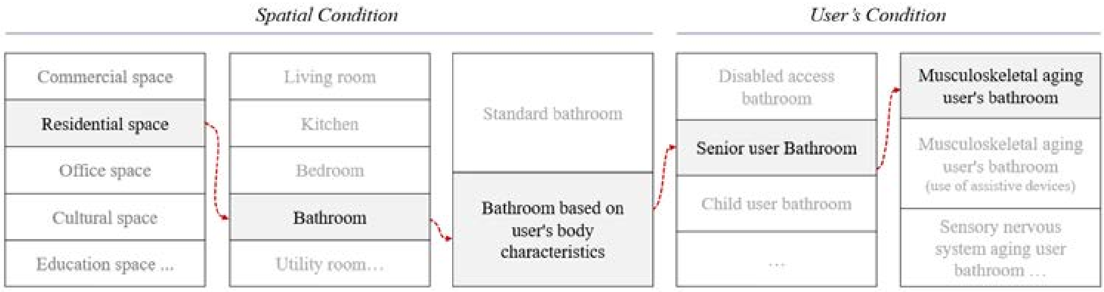

Figure 2 Scope of Work

bathroom layouts, incorporating safety equipment based on the aging characteristics of the elderly, is crucial. Additionally, the collection of fundamental components necessary for spatial Building Information Modeling (BIM) is paramount. In this paper, we have developed an additional training model that centers around musculoskeletal aging, a facet of the aging process significantly influenced by environmental factors and exerting significant effects. To ensure the safe use of the bathroom, safety equipment that can be installed includes bathroom grab bars, floor mats, shower chairs, and more(Gitlin, *et al*. 1999)(Aminzadeh, *et al*. 2000).

Table 2 Information about Properties of BIM Objects

N	*Bathroom facilities*	*Height (mm)*	*Width (mm)*	*Depth (mm)*	*N*	*Bathroom facilities*	*Height (mm)*	*Width (mm)*	*Depth (mm)*
1	A washbasin with a wide top	120	750	470	6	Walk-in bathtub	780	1150	930
2	Toilet wall grab bar	304	685	50	7	Draw-out faucet	220	505	273
3	Washbasin with chair	750	595	455	8	Folding shower chair	424	-	604
4	Nonslip floor	-	-	12.7	9	Bathtub/shower grab bar	889	482	50
5	Toilet side grab bar	300	100	738	10	Shower curtain	1803	107	80

<Table 2> represents a list of BIM objects for bathroom safety equipment collected for the purpose of BIM modeling. This list is a compilation of objects sourced either from the bimobject website, which offers downloadable objects for 3D modeling, or generated directly. The collected objects are categorized based on users' physical characteristic, bathroom areas, and expected effects. This categorization serves as the foundation for crafting content in the training text, enabling the generation of images in accordance with prompts entered by users during the image generation process. The contextual text concerning bathroom areas and anticipated effects will be utilized in the future for the individualized training of each object when they are added separately to the model.

Table 3 Categorization of Safety Facilities

Classification criteria		Bathroom facility BIM object									
		1	2	3	4	5	6	7	8	9	10

	C-6 Wall										

4.2 Additional Training

To facilitate further learning, a dataset for additional training model is established by modeling safety-equipped bathrooms suitable for each stage of aging that was previously generated<Figure 3>. This dataset encompasses

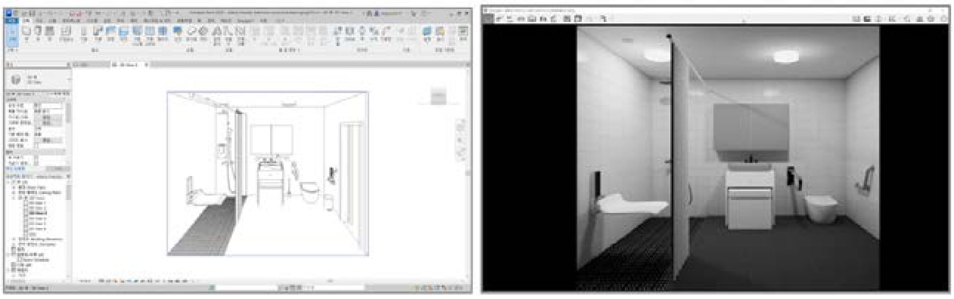

Figure 3 3D Space Modeling and Rendering

training image data sets and individual text files (.txt) associated with each image. These efforts are aimed at constructing a dataset for generating additional training models.

The generation of text files is facilitated through the utilization of BLIP Captioning within the Koha_ss GUI, an option found under Utilities. BLIP Captioning enables the individual generation of text files for a substantial number of images. For the task of further training, a LoRA model is generated employing Dreambooth-based LoRA GUI, Kohya_ss. LoRA, denoting Low-Rank Adaptation, effectively trains on high-quality images. The training settings for Dreambooth LoRA include parameters such as Train batch size: 1, Epoch: 120, Learning rate: 0.0001, Learning rate scheduler: cosine, and Learning rate warmup: 10. The model employs the Stable-Diffusion-v1.5 as a pre-trained model. The training environment was executed on a PC equipped with an RTX A6000 GPU model. Utilizing prepared training data, the model generation results in a .safetensors formatted model file of size 144MB.

5. EVALUATION OF ADDITIONAL TRAINING MODELS

5.1 Evaluating Enhanced Model Performance

The manipulation of model weights in its application allows for varying degrees of reflection in the generated images. When prompts are entered, the LoRA augmented model, along with its associated weight, can be specified for incorporation, as illustrated in <Table 4> presenting the test images. The weight values, ranging from low 0 to high 1, facilitate a continuum of image representation. A weight value of 0 corresponds to an image where the model has not been applied, thus lacking the reflection of Korean-style bathroom structures and characteristics. Conversely, as the weight approaches 1, a gradual integration of Korean-style bathroom imagery becomes apparent.

Table 4 Generated image result according to model weight

Weight	Generated Images				
0.0					
0.3					

0.7	

5.2 Utilization Scenarios of the Additional Training Model

For the purpose of generating bathroom spatial design images based on physical characteristics, further training was conducted specifically focusing on age-related musculoskeletal changes. In the context of this study, a comparative analysis is carried out between images generated using the trained model and images generated without the utilization of the model. The intent is to contrast the images produced by the model-based approach with those produced independently, as illustrated in the table below.

Table 5 Comparing images for elderly users' bathrooms with/without extra models.

		Case A	Case B
Design Requirement	Space	Bathroom (Residential Space)	
	User physical characteristics	Musculoskeletal aging user	
INPUT	Model	N/A	Musculoskeletal aging user bathroom (.safetensor)
	Positive prompt	AIP_Elderly-friendly bathroom, Musculoskeletal aging, senior-friendly, senior housing, safety, fall prevention, bathroom, restroom, elderly, senior citizens, elderly users over 70, supporting device, device for safe toilet use, nonslip tile, toilet wall grab bar, toilet side grab bar, shower curtain, basin chair, folding chair	
	Negative prompt	Bad quality, duplicate, blurry, bad proportions, confusing details	
OUTPUT	Generated image		
		 …	 …

Overall, when comparing the generated images of Case A, which were produced without utilizing the augmented training model, with the images of Case B generated using the augmented training model, it becomes evident that Case A exhibits inaccuracies in the positioning and forms of the attached fixtures. Conversely, for Case B, where the augmented training model was employed, no errors are observed in the placement and forms of the safety equipment.

6. CONCLUSION

In conclusion, this paper explores the integration of AI in spatial remodeling and initial design stages with a focus on generating spatial images that reflect user physical characteristics. The objective is to provide users with safe spatial images, taking into consideration the user's physical attributes and real-world usage within the space.

Therefore, this paper targets the bathroom space and selects elderly individuals as the space users, aiming to generate safe bathroom images for seniors experiencing physical characteristics related to musculoskeletal aging through additional model training.

To facilitate additional training, suitable safety equipment for the user's physical aging characteristics was investigated, and high-quality training data were constructed by generating image data independently. Corresponding training text files were created for each image to ensure specific training for the images. As a result, it was observed that the images generated using the additional training model had fewer errors related to safety equipment compared to using the existing model, and suitable safety equipment was placed within the space, demonstrating a different outcome. This cost-effective approach recognizes the potential of AI in the field of spatial design, prioritizes a user-centric approach at the intersection of AI and architectural design, and advances and improves the design process. In addition to musculoskeletal aging, which was the focus of selecting elderly individuals as the target for additional training model creation in this paper, a comprehensive examination of aging occurring in various body structures or the selection of a more diverse range of subjects can expand the scope and target of additional training. Beyond simple visualization, this enables detailed spatial visualization based on user requirements through text input for image generation, which can be expected to be utilized in various fields for AI-generated images.

Seunghyun Cha
Korea Advanced Institute of Science and Technology (KAIST), South Korea

Jin-Kook Lee
Dept of Interior Architecture and Built Environment, Yonsei University, South Korea

ABSTRACT: *This paper explores the applicability of Image-generation AI in the field of interior architectural design, with a particular focus on automating interior design representation based on design styles. Interior design representation involves a complex process that integrates visual elements with functionality and user experience. Effectively visualizing this process is essential for facilitating communication among the various stakeholders involved in the design process. However, traditional visualization methods are constrained by expert resources, costs, and time limitations. In contrast, image-generation AI has the potential to automate various design elements, including design styles, components, and spatial arrangements, to enhance representation. In this study, we evaluated the performance of a base model using various design styles and, based on the evaluation results, selected styles for fine-tuning. The methodology for fine-tuning these design styles involved the following steps: 1) data preparation and preprocessing, 2) hyperparameter optimization, and 3) model training and construction. Utilizing the fine-tuned model thus constructed, we conducted image generation demonstrations. The research results revealed that design styles not well represented by the base model were effectively captured, and high-quality images were generated by the fine-tuned model. Notably, this fine-tuned model demonstrated the ability to represent images of specific design styles with a high degree of accuracy in capturing the characteristics and keywords associated with each style, compared to the base model. This implies that through fine-tuning image-generation AI, a wide range of applications can be inferred when aiming to create customized designs by considering these aspects. In conclusion, this study explores an efficient approach to interior design representation in the field of interior architecture by employing image-generation AI and proposes a method to effectively generate visualized images by training on design style keywords. Through this approach, our study can contribute to improving the interior design process by facilitating the generation of visualized images that reflect design styles. Furthermore, the study aims to suggest the potential for applying this approach not only to the field of interior architecture but also across various domains to achieve effective visualization.*

1. INTRODUCTION

Interior design representation plays a crucial role in the field of interior architecture, effectively conveying ideas and designs through visual media and facilitating effective communication among various stakeholders involved in the design process (Chiu, 1995). In interior spaces, design styles signify the approach and method of planning and decorating a space, shaping and emphasizing the aesthetic, functional, and psychological aspects of the space. Design styles encompass a variety of preferences and trends influenced by the users and purposes of the space, impacting choices in color, patterns, materials, furniture, and accessories (Goldschmidt et al., 1998; Eckert et al., 2000). Additionally, they serve as a means to reflect individual identity and lifestyle, reflecting personal preferences and tastes.

Therefore, understanding and proposing customized designs that consider user preferences in the spatial visualization process is essential. However, this process necessitates expertise to comprehend the diverse preferences and requirements of users, as well as the desired design styles and spatial elements for visualization. This requires a significant investment of time, cost, and effort for both experts and non-experts (Lee et al., 2020).

Recent advancements in deep learning technology have sparked significant interest in generative artificial intelligence (Gen AI). As a result, various research endeavors are underway in the realm of visual content creation using image-generation AI (Image-Gen AI) based on large language models (LLMs). Expanding upon this trend, our study aims to propose an approach for automating interior design representation using Image-Gen AI. This

approach allows for the generation of diverse design visualization alternatives based on user preferences and objectives, all without the need for specialized expertise.

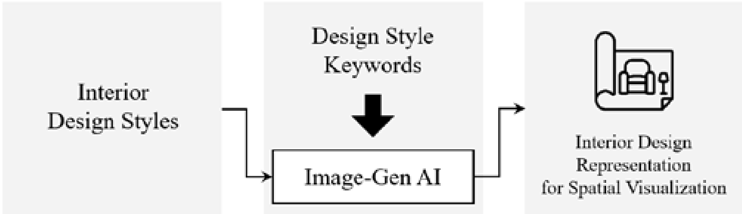

Fig 1: An Overview of the Study

2. BACKGROUND

2.1 Deep Learning-based Image-Gen AI

Image-Gen AI is based on deep learning and is a versatile technology applicable in various fields, including natural language understanding, computer vision, image processing, data generation, prediction, and more (Liu et al., 2021) This technology is used to generate new image content or outputs based on given data or information. To accomplish this, Image-Gen AI is pre-trained on large datasets and then fine-tuned for specific targets. During the training phase, Image-Gen AI learns features and patterns from the data, and in the generation phase, it uses this learned information to generate new image data. This process can be considered an example of transfer learning, allowing effective generation results even with limited data. Image-Gen AI can be trained to incorporate additional conditions such as image type, style, color, and more, enabling it to generate images that meet specific criteria. This reduces the need for extensive training on the target while enabling various applications like style transformation, ensuring similarity between images, image synthesis, and more (Nichol et al., 2021).

For these reasons, recent applied research efforts are being conducted in the field of visual content creation using a variety of Image-Gen AI models such as Midjourney (Oppenlaender, 2022), DALL-E 2 (Ramesh et al., 2022), Stable Diffusion, and others (Ramesh et al., 2022; Saharia et al., 2022; Rombach et al., 2022; Oppenlaender, 2022). While research using Image-Gen AI has been extensive, it remains limited in the field of interior architecture. Therefore, in this study, we aim to explore an approach to fine-tune Image-Gen AI models based on design styles and implement a model for the automatic visualization of interior design representation.

2.2 Potential for Automating Interior Design Representation through Image-Gen AI

In the field of interior architecture, the evolution of deep learning technology is reshaping the way spaces are conceptualized and realized. In the past, designers relied on manual sketches and 2D drawings to convey ideas for spatial visualization reflecting interior design representation (Ching, 2011). However, with the emergence of advanced technology and computer-aided tools, spatial visualization has undergone a paradigm shift (Karras et al., 2018). The integration of sophisticated software, computer-aided design, and 3D modeling tools has empowered designers to visualize spaces realistically and immersively. Thanks to these advancements, designers can accurately represent intricate details such as lighting, materials, textures, and shadows, not just the physical layout. As a result, stakeholders, including clients and project collaborators, can experience the proposed design in a lifelike manner before actual construction commences (Ah-soon & Tombre, 1997; Oxman, 2006).

With the continuous advancement of deep learning technology, Image-Gen AI can effectively generate images that match the intended target by fine-tuning a base model pretrained on large datasets. Leveraging these characteristics of Image-Gen AI, it is possible to implement an interior design representation model based on specific design keywords, fine-tuning it to reflect the desired design style. This model can be utilized as a tool to generate a variety of design alternatives that users desire during the design process and enhance the decision-making process (Jeong & Lee, 2023). Therefore, in this study, we aim to conduct fine-tuning of design styles on Image-Gen AI and explore methods for automating interior design representation.

3. MODEL FINE-TUNING FOR INTERIOR DESIGN REPRESENTATION

3.1 Overall Process

In this study, the image generation performance of three major AI platforms in the Image-Gen AI field, Stable Diffusion, DALL-E 2, and Midjourney, was examined and compared. First, these Image-Gen AI platforms employ two main methods: text-to-image (Txt2img) and image-to-image (Img2img). Each of these platforms has unique and distinctive image generation capabilities, along with their specific technical attributes, strengths, and limitations.

DALL-E 2, trained on a large-scale image dataset, demonstrates exceptional abilities in generating detailed and complex images. However, due to its complexity and resource-intensive nature, it may have longer processing times, and its dependency on text prompts might result in shortcomings in image stability and consistency. Midjourney excels in generating images inspired by specific visual styles or artistic aesthetics. However, its emphasis on artistic expression may result in relatively less accurate representation of real objects or scenes. Stable Diffusion prioritizes stability and accuracy in image generation. It is based on LLMs and provided as an open-source platform, making it user-friendly for customization. The transparency of the source code allows users to understand, modify, and apply the underlying algorithms, enabling them to verify, align with their intended purposes, and enhance image generation results.

Each platform has its unique strengths and specific limitations. Considering these factors, this study utilized Stable Diffusion, which demonstrated the most outstanding performance in terms of image generation stability, accuracy, and the ability to cater to specific requirements through open-source access. The research methodology, rooted in the utilization of Stable Diffusion, is structured into three primary phases. Step 1: Testing image generation via text descriptions for design styles, Step 2: Model Fine-tuning, Step 3: Evaluation of Fine-tuned Models. The schematic representation of the entire process outlined in this section is depicted in Fig 2 below.

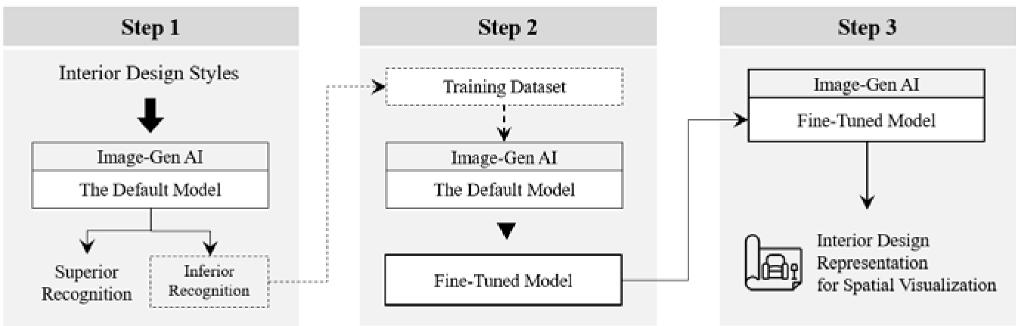

Fig 2: The Process of Model Fine-tuning

3.2 Step 1: Testing Image Generation via Text Descriptions for Design Styles

In this section, we conduct tests to evaluate the performance of the Image-Gen AI model for various interior design styles. Our study focuses on the text-to-image (txt2img) approach, generating images based on text descriptions. To prevent the Image-Gen AI model from inferring styles solely from text descriptions, we perform prompt engineering adhering to guidelines. This prompt consists of two key components: 1) prompts for the target design style, and 2) prompts for image quality. Additionally, we categorize positive and negative aspects that encompass both reflective and non-reflective elements of the generated images.

The image generation process utilized the DPM+2M Karras sampler along with the widely used open-source model, SD1.5V checkpoint (v1-5-pruned.ckpt). Essential configurations, including sampling steps and CFG scales, were set to default values, and the image size was defined as 1024x512 pixels. Each image generation took an average processing time of approximately 5 seconds. Table 1 below illustrates the configuration settings employed in the image generation process, and Table 2 showcases the standard format of the text prompts utilized for image generation.

Based on the preceding discussion of the image generation process, we conducted an evaluation of the recognition level for interior design styles using the generated images. Table 3 below provides outcomes of the generated images based on their recognition levels. The base model of Stable Diffusion demonstrated a stable generation capability for high-quality images across most styles. However, its expressive capacity was relatively limited in terms of being recognized as specific design styles, particularly due to lower comprehension of certain styles. To address these constraints and enhance image generation accuracy, we deduce that fine-tuning for specific targets is imperative.

Table 1: Configuration Settings for Image Generation

GPU	Base model	Sampling Method	Sampling steps	CFG Scale	Resolution
A6000 47.5 VRAM	SD v1.5 ckpt	DPM+ 2M Karras	25	13	1024×512 (2:1)

Table 2: The Standard Format of Prompts Used for Image Generation

Prompts	Positive	Negative
Design Style	Design Style interior, Space zoning	*None*
Image Quality	Professional photograph, photorealistic rendering, realistic, enhance-detail, v ray rendering, full HD, masterpiece, highly detailed, high quality, 8k, full shot, deep depth of field, f/22, 35mm	Bad proportion, Low quality, awkward shadows, unrealistic lighting, pixelated textures, Worst, noisy, unrealistic reflections, normal quality, watermark

Table 3: Sample Results of Generated Images based on Recognition Levels

Recognition Level	Superior	Inferior
Image-Gen AI based generated Images	 "*Industrial* Style Interior, A living room"	 "*Brutalism* Style Interior, A living room"

3.3 Step 2: Model Fine-Tuning for Design Styles

In this section, the process of fine-tuning the model for the target design style (ex. Brutalism) encompasses three key steps: 1) Data Preparation, 2) Hyperparameter Optimization, and 3) Training.

Firstly, in the Data Preparation step, we focused on the collection and preprocessing of data tailored to the specific target design style. This Training Dataset requires two primary components: Image Data and Text Data. Table 4 provides an example of the training dataset.

Table 4: An example of the training dataset / ***content*** (*e.g.*, a space), ***style*** (*e.g.*, a design style) and *scene description*.

Image Data	Text Data
	"A ***Brutalism style*** interior in a ***Living room*** *with sharp lines that exemplify the brutalist aesthetics. Featuring shades of grey, concrete, and metallic tones, it showcases a minimalist living room characterized by grey hues and a monochrome color scheme."*

The subsequent stage involved the optimization of the model's hyperparameters to elevate its image generation performance for the specified design styles. This process encompassed the refinement of parameters like learning rate, batch size, and network architecture to attain improved outcomes. Table 5 presents the hyperparameters employed during the model fine-tuning.

Table 1: Optimized Hyperparameters for Model Fine-tuning

Training data	Epoch (Training steps)	Batch size to train	Learning rate	Learning rate Scheduler	Learning rate warmup
15	100	1	0.0001	Constant	10

The ultimate training phase involved the model being subjected to training using the meticulously prepared dataset and meticulously optimized hyperparameters. The process of model fine-tuning was executed using the training dataset and specified hyperparameter configurations to create the target model. The training duration amounted to approximately 25 minutes. Through this training, the model was tasked with comprehending the distinct attributes and intricacies of the designated design style, consequently empowering it to craft images that exhibit a heightened alignment with the intended aesthetic. This fine-tuned model is utilized in conjunction with the default model during subsequent image generation endeavors.

3.4 Step 3: Evaluation of Fine-tuned Models

Through the subsequent fine-tuning process, the model learned from both image and text data related to design styles that initially exhibited inferior recognition. As a result, it was enhanced to effectively depict the distinctive characteristics of the trained design styles, showcasing a heightened ability to generate high-quality images. Table 6 below illustrates the results of image generation based on the application or absence of the fine-tuned model. This highlights the tangible impact and comparison of interior design style image generation that was not achievable before the model's fine-tuning adjustments. Additionally, the weights of the model parameters correspond to finer adjustments made to the model, reflecting a more distinct influence on the image generation process.

Table 6: Qualitative Comparison of Image Generation: Impact of Applying Fine-Tuned Model

Weight of Fine-Tuned Model	at W 30%	at W 60%	at W 90%
Image-Gen AI based generated Images				"*Brutalism* Style Interior, A living room"		

4. DEMONSTRATION

In this study, based on the procedures outlined in the previous Section 3, a demonstration was conducted using Image-Gen AI to generate images of more than 15 interior design styles. The target space was limited to residential living rooms. The generated image results for each design style are presented in Table 7, encompassing both the default model and the fine-tuned model for image generation. This demonstration facilitates practical comparisons in the interior space visualization process through the generation of design alternatives, as proposed in this study. Additionally, it allows for the observation of the potential for learning various customized design styles.

5. CONCLUSION

In this study, we investigated a method for fine-tuning design styles using Image-Gen AI and automatically generating spatial images reflecting interior design representation. During the research process, we conducted an evaluation of the recognition level for interior design styles by the base model. We implemented a design style visualization model based on detailed keywords for the Brutalism style, which was chosen as one of the fine-tuning targets. The model effectively learned the characteristics of the style and demonstrated the ability to intricately represent the visual attributes of the style.

Through comparative analysis with the base model, we confirmed the high likelihood of visualizing the features of the style, thus validating the capability to effectively visualize spaces that align with user preferences through additional fine-tuning for interior design styles. Furthermore, this research approach showcases the potential for Image-Gen AI to be utilized in various fields, and we aim to suggest its applicability in future research and application domains.

EARLY VISUALIZATION APPROACH TO THE GENERATIVE ARCHITECTURAL SIMULATION USING LIGHT ANALYSIS IMAGES

Bomin Kim, Sumin Chae, Youngjin Yoo & Jin-Kook Lee
Dept of Interior Architecture and Built Environment, Yonsei University, Seoul, Republic of Korea

ABSTRACT: *This paper presents the potential utility of generative artificial intelligence-based light analysis simulation visualization image in the early phase of architectural planning and design. Facilitating the simulation of a building's performance during the early stages of planning and design presents numerous advantages, such as cost savings and enhanced ease of communication among stakeholders. However, the assessment of design performance is typically conducted during the design development phase or post-design completion. Processing a substantial volume of data based on design alternatives demands considerable time and resources, thus constraining the immediate provision of simulation results. This paper aims to utilize generative AI to produce visualization results of simulations with a predefined level of accuracy, with a specific focus on the architectural aspect rather than the physical and engineering functionalities of the simulation. Consequently, the study employs the following approach: 1) Analyze prominent characteristics and elements within light analysis simulation. 2) Based on this analysis, generate high-quality visualization image data additionally through Building Information Modeling (BIM). 3) Construct a dataset by pairing the generated lighting analysis visualization image with prompts. 4) Utilize the established dataset to create an additional learning model for light analysis visualization images. This study is expected to provide immediate and efficient assistance in design decision-making during the early phases by generating visualization images with high accuracy, reflecting prominent qualitative aspects related to light analysis and processing within the simulation.*

KEYWORDS: *Architectural Design, Architectural Visualization, Generative AI, BIM (building information modeling), Fine Tuning Model*

1. INTRODUCTION

This study aims to utilize generative artificial intelligence (AI) to create and employ light analysis visualization images within architectural spaces. The current simulation methods quantitatively derive predictive outcomes based on physically designed environmental conditions, which are then visualized. However, as the number of design alternatives increases, processing extensive data incurs time and cost, posing a limitation, particularly in promptly delivering results during the design phase. In the initial design stages, swift generation and evaluation of various design alternatives are vital to meet given requirements. During this process, offering intuitive visualization results rapidly proves more effective than ensuring the precision of simulation outcomes. Therefore, this research is conducted with a primary focus on architectural visualization, which aids in the early design phase, rather than solely relying on physical and engineering-based imagery. In the initial design phase, the precision of the design model is diminished due to the uncertainty of design conditions. However, the utilization of this technology enables straightforward assessment of visual performance aspects, such as a building's energy efficiency and lighting environment, even at the conceptual model level. Particularly, these visualizations serve as effective tools for comparing and evaluating various design alternatives, fostering communication among stakeholders.

Building upon this foundation, a test of the potential for light analysis visualization images in architectural spaces is conducted using image-generating AI. However, the generated images lack reflection of the elements and characteristics of light analysis visualization within spaces, thus clearly indicating the need for further refinement through additional training. For the purpose of generating light analysis images using AI, a process involving '1) Setting the Scope of Light Analysis, 2) Data Preparation, and 3) Training' is carried out. Representative elements of general characteristics from light analysis images are chosen to define the range of training data generation. Model construction employs a diffusion-based model implemented based on the Large Language Model (LLM) for additional training, and hyperparameters are adjusted to ensure the generation of high-resolution images. The constructed supplementary training model is demonstrated in real-world applications of image-generating AI, such as the creation of light analysis visualization images based on different time periods.

2. BACKGROUNDS

2.1 Image Generation Artificial Intelligence (AI)

The recently emerged generative AI paradigm has entered its preliminary stages, yet it wields substantial influence across diverse industrial sectors. It is anticipated that with ongoing technological advancements, this nascent field will expand the horizons of innovation [Mackinsey, 2023]. Image generative AI such as Stable Diffusion and DALL-E have instigated substantial transformations akin to sectors beyond, including art and entertainment, within the domain of architectural design as well. However, the latent potential within the realm of architectural design visualization remains notably underdeveloped.

This study aims to propose a novel approach to architectural design visualization through the utilization of image generative AI models. Architectural design methodologies intertwined with AI offer a departure from conventional design practices that have traditionally relied upon designers' creativity and expertise to address multifaceted requirements. By systematizing the data generated and incorporated during the design and construction processes through automated tools, the objective is to assist in resolving ambiguities, risks, and other issues that might arise in human-executed tasks by architects, contractors, and related stakeholders.

Given the advancements in LLM models and image generation technologies, the capacity to generate architectural visualization images founded on provided textual input has now materialized. Termed as the process of text-to-image generation, this procedure holds the capability to engender highly realistic images, thereby serving as a multifunctional instrument for the creation of an extensive gamut of architectural visualization content. In light of the continued evolution of AI technology, text-to-image generation is anticipated to assume a pivotal role within the architectural domain. Consequently, image generative AI augments the prospects of creative potential beyond conventional methodologies.

2.2 Potentials of Generative AI on Architectural Visualization

Architectural visualization plays a crucial role in effective communication during the design process due to the intricate nature of design and spatial characteristics [Chiu, 1995]. Notably, architectural visualization techniques such as 3D modeling provide a comprehensive understanding of spatial relationships [Eastman, 1999]. They serve as essential tools for visually expressing complex designs and enabling clear communication with clients and stakeholders. This facilitates the facile comprehension and assessment of project concepts and designs, enabling the early identification of design flaws, leading to cost and time savings and enhancing satisfaction. In the initial stages of design, they prove particularly effective for comparative analysis and review of various design alternatives. Historically, the generation of architectural visualization images required specialized hardware such as GPUs, along with the utilization of dedicated architectural software. This demanded a significant investment of time and effort, ranging from conceptual design configurations to comprehensive design processes. However, with the advent of generative AI, the landscape has transformed. Now, it is possible to efficiently create numerous architectural visualization images with high-performance GPUs, without the necessity for separate platform installations. Through web browsers, one can seamlessly generate highly detailed, high-quality visual images using text-based commands (prompts). This transformation marks a paradigm shift in architectural visualization, affording designers an unprecedented level of efficiency and versatility in the creation and communication of their spatial visions.

3. INTENSIVE TEST USING GENERATIVE AI FOR SPATIAL LIGHT ANALYSIS VISUALIZATON IMAGE

3.1 Image Generation Test for Spatial Light Analysis Visualization Image

In this study, an examination was conducted to assess the feasibility of employing generative AI, utilizing the open-source image generation model "Stable Diffusion" (2022, Stability AI), for the immediate generation of spatial light analysis visualization images. During the testing phase, emphasis was placed on conducting comparative analyses of text-image generation and visualization performance. Furthermore, the scope was delimited to prioritizing visual effects and approximate simulation result visualization, rather than accuracy and precision. While there are two main approaches for AI-assisted image generation, namely, 1) image-to-image (img2img) and 2) text-to-image (txt2img), the latter method of using AI to generate architectural schematics was adopted for testing purposes.

Prompts were formulated under four categories: 1) Scene Description, 2) Geographic Location, 3) Image Quality, and 4) Light Analysis Conditions. The generated images were set to a resolution of 1024x512 pixels. The testing was conducted using the SD model within a local PC environment. A total of 2,000 images were generated through 200 images per testing scenario. On average, it took approximately 5 seconds to generate a single image.

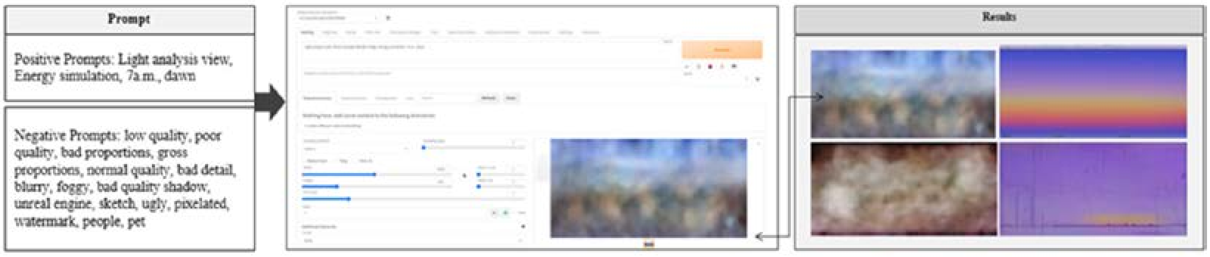

Fig. 1: Procedure for Spatial Light Analysis Visualization Image Generation Test

3.2 Results of Spatial Light Analysis Visualization Image Generation Tests

Based on the results of the previously conducted spatial light analysis simulation visualization tests, the current model has been found unable to generate interior light analysis visualization images of spaces. The lighting simulation visualization images generated through existing image generation models did not exhibit the characteristics of typical simulation images produced using simulation tools, revealing two key issues. Firstly, the model failed to recognize objects composing the space such as windows, ceilings, and walls, as well as lighting fixtures; hence, properties like shading and luminance were not accurately reflected. In essence, these simulation visualizations did not consider the lighting analysis environment. Secondly, there was a lack of consistency in the simulation image outputs, indicative of the absence of defined methods for visualizing quantitative lighting analysis outcomes (view type, visualization style). Consequently, the comparison of design alternatives under uniform conditions became unfeasible. To address these challenges, it is imperative to undergo additional training using lighting analysis images that incorporate the visualization elements and attributes pertinent to lighting simulation. While the existing model proves efficient in generating images across a wide range of domains, enhancing the model's capabilities through additional training is essential for tailored image generation in specific fields due to the constraints posed therein.

4. ADDITIONAL TRAINING FOR VISUALIZING LIGHT ANALYSIS

For the purpose of AI-driven light analysis image generation, an approach involving the following processes: 1) D Definition of the scope of Light Analysis, 2) Data preparation, and 3) Training, is proposed.

4.1 Definition of the scope of Light Analysis

This study focuses on indoor lighting visualization images achievable during the initial stages of interior architecture design through AI methodologies. The light analysis is applicable across the first three stages of design elaboration as outlined in ISO16817 (Project definition – Conceptual design schematic design – Detailed design – Final design). Given that decisions made during the initial design phase significantly influence the subsequent design process direction, preemptively understanding the potential impact of initial design decisions holds paramount importance [Kalay, Y. E. (2004)].

4.2 Data preparation

During the stage of Data Preparation, meticulous consideration was given to the types of training data, the extent of generative scope, and the methods of data creation. Through the utilization of Building Information Modeling (BIM) and rendering techniques for lighting simulation imagery, a process was employed to define the range of light influence elements within the visualization components of lighting simulation, thus facilitating the generation of training data comprising Light Analysis simulation images for indoor spaces.

4.2.1 Categorization of Training Data and Scope of Generation

Within the framework of this study, the scope for generating training data was determined based on considerations encompassing spatial design elements, lighting design components, and visualization techniques. Spatial dimensions were confined to the living room, accounting for spatial design elements such as ceilings, floors, walls, and windows (with respective sizes). Lighting design elements were delimited to natural light (primary light source) and specific timeframes (7 a.m., 12 p.m., 6 p.m.), with sunrise at 7 a.m., noon at 12 p.m., and sunset at 6 p.m. The visualization techniques were confined to interior views and photorealistic representations, serving as the basis for generating the training dataset.

4.2.2 Methodology for Generating Training Data and Illustrative Cases

For the process of generating training data, the BIM software named "Revit" was employed to execute interior space (living room) BIM modeling. Subsequent to this, the Revit plug-in program known as "Enscape" was utilized to generate light analysis simulations and rendering images of the modeled interior space. The ensuing outcome images arising from these procedures have been presented in the table indicated by the respective table number.

Table 1: BIM Rendering Image for Additional Training

Training Data Type	Training Data Image			
Light analysis view render image_7a.m.				Light analysis view render image_12p.m.				
Light analysis view render image_6p.m				

4.3 Training

The Additional training was carried out on a local PC equipped with an RTX A6000 GPU model boasting 47.5GB of memory capacity. Two distinct methodologies were employed for additional training: 1) Fine-tuning of the Stable Diffusion (SD) model using the Dreambooth approach, and 2) Training of the SD model using the Low-Rank Adaptation of large Language Models (LoRA) technique. LoRA, a technology employed for image generative AI fine-tuning, facilitates the creation of additional training model files in a brief time frame without necessitating intensive GPU performance. LoRA enables few-shot learning and offers the advantage of promptly and easily observing the impact of styles by altering model file weights. The resultant ". safetensors" LoRA model files, generated upon completion of additional training, can be copied and utilized on other devices.

Fine-tuned models were developed, categorized into cases of fine-tuning the SD model itself and fine-tuning the SD model with the application of LoRA. Each category encompassed three learning types corresponding to different time frames influenced by natural light (7 a.m., 12 p.m., 6 p.m.). Rigorous hyperparameter configuration and combinations were systematically implemented to facilitate precise additional training. Hyperparameter optimization enhanced the quality of generated training model images. The array of hyperparameters considered in this study ranged from image size, batch size, epoch, Caption Extension, learning rate, learning rate scheduler, to learning rate warmup. Given the utilization of LLM-based models for additional training, the process encompassed engineering and pairing image and text (prompt) data. Prompts were classified into Positive prompts and Negative prompts, based on their application status.

Table 2: Configuration Values of Hyperparameters for Additional Training

Model		Training data				Fine tuning hyperparameters
Base Model	Fine-tuned Model	Image type	Number	Prompt text		
				Positive prompt	Negative prompt	

V1-5-puned ckpt	Model 1	Light analysis view render image_7a.m.	10	Light analysis view, Interior image, Revit, Enscape, Render image, Energy simulation, 7a.m., dawn	low quality, poor quality, bad proportions, gross proportions, normal quality, bad detail, blurry, foggy, bad quality shadow, unreal engine, sketch, ugly, pixelated, watermark, people, pet	· Train Batch Size: 2 · Epoch: 150 · Caption Extension: .txt · Learning rate:0.001 · Learning Rate Scheduler: Constant · Learning Rate Warmup:10

5. OUTPUTS OF ADDITIONAL TRAINED MODEL

Within the realm of AI-driven image generation, two primary approaches exist: 1) Text-to-Image (txt2img), and 2) Image-to-Image (img2img). The txt2img approach generates architectural visualization images based on given textual descriptions. This process demands precision in design due to its sensitivity to factors such as the words utilized, accurate descriptions, and word arrangement. Nonetheless, this approach offers the advantage of efficiently generating realistic images. In contrast, the img2img approach provides the functionality to manipulate and enhance images or photographs, facilitating their reprocessing and utilization. In this section, we aim to demonstrate the outcomes of the trained additional models using both of these image generation approaches, showcasing their capabilities based on the previously conducted additional training.

5.1 Generation of Visualized Images Using the Text-to-Image (txt2img) Approach

To facilitate a comparative analysis between pre and post additional training outcomes, the identical prompts utilized during the preceding intensive test were employed. Prompts were categorized into Positive prompts and Negative prompts based on their application status. Positive prompts were further classified into Scene Description, Geographic Location, Image Quality, and Light Analysis Condition, generating visualization images of spatial light analysis tailored to the characteristics defined by these prompts.

Table 3: Image Generation from Txt2img Approach

Model	Light analysis view render image_7a.m.	Light analysis view render image_12p.m.	Light analysis view render image_6p.m.
Negative prompt	low quality, poor quality, bad proportions, gross proportions, normal quality, bad detail, blurry, foggy, bad quality shadow, unreal engine, sketch, ugly, pixelated, watermark, people, pet

6. CONCLUSION

According to the approach proposed in this study, the utilization of Image Generation AI has yielded the capability to generate visualized light analysis images within spatial contexts during the initial design stage, obviating the need for simulation processes. Notably, even at the nascent phase characterized by mere design concepts, the potential for inferring light influx within a space based solely on text descriptions related to these design concepts was evident. This approach has been substantiated by showcasing its capacity to transform not only text but also 3D rendering images into light analysis visualization images. It is worth noting that this study, with its emphasis on visualization from an architectural perspective over a purely engineering one in the light analysis simulation process, may have certain limitations. Nonetheless, this approach harbors the potential to construct models that yield more precise and accurate light analysis outcomes. Particularly focused on the Stable Diffusion model and conducted as an exploratory endeavor into the architectural visualization potential through Image Generation AI at its nascent stages, there lies an opportunity to derive more intricate results through the utilization of diverse generative AI programs and supplementary functionalities. By incorporating these components, the potential for producing even more detailed outcomes is substantial. Furthermore, through the integration of specific requirements of light analysis simulations and domain knowledge-based additional training, there lies the potential for enhancement, affirming the robust potential of Image Generation AI. This study underscores the substantial potential of Image Generation AI by emphasizing its ability to explore the possibilities of architectural visualization.

ABSTRACT: *Directed energy deposition (DED) is a major metal additive manufacturing (AM) technology that is increasingly used in many industries due to its ability to manufacture complex components of arbitrary shapes and sizes. However, a lack of timely geometry assessment and the consequent geometry control hinders the development of DED towards zero defect manufacturing. In this study, a real-time geometry assessment methodology is developed for laser pow-der directed energy deposition (LP-DED). A geometry assessment system is developed using a laser line scanner capable of inspecting the melt pool area, the just solidified area, as well as layer-wise inspection. An image processing method with an encoder-decoder based profile completion network was developed to obtain accurate track profile in images from real-time inspection. Experiments have been conducted to validate the proposed methodology by depositing multi-layer X-shape objects.*

KEYWORDS: *Additive Manufacturing, Directed energy deposition, Real-time geometry assessment, Laser line scanning*

1. INTRODUCTION

Metal additive manufacturing (AM) technologies' potential to revolutionize the manufacturing industry has not only been well-recognized but has inspired many fields [1]. According to the American Society for Testing and Materials (ASTM) standard [2], the two main groups of met-al additive manufacturing technologies are directed energy deposition (DED) and powder bed fusion (PBF), both of which have been widely applied in, for example, the aerospace, automobile, and biomedical industries. In recent years, DED has gained attention as a viable manufacturing method in the construction industry where metallic materials are used extensively in distinctive and complex designs [3]. Often, traditional techniques such as hot rolling, cold forming, and extrusion can only produce regularly shaped, prismatic metallic components [4], which limits the potential use of metallic materials in construction and design. DED can complement traditional methods and produce components with almost any shapes with high precision.

However, DED is somewhat plagued by geometry problems [5]. For example, the thicknesses of the deposited ("printed") layers often deviate from their design values [6]. When more and more layers are deposited, heat accumulation tends to cause the layers to spread, increasing their width but decreasing their height [7]. In addition, as the nozzle comes to deposit the object's corners or intersections, the resulting geometry also quite often deviates from the design [8]. The geometrical dimensions of the deposited object often fail to meet the quality requirement or even collapse when geometry deviation occurs during the deposition and is not solved in a timely manner, which will lead to time and cost waste. Moreover, an accurate geometry profile is quite helpful for other quality analysis during the printing process, such as the online stress measurement [9]. Therefore, it is important that the geometry of the printed object is continuously inspected in real time, as more material gets deposited.

Vision cameras and laser line scanners are often employed to assess the geometry of an object being printed via DED [10]. However, though vision cameras can assess the geometry in real-time, only either the track width or track height is measured, but not the whole track pro-file [11]. On the other hand, laser line scanners are mostly used post-DED, at which point the influence of powder and deposition laser is quite small so that the measuring accuracy is high. Besides, previous studies on geometry assessment have tended to focus on single- or multi-layer straight line deposition; multi-layer deposition of components with sharp features such as intersections or corners,

Liu Yang, Boyu Wang, Jack C.P. Cheng, Peipei Liu, Hoon Sohn, *Real-Time Geometry Assessment Using Laser Line Scanner During Laser Powder Directed Energy Deposition Additive Manufacturing of SS316L Component with Sharp Feature,* pp. 965-976, DOI 10.36253/979-12-215-0289-3.97

is important but not well studied. Therefore, the objective of this study is to develop a system capable of conducting real-time 3D geometry assessment during multi-layer deposition of objects with sharp features. There are four main contributions: (1) A geometry assessment system was developed to achieve both real-time inspection and layer-wise inspection during the LP-DED process; (2) In real-time inspection, an image processing method including a novel encoder-decoder based profile completion network was developed to obtain an accurate track profile; and (3) geometry assessment of multi-layer X-shape deposition has been achieved.

This paper is organized as follows. Section 2 gives some background on our research, which includes the working principle of a laser line scanner, a description of LP-DED and geometry assessment during DED. Section 3 explains the developed geometry assessment methodology. Section 4 provides the experimental results and discussion of the proposed methodology. Section 5 concludes the paper by presenting a summary, limitations, and future work.

2. RESEARCH BACKGROUND

2.1 Description of laser line scanner

A laser line scanner is a piece of non-destructive testing (NDT) equipment that has been used successfully to capture the shape of an object. The scanner operates based on the principle of laser triangulation as shown in Figure 2-2. By selecting the bottom of the sensor as a reference as shown on Figure 2-2, the basic triangulation calculation is expressed in equation (1).

$$b_1 = \frac{a_1}{\tan \alpha_1} \tag{1}$$

For laser line scanner, instead of projecting a single point, a laser line is projected on the target surface. After that, the diffusely reflected light of the laser line is detected by a high-quality sensors array called CMOS sensor matrix. Each projected point corresponds to one column on the sensor matrix. Based on the position of the detected laser beam on the corresponding column on sensor matrix, the distance of one measuring point to a defined reference in the sensor (Z coordinate) and can be calculated via triangulation, and the exact position of each point on the laser line (X coordinate) is acquired accordingly.

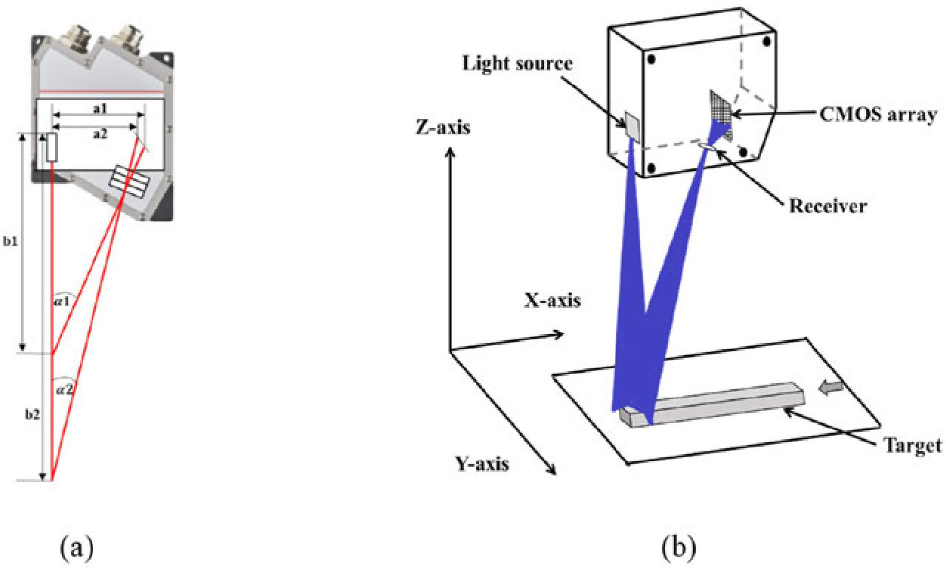

Fig. 1: (a) Principle of optical triangulation, (b) Principle of laser line scanner

In addition, a band filter is embedded right before the CMOS sensor to avoid the reflection of light beyond the expected wavelength, and only captures the reflection of the projected laser line. With respect to laser light, red and blue laser diodes are commonly available for laser line scanners. The red laser scanner is ideal for common measurement tasks especially with extremely dark surfaces whereas the blue laser scanner is ideal for transparent, organic, and red-hot glowing surfaces. In the DED process, when the high power-density laser is focused on a continuous stream of metal powder, the substrate becomes red- hot glowing surface. Thus, for this study a blue laser diode line scanner is used to achieve an accurate result. In addition, the blue laser is preferred to the red one since it is an extremely sharp-focused laser line that does not penetrate the surface.

2.2 Geometry assessment during DED

The geometry assessment targets include the geometry of the melt pool area and the just solidified area as well as the layer geometry of the deposited object. Much research in recent years has focused on inspecting the geometry of the melt pool, since it can be used for real-time geometry control [10]. Camera-based methods are popularly used to inspect the melt pool geometry, including vision camera and infrared camera. Vision cameras can be used to measure either the width or the height of the melt pool depending on the installation location and the target measurement field [11], while infrared cameras are normally used to measure the width and length of the melt pool [17]. Some recent papers have attempted to estimate the melt pool height using infrared cameras with the help of deep learning methods. However, these methods cannot measure the spatial profile of the melt pool area. The inspection of just solidified area is important as it is reported that this can be used for online stress estimation [9]. Moreover, compared with the melt pool area, the just solidified area might better represent the final geometry of the deposited track since thermal shrinking occurs during the solidification process [18]. The just solidified area is quite close to the melt pool area so that some studies use it for real-time geometry control though there is bound to be a small lag. Similarly, camera-based methods are used but a spatial profile cannot be obtained [19]. While laser line scanners can be used to obtain a special profile [20], its performance are affected by powder reflection and high intensity melting laser during LP-DED process, which prevents it from obtaining accurate spatial profile, thus it is often used for layer-wise geometry inspection rather than real-time geometry inspection. The inspection of layer geometry after printing each layer has been studied as well. This method needs to consider inspection path during the design process, which increases design effort and printing time. However, it is applicable to all kinds of printing shapes and toolpaths. In addition, for layer-wise control which does not need instant feedback, it is a better choice [21]. To address geometry assessment of all three targets, a geometry assessment system is developed in this study which aims to achieve both real-time inspection and layer-wise inspection of the track profile using laser line scanner.

Note that the term "real-time" might be ambiguous, as it has been used in a different sense in the literature from field to field. In this study, inspections with the laser line of a line scanner located at just a solidified area or melting pool area are called real-time inspection, where a small delay relative to the deposition is expected. On the other hand, inspection that takes place after each layer has been printed is called layer-wise inspection, since normally a large delay exists.

3. METHODOLOGY

3.1 Overview of the geometry assessment methodology

For real-time inspection, images are captured during deposition. Here there are three apparent problems that would prevent us from obtaining an accurate profile: (1) powder reflection, (2) melt-influenced area and (3) track profile missing, as illustrated in Fig. 4. The following steps are proposed to overcome these three problems.

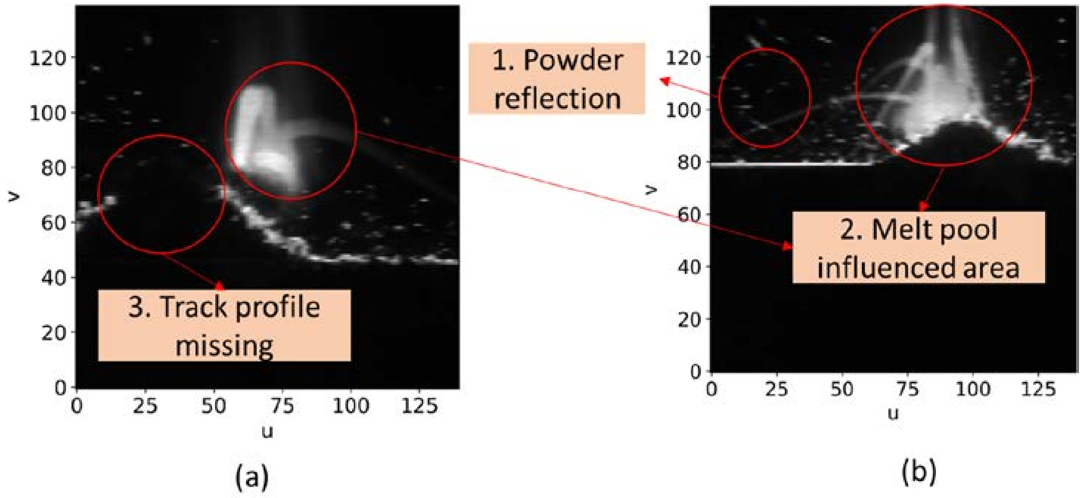

Fig. 4 Problems with raw images: (a) typical profile from real-time inspection of melt pool area, (b) typical profile from real-time inspection of just solidified area

3.2 Powder reflection removal

Firstly, an image enhancement technique, namely contrast stretching, is applied to improve the contrast in each image by converting the original intensity value of a smaller range to a larger range of intensity values, as shown in Eq. (3) and Fig. 5.

$$s = T(r) \tag{3}$$

where r is the input intensity, s is the output intensity, and T is the intensity transformation function. By applying this function, the brighter pixels become even brighter, and darker pixels become even dimmer. Since powder reflection always has lower intensity, it can remove the pixels of powder reflection.

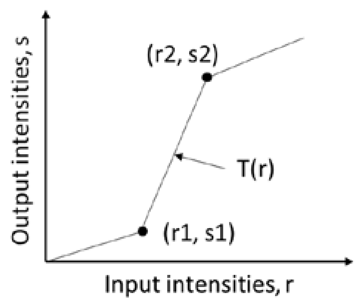

Fig. 5 Powder reflection removal: contrast stretching

3.3 Melt-influenced area removal

To remove the melt-influenced area, a DBSCAN clustering algorithm is applied on the image. As shown in Fig. 6(a), for all non-zero pixels in the image, a core pixel is selected if the pixel has n number of neighbors, where the neighbors are pixels within a distance ε from the core pixel. The distance between two pixels is calculated using Eq. (4):

$$d_{ij} = \sqrt{(u_j - u_i)^2 + (v_j - v_i)^2} \tag{4}$$

where (u_i, v_i) and (u_j, v_j) are the U-V coordinates of pixels i and j. A cluster is formed by recursively taking a core pixel, finding among all of its neighbor pixels that are core pixels, in turn finding all of their neighbors that are core pixels, and so on. After clustering, the cluster with the largest mean v value will be removed. For some images, the melt-influenced area will be connected to the track profile, and the track profile will be removed as shown in Fig. 6 (b). To solve this problem, a modified DBSCAN is proposed by adding an additional coordinate m to represent the distance to the lowest non-zero pixels for each column as illustrated in Fig. 6 (c) and the distance between two pixels is calculated using Eq. (5). After that, the DBSCAN algorithm is applied, and the result can be seen in Fig. 6(d)

$$d_{ij} = \sqrt{(u_j - u_i)^2 + (v_j - v_i)^2 + (m_j - m_i)^2} \tag{5}$$

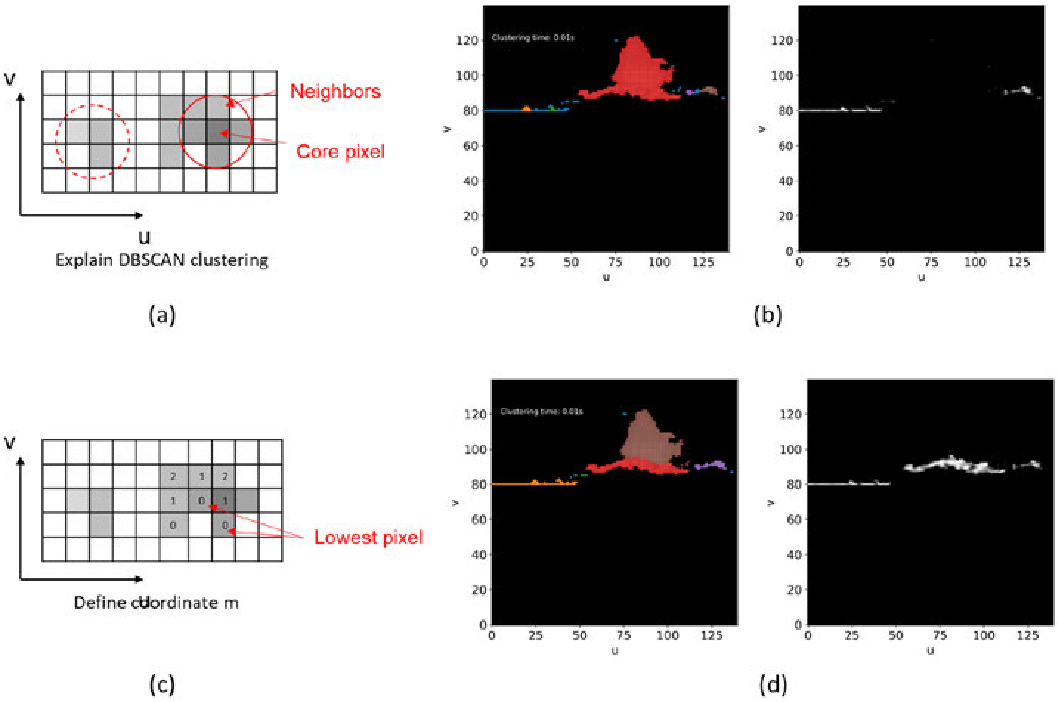

Fig. 6 Melt-influenced area removal: (a) explain DBSCAN clustering on the image, (b) directly apply DSCAN, (c) add coordinate m and (d) apply modified DBSCAN

3.4 Encoder-decoder based profile completion

After melt-influenced area removal, the track profile is extracted. However, there exists severe profile missing problems, which will severely deteriorate the quality of 3D point cloud for geometry assessment. The profile missing problem is mainly due to bad reflection on the deposited metal surfaces, especially when there is high-intensity laser radiation from the printer. As shown in Fig. 7, the cross-sections at different locations on the X-shape represents different types of profile missing, and a pattern can be observed for each track: (1) at the beginning of each track (location A), the opposite side of the melt-pool influenced area are missing for the one-peak cross section; (2) when approaching the intersection (location B), the line scanner captures two-peak cross section and the middle part of the two-peak cross section is missing; (3) at the intersection (location C), the top part of the one-peak cross section is missing; (4) when getting away from the intersection (location D), two side parts of the two-peak cross section are missing; (5) at the end of each track (location E), same as in location A, the opposite side missing of one-peak cross-section can be observed. For such varied types of profile missing problems, traditional completion methods such as curve fitting [22] or interpolation methods cannot achieve satisfied result, especially for the middle part missing of two-peak cross section.

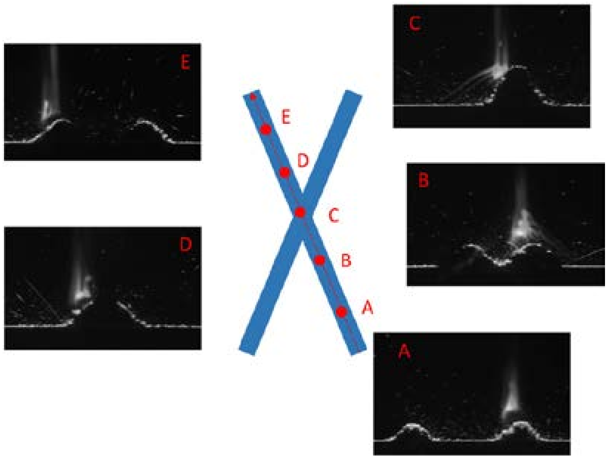

Fig. 7 Track profile missing problem

To complete the track profile in captured images, an encoder-decoder based profile completion algorithm is proposed. The idea of adopting an encoder-decoder based network comes from point cloud completion techniques. Encoder-decoder based networks are widely used in 3D point cloud completion tasks [23], [24], as the encoder can summarize the geometric information from an incomplete input point cloud to form a feature vector, and, based on the feature vector, the decoder will predict the complete shape of the point cloud. The proposed algorithm is revised from DeepLabv3+ [25], which is a popular encoder-decoder network with images as input.

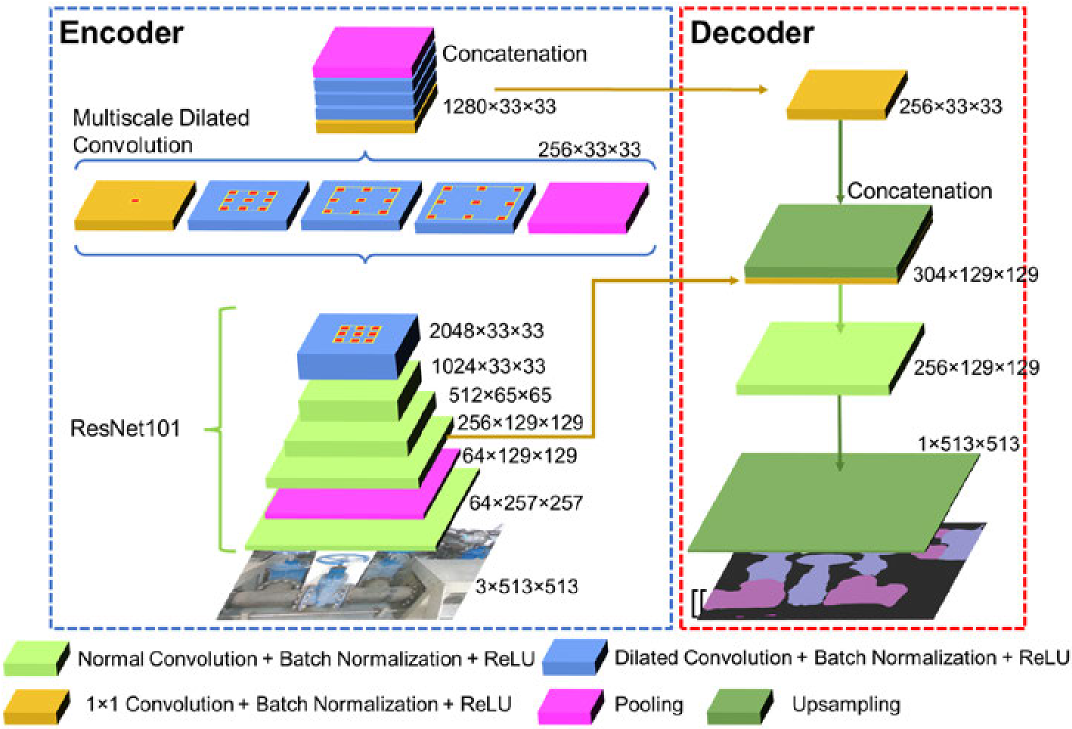

Fig. 8 Proposed encoder-decoder based profile completion network

In this study, the useful information in preprocessed images is the track profile pixels, which take up a small proportion of the whole image. Therefore, to make an efficient use of information in the images, the images from previous steps are further converted to 1D array and fed as input. A novel deeplab1D network is proposed which changes 2D operation in all layers of the DeepLabv3+ network to a 1D operation. Moreover, since previous profiles might provide useful information for the completion of current profile, therefore the previous (t – 1) profiles are considered as input for the proposed network. When t equals 1, only the current profile is considered.

The architecture of the proposed encoder-decoder based network is shown in Fig. 8. First, the image of 140 × 220 pixels from previous steps is converted into a 1 × 220 array. For each column of the array of the image, the gravity of the intensity plot on the v axis is taken as one of the values in the 1 × 220 array. The 1 × 220 array is inputted into the proposed network, which includes an encoder and a decoder. The encoder consists of a ResNet1D and an ASPP1D module. The ResNet1D module is based on ResNet-101 [26]. The ASPP1D module has evolved from Atrous Spatial Pyramid Pooling (ASPP) [27], which conducts several parallel Atrous convolutions with different rates. An Atrous convolution is described in Eq. (6).

$$y[i] = \sum_{k} x[i + r \cdot k]\, w[k] \tag{6}$$

where i is the location on the output feature map y, w is a convolution filter applied over the input feature map x. The Atrous rate r determines the stride that samples the input signal. Note that an Atrous convolution with $r = 1$ is equal to a standard convolution. In the encoder module, the concatenated output from ASPP1D is processed by a 1 × 1 convolution and an interpolation by a factor of 4, then concatenated with the convolved low-level feature from the ResNet1D. After this concatenation, a few convolutions are applied to refine the features followed by interpolation by a factor of 4 to recover the final output shape (a 1 × 220 array).

3.5 Point cloud generation

The captured data from real-time inspection and layer-wise inspection is in its local coordinate system. For subsequent geometry assessment, such as comparing as-designed geometry with as-built geometry, the captured data needs to be converted to the global coordinate system. For real-time inspection, the U-V to X-Z coordinates conversion and X-Z coordinate transformation are needed to obtain the point cloud of target cross-section from captured images. While for layer-wise inspection, 2D points are collected, thus only X-Z coordinate transformation is conducted.

Since the commercial line scanner normally uses a CCD sensor to capture its emitted laser reflection on the target surface, this process can be modeled using a pin-hole model, which is the basis camera model based on the perspective projection principle [28].

First, intrinsic calibration is conducted, which is to reconstruct the X-Z coordinates in the real-world coordinate system, given the U-V coordinates in the image coordinate system using the following equation.

$$\begin{bmatrix} x_l \\ z_l \\ 1 \end{bmatrix} = \begin{bmatrix} k_{11}' & k_{12}' & k_{13}' \\ k_{21}' & k_{22}' & k_{23}' \\ k_{31}' & k_{32}' & k_{33}' \end{bmatrix} \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} \tag{10}$$

By getting several pairs of U-V and X-Z coordinates, a least-square solution can be used, and the intrinsic transformation matrix K can be obtained.

Second, after obtaining the X-Z coordinates in the line scanner's local coordinate system (X_L, Z_L), a translation matrix is needed to convert the X-Z coordinates into the global coordinate system (X_G, Z_G), which is the extrinsic calibration process. After installing the laser line scanner, a rectangular calibration bar with known dimension is put at the origin of the global coordinate system, thus the as-designed cross section profile of the calibration bar in the global coordinate system can be obtained. Finally, after obtaining coordinates of measure profile in nozzle's coordinate system, the 3D coordinates of the measured profile in the global coordinate system can be calculated by fusing the nozzle's position using Eq. (16).

$$\begin{bmatrix} x_g \\ y_g \\ z_g \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & tx_2 \\ 0 & 1 & 0 & ty_2 \\ 0 & 0 & 1 & tz_2 \end{bmatrix} \begin{bmatrix} x_n \\ y_n \\ z_n \\ 1 \end{bmatrix} \tag{16}$$

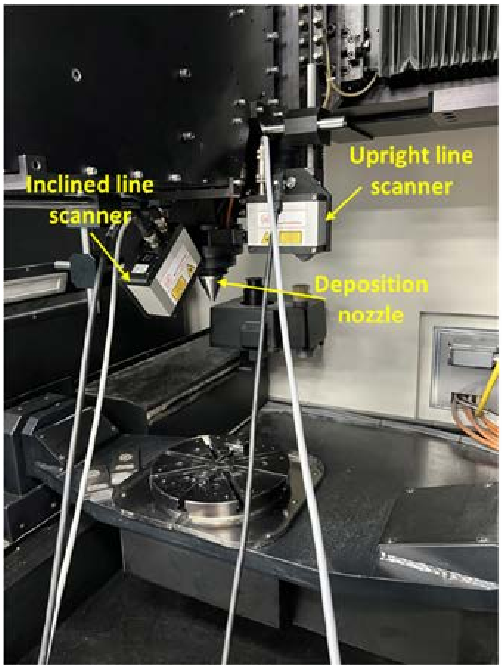
where the tx_2, ty_2 and tz_2 are the coordinates of the printing position in the global coordinate system, i.e., the nozzle's position. To obtain the nozzle's position for each captured profile, a log file is extracted from the DED printer during deposition which contains the location of the nozzle and a timestamp at each location.

4. EXPERIMENT AND DISCUSSION

4.1 Experiment setup

The LP-DED printer used in this study is an InssTek MX-400, which is a commercial metal printer equipped with a 5-degree-of-freedom mechanical moving stage, a Ytterbium fiber laser with a wavelength of 1070 nm, a maximum power of 1kW, and a focal laser beam diameter of 800 µm, as well as a metal powder delivery system with shield gas and carrier gas (Argon gas). A 316 L stainless-steel powder with an average particle size of 100 µm was used for deposition and a substrate using the same material as the powder with dimensions 100 mm × 50 mm × 10 mm was placed on the moving stage.

Two laser line scanners (Micro-Epsilon scanCONTROL 3000-25/BL), an inclined line scanner and an upright line scanner (Fig. 13), are installed for real-time and layer-wise inspection, respectively. Calibrations are conducted for both line scanners to get the transformation matrix used for 3D point cloud generation before deposition. For the inclined line scanner, intrinsic and extrinsic calibration are conducted; for the upright line scanner, only extrinsic calibration is needed. The exposure time was set to 20 ms (determined based on experience) to get a better reflection from the metal surfaces. The deposited object is a 20-layer X-shaped object. Two experiments are conducted: Experiment 1: deposition with real-time inspection of melt pool area ($d = 0mm$) and layer-wise inspection; Experiment 2: deposition with real-time inspection of just solidified area ($d = 3mm$) and layer-wise inspection.



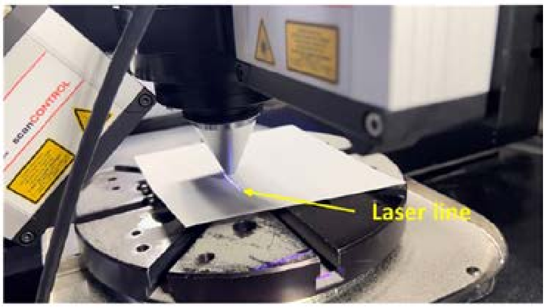


Fig. 13 Experiment setup: Geometry assessment system

4.2 Processing result

During the deposition of each layer, the inclined line scanner with laser line pointing at the melt pool or just solidified area captures and transfers images to the software for processing. After the deposition of each layer, layer-wise inspection is conducted by the upright line scanner, and point profiles are collected. For layer-wise inspection, 2D points of each cross-section are obtained and 3D point cloud data can be generated using extrinsic calibration matrix and fusing printer information. For real-time inspection, powder reflection removal and melt-influenced area removal are conducted for each image. Then the developed encoder-decoder based profile completion network is used to complete the profile on each image and the U-V coordinates are obtained. Finally, a 3D point cloud data of the deposition X-shape object in the global coordinate system can be generated using the proposed method.

Two experiments are conducted and each with 20 layers of data collected. Experiment 1 collects 1167 images and Experiment 2 collects 1157 images in total. Given the traverse speed of the printer (10 mm/s) and the total tool path length of each deposition (993.86 mm), the actual profile rate of the real-time inspection is about 12 frames per second. In this study, the paired image data from experiment 1 is used for model training and validation, which is divided into training and validation data in a ratio of 0.8, 0.2, respectively. The collected data from experiment 2 is used for model testing. The training process was conducted on GPU (NVIDIA GeForce GTX1080) using Python 3.9, Pytorch 11.7 and CUDA 11.8. Since previous profile is considered, t equals 1 to 5 are considered. For each t value, 80 epochs are trained, the validation dataset is used to choose the best model, then the best model is used for testing.

Root mean squared error (RMSE) was calculated between the output prediction array and the ground truth array. The average RMSE of all profiles in each layer was obtained for each t for comparison (Table 4). For higher layers, the RMSE becomes larger. This is due to the fact that when the layer height becomes higher, the sides of the deposited object will have a more inclined angle of 90 degrees, resulting in a worse reflection of the laser from the line scanner projected on the side of the deposited object. Thus, there will be a more serious profile missing problem for the higher layers, making it more difficult to complete the profile. In addition, when the absolute deposition height increases, the network prediction error also tends to increase, but the proportion of the error with respect to absolute deposition height may remain the same. Therefore, an RMSE-H ratio is calculated for each layer, which is the RMSE error divided by the design height (Table 4). As seen, there is not much difference in the RMSE-H ratio for each layer. The RMSE-H ratio of the first few layers is larger. Considering that the profiles of the first five layers are not seriously missing and the completion model may not be effective in such cases, the profile completion can be applied to the higher layers without the first five layers. When more previous layers are involved, there is little difference in the performance of the proposed model. A slight decrease of RMSE can be observed when t equals 2. Therefore, the model with $t = 2$ is finally selected as the profile completion model in our geometry assessment system, which can generate point cloud with an RMSE of 0.21 mm compared with the ground truth.

Table 4: Test results of the proposed model for different values of t

Test result		As-designed height (mm)	RMSE (mm)					RMSE-H ratio				
			$t = 1$	$t = 2$	$t = 3$	$t = 4$	$t = 5$	$t = 1$	$t = 2$	$t = 3$	$t = 4$	$t = 5$

5. CONCLUSION

This study has developed a real-time geometry assessment methodology for LP-DED using laser line scanner. A geometry assessment system has also been developed to achieve real-time inspection of the melt pool area and the just solidified area, as well as layer-wise inspection of the layers' geometry. An image processing method has been proposed including powder reflection removal, melt-influenced area removal and an encoder-decoder based profile completion network to obtain track profile on images. Then a point cloud generation method was developed including U-V to X-Z coordinates conversion, X-Z coordinate transformation, and 3D point cloud generation by fusing printer information. Experiments have been conducted to validate the proposed method and the result shows that an average RMSE of 0.21 mm can be achieved from point cloud comparison between the point clouds obtained in realtime and obtained layer-wise. The proposed real-time inspection method was able to achieve better performance compared with the line scanner's built-in method, and the developed encoder-decoder profile completion model has been validated which outperforms baseline model. The deposition heights of the melt pool and solidified layer were compared, and the result showed that the differences were not significant using the proposed method.

OPTIMAL NUMBER OF CUE OBJECTS FOR PHOTO-BASED INDOOR LOCALIZATION

Youngsun Chung, Daeyoung Gil & Ghang Lee
Department of Architecture and Architectural Engineering, Yonsei University, South Korea

ABSTRACT: *Building information modeling (BIM) is widely used to generate indoor images for indoor localization. However, changes in camera angles and indoor conditions mean that photos are much more changeable than BIM images. This makes any attempt at localization based on the similarity between real photos and BIM images challenging. To overcome this limitation, we propose a reasoning-based approach for determining the location of a photo by detecting the cue objects in the photo and the relationships between them. The aim of this preliminary study was to determine the optimal number of cue objects required for an indoor image. If there are too few cue objects in an indoor image, it results in an excessive number of location candidates. Conversely, if there are too many cue objects, the accuracy of object detection in an image decreases. Theoretically, a larger number of cue objects would improve the reasoning process; however, too many cue objects could lead to declining object detection performance. The experimental results demonstrated that of two to five cue objects, three cue objects is most likely to yield optimal performance.*

KEYWORDS: *indoor location determination, BIM, reasoning*

1. INTRODUCTION

Photos are commonly used as a medium to support building maintenance and defect management (Kim et al., 2014). These photos are sometimes taken by experienced field workers, but most are captured by unskilled workers or individuals with a limited understanding of the building, such as occupants (Kang et al., 2019). In existing maintenance systems, users are typically required to manually tag the locations where a photo was taken to utilize the system effectively. In particular, when occupants report defects, the specific locations and conditions of the defects are often described in unstructured text, making management even more challenging. Various methods have been used to accurately determine the locations where photos were taken. Several image-based indoor positioning methods have been explored, including approaches which search for the most similar BIM screenshot image to a target photo (Ha et al., 2018) or regress the camera position using deep learning algorithms (Acharya et al., 2019). Nevertheless, image-based methods typically rely on extensive image training and are sensitive to changes in indoor conditions (Kim & Kim, 2023). This sensitivity becomes especially problematic in buildings that have multiple varying factors, including interior fittings and lighting.

To overcome these limitations, especially the sensitivity to changes in indoor conditions, we propose an indoor localization method based on reasoning-based localization method that uses cue objects and their spatial relationships. Unlike furniture, cue objects, such as doors and windows, can serve as stable reference points because they rarely change. To achieve this goal, the first step is to determine the optimal number of cue objects required. If there are too few cue objects, they may not provide sufficient information for localization. However, if there are too many cue objects, the accumulated accuracy of cue-object detection decreases. The aim of this preliminary study was to validate our proposed method by determining the optimal number of cue objects required in an image to accurately locate the positions of indoor photos. To select the optimal number, we developed a prototype localization method based on the spatial relationships among cue objects, which involved comparing the similarities between cue objects and their spatial relationships in a target indoor image with those in a BIM model. We evaluated the performance of the proposed method by varying the number of cue objects in an indoor image, using the mean probability to accurately determine the location where the image was taken. To validate the proposed method, we measured the performance using the mean probability of localization and varied the number of objects within the photos.

This paper consists of five sections. Following this introduction, the second section discusses previous studies related to the research. The third section describes the research methodology and explains the details of the experiments. The fourth section presents the analysis and results of the experiments, and the final section concludes the paper by discussing the main findings, contributions, and limitations of the research.

2. BACKGROUND

2.1 Indoor Localization Using Images

Recent developments in computer vision have led to many attempts at indoor localization. Ha et al. (2018) suggested an indoor localization approach using BIM and a visual geometry group (VGG) model (Simonyan & Zisserman, 2015). They used the proposed model to retrieve the most similar BIM screenshot image to a given photo and to determine where the photo was taken. Alam et al. (2022) conducted a similar investigation based on recurrent neural networks (RNNs) to find the correct position of an indoor camera. These methods were intuitive and moderately effective but sensitive to variations in indoor decorations and lighting conditions arising due to their reliance on identifying the most similar screenshot images.

To enhance robustness, developers have attempted to utilize image datasets with camera trajectory data. In the context of BIM-PoseNet (Acharya et al., 2019) and related studies, various researchers have trained models based on deep convolutional neural networks (DCNNs) and large datasets of indoor BIM screenshot images to determine the positions and angles of the cameras used to capture photos. Two such studies were based on RNNs (Acharya et al., 2020) and channel-wise transformer localization (CT-Loc; Kim & Kim, 2023). Although BIM-PoseNet and CT-Loc applications are robust under varying lighting conditions due to an edge extraction method, they still cannot adapt to changes in furniture arrangements or interior decorations. Additionally, the studies were limited to the fixed linear paths of the cameras and excluded the simultaneous handling of close-range and wide-angle images. However, close-up photos are typically taken to capture the appearance of small-sized defects clearly, but for effective building defect management, both wide- and close-range images are required (i.e., photos need to be taken from a distance to address defects that cover a wide area or where the spatial context of the defects is crucial).

2.2 Indoor Localization Using Objects

To overcome the problem of condition changes in images, several researchers have proposed methods that utilize objects within images for indoor localization. Bay et al. (2006) investigated image-based indoor localization using speed-up robust features (SURF; Guan et al., 2016) and unique landmarks, such as posters or logos. Similarly, Li et al. (2022) used multiple visual landmarks and incorporated smartphone compass readings to improve performance. However, using posters as references is not practical because posters may change frequently, causing difficulties in keeping indoor landmark databases up to date.

To overcome these limitations, our author team proposed a method that used semantic segmentation and pose estimation for the positions of cue objects in indoor photos. They aimed to identify the indoor location where the cue objects in photos and conducted a proof-of-concept study (Kim, 2022). However, the method was only tested on objects photographed at relatively short distances.

In summary, previous localization methods based on images have revealed weaknesses in analyzing images under varying conditions. While the methods that employed edge-rendered images and semantic segmentation proved helpful in increasing the robustness of localization under different lighting conditions, they were still ineffective in capturing changes in interior items or furniture. As a solution, we previously proposed a method that focused on cue objects that rarely changed over time, such as light switches and fire extinguishers, and conducted a preliminary study (Kim, 2022). To further develop the method, in this study, we conducted a set of experiments to determine the optimal number of cue objects required for the method.

3. RESEARCH METHOD

The research flowchart for this study is depicted in Fig. 1. The indoor localization method first obtains information about cue objects and their spatial relationships using computer vision technology. We trained and validated the object detection model on an object detection training dataset using the object types and spatial order of the bounding boxes detected to reason indoor locations by comparing them with the spatial relationships among BIM cue objects. This method is based on left–right relationships of cue objects. Location reasoning may result in one or more specific sets of candidate cue objects. Each candidate represents a potential location depicted in the image. We evaluated the performance of the reasoning model based on the probability of accurately determining the location where the photo was taken, considering the number of candidates and the object detection accuracy. We tested the method with varying numbers of cue objects and found the optimal number when the model achieved the highest performance.

In the experimental phase, to which this paper relates, we began by determining the types of objects that would be used as cue objects and establishing the range of objects present in the image. We then created a sample for the BIM model of a housing unit, shown as a BIM DB in Fig. 1, which incorporated 10 different types of cue objects across 11 rooms. We generated 12,861 BIM screenshot images and used 12,671 images to train and validate the object detection model. We employed the remaining 190 images, each of which included 2–5 cue objects, to evaluate indoor localization performance and find the optimal number of cue objects.

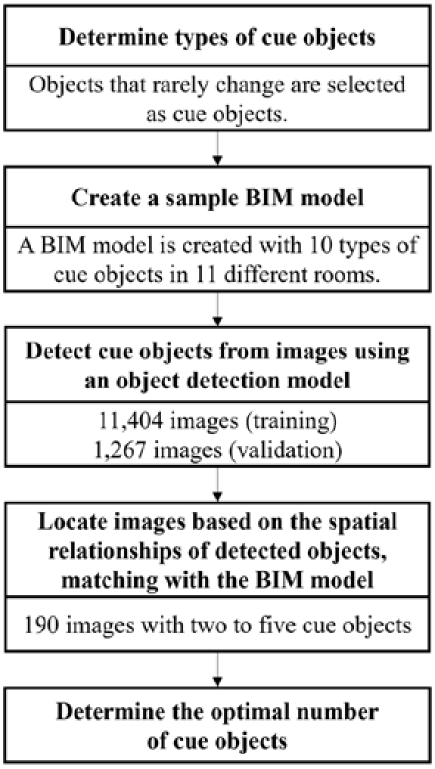

Fig. 1: Research flowchart

3.1 Selection of Cue Objects

For the experiments, we set the following criteria for cue objects:

1) The appearances or positions of cue objects should rarely change; thus, transient items, such as tables and posters, should not be considered cue objects.

2) Ideally, objects should be unique to a certain space and representative of the space. However, since a few objects remain constant over time and are exclusive to a particular space, non-unique objects, such as light switches or doors, could also be considered cue objects.

To determine positions using the spatial relationships among objects that remained relatively constant, we selected objects that fulfilled the above criteria, which resulted in the 10 cue objects listed in Table 1, including three types of doors, a window, a power socket, a light switch, a sink, a toilet bowl, a showerhead, and a kitchen cabinet, being chosen for the experiments.

3.2 BIM Model Creation

We created a sample BIM, we created a model of a housing unit for the experiment. Fig. 2 presents the axonometric view and the plan of the unit model. The model consisted of 11 rooms (the living-dining-kitchen [LDK] space, bedroom 1, bedroom 2, bedroom 3, bedroom 4, bathroom 1, bathroom 2, pantry, closet, balcony, and entrance), all of which had boundary walls, except for the LDK space and the entrance. Although some rooms were significantly different from one another (e.g., bedroom 1 and 2), there were also similarities between certain rooms (e.g., bedrooms 2 and 3). Table 1 provides detailed room information for the housing unit, including the room number, name, and list of cue objects present inside each room, along with their respective quantities. We placed the cue objects in plausible locations and varied their numbers and placements. We classified cue objects with differing appearances within the same category as distinct types. For example, we categorized doors into three different types. Doors A and B were both indoor wooden doors, but door B differed from door A by having two panels. Meanwhile, door C was a steel front door.

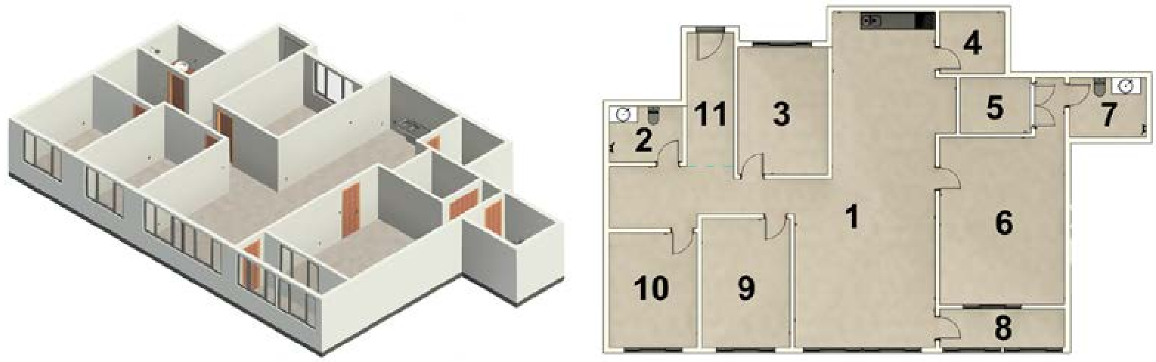

Fig. 2: Axonometric view of the housing unit model (left) and plan of the unit (right)

Table 1: Room information (number, name, and cue objects) for the BIM model of housing unit

Room Number	Room Name	Object Name and Quantity
1	LDK	Door A, 7; Window, 2; Power socket, 8; Light switch, 5; Kitchen cabinet, 1
2	Bathroom 1	Door A, 1; Power socket, 1; Sink, 1; Toilet, 1; Showerhead, 1
3	Bedroom4	Door A, 1; Window, 1; Power socket, 1; Light switch, 1
4	Pantry	Door A, 1; Power socket, 1
5	Closet	Door B, 1; Power socket, 1; Light switch, 1
6	Bedroom 1	Door A, 2; Door B, 1; Window, 1; Power socket, 4; Light switch, 2
7	Bathroom 2	Door A, 1; Power socket, 1; Sink, 1; Toilet, 1; Showerhead, 1
8	Balcony	Door A, 1; Window, 2; Power socket, 1
9	Bedroom 3	Door A, 1; Window, 1; Power socket, 1; Light switch, 1
10	Bedroom 2	Door A, 1; Window, 1; Power socket, 1; Switch, 1
11	Entrance	Door C, 1

3.3 Image Dataset Preparation

To train the model and evaluate the performance of the indoor localization method, we generated 12,861 BIM screenshot images, of which 12,671 were used for object detection and 190 for indoor localization method evaluation. Specifically, we used 11,404 images (roughly 90% of the object detection dataset) for training and 1,267 images for model validation. The dataset with 190 images for the indoor localization method was labeled differently from the previous dataset. The dataset for object detection was labeled according to bounded boxes, whereas the dataset for localization was annotated according to the information for the target room. Table 2 shows the major characteristics of the two image datasets. We created the dataset for object detection using a script that automatically captured the appearance of objects within the BIM model and labeled them accordingly. However, we manually created the dataset to validate the indoor localization method by directly capturing BIM model views.

Table 2: Characteristics of each image dataset

	Dataset for object detection	Dataset for indoor localization method evaluation
Purpose	To train and validate the object detection model	To validate the indoor localization method
Labeling	Cue objects with bounded boxes	Rooms and associated cue objects
Data size	11,404 (training)/1,267 (validation)	190 (validation)
Creation method	Automatically captured BIM model views	Manually captured BIM model views
Image size	785 × 785	1024 × 767

The images used for training and validating the object detection model were square, measured 785 pixels on each side, and were rendered in a realistic style. The dataset creation method is depicted in Fig. 3. We employed visual scripting to automatically generate these images. The viewing point from the camera's location and the target point where it is directed are both required to capture BIM screenshots. We began the viewing point and target point acquisition process by extracting room boundaries from the model and calculating the midpoint of each boundary side. We established viewing points by vertically elevating the midpoint of each boundary 150 cm from the floor to position the camera at average eye level. Viewing points were positioned along room boundaries rather than at the room centroids to capture images from the maximum distance within a room and thereby capture a greater number of cue objects. The scale of the captured objects was similar to that of the objects captured in the indoor localization method evaluation dataset when the viewing points were positioned along room boundaries. We then set target points by vertically elevating the midpoint of each boundary, spanning 40–200 cm, at intervals of 20 cm from the floor. To capture the desired views, we positioned a camera with a field of view (FOV) of 50°, which is the base angle of a normal lens, at the viewing point and directed it toward the target points. We repeated this process for each room in the BIM housing unit model. We produced the initial BIM images using Dynamo. Each was 1,047 × 785 pixels and was subsequently cropped into left, center, and right portions to create 785 × 785-pixel images. We removed redundant images that did not contain any cue objects. In total, we generated 12,671 images and used them to train and validate the object detection model.

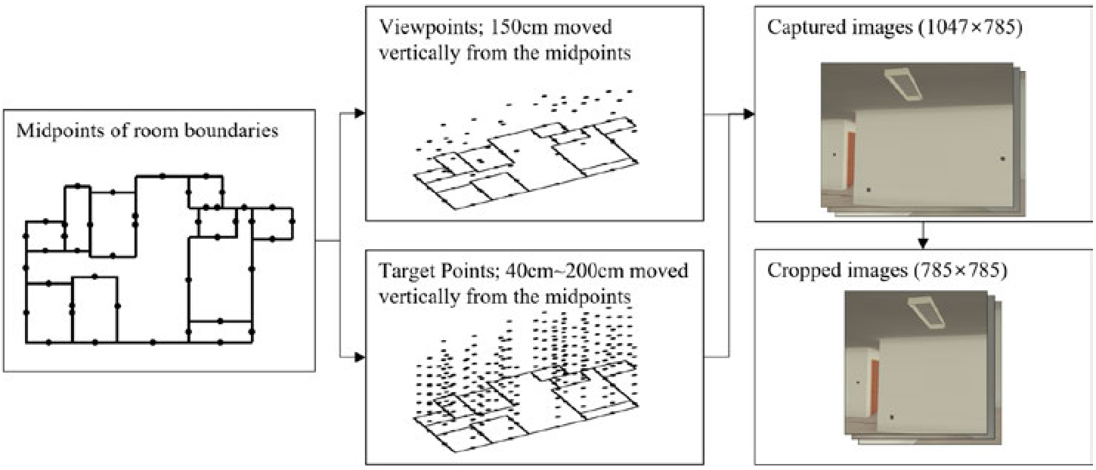

Fig. 3: Dataset creation for the object detection model

Additionally, we manually generated 190 images with varying numbers of cue objects, ranging from two to five, to determine the optimal number of cue objects for an image. The images were divided based on the number of cue objects (n) present in each image. We determined the range of n based on the following rationale: To deduce the location based on the spatial relationship between objects, at least two cue objects were minimally required. For the maximum number of cue objects, assuming that all cue objects were accurately detected, having more cue objects in the image made it easier to accurately determine the location. However, it was very unlikely for an image to include more than five cue objects. Moreover, as the number of cue objects necessary for the proposed method increased, the cumulative object detection error rate increased accordingly. Therefore, we set the maximum n-value to 5. Table 3 provides the distribution of images across the rooms. For scenarios with 2, 3, or 4 cue objects, 50 images were captured for each scenario. For scenarios with 5 cue objects, 40 images were captured, due to the limited existence of views that met the criteria. We determined the number of images for each room based on the availability of the desired view and the size of the room. Initially, we assessed whether each room could provide a view with a certain number of cue objects within the FOV of 50°. Then, considering the available rooms, we allocated the number of images for each room proportionally based on their respective areas. As shown in Table 3, the number of available rooms decreased significantly as the number of cue objects in the image increased. To fulfill the research objective, the image needed to include all contiguous cue objects. Further details regarding this condition will be discussed in Section 3.4.

Table 3: Number of images taken for each room

	Number	1	2	3	4	5	6	7	8	9	10	11	Total
Room information	Area (m^2)	60	5	14	5	5	27	5	6	13	12	8	160
	Cue object quantity	23	5	5	2	3	10	5	5	5	5	1	69
Number of images	$n = 2$	20	2	5	0	2	9	2	2	4	4	0	50
	$n = 3$	20	2	5	0	2	9	2	2	4	4	0	50
	$n = 4$	29	2	0	0	0	13	3	3	0	0	0	50
	$n = 5$	34	0	0	0	0	6	0	0	0	0	0	40

3.4 Object Detection

We used You Only Look Once (YOLO) (Redmon et al., 2016) for this study, which is one of the most widely used networks for object detection. We trained the model using 11,404 images and set aside 1,267 images for model validation. To rationalize the indoor location and the spatial relationships among cue objects within an image, we applied the trained object detection model to the indoor localization method evaluation image dataset, which varied the number of cue objects contained in each image.

3.5 Indoor Location Reasoning

The goal of indoor location reasoning is to determine the locations at which the positional relationships between cue objects obtained through object detection in the images align with the positional relationships the cue objects have within the BIM model. This involves analyzing the X and Y coordinates of the bounding boxes of cue objects in the images to infer whether one object is to the left or right of another object, or above or below it. However, in this experiment, we specifically focused on the left–right relationships between cue objects, as they tended to have fewer variations and provided greater accuracy. Based on the object detection results, we created a cue object list by arranging the objects in ascending order according to their X-coordinate values.

To identify the locations where the BIM information matched the information from the image, we considered how the model's information would manifest in the image. To determine which objects could be observed to the left or right of a specific object when taking a photo, we employed clockwise ordering of the objects present in each room. First, we extracted the positions of the cue objects and the room boundaries, which enabled us to determine the locations and relationships of cue objects within each room. Based on the extracted information, we sequentially listed all the objects in a clockwise direction along the boundaries of each room. Subsequently, to ensure that the list represented the relationships between objects, regardless of the starting point, we copied the elements from the front of the list, counting one less than the number of objects found in the image, and added them to the end of the list. If the quantity of elements added to the list exceeded the count of objects identified in the picture minus one, it could potentially result in duplicates during localization. Conversely, if the number of added elements was less than the count of objects identified in the picture minus one, it could lead to potential omissions during localization. Fig. 4 depicts an example. If the cue objects in a room were arranged clockwise as a, b, c, d, and e, the original list was [a, b, c, d, e]. If the image contained three cue objects, additional elements of the list 'a, b', which was one less than the total number of cue objects in the image, were appended at the end of the list, resulting in [a, b, c, d, e, a, b]. Matching parts were then sought between the cue object list created for each room and the list of cue objects present in the image. The matched cue objects were considered candidates for the location from which the photo was taken. For instance, if the cue object list for room A is [a, b, c, d, e, a, b], and the cue object list for the image is [a, b, c], there is one matching object arrangement. Therefore, [a, b, c] inside room A ([**a, b, c**, d, e, a, b]) becomes a candidate location. There could be multiple candidates for each image, or no candidates if the object detection result was incorrect.

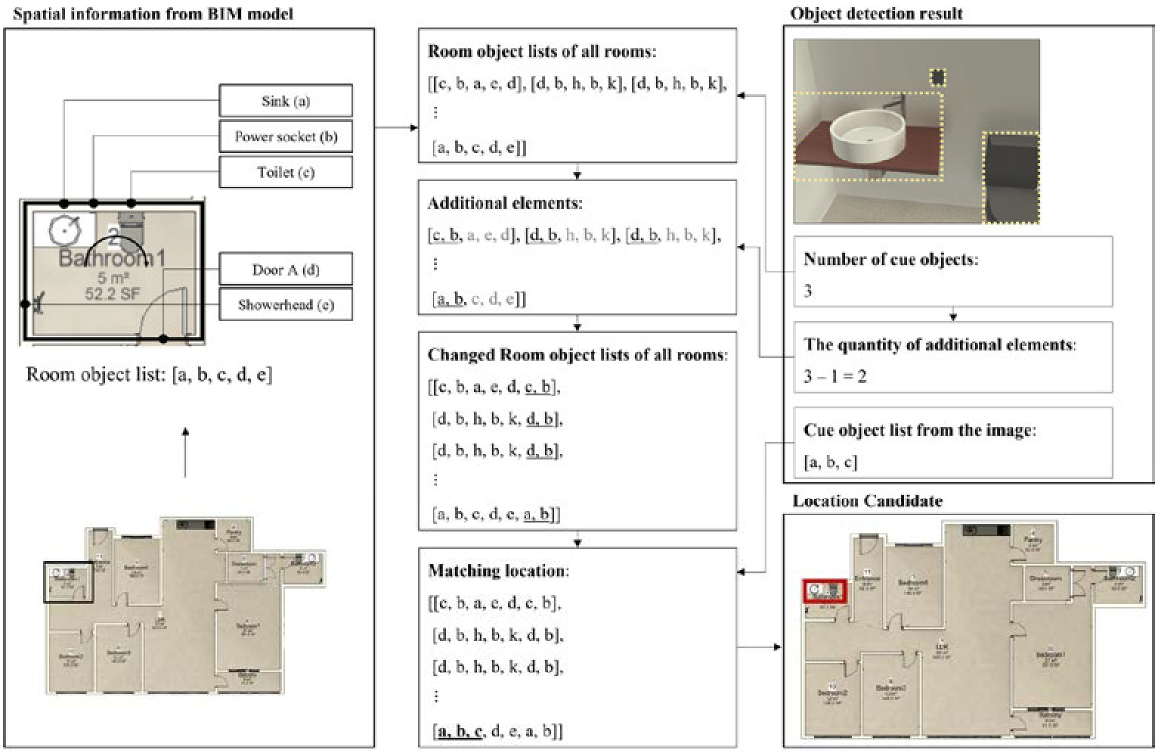

Fig. 4: The process of object location matching

4. RESULTS

4.1 Object Detection

Table 4 presents the model's performance metrics. The object detection model used in the study achieved $mAP_{0.5}$ of 0.9403 and F1 score of 0.9595 (Table 4). Accurate object detection within images certainly resulted in improved performance in subsequent indoor localization tasks because our proposed method relies on the results of object detection; however, the performance tended to degrade exponentially as the number of objects within the images increased as long as the object detection performance reached 100%. The results in Table 4 show that the overall performance decreased, theoretically, by about 6% on average with the addition of each cue object, considering the $mAP_{0.5}$ performance. The proposed localization method also relies on location reasoning, which is positively influenced by increases in cue objects. Thus, the number of cue objects, whether too large or too small, can be detrimental to performance, emphasizing the importance of optimizing the number of cue objects. In addition, Fig. 5 illustrates that the method performed better for objects with less skewness and larger sizes. Due to the presence of only one door B in the BIM model with significant skewness in the image, the accuracy was low for this object. The accuracy for light switches (the smallest of the objects) was slightly lower than for the other objects. Based on the results, it appears that choosing larger cue objects for the localization method would probably have resulted in improved performance.

Table 4: Performance of the object detection model based on the validation dataset

Precision	Recall	F1 score	mAP_0.5
0.9914	0.9295	0.9595	0.9403

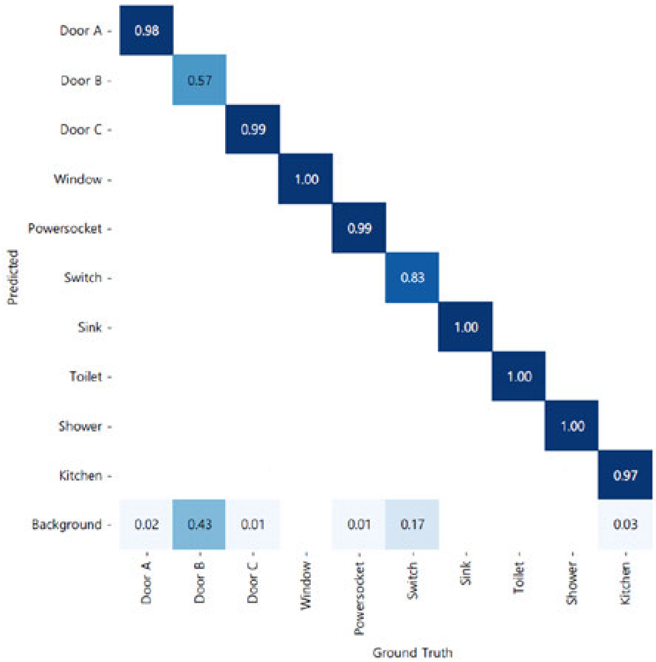

Fig. 5: Confusion matrix for the object detection results

4.2 Optimal Number of Cue Objects

Table 5 shows the evaluation results for the indoor localization method based on object detection and location reasoning for each number of cue objects in the images. Since the first step of the proposed method is to correctly detect every cue object in an image, only cases of every cue object in an image being predicted correctly are considered correct cases. As the number of objects in the image increased, object detection accuracy tended to decrease. This decrease in accuracy was minimal when the number of cue objects (n) changed from 2 (0.88) to 3 (0.80). The magnitude of the decrease was exponential, resulting in an accuracy of 0.20 when $n = 5$. The magnitude of the decrease was more significant than the theoretically estimated 6% decrease for the addition of an object, which was based on the object detection model performance for an individual object.

To identify the correct location among the candidate locations, the object detection results must be accurate. If object detection yields incorrect results, there may be no correct candidates or no candidates present. However, if the object detection results are correct, then at least one of the generated candidates is guaranteed to be correct. Therefore, after performing object detection, we conducted location reasoning for cases where there was a correct candidate and counted the number of generated candidates. Assuming that there was a correct candidate among the generated candidates, we calculated the probability of finding the correct location. However, in cases where the object detection results are wrong, there may be no correct candidate. Therefore, we multiplied the probability of finding the correct location when the correct location was present among the candidates by using object detection accuracy to calculate the probability of locating the correct position using the given method.

We used three metrics to evaluate the performance of the indoor localization method: (A) the mean number of location candidates when the correct location was present among the candidates, (B) the mean probability of finding the correct location when the correct location was present among the candidates, and (C) the mean probability of finding the correct location for both cases when the correct location was present among the candidates and when it was not. The three metrics provided answers to three research questions: (A) How many location candidates will be generated, depending on the number of cue objects? (B) What is the probability of finding the correct location from among the location candidates if the object detection is conducted correctly? (C) What is the probability of finding the correct location with the proposed method, considering both object detection accuracy and the performance of location reasoning. Metric (C) was the primary metric for assessing the model's performance. To compare the performance of the model with and without the influence of object detection, we considered the results based on predicted and actual object information. (A) decreased as the number of cue objects in the image decreased and reached 1.000 when $n = 5$, and (B) could be calculated as the mean value of the inverse of (A), with a higher value indicating better performance. Since (C) considered both the object detection accuracy and the localization reasoning performance, it could be calculated by multiplying the object detection accuracy with (B); hence, a higher value of (C) indicated superior overall model performance.

When cases with correct object detection were considered, the localization performance increased as n increased. However, localization performance did not increase proportionally to n because the accuracy of object detection significantly decreased as n increased. Therefore, when using the predicted object information, the highest performance was observed at $n = 3$, with a probability of 0.283 for finding the correct location. At $n = 4$, the probability of finding the correct location was 0.276, which represented a slight decrease but showed a similar performance to that at $n = 3$. Therefore, even a slight improvement in object detection accuracy for $n = 4$ had the potential to yield a better score than the case at $n = 3$. This result shows that the presence of three to four cue objects in the image yielded optimal results within the given framework.

Table 5: Model evaluation results

Number of cue objects in the image (*n*)	**Object detection accuracy**	**Localization performance based on predicted object information**			**Localization performance based on actual object information**		
		(A)	**(B)**	**(C)**	**(A)**	**(B)**	**(C)**
2	0.88	3.841	0.260	0.229	3.800	0.263	0.263
3	0.80	2.825	0.354	0.283	2.816	0.355	0.355
4	0.52	1.885	0.531	0.276	1.700	0.588	0.588
5	0.20	1.000	1.000	0.200	1.000	1.000	1.000

(A) The mean number of location candidates when the correct location was present among the candidates

(B) The mean probability of finding the correct location when the correct location was included among the candidates.

(C) The mean probability of finding the correct location for both cases when the correct location was present within the candidates and when it was not.

5. CONCLUSION

Many previous studies on indoor localization have been based on the similarities between photos and BIM images. However, these approaches may exhibit weaknesses under varied lighting conditions and with different wallpapers and furniture locations. To overcome these limitations, we propose a reasoning-based approach based on cue objects in photos. With this approach, it is essential to optimize the number of cue objects for detection since it significantly influences performance. Hence, the aim of this preliminary study was to find the optimal number of cue objects in a photo that yielded the best localization performance. The proposed localization method uses spatial information on cue objects detected by a computer vision algorithm to locate shots by analyzing the spatial relationships among the objects found in an image and comparing them with those in the BIM model. We evaluated the method's performance by assessing the probability of accurately determining the location from which a photo was taken, varying the number of cue objects in each photo from two to five.

The experimental results indicated that the model showed the best performance when three cue objects were present in an image. When the number of cue objects increased to four, the probability of accurately determining the exact location decreased slightly compared to the case with three cue objects, mainly due to the dramatic decrease in object detection accuracy. As the number of cue objects captured from the image increased, the number of small and skewed objects also tended to increase, which led to a decrease in overall accuracy. Having a higher number of cue objects can make it easier to deduce the location of a shot accurately, but it may decrease object detection accuracy.

The major contribution of this study lies in suggesting the optimal number of cue objects that should be present in images to determine the locations of photos shot in indoor spaces. This finding highlights the importance of balancing detection performance and reasoning capability in object detection-based indoor localization and considering the number of detected objects. The experimental results provide insights into areas for improvement in future research. First, the method did not perform well when cue-object arrangements in rooms were similar. This limitation could be addressed by considering the size of cue objects and incorporating more diverse spatial information. Second, the error rate accumulated at each stage: the cue-object detection stage, the spatial relationship detection stage, and the location deduction stage. Further research is expected to improve the proposed method to a practically applicable level. The results of this research will be integrated into construction management and maintenance software, enabling the automatic tagging of locations in provided images.

INTEGRATING GREEN ROOFS INTO BUILDING INFORMATION MODELING (BIM): A COMPUTATIONAL APPROACH FOR SUSTAINABLE BUILDING DESIGN

Cascone Stefano
Mediterranea University of Reggio Calabria, Italy

ABSTRACT: *The construction industry is currently witnessing a transformative period characterized by the convergence of the green and digital transitions. The green transition seeks to address environmental challenges such as climate change and resource depletion, while the digital transition leverages advanced technologies to enhance construction processes. This paper specifically explores the integration of green roofs, as component of sustainable buildings, into the Building Information Modeling (BIM) framework, a key enabler of the digital transition. Green roofs, known for their environmental benefits, consist of layers that contribute to energy efficiency, stormwater management, and biodiversity enhancement. To optimize their design and performance, this research employs Dynamo Visual Programming Language (VPL) within Autodesk Revit to create parametric models of green roofs. These models facilitate the evaluation of thermal and structural characteristics under varying water content conditions (dry and saturated). Results reveal that the choice of substrate and drainage materials significantly impacts thermal resistance, particularly in dry conditions. However, in saturated conditions, the influence on thermal performance converges, emphasizing the importance of structural considerations in both scenarios. The research also highlights various limitations and outlines avenues for future studies, including expanding the range of materials, exploring additional performance metrics, and incorporating AI and machine learning techniques. By addressing these aspects, this research contributes to a comprehensive understanding of the integration of green roofs and BIM. It provides designers and researchers with a practical tool for optimizing green roof designs, aligning with contemporary sustainable construction practices, and promoting the holistic development of green buildings.*

KEYWORDS: *Sustainability integration; Parametric modeling; Digital Transformation*

1. INTRODUCTION

The construction sector is currently undergoing significant transformations driven by the green and digital transitions. The green transition refers to the shift towards sustainable practices and environmentally friendly solutions within the industry (Mina et al., 2021). This transition is motivated by the urgent need to address climate change, resource depletion, and environmental degradation (Bherwani et al., 2022). As a result, the construction sector is increasingly adopting strategies and technologies that reduce the environmental impact of buildings and infrastructure. Simultaneously, the digital transition has brought about a profound change in the construction industry, fueled by the rapid advancements in digital technologies (Huang et al., 2021). This transition involves the integration of digital tools, processes, and data management systems to improve efficiency, productivity, and collaboration across all stages of the building life cycle (Giovanardi et al., 2023). Building Information Modeling (BIM) has emerged as a key component of the digital transition, revolutionizing the way information is shared, analyzed, and utilized within the construction industry.

Among the various components employed in green buildings, green roofs have gained recognition as an effective technological solution for improving sustainability and the life cycle performance of buildings (S. Cascone, 2022). A green roof, also known as a living roof or vegetated roof, refers to a roofing system that incorporates vegetation, growing medium, and waterproofing layers (Vijayaraghavan, 2016). It offers numerous environmental, social, and economic benefits, making it an integral part of green building practices (Shafique et al., 2020). Each layer of the green roof system works in tandem to provide a range of benefits. The waterproofing layer ensures the building's protection, while the root barrier prevents potential damage. The drainage layer manages stormwater, preventing flooding and alleviating pressure on drainage infrastructure. The growing medium layer supports plant growth by providing adequate nutrients and moisture retention. Finally, the vegetation layer enhances biodiversity, improves air quality, reduces energy consumption, and mitigates the environmental impact of the building.

The digital transition has ushered in a new era of possibilities and advancements in the construction industry, necessitating the adoption of digital tools and processes to optimize project outcomes (Mehrbod et al., 2019). At the forefront of this transition is Building Information Modeling (BIM), a powerful technology that revolutionizes the way information is managed, shared, and utilized throughout the building life cycle (Wang et al., 2019). BIM

is a collaborative process that involves creating and managing digital representations of physical and functional characteristics of a building. It enables stakeholders, including architects, engineers, contractors, and facility managers, to work together in a coordinated manner, streamlining communication and enhancing decision-making. BIM serves as a digital repository of information, encompassing 3D models, 2D drawings, specifications, schedules, and other pertinent data related to the building (Gimenez et al., 2015).

One of the key advantages of BIM lies in its ability to support the supply, integration, and management of information throughout the entire life cycle of a building (Alireza et al., 2017). During the design phase, BIM facilitates the creation of detailed 3D models that allow for visualization, clash detection, and simulation of various design scenarios. Therefore, to fully capitalize on the advantages of green roofs, the integration of these systems with BIM is of utmost importance. Previous research (Korol et al., 2019) discussed the integration between green roof and BIM technologies used in the engineering design of such systems. This previous research explained that to create a BIM object of an extensive green roof system, complex programs such as AECOsim, ARCHICAD, IFC, Revit, and Vectorworks are needed. The authors also mentioned that the NBS National BIM Library in the UK sets an industry standard for quality, efficient generic and manufacturers' objects, including green roof systems. However, they did not provide detailed information on the integration process between green roof and BIM. Other authors (Yu et al., 2017) discussed the application of BIM in the case study of green roof innovation. Specifically, the authors incorporated BIM and energy consumption analysis software to demonstrate the benefits of the proposed eco-innovative green roof alternative. Finally, in a further study (Kasmion et al., 2000) reported on a simulation study using Autodesk Revit BIM software to investigate how types of roof design and green roof application may reflect on container's heat absorption. This study found that a curved roof surface with green roof produces a better heat absorption quality.

While there is a growing recognition of the benefits of green roofs and the potential of BIM in the construction industry, there is a notable gap in research that specifically explores the integration of these two domains. The gap in scientific knowledge lies in the lack of established frameworks, guidelines, and best practices for effectively integrating green roofs within the BIM environment. There is limited research that examines the specific workflows, data management strategies, and computational automation techniques required to successfully incorporate green roofs into the BIM framework. Furthermore, the understanding of how green roof components, materials, and performance characteristics can be accurately represented and analyzed within the BIM environment is also lacking.

In this paper, the focus lies in studying the integration methods between green buildings and BIM, specifically emphasizing the incorporation of green roofs. Green roofs, also comprising innovative components and products, such as recycled polyethylene, offer unique opportunities to enhance the sustainability of buildings. To achieve this integration, the Dynamo Visual Programming Language (VPL) workflow within Autodesk Revit, the most widely used BIM authoring software, was employed. Dynamo enabled computational automation, allowing for the development of parametric and informative models of green roofs. These models provided computational automation for determining the thermal and structural characteristics of the different green roof technologies in different water content conditions (dry and saturated) that can be used for controlling and coordinating the entire life cycle of a green roof, especially during the initial design stage.

This research aims to contribute to a deeper understanding of how the combined power of green building practices and BIM technology can foster sustainable development in the construction sector.

2. MATERIALS AND METHODS

The research is focused on investigating the integration methods between green buildings and Building Information Modeling (BIM), with a specific emphasis on the incorporation of green roofs, and it involves the computational modelling using the Dynamo Visual Programming Language (VPL) workflow within Autodesk Revit. The parametric models enable the manipulation of design parameters, such as green roof technologies and water content conditions (dry and saturated), to assess their impact on thermal and structural characteristics.

2.1. Green roof technologies

The material characteristics of the drainage layer and substrate in green roofs were evaluated through previous experimental studies. Three types of drainage layers and substrates were considered in this study. In terms of the drainage layers, commercially available granular products such as perlite and expanded clay were examined. Additionally, previous research proposed recycled polyethylene as a potential drainage layer for green roofs, aiming to enhance sustainability while reducing environmental and economic impacts associated with production and transportation.

Regarding the substrates, three different compositions were investigated. Substrate S1 consisted of lapilli, pumice, zeolites, peat, and slow-release fertilizers. Substrate S2 comprised a mixture of mineral volcanic materials combined with organic substances, while Substrate S3 was formulated with a higher percentage of organic matter compared to the other substrates to increase water retention. It was also composed of locally available materials.

Following laboratory tests conducted in previous research, the thermal and physical characteristics of the materials used for both the drainage layer and substrate were considered under dry and saturated conditions. In a green roof system, saturated conditions are reached after a rain or irrigation event, while dry conditions are obtained when the water has completely evaporated during prolonged droughts. As evidenced by Table 1 and Table 2, altering the water content in the materials resulted in changes to their thermal and physical properties.

These evaluations provide valuable insights into the performance of drainage layer and substrate materials, offering a comprehensive understanding of their behavior under different water content conditions. This knowledge is essential for optimizing the design and performance of green roofs, enabling informed decision-making and promoting sustainable practices within the construction industry.

Table 1: Thermal and physical properties for drainage layer materials (Cascone & Gagliano, 2022).

	Dry conditions		**Saturated conditions**	
	Thermal conductivity [W/mK]	Density [kg/m3]	Thermal conductivity [W/mK]	Density [kg/m3]
Perlite	0.076	164.2	0.312	510.5
Expanded clay	0.124	410.4	0.234	579.3
Recycled polyethylene	0.098	329.4	0.144	411.7

Table 2: Thermal and physical properties for substrate materials (S. Cascone & Gagliano, 2023).

	Dry conditions		**Saturated conditions**	
	Thermal conductivity [W/mK]	Density [kg/m3]	Thermal conductivity [W/mK]	Density [kg/m3]
Substrate S1	0.113	1000.2	0.463	1355.5
Substrate S2	0.134	919.4	0.458	1358.4
Substrate S3	0.084	605.4	0.418	1183.9

2.2. Computational modelling with Dynamo Visual Programming Language (VPL)

To achieve the integration of green buildings and Building Information Modeling (BIM), the research employs the Dynamo Visual Programming Language (VPL) as a key tool within Autodesk Revit. Dynamo VPL enables computational automation and facilitates the development of parametric and informative models specifically tailored to green roofs.

The initial step involved modeling the materials utilized for green roof layers within the Dynamo environment. This was accomplished by duplicating existing materials from the Revit Material's Asset and renaming them using custom nodes based on Python scripts previously developed within Dynamo. This approach was necessary as standard nodes do not directly manipulate the Revit Material's Asset.

The "Thermal conductivity" and "Density" nodes provide the property values under both dry and saturated conditions, as indicated in Table 1 and Table 2 (Fig. 1 depicts the Dynamo workflow for creating the perlite drainage material). The "If" node automatically switches the thermal conductivity and density values between dry and saturated conditions. In this research, "true" represents dry conditions and "false" represents saturated conditions. For example, in the case of perlite, when the water condition is set to dry, the thermal conductivity is

0.076 W/mK and the density is 164.2 kg/m^3. Conversely, when the water condition is set to saturated, the thermal conductivity becomes 0.312 W/mK and the density changes to 510.5 kg/m^3.

This aspect of the workflow is particularly noteworthy as it enables the computational automation of thermal and physical properties for green roofs during the design stage, depending on the water content. With just a single click, users can assess the thermal and physical performance of green roofs under dry or saturated conditions, as described later in the research.

The "Material.SetThermal" node is responsible for creating new materials, such as "Perlite" in Fig. 1, with properties defined in "Thermal.SetProperties" that vary based on the input from the "True/False" node positioned at the beginning of the workflow.

The workflow illustrated in Fig. 1 for creating perlite serves as the basis for generating the other drainage and substrate materials. Fig. 2 showcases the workflow with all the materials created. All the "Thermal conductivity" and "Density" nodes are connected to the same "True/False" (dry/saturated) node, ensuring the water content condition is automatically considered.

2.3. Thermal and structural characteristics

The first step involves assigning the green roof materials to the "Green roof" type, which consists of two layers: one for the substrate and another for the drainage layer. The impact of waterproof and anti-root membranes, as well as the filter layer, on the thermal and structural characteristics of the green roof is negligible and, therefore, not considered.

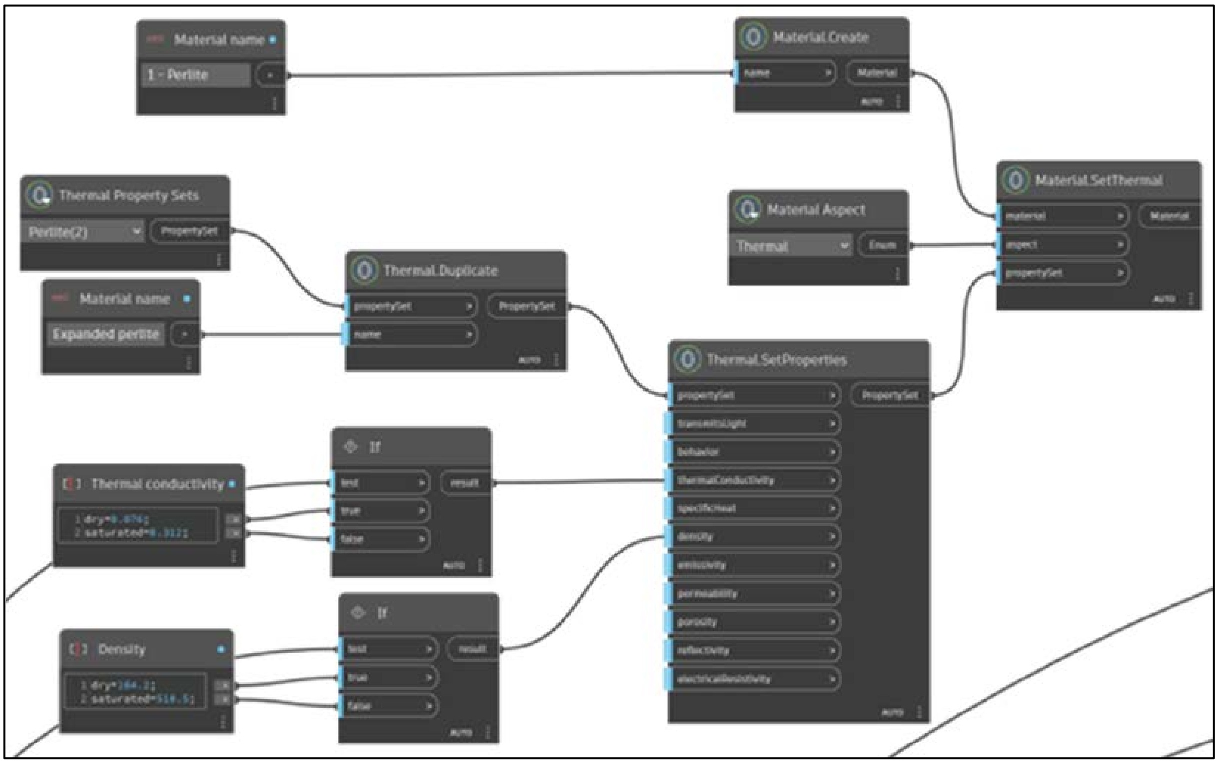

Fig. 1: Material creation in Revit by using Dynamo workflow.

To facilitate the evaluation of the thermal and structural characteristics of the green roof, custom nodes were developed (Fig. 3). The "Index" parameter indicates the layer position, with "0" representing the substrate (upper layer) and "1" representing the drainage layer (lower layer). Since the thickness of the materials plays a crucial role in determining the performance of the green roof, the workflow incorporates a component that automatically adjusts the material thicknesses.

Given the focus on extensive green roofs in this research, the substrate thickness varies between 10 cm and 20 cm, while the drainage layer thickness ranges from 4 cm to 6 cm. As an average value, a substrate thickness of 15 cm and a drainage layer thickness of 5 cm were adopted.

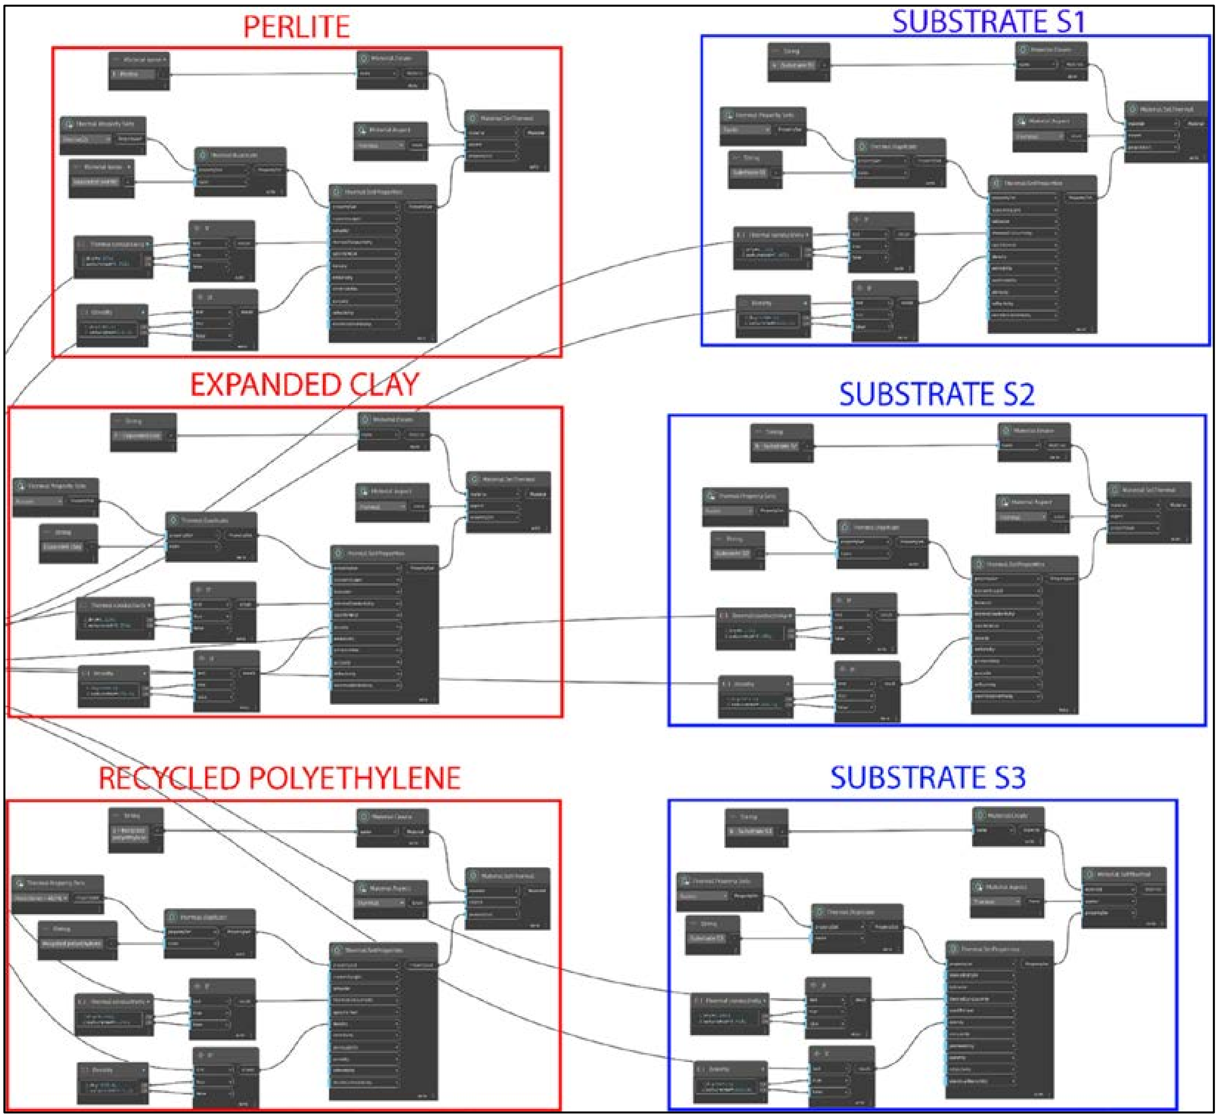

Fig. 2: Material creation for drainage layers (in red) and substrates (in blue).

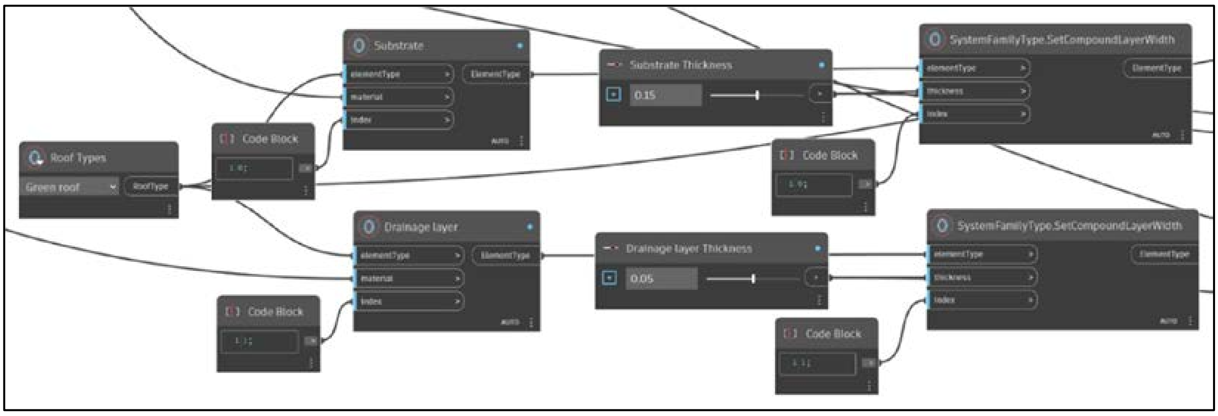

Fig. 3: Layer creation into the green roof type and parametric thickness modelling.

By selecting the appropriate materials within the "Substrate" and "Drainage layer" nodes, the new materials are automatically assigned to the Revit model, ensuring seamless integration and representation of the green roof components.

Finally, Fig. 4 illustrates the workflow employed to evaluate the thermal and structural characteristics of green roofs. In terms of thermal performance, the thermal resistance was a key factor considered. This property was automatically measured by Revit and imported into Dynamo, considering the thermal conductivities of the various substrate and drainage materials, which are influenced by the water content conditions (dry or saturated), as well as the material thicknesses.

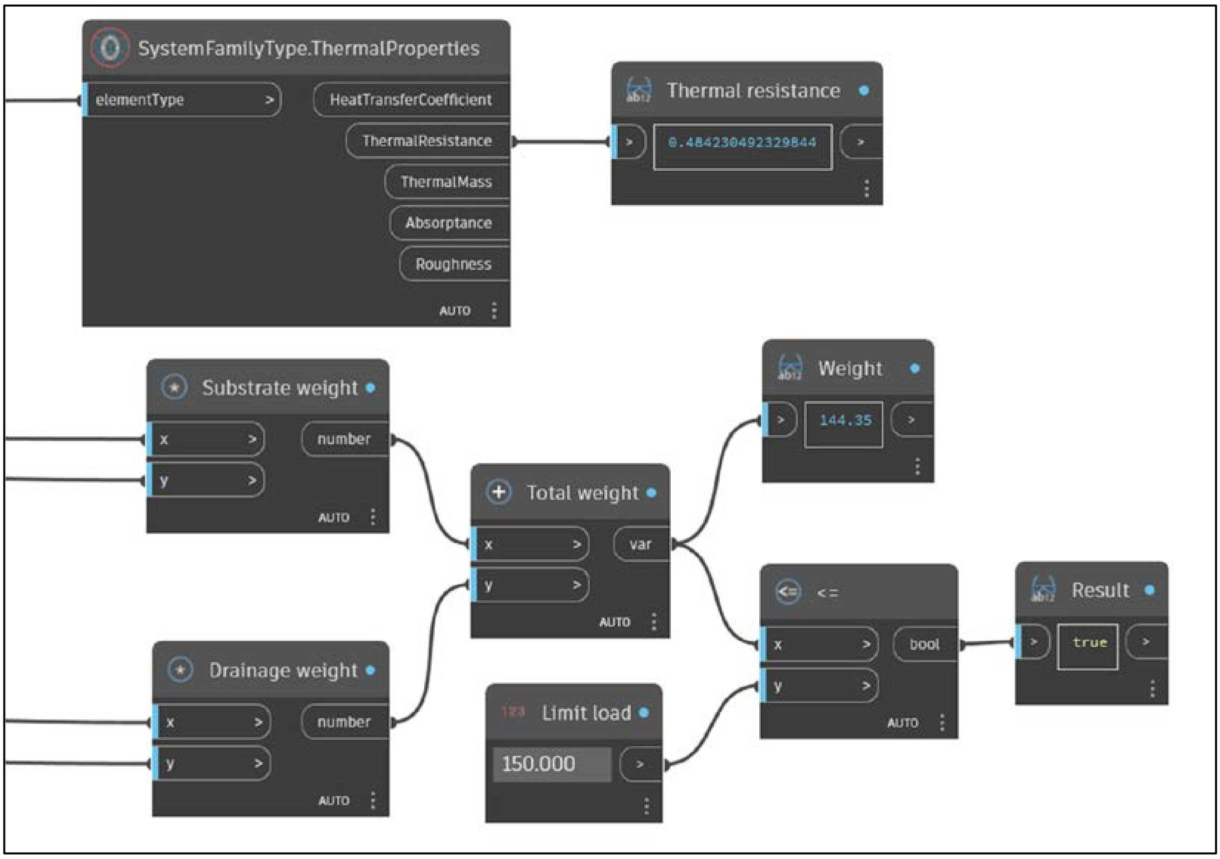

Fig. 4: Thermal and structural characteristics of green roof evaluation.

Regarding the structural performance, the weight of the different green roof configurations was determined. The total weight depends on the density of the substrate and drainage layers, which are also influenced by the water content conditions and the material thicknesses. By multiplying the density of the materials by their respective thicknesses, the total weight of each green roof configuration was calculated.

According to the European standard, if a roof is intended to be walkable during the design stage, it should be able to withstand a maximum load of 200 kg/m^2. The total weight of the different green roof solutions was compared to this limit to assess their compatibility with existing buildings, aiming to avoid costly structural modifications.

By considering both the thermal and structural characteristics aspects, this workflow provides valuable insights into the suitability of different green roof options, facilitating informed decision-making during the design stage. It enables designers and researchers to assess the thermal efficiency and structural integrity of green roofs, ensuring their compatibility with existing building structures and meeting the required standards.

3. RESULTS AND DISCUSSION

Table 3 and Table 4 present the results for green roofs in dry and saturated conditions, respectively. In terms of thermal resistance in dry conditions, the highest performance was observed when combining Substrate S3 with perlite (2.44 m2K/W), while the lowest performance was measured when Substrate S2 was coupled with expanded clay (1.52 m2K/W). These results highlight the significant impact of substrate and drainage material combinations on the thermal performance of green roofs in dry conditions. Therefore, in dry conditions, the materials tested have similar thermal performance of 3-cm insulation materials.

Table 3: Thermal and structural characteristics in dry condition.

	Perlite		Expanded clay		Recycled polyethylene	
	Thermal Resistance [m^2K/W]	Weight [kg/m^2]	Thermal Resistance [m^2K/W]	Weight [kg/m^2]	Thermal Resistance [m^2K/W]	Weight [kg/m^2]
Substrate S1	1.99	158.2	1.73	170.5	1.84	166.5
Substrate S2	1.78	146.1	1.52	158.4	1.63	154.4
Substrate S3	2.44	99.0	2.19	111.3	2.30	107.3

Table 4: Thermal and structural characteristics in saturated condition.

	Perlite		Expanded clay		Recycled polyethylene	
	Thermal Resistance [m2K/W]	Weight [kg/m2]	Thermal Resistance [m2K/W]	Weight [kg/m2]	Thermal Resistance [m2K/W]	Weight [kg/m2]
Substrate S1	0.48	228.8	0.54	232.3	0.67	223.9
Substrate S2	0.49	229.3	0.54	232.7	0.67	224.3
Substrate S3	0.52	203.1	0.57	206.6	0.71	198.2

In saturated conditions, the thermal resistance decreased due to the higher thermal conductivity of water. As a result, the thermal performance of different green roofs became similar, with an average value of 0.55 m2K/W. These findings indicate that under saturated conditions, the thermal performance of green roofs is less influenced by the specific substrate and drainage material combinations and tends to converge to a similar performance level across the tested variants. This resistance value is close to the one measured for natural materials, such as wood, straw, etc. Designers can consider these average values during the design stage to estimate the energy performance of green roofs in terms of energy consumption.

Regarding the structural performance, all green roof configurations exhibited weights lower than the imposed limit overload of 200 kg/m2 in dry conditions, with the lighter solution being the Substrate S3, due to its composition, when coupled with perlite as drainage layer. The heaviest solution is the Substrate S1 in combination with expanded clay. However, in saturated conditions, only when Substrate S3 was coupled with recycled polyethylene as drainage materials, the weight remained below the limit overload due to hygroscopic structure of the granular materials used for the green roof. In fact, the recycled plastic does not absorb water differently from perlite and expanded clay. This finding is significant, particularly for the retrofitting of existing buildings, as it highlights the importance of considering the structural performance of green roofs not only in dry conditions, as is often the case, but also in saturated conditions.

The workflow created using Dynamo within Revit proved to be effective in automating the determination of thermal and structural characteristics of green roofs during the design stage. This automation allowed for seamless transition between dry and saturated conditions by adjusting the material properties accordingly. The ability to rapidly assess these characteristics enables designers to make informed decisions during the early design stage.

Designers can employ the algorithm to explore various green roof configurations and materials, considering both thermal resistance and structural weight. By inputting different parameters into the Dynamo workflow, such as substrate types and drainage materials, designers can optimize green roof designs for specific project requirements. For instance, if the primary goal is to maximize thermal resistance while keeping structural weight within a certain limit, the algorithm can assist in identifying the most suitable combinations of materials.

Furthermore, the algorithm's flexibility extends to various climate conditions and building types. Designers can use it to assess the performance of green roofs in different regions, taking into account variations in temperature, precipitation, and structural load requirements. This adaptability empowers architects and engineers to tailor green roof designs to meet energy efficiency goals and structural integrity standards in diverse contexts.

Overall, the results demonstrate the importance of considering both thermal and structural characteristics of green roofs, not only in dry conditions but also in saturated conditions. The integration of the developed workflow using Dynamo and Revit provides a practical and efficient means to assess and compare the performance of green roof options, facilitating informed decision-making during the design stage. These findings contribute to the understanding and optimization of green roof designs in terms of energy consumption and structural integrity.

By incorporating this algorithm into the design process, architects and engineers can enhance the sustainability of buildings by leveraging green roofs as energy-efficient and structurally viable components. This technology-driven approach aligns with contemporary design practices that prioritize eco-friendly solutions while maintaining building performance standards.

4. LIMITATIONS AND FUTURE DEVELOPMENTS

This section outlines the limitations of the current study and presents directions for future research to address these limitations.

Future research should include real-world case studies to provide a more concrete understanding of the algorithm's practical use and effectiveness. These case studies can demonstrate how the Dynamo Visual Programming Language (VPL) workflow within Autodesk Revit can be effectively applied to model green roofs in various construction projects, thus contextualizing the algorithm within practical design scenarios.

The analysis in the current study primarily focused on thermal resistance and structural weight as key performance metrics. However, a broader range of performance indicators, including water retention, stormwater management, biodiversity enhancement, and acoustics, should be explored in future research. This will enable a more comprehensive evaluation of green roof performance, considering their contributions to sustainable construction from multiple angles.

While the current research addressed the design phase of green roofs and their integration with BIM, it did not extensively explore the construction and maintenance phases. Future research should encompass these phases to gain a holistic understanding of green roofs' performance, durability, and maintenance requirements throughout the entire building lifecycle.

To ensure the robustness and adaptability of the methodology, future research should consider alternative methodologies and tools. This diversification will accommodate different research questions and potential variations in results. Additionally, exploring interoperability with other BIM software platforms will enhance the methodology's relevance and applicability.

Integration of artificial intelligence (AI) and machine learning techniques within the BIM environment should be explored in future research. This will enable the optimization of green roof designs, prediction of performance outcomes, and data-driven recommendations for materials and configurations, aligning the work with emerging trends in construction technology.

Future research should involve the development of standardized guidelines and protocols for integrating green roofs within the BIM framework. These guidelines can streamline data exchange, model interoperability, and collaboration among stakeholders, promoting efficient and consistent implementation of green roof projects. Additionally, analyzing the economic aspects, including life cycle costs, return on investment, and financial incentives, should be a focus. Assessing the economic benefits of green roofs in terms of energy savings, improved building performance, and increased property value will provide valuable insights for decision-makers.

To promote holistic and integrated sustainable building solutions, collaborative research efforts should be initiated to explore potential synergies between green roofs and other sustainable building strategies, such as renewable energy systems, water conservation measures, and smart technologies. Integrating these strategies within the BIM framework will contribute to a more comprehensive approach to sustainable construction, thereby addressing the de-contextualization issue raised by the reviewer.

Incorporating these considerations into future research agendas will provide a more comprehensive and contextualized view of the integration of green roofs and BIM, addressing the reviewer's concerns and enhancing the practicality and relevance of the work.

5. CONCLUSIONS

In conclusion, this research contributes to a deeper understanding of the integration methods between green buildings and Building Information Modeling (BIM), with a specific focus on the incorporation of green roofs. By employing the Dynamo Visual Programming Language (VPL) workflow within Autodesk Revit, computational automation was achieved, enabling the development of parametric and informative models of green roofs.

The analysis in dry and saturated conditions provided valuable insights into the thermal and structural characteristics of different green roof technologies. The findings highlight the importance of substrate and drainage material combinations in influencing thermal resistance in dry conditions, as well as the significance of considering structural performance in both dry and saturated conditions.

However, it is important to acknowledge the limitations of this research, including the specific focus on certain green roof technologies, the limited scope of performance metrics, and the emphasis on the design stage. Future developments can address these limitations and further advance the integration of green buildings and BIM:

- Exploring a wider range of green roof technologies and materials.
- Investigating additional performance metrics related to water retention, stormwater management, biodiversity enhancement, and acoustics.
- Extending the research to include the construction and maintenance phases.
- Considering alternative methodologies and software tools.
- Integrating artificial intelligence and machine learning techniques, developing standardized guidelines, assessing the economic aspects, and exploring synergies with other sustainable building strategies.

By addressing these limitations and pursuing future developments, the integration of green buildings and BIM can be further optimized, contributing to the advancement of sustainable development in the construction sector.

ABSTRACT: *Researchers have long focused on disaster resilience to mitigate calamity disruption. Disaster resilience is a complex and multi-faceted concept that is challenging to measure. Quantitative methods have traditionally been used to assess disaster resilience, but a growing interest in qualitative methods like open-ended interviews has emerged to understand experiences and perspectives. To gain deep and consistent knowledge, an open-ended interview should focus on an interviewee's point of view and ask follow-up questions from a knowledge base that consists of relevant information; otherwise, this can lead an open-ended interview to deviate from the interviewee's point of view to the interviewer's point of view. In contrast to what is desired, individual interviews with last year's students in the field of civil engineering with a predefined and limited knowledge base demonstrated inconsistency in asking a follow-up question from an already existing open-ended interview. To tackle this gap, firstly, we suggest a knowledge base that can be built from peer-reviewed papers published in the disaster resilience field; secondly, we suggest a Natural Language Processing based Decision Support System using Sentence Embedding that can analyze the interviewee's response and find resources from the knowledge base to assist the interviewer in making a consistent follow-up question.*

KEYWORDS: *Disaster resilience; Decision support systems; Open-ended interviews; Knowledge management; NLP*

1. INTRODUCTION

Disaster resilience is a critical aspect of construction technology that plays a pivotal role in mitigating the impacts of various natural and human-induced hazards on built infrastructure (Malalgoda, Amaratunga, & Haigh, 2014). In recent years, there has been an increasing emphasis on enhancing disaster resilience in the construction industry due to the rising frequency and intensity of disasters worldwide (Harrison & Williams, 2016). Ensuring the resilience of constructed facilities not only safeguards public safety but also minimizes economic losses and facilitates rapid recovery in the aftermath of disruptive events (Ouyang, Dueñas-Osorio, & Min, 2012).

The challenges posed by disasters necessitate a comprehensive understanding of the factors influencing resilience in the context of construction projects. Traditional research methodologies, such as closed-ended interviews and surveys, have been instrumental in gathering valuable data on disaster resilience (Cai et al., 2018). However, these methods often fall short in capturing the full depth of participants' experiences and viewpoints, leading to potential biases in data collection.

The specific research objectives of this paper are as follows:

1. To investigate the impact of consistency in open-ended interviews on disaster resilience measurement within the disaster resilience domain.
2. To develop and implement advanced Natural Language Processing (NLP) based Decision Support System (DSS) with sentence embedding techniques to enhance data collection in open-ended interviews.
3. To create a knowledge base that aggregates and organizes peer-reviewed papers and experts' insights related to disaster resilience in construction projects.

The research questions guiding this study are:

Research Question 1: How does consistency in open-ended interviews influence the reliability and depth of data collected for disaster resilience measurement in construction technology?

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Milad Katebi, Mani Poshdar, Mostafa Babaeian Jelodar, Morteza Zihayat, *Enhancing Disaster Resilience Studies: Leveraging Linked Data and Natural Language Processing for Consistent Open-Ended Interviews,* pp. 998-1009, © 2023 Author(s), CC BY NC 4.0, DOI 10.36253/979-12-215-0289-3.100

Research Question 2: Can leveraging NLP and sentence embedding techniques enhance the contextual relevance of follow-up questions in open-ended interviews within the construction technology domain?

Research Question 3: How does the proposed decision support system, empowered by the knowledge base, improve data collection and analysis in open-ended interviews on disaster resilience in construction projects?

This paper addresses the significance of consistency in open-ended interviews concerning disaster resilience measurement within the domain of construction technology. We recognize the limitations of conventional interview techniques and aim to enhance data collection by leveraging advanced NLP and sentence embedding techniques. By utilizing a knowledge base of relevant topics in the field of disaster resilience, our proposed approach generates contextually relevant follow-up questions that align more closely with the interviewee's point of view.

The contributions of this work are threefold. In this research, first, we demonstrate the existent level of inconsistency in disaster resilience measurement domain. Next, we introduce a knowledge base that aggregates and organizes peer-reviewed papers and experts' insights in the mentioned domain. This knowledge base empowers our decision support system to identify and generate pertinent follow-up questions for interviewees, facilitating a more nuanced understanding of their perspectives. Last, we leverage state-of-the-art NLP and sentence embedding techniques to ensure the semantic similarity between the interview responses and the knowledge base, enabling a more accurate assessment of disaster resilience.

Using a decision support system is one method of reducing cognitive errors. To help people with complicated decision-making tasks, DSSs offer tools and cognitive aids, minimizing reliance on memory and cognitive processes alone (Arnott, 2006). DSS assists people in avoiding biases, mistakes, and oversights that may result from impaired cognitive function or flawed heuristics by offloading cognitive burden and offering organized advice. Such decision support systems can be implemented and used to improve human performance and decision outcomes in a variety of domains.

In the following sections, we detail our methodology, including the data collection process, the implementation of sentence embedding and NLP algorithms, and the evaluation of our decision support system. We also present the results of our experiments and discuss their implications for the construction technology field. Ultimately, we believe that our approach holds great promise in improving the consistency and depth of data collected from open-ended interviews, thereby advancing the measurement, and understanding of disaster resilience in construction projects.

2. LITERATURE REVIEW

As discussed, interviews serve as the primary data gathering method for disaster resilience measurement. Moreover, open-ended interviews offer valuable insights into individuals' perspectives; however, the variation in follow-up questions among different interviewers can lead to inconsistency and reduced reliability of data gathered. This section examines the focus of existing solutions in various domains, particularly in healthcare, where NLP has been applied to assist in decision-making processes. Additionally, the lack of existing any DSS that utilizes NLP to aid in interview processes within the domain of disaster resilience will be highlighted.

The literature review section follows a systematic literature review process as described by (Y. Xiao & Watson, 2019), with step-by-step details presented in Fig. 1. The literature review commenced by defining a set of keywords, namely (NLP OR (natural AND language AND processing)) AND (dss OR (decision AND support AND system*)) AND interview to cover the scope of our research. Wildcard characters and special terms were employed to identify relevant papers. The keywords were used to search in the abstract, keywords and titles of peer-reviewed papers. The search yielded 32, 8, 3, and 11 papers from Scopus, IEEE, ScienceDirect, and PubMed databases, resulting in a total of 54 papers. By following Fig. 1, the reasoning and numbers of each step is discussed.

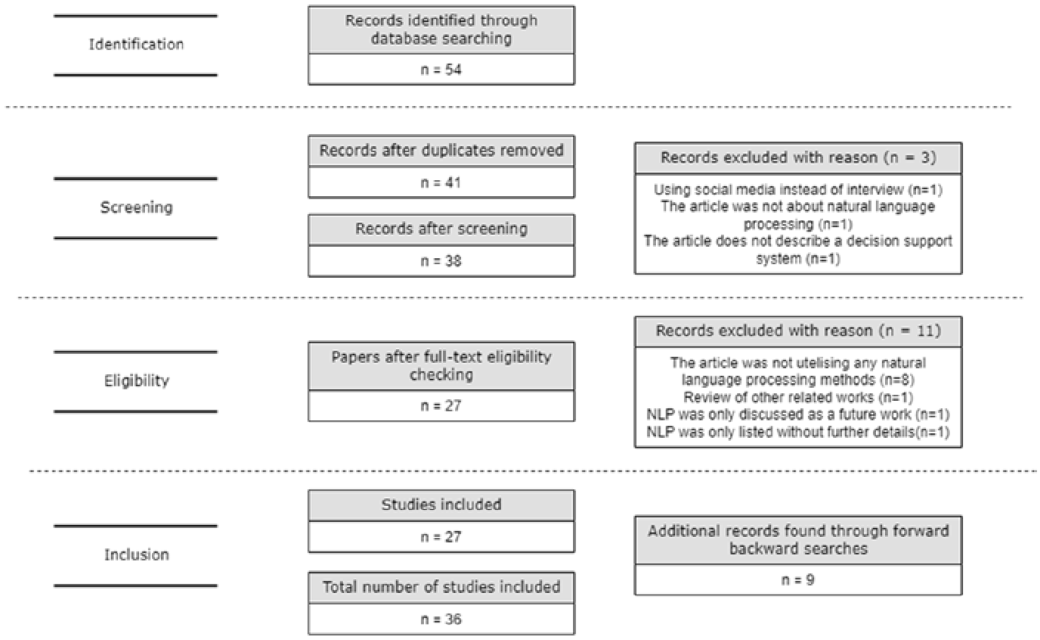

Fig. 1: Literature review's strategy applied by following Xiao's systematic literature review process (Xiao and Watson 2019).

The list of selected papers, along with their domain classifications, is presented in Table 1. The classification was done by finding relevant keywords to a specific field that an NLP based DSS was designed for. The classification categories included healthcare, engineering, HR, law, and business domains. Healthcare classification was related to any health-related papers and engineering ones were the papers mostly focusing on engineering fields like mechanical engineering, constructions, and related topics. Any paper within the concept of law, court, and advocacy sat within the classification of law leaving HR related ones for hiring related topics and the only business one addressing an NLP based DSS within an enterprise.

Fig. 2 illustrates the distribution of covered domains, with healthcare prominently represented. While other domains are gaining attention, healthcare remains the dominant focus in NLP-based DSS research. Of particular significance, the inclusion of disaster-related keywords in our search strategy consistently yielded zero papers, underscoring the absence of NLP-based DSS designed for disaster-related open-ended interviews. Hence, this paper addresses the imperative need for such a system and provides a solution to bridge this gap in research.

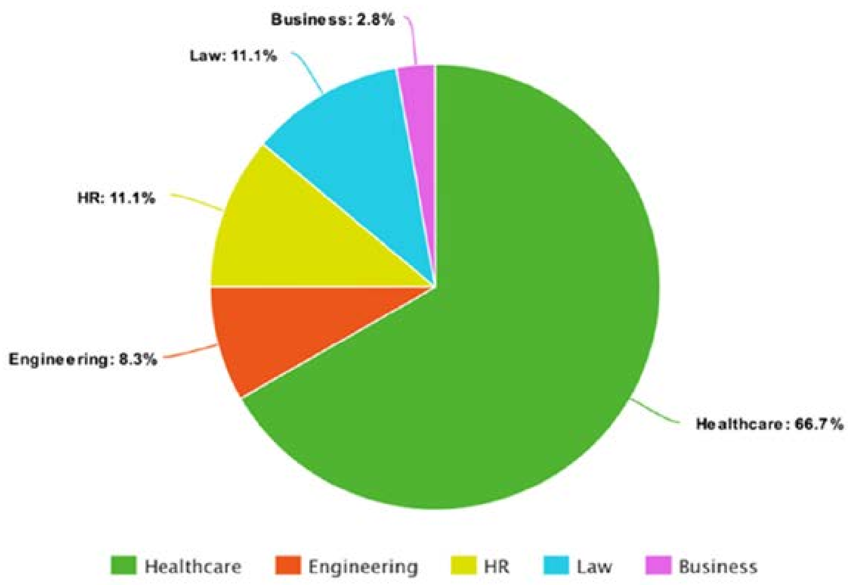

Fig. 2: Percentage of papers using NLP for DSS by domain.

3. METHOD

This paper introduces a two-stage design aimed at enhancing disaster resilience open-ended interviews. Initially, open-ended interviews were conducted with selected participants using a limited knowledge base. Each participant was provided with two open-ended questions along with their respective answers. The participants were then asked to generate follow-up questions based on the provided knowledge base. This stage aimed to assess the current level of discrepancy in existing open-ended interviews. The second stage presents our designed framework, an assistant tool, aimed at enhancing the open-ended interview process. This framework incorporates a modifiable and decent-sized knowledge base. Additionally, we propose the utilization of an NLP technique to facilitate the decision-making process by offering suggestions to the interviewer.

Ideally, a follow-up question should align with both the knowledge base and the interviewee's response, unaffected by any other factors. In this scenario, the interviewer's role is that of a mediator between the knowledge base and the interviewee. Nonetheless, as highlighted by (Gluyas & Morrison, 2014) "human beings are error prone, and the flaws are inherent in human cognitive processes, which are exacerbated by situations in which the individual making the error is distracted, stressed or overloaded, or does not have sufficient knowledge to undertake an action correctly". In this paper, this cognitive error is referred to as Interviewer's Perception. In Fig. 3, which is our perception of Jameel's design for an open-ended interview (Jameel, Shaheen, & Majid, 2018), the interviewer's perception can be seen as the extra factor highlighted in red which should either be eliminated or reduced to certain degree for data collection to be more reliable.

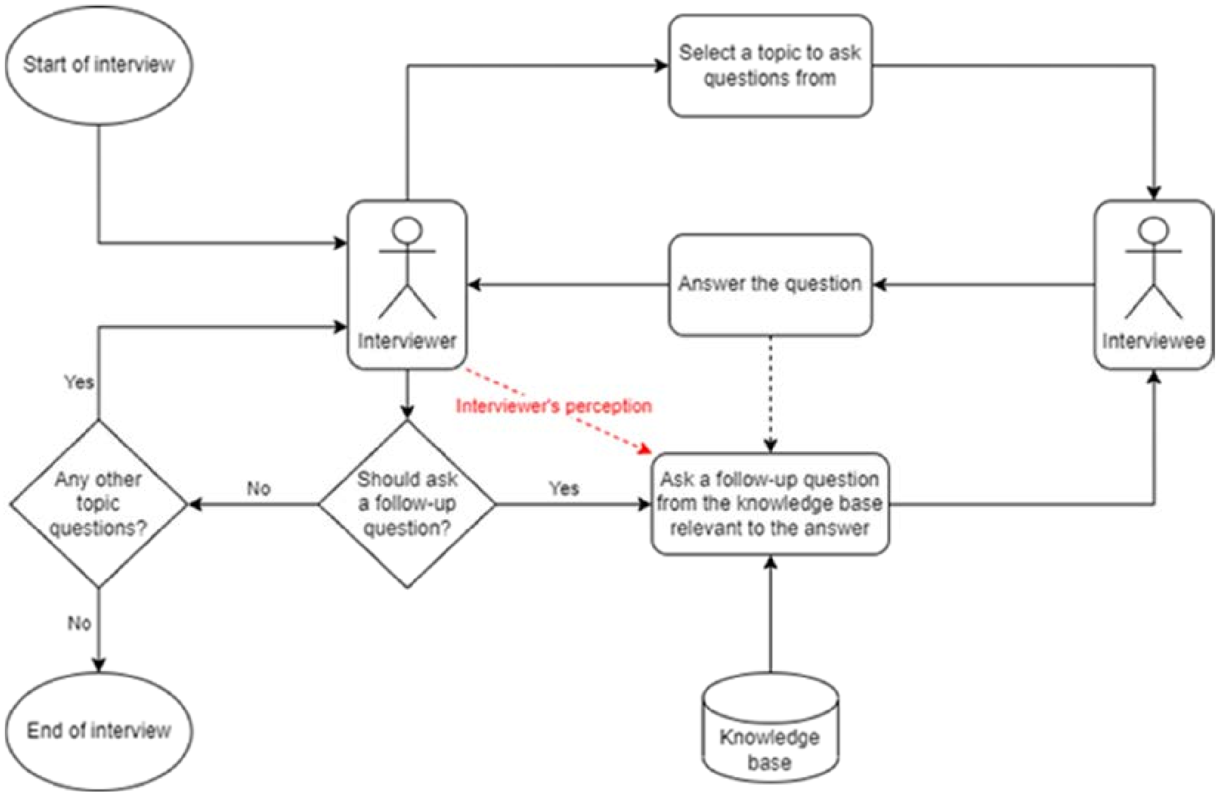

Fig. 3: Process of an open-ended interview based on our perception from Jameel's work (Jameel, Shaheen, & Majid, 2018)

An interview was strategically designed to assess the impact of interviewer's perception on the process of asking follow-up questions during open-ended interviews in the domain of disaster resilience measurement. The interview protocol comprised the following steps:

- Participants: Thirteen students with civil engineering academic backgrounds were recruited for the study. Population sample size was determined based on the number of papers published in 2022 with the keyword "open AND ended AND disaster* AND resilient*" in Scopus, which yielded thirteen papers. The Cochran's formula for small population sizes was applied with a confidence level of 95% resulting in a sample size of 13 (Nanjundeswaraswamy & Divakar, 2021).
- Interview protocol: Two sets of open-ended questions with answers were developed to elicit rich data of decision-making in open-ended interviews of disaster resilience measurement. The interview protocol included prompting the participants to elaborate on their responses and give reasoning for their decision-making thoughts. Each student is supposed to select two topics for each set of open-ended questions.
- Knowledge base: A specific knowledge base for the research domain was created by selecting the top twelve topics of peer-reviewed papers from Scopus, aligning with the keywords used in the open-ended questions in step 2. The topics were directly extracted from the papers. The purpose of the knowledge base was to enhance the interview process by narrowing down the choices for follow-up questions and reducing the need for students to possess prior knowledge for asking such questions.

3.1 Analysis

In our structured interview design, we recognize the practical constraints of interviewers reviewing numerous options during the interview process. As a result, we restricted the number of topics to a manageable dozen for each question. Each topic is supposed to cover a chain of thoughts from the interviewee's point of view. However, acknowledging that a dozen topics present limitations, it becomes evident that such a limited number may not encompass every potential point of view expressed by interviewees during an open-ended interview. In practice, a more substantial number of topics would be necessary to encompass a broader range of existing knowledge and adequately cover an interviewee's perspectives. Conversely, with a larger knowledge base, the probability of each choice being seen and selected diminishes.

To calculate the probability, we can use the complement rule. To calculate the probability of selecting at least one topic in two chances equals to the complement of not selecting a topic in two chances. If we consider the number of topics as n, the probability of not selecting a topic in one chance is (n-1)/n, and the probability of not selecting a topic in two chances is $(n-1)/n \times (n-2)/(n-1)$. Using the complement rule, the probability of selecting at least one topic in two chances can be calculated as (Lefebvre, 2009):

$$Probability\ of\ a\ topic\ selection\ in\ two\ chances\ (PTS) = (1 - (n-1)/n \times (n-2)/(n-1)) \times 100$$

Simplifying further:

$$PTS = \left(\frac{n}{n} - \frac{n-2}{n}\right) \times 100 = \frac{200}{n} \qquad (1)$$

Considering our interview scenario with only a dozen topics, the rounded value of Probability of Topic Selection (PTS) is 16.67. Obviously, the greater the n, the lower the probability of a choice to be selected and with only two topics, each of them will have the probability of 100% to be selected. Let us now examine the selection process from the knowledge base, which is executed by the interviewer to choose a follow-up topic.

In the perfect scenario, we would assume that every student only selected a pair of topics and no other topics for the follow-up questions. However, in case of reality, which probably differs from the perfect scenario, we will consider the most selected choice added to the second most selected as the probable answer and the number of times that they were selected as PA and number of times that other choices were made as SC. Thus, we can simply calculate the ratio of discrepancy by using the following formula:

$$Discrepancy\ Ratio\ (DR) = SC/(PA + SC) \times 100 \qquad (2)$$

A lower DR indicates a closer approximation to a perfect interview with minimal errors, approaching a DR score of zero. Since we had two sets of questions, we measured them both separately and reported the result with the average of them DRs as we put an equal weight on each of the questions. The maximum value of DR can only be achieved if each topic for follow-up question topic is selected exactly once or twice. In this case, PA will be equal to 6 (3 for the most selected plus 3 for the second most selected choice) and SC will be equal to total number of votes which is 26 (13 students and each of which could select 2 topics) minus the rest of the votes which is 20. By applying the formula, the result will be 77%. 77% error is a significant value that can impact data collection; thus, measuring DR in a real-case scenario is important and furthermore it implies the significance of this study. It should be noted that the value of DR can fluctuate between 0% to 77% with the median of 39%.

In order to comprehensively assess an interview's thoroughness, consistency, and the presence of discrepancies in the selection of follow-up question topics, we have devised a novel metric. This simple metric involves the multiplication of PTS and DR, with lower values indicating a more valid and reliable interview. We term this metric 'Interview's Inconsistency Mark' and it is calculated as follows:

$$Interview's\ Inconsisteny\ (IIC) = (PTS\ \times DR)/100 \qquad (3)$$

The reason that we multiply the values is the importance of DR being zero. It means that if the two obvious topics will be selected, it doesn't matter what is the probability of each topic. Considering our designed interview, the Interview's Inconsistency (IIC) can vary between zero and 12.84 (approximately 13). An IIC value of 13 indicates an interview with highly unreliable data gathering due to inconsistencies in the interviewer's follow-up questioning.

4. FINDINGS

In this section, the obtained results from the interview described in the previous section will be reviewed. The outcome of this interview provides insights into the practical aspects of conducting open-ended disaster resilience measurements by various interviewers. The interview, which simulates a real-case scenario of open-ended disaster resilience measurement, can demonstrate how significant inconsistencies can be in real-world, further implying the need of our designed decision support system. Furthermore, an exemplified DR value will be presented to facilitate a comprehensive understanding and performance comparison of our devised framework. Additionally, our framework will be introduced, aimed at assisting interviewers in formulating more consistent follow-up questions during open-ended disaster resilience interviews.

Prior to delving into the interview results and our framework, an essential concept gleaned from the literature review emphasizes the significance of a robust knowledge base during interview processes. In qualitative and open-ended interviews, interviewers are more adept at formulating relevant questions when equipped with pertinent information and prior knowledge of the subject (Kallio, Pietilä, Johnson, & Kangasniemi, 2016). As the interviewee sees the interviewer as educated and well-prepared, it aids in building trust and rapport. A strong knowledge base also enables the interviewer to go into complex subjects in more depth, pose probing questions, and elicit perceptive responses. This in turn aids in the collection of reliable data during interviews. Therefore, it is essential for interviewers to have access to a broad knowledge base which for instance, it is made from literature reviews, professional consultations, and in-depth studies to conduct effective and relevant interviews.

In addition to a solid knowledge base, interviewers must exercise caution when posing follow-up questions to avoid making arbitrary assumptions. Follow-up questions serve the purpose of elucidating or further examining specific aspects of the interviewee's response. However, by phrasing their follow-up questions based on their own beliefs or preconceived notions, interviewers unwittingly introduce bias or influence the interviewee's answers (Hunt, 2009). The objectivity and dependability of the interview data may suffer as a result. Interviewers should approach follow-up questions with an open and impartial mindset, allowing the interviewee's perspective to guide the dialogue and mitigate potential bias. Interviewers can foster a more accurate and thorough grasp of the interviewee's experiences and opinions by actively listening, refraining from asking leading questions, and keeping conscious of personal biases. Referring to Wreathall, the skill of avoiding cognitive human errors in such decision making can be achieved by investing a lot of time and effort and they need constant investment (Wreathall & Reason, 1992).

4.1 Findings from the conducted interview

In our designed interview, the first question, the first question yielded 11 and 7 selections for the most and second-most preferred choices, respectively. This implies a Disaster Resilience (DR) value of 30.77, and with the pre-calculated PTS value of 16.67, the Interview's Inconsistency (IIC) equals 5.13, indicating a moderate level of discrepancy within the range of 0 to 13. On the other hand, in our second designed interview, we obtained 12 and 9 selections for the most and second most selected choices. Upon applying the formulas, we derived an IIC of 1.35 representing a favorable level of data reliability and reduced inconsistency within the range of 0 to 13. These results indicate values falling within the lower half of the normal distribution (between 0 and 13) concerning real-world open-ended disaster resilience measurement interviews. However, this does not negate the possibility of encountering discrepancies near values such as 5.13, which align with the median value of 6.5. While these numbers serve as indicators, they emphasize the need for caution regarding inconsistency, which can potentially undermine the validity of the collected data.

4.2 Our proposed framework

To address this concern, our designed framework incorporates two essential steps. First, a knowledge base which has enough knowledge related to disaster resilience for the moment that an interviewee gives an answer to a question and the interviewer needs to ask a follow-up question from it. Second, a decision-making technique for a follow-up question selection from the designed knowledge base.

Historically, an interviewer's prior knowledge has been primarily regarded as the knowledge base. This has been one of the roots causes where we detected the inconsistency of open-ended interviews in disaster resilience measurement exists. Therefore, our primary objective in designing the framework was to establish a comprehensive knowledge base. We have identified two primary avenues for obtaining information: the existing literature on disaster resilience measurement and the expertise of disaster resilience measurement specialists. Given the considerable effort required to access and elicit knowledge from diverse experts, we deemed the first option more feasible. We opted for Scopus as our literature database, utilizing automation to extract all relevant peer-reviewed papers based on specific keywords pertaining to open-ended questions in the field of disaster resilience measurement. This automation allows us to expand beyond a limited number of topics to access thousands of thoroughly researched papers, ensuring a reliable and extensive knowledge base. During our preliminary tests of the automation system, we successfully retrieved a maximum of 1500 peer-reviewed papers for each set of question keywords that were given to the students in our conducted interview. To run queries against the knowledge base, we indexed the knowledge base with Anserini's Information Retrieval library for Python, called Pyserini, that has a low latency for information retrieval (P. Yang, Fang, & Lin, 2017). As a result, the PTS value from formula 3.1.1 equates to 0.13, implying an extremely low probability of a topic being selected from a knowledge base of this magnitude, assuming equal weightage for each topic. Conversely, this approach instils a higher confidence level in our knowledge base, encompassing a diverse range of topics that interviewers can choose from, aligning more closely with the interviewee's perspective.

In the context of decision-making techniques and drawing from relevant papers in the literature review section, we propose a methodological approach that utilizes Sentence Embedding techniques to generate follow-up questions aligned closely with the interviewee's perspective. Sentence Embedding is an NLP problem that deals with identifying text that have similarities based on context, meaning and subject etc. based on which classification, generation, syntactic parsing etc. of the text can be done (Ryu, Kim, Choi, Yu, & Lee, 2017).Given this definition, it becomes evident why this technique captured our interest. Combined as one of the most recent advancements in the field of NLP, it considers a sentence as a whole and find similarities, which in our case, sentence embedding plays the role of an interpreter in finding similar topics from a knowledge base of relevant topics in the domain of disaster resilience. To query the indexed knowledge base, we used T5 doc2query since it has the primary advantage of low retrieval latency, keeping an open-ended interview's follow up question generation to be in real-time (Nogueira, Yang, Lin, & Cho, 2019). We utilized cosine similarity to measure semantic similarity between the embeddings. The top one percent of highest-ranking topics were made available for the interviewer's selection. With these considerations, assuming a population of fifteen interviewers using our decision support system, and the algorithm identifying 1500 topics for a follow-up question, with a selection of two topics from the top one percent (15 topics), the resulting DR value could range from zero to 86.67. Although we analyzed 1500 topics, we did not observe significant progress in terms of DR. Nonetheless, it is essential to acknowledge that the user can modify the one percent value, and 1500 topics represented one of the highest feasible retrieved numbers from Scopus. Nevertheless, the IIC value from formula 3.1.3 in this context will vary between zero and 0.11, which stands in stark contrast to the actual interview with an IIC of 5.13, and even the lowest recorded case with an IIC value of 1.35, as well as the worst-case scenario with an IIC value of 13. The minimal fluctuation achieved represents a significant level of consistency for future open-ended interviews in the domain of disaster resilience measurement.

4.3 Conclusion, future works and limitations

In this article, we demonstrated the significance of consistency of open-ended interviews in the domain of disaster resilience measurement. Furthermore, with a methodological approach, we aimed to address the potential limitations of open-ended interviews by utilizing sentence embedding techniques and introducing a knowledge base to generate contextually relevant follow-up questions. By leveraging sentence embedding techniques and a knowledge base generated from peer-reviewed papers, our approach enables interviewers to gather more comprehensive and contextually relevant data during open-ended interviews. This enhanced data collection process leads to a deeper understanding of participants' experiences and viewpoints, facilitating better-informed decision-making for disaster resilience measures in construction projects.

Moving forward, potential avenues for future research and development include expanding the knowledge base by involving experts to review and contribute their insights. Additionally, continuous advancements in Natural Language Processing (NLP) algorithms offer opportunities to improve the performance and efficiency of the sentence embedding technique used in our system. Further research can explore the integration of additional data sources and domains to enhance the decision support system's versatility and applicability in diverse construction technology contexts.

ABSTRACT: *Semantok Dam located in Semantok River Stream, Nganjuk District, East Java. Dominated by lowlands and mountains, the 1900-hectare fertile agricultural land will be irrigated by this nominated "The Longest Dam in Southeast Asia". The construction of this three kilometers long dam requires enormous resources of rockfills as the dominant material to build the main dam body. While the process of excavation, mobilization, and material settings are the dominant contributor aspects of the project's carbon footprint, at the same time this project encounter a challenge on insufficiency of existing quarry. This situation drives a comprehensive strategy not only to find the most efficient and accessible material, but also to minimize and mitigate environmental damage, ultimately by reducing the material carbon footprint. Thus, an innovative engineering solution is applied to overcome this challenge such as utilizing the available material in surrounding project site which is random rock soil by using geotechnical analysis tools for design optimization and material usage simulation also collaborating with Building Information Modeling (BIM) to visualize and calculate the estimated cost. Eventually, this analysis plays a big role in ensuring the environmental sustainability in an infrastructure project by deciding the appropriate alternative which produce the least carbon emission.*

KEYWORDS: *BIM, Carbon Footprint, Engineering Analysis, Resource Management, Sustainability*

1. INTRODUCTION

Embodied carbon represents the million tons of carbon emissions released during the lifecycle of infrastructure building materials; including extraction, manufacturing, transport, construction, and disposal. Concrete, steel, and insulation are all examples of materials that contribute to embodied carbon emissions [1]. Furthermore, other activities like excavating and earthmoving materials like rocks, soil, sand, and other similar substances can also significantly contribute to embodied carbon emissions especially when used in large volumes. The buildings and construction sector accounted for 36% of final energy use and 39% of energy and process-related carbon dioxide (CO_2) emissions in 2018 [2]. Global buildings and construction sector emissions increased 2% from 2017 to 2018, to reach a record high, while final energy demand rose 1% from 2017 and 7% from 2010. Increases were driven by strong floor area and population expansions [2].

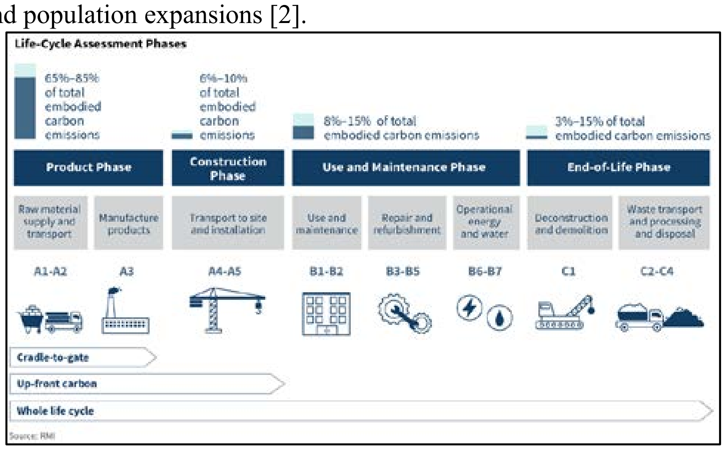

Fig. 1: Life-Cycle Assessment Phases of Embodied Carbon Emission in General Building
Source: RMI

While infrastructure buildings sector efficiency improvements continued to be made, they were not adequate to outpace demand growth. 2020 is a key year for countries to enhance their Nationally Determined Contributions (NDCs), especially concerning further actions to address energy use and emissions including embodied emissions in the buildings and construction sector [2]. Countries are innovating and implementing measures to improve efficiency and reduce emissions from their building stock. As sharing effective measures globally would amplify

their impact, regional roadmaps are being developed for this purpose [2].

Indonesia seriously and consistently continues to conduct its commitment to address climate change through Low Carbon Development Planning (PPRK) [3]. PPRK is a strategic transformation of the National Action Plan for Reducing Greenhouse Gas Emissions (RAN-GRK) program as stipulated in Presidential Regulation No.61 Year 2011 [3]. As a form of consistency in efforts to address climate change, the issue is one of the national priorities that becomes a cross-cutting program in the 2015-2019 National Medium-Term Development Plan (RPJMN) document. President Joko Widodo has delivered a commitment at the UN Climate Change Conference (COP21) in Paris, France, on 12 December 2015, which is to reduce emissions by 29% (Fair scenario / using own capabilities) and by 41% (ambitious scenario / if you get international support) [3]. The commitment was ratified through Law No.16/2016 on the Ratification of the Paris Agreement to the United Nations Framework Convention on Climate Change [3]. Aligning with these commitments, Indonesia's efforts directly support the objectives of the United Nations Sustainable Development Goals (SDGs), specifically SDG 13, which is "Climate Action." By focusing on Low Carbon Development Planning and reducing greenhouse gas emissions. By synchronizing its national strategies with global sustainability targets, Indonesia not only demonstrates its dedication to combatting climate change domestically but also champions a collective global responsibility.

Carbon emissions mitigation in the construction sector is not easy. The adoption of digital construction technologies emerges as a potent strategy to mitigate carbon emissions in the construction sector. Leveraging digitalization allows architects, engineers, and stakeholders to collaboratively refine building designs, emphasizing energy efficiency. Energy efficiency could be achieved through several things, such as insulation, natural lighting, and heating and cooling systems, effectively diminishing a building's carbon output over its entire lifecycle. Digital engineering improvements such as reducing waste and promoting the selection of materials through good planning can reduce carbon footprints. Hence, embracing digitalization not only signifies technological progression but also propels industry towards the broader objective of environmentally sustainable construction and reduced carbon emissions.

2. BACKGROUND OF STUDY

The construction industry is faced with challenges such as project delays, over budget costs, quality issues, and environmental concerns. Digital construction technologies such as engineering analysis, digital survey tools, Building Information Modelling (BIM), and Geographic Information System (GIS) are proposed as a solution to these problems. The integration of those technologies plays a big role in optimizing productivity in project construction and to ensure engineering validation accuracy. The data which was given by the planning consultant will be validated so it can be executed on the field. Initial mapping is processed using digital survey tools. The mapping results are used as a basis for the BIM reality model to aid the design team gain a better understanding of the project's characteristics. Furthermore, the use of BIM enables real-time monitoring and simulating through the entire building life cycle process. GIS is utilized to enhance decision-making for continued management monitoring, reducing all risks that could arise throughout the project execution phases.

According to the Indonesian Public Works and Housing Ministry's Regulation No. 9 of 2021 on sustainable development guidelines, the implementation of BIM is mandatory. BIM facilitates the visualization of plans and their execution, ensuring a consistent interpretation amongst all stakeholders, thereby minimizing the potential for errors or misunderstandings. Although the design process is usually established at the beginning there are often real project conditions that do not match the initial design, which triggers design changes. BIM plays a crucial role in speeding up the analysis of these design alterations. With the acceleration of this decision-making process, BIM also contributes to cost and time efficiency.

Besides all the benefits that can be provided by BIM tools, to boost the impact on calculating carbon emissions on a construction project, the data produced by BIM should be integrated with comprehensive analytical calculations to ensure the carbon footprint is determined in a scientifically accurate way.

Completely eliminating carbon emissions in a project may not be an option, but the project management can control and minimize these emissions through responsible selection of materials, designs and working methods. Before making these choices, it is important to assess the impact of each option. Thus, the most effective options can be selected and implemented in the field.

This study aims to compare the embodied carbon contained in the initial design of an infrastructure project and the alternate design after validating the latest situation on the project site. The necessity for this comparison arises from differences in the field conditions, particularly the availability of materials, which did not align with the conditions assumed in the initial design.

3. PROJECT OVERVIEW

The Semantok Dam Project is one of the National Strategic Projects in Indonesia, located in the Semantok River Stream, Nganjuk District, 115 km West of the Surabaya City, East Java. The Semantok Dam's primary objectives are to lessen flood discharge and assure water availability on its coverage area during both the rainy and dry seasons due to the intense annual rainfall. The terrain of the Nganjuk district is dominated by the lowlands and the mountains, making the soil condition fertile for cultivating plants. Semantok Dam will irrigate the 1900-hectare coverage agricultural area in Nganjuk District where its existence expected to boost agricultural productivity from 186.33% to 300%. Moreover, the presence of this dam will be the new tourism destination in East Java Province.

The construction cost of this project reaches 87.9 million USD covering dewatering process, main dam, spillway, intake channel, facility building, geotechnical and hydromechanical works. With the total main dam's length of 3.1 km and height of 31.56 m, Semantok Dam is claimed as "The Longest Dam in Southeast Asia". The total capacity of the main dam is approximately 33 million m^3. The length of Semantok's spillway is 62.69 m with overflow discharge of 574.54 m^3/second. While the length of the dam's intake is 16.38 m with the tower dimension of 1.75 x 1.75 m using reinforced concrete.

According to the initial design, rockfills were used as the primary material for the dam. However, the rockfills quantity was insufficient in the existing quarry. Therefore, two alternatives were solving the problems. Firstly, choosing a new quarry where rockfills are available, but it would drive a significant cost addition and wellness issue for the surrounding society. Secondly, using the available materials in the existing quarry, which was random soil. Considering the environmental matters, Hutama Karya, as the lead contractor, validated the cost, time, and environmental implications and preferred to use random soil as the primary materials. However, a slope redesign was required, as the strength of random soil was below that of the rockfills.

4. JUSTIFICATION DESIGN

Before the construction of the dam began, Hutama Karya as the lead contractor initiated an advanced design study to ensure the feasibility of the initial design, which would then be adapted based on current field conditions. This study included a preliminary geological investigation of the construction site and a review of the dam body's zoning design, adjusted for the availability of fill materials. The consultant engineers initially developed a grouting system as the foundation for the main part of dam, however, Hutama Karya discovered the brittle and loose sandy soil layer would cause persistent water leaks over the maximum amount permitted. Hutama Karyaneeded to undertake soil analysis to determine alternative design methods and ensure the dam would be strong enough to contain water from intense rains without flooding. The results from the initial geological investigation of the construction location differed from the initial planning design, necessitating further studies into the dam foundation repair plan.

The Bendoasri and Teritik Quarry are still on the planning stage. In the initial design provided by the consultant engineers, the zoning of the dam body is an upright core type with rockfill. However, based on the results of the initial geological investigation on construction phase, the two quarries did not have sufficient stone material available. The quantity/volume of stone material availability was quite limited, on contrary random soil material was abundant. The plan became difficult to accomplish, as the nearby quarry could not produce enough rock for the long dam without deep damaging excavation. Another option is digging a new quarry for the site, but that would be costly.

The insufficiency of rockfills in the existing quarry is one of the biggest matters in the Semantok Dam Project. Due to environmental and material availability considerations, the project team replaced the rockfills with random soils – available material in the fields. However, the random soil strength was below the rockfills. The insufficiency of rock created risk to potentially redesigning the dam slope. Engineering analysis software was utilized to model the material replacement and verify whether the initial slope design was still applicable in the fields.

In the beginning, Hutama Karya tried to model the random soil in the initial design and found that the safety factor of the slope (1.183) was below the minimum requirements (1.302) and showing that the slope was inapplicable. Thus, with engineering analysis software, a process of trial and error was undertaken to find the safest and most optimized design. As a result, the assessment indicated that the slope should have a steeper incline of 1:3 on the left side and 1:2.75 on the right side to produce the safety factor of 1.644, which fulfilled the minimum requirements. Not only did solve the problems, but also able to gain more value in terms of materials and method efficiently. Hutama Karya was able to avoid 1.8 million USD of reworking by renewing the slope design.

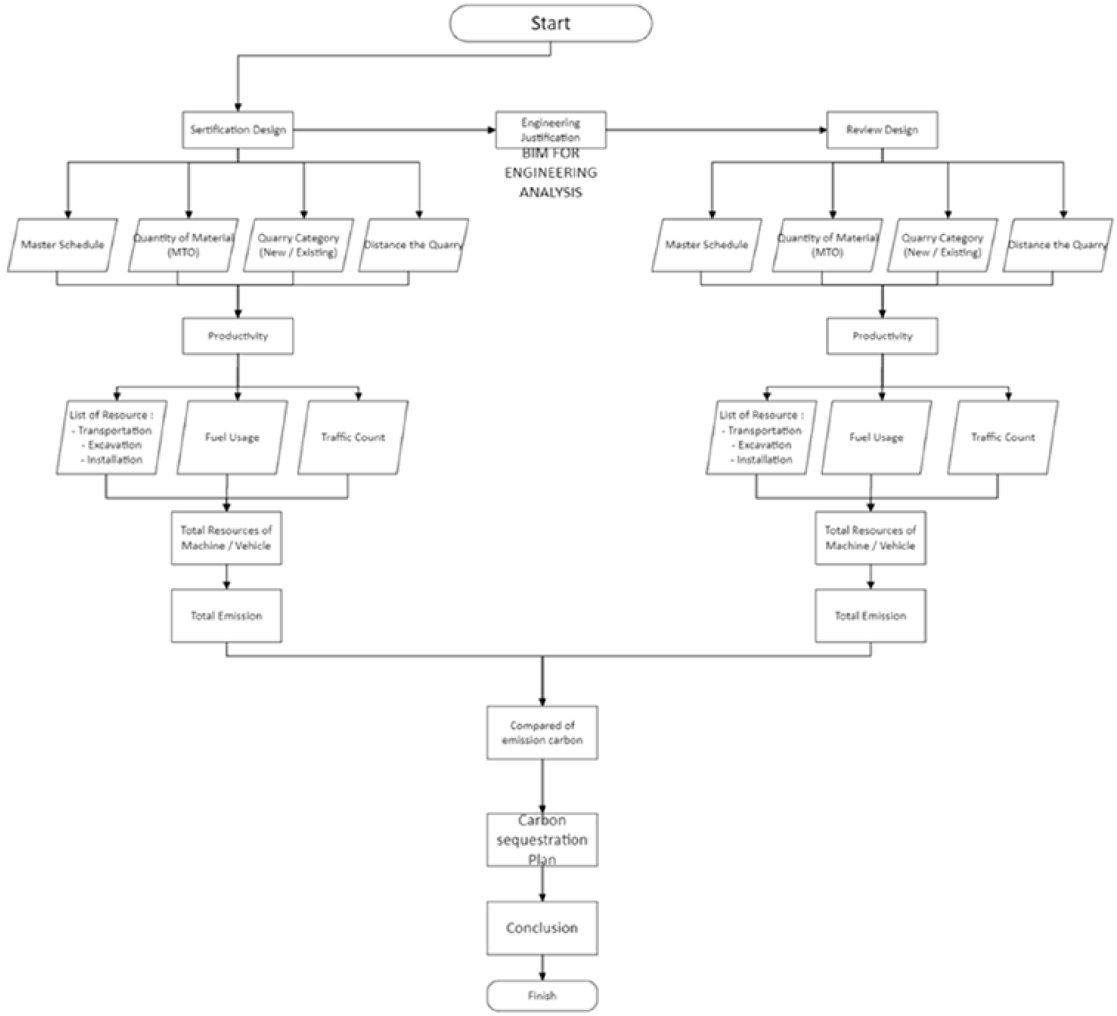

Fig. 2: Calculation Flow

5. LIMITATION OF STUDY

This study will focus on emphasizing the calculation of the carbon footprint arising from design changes because of engineering justification using Building Information Modelling (BIM) & engineering analysis software. In this context, the case that becomes the focus point is the change in the selection of the main material used in the construction of the dam body.

This process of calculating the carbon footprint does not cover all aspects of construction, but rather focuses on some essential elements that are directly affected by changes in design. These aspects include the creation of a new quarry which is the main source of construction materials, the distance of material delivery from the quarry to the construction site, the number and type of equipment used in material delivery and the construction process itself.

Therefore, this study aims to provide a clear and comprehensive picture of how design changes using BIM and engineering analysis software can affect the carbon footprint in construction projects and provide a foundation for more informed and sustainable decision-making.

6. CALCULATION METHODS

This Figure shows the flow of study methods.

In this study, as illustrated in Figure 2, the calculation method involves comparing two distinct scenarios. In the first scenario, we consider the initial design or Design Certification, which upon implementation, has been found lacking in terms of material sufficiency. The available quarry is incapable of providing the necessary quantity of materials, leading to the need for another quarry that is considerably distant from the project site.

The second scenario maintains the usage of the first quarry that planned available material, in proximity to the project site but demands alterations in the design, necessitating recalculations and technical justifications. The changes are to ensure that the local materials meet the specifications required for dam construction. But the first quarry was originally a pine forest area, so the utilization of the quarry will require land conversion, also calculate how much carbon stock is lost and how many trees were cut down to facilitate reforestation after construction finished.

Data is collected for both scenarios, including the quantity of materials needed per the initial and revised designs, the dam project completion schedule, and the distance between the quarry and the project site. From these data, we can establish productivity targets for the work, thus enabling the detection of resource requirements.

After determining the necessary equipment, the next step is to calculate fuel consumption during the construction process for each heavy equipment used. Once the total fuel used is determined, this amount is then converted to a form of energy. Energy conversion from the use of diesel fuel to other forms of energy is an average of 38.243 MJ/Liter or 38.243 x 10^-6 TJ/Liter. After being converted to a form of energy (TJ), the next step is to calculate the resulting carbon emissions. To calculate this, we use a formula derived from the IPCC Guidelines for National Greenhouse Gas Inventories (2006).

$$Emission = \sum_{j}^{n} \left(Fuel_j \times EF_j\right) \quad \text{(1)}$$

Where:

Emission = Total of Emission (Kg)

Fuel = Fuel Consumed (TJ)

EF = Emission Factor (Kg/TJ)

j = Fuel Type

For the type of fuel, all heavy equipment used uses diesel oil. The emission factor for the type of diesel oil fuel is 74,100 Kg/TJ, as shown in Table 1.

Table 1: Road Transport Default CO_2 Emissions Factors and Uncertainty Ranges

Fuel Type	Default (Kg/TJ)	Lower	Upper
Motor Gasoline	69300	67500	73000
Gas / Diesel Oil	**74100**	**72600**	**74800**
Liquefied Petroleum Gases	63100	61600	65600
Kerosene	71900	70800	73700
Lubricants	73300	71900	75200
Compressed Natural Gas	56100	54300	58300
Liquefied Natural Gases	56100	54300	58300

Source: IPCC Guidelines for National Greenhouse Gas Inventories (2006)

Subsequently, these results are utilized to calculate the carbon emission resulting from each scenario. Finally, the data from both scenarios is compared to draw insightful conclusions then plan to replace the carbon lost due to land conversion.

7. DATA COLLECTION

As initial information, to find out the body parts of the dam, below is a typical picture of the cross section of the dam building structure.

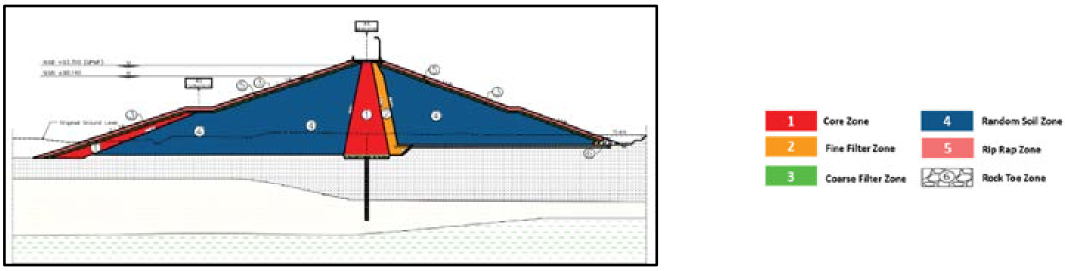

Fig. 3: Typical Cross Section of Dam

The insufficient material is in the Zone 4, which is the most dominant part of the entire dam structure, comprising 67% of the total volume of the dam. According to the master schedule and contract, the work on the zone four must be completed within 24 months or 730 Days to avoid disrupting subsequent tasks. The quarry has two alternative locations. The first quarry is in the Bendo Asri & Tritik area, but it does not contain rock soil materials that passed the required specifications. The second quarry is in the Blitar & Kediri area and the rock soil materials there passed the required specifications. Figure 4 shows the distance between the project's site to each quarry. The distance to the first quarry is approximately 10.5 Km and the distance to the second quarry is approximately 84.6 Km.

Fig. 4: Distance Between First Quarry (Bendoasri & Tritik) and Second Quarry (Kediri & Blitar) with The Project

The result of the assessment on the potential quarry sites shows that the first quarry is in an area originally covered by a pine forest. Utilizing this site would convert the landscape of the surrounding area from forest to quarry. The second quarry, for comparison, is a pre-existing site so there is no additional land conversion would be required for it to be operational, but it has downside which is the distance between the quarry and the project's site.

7.1. Initial design / design certification

This project's initial design stage is also known as the design certification. At this stage, the initial design specifies Rockfills material for the zone four of dam's body. The material shall be obtained from quarry sources in the Bendoasri and Tritik localities, approximately ten kilometers from the project site, as shown in Figure 4. Based on Table 2, the initial design data indicates that rockfill material can be sourced from the Bendo Asri & Tritik quarry, ensuring sufficient supply.

Table 2: Initial Condition Based on Design Certification

Material	Before Soil Investigation					
	Volume required (m^3)	Volume Quarry (m^3)	Location	Distance (KM)	Ratio	Availability
Rockfills	1,998,934	2,390,000	Bendo Asri &Tritik	10	1.20	Fulfilled

Upon further soil investigation in the pre-construction phase, it was found that the quarry did not contain rockfill material that met the initial design specifications, rendering it unsuitable as a rockfill quarry. To address this issue, an alternative location was sought that contained rockfill material meeting the specifications. A suitable quarry was found in the second quarry at the Kediri and Blitar areas, approximately 85 KM away, as illustrated in Figure 4. Therefore, Case A involves replacing the original quarry with the second quarry, which contains suitable rockfill material. This switch leads to changes in the data, as depicted in Table 3.

Table 3: Initial Condition Based on Design Certification After Change to Second Quarry

Material	Alternative Quarry After Soil Investigation					
	Volume required (m^3)	Volume Quarry (m^3)	Location	Distance (KM)	Ratio	Availability
Rockfills	1,998,934	3,107,000	Kediri & Blitar	85	1.55	Fulfilled

7.2. Design change / design review

Following the soil investigation, it was discovered that most of the material at the original quarry located in Bendo Asri & Tritik, is random soil. To prevent relocating the quarry, a design review was conducted, which involved changing the dam body material from rockfills to random soil. Hutama karya determined that the design issues can be solve by using reality modeling and geotechnical design.

First, a laser scanner undertook at the project area, created point clouds, and molded them into a digital replica of the site by using Context Capture Software. The digital replica helped the project team understand the existing condition of the field and plan local quarry locations, minimizing the excavation depth to limit the impact on the environment. The team then imported reality modeling data into their bespoke project management information system, giving the project manager insight into real-time conditions. Next, the organization then augmented the reality model with geotechnical analysis via Plaxis Software, enabling them to simulate foundation options and test the groundwater flow. Plaxis enabled them to model soil fill within the proposed dam design and test its performance within the area's terrain. Though the initial slope design did not meet safety requirements, they used OpenRoads Designer Software to evaluate other slope designs, eventually realizing that a greater slope on the left side of 1:3 combined with a lesser slope of 1:2.75 on the right side would meet safety requirements for both construction and operations while incorporating the sandy soil as fill. This adjustment will increase the safety factor and strength, leading to an expansion in the volume of the dam body in Zone 4. Accordingly, fortification calculations were conducted using the Plaxis and OpenRoads Designer Software, as shown in Figure 5.

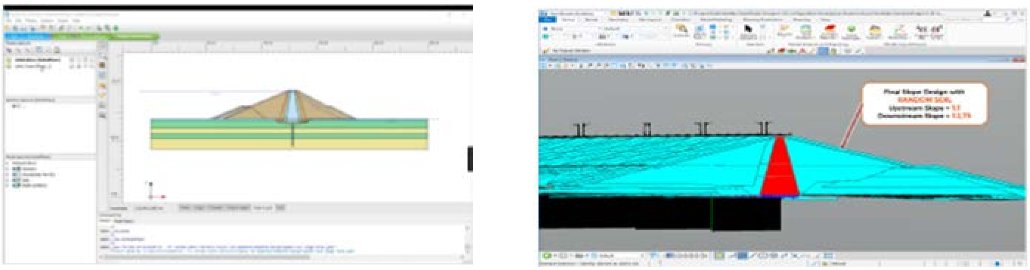

Fig. 5: Redesign Calculation of the Dam Body Using Plaxis and OpenRoads Designer Software

Lastly, to ensure the changes to the design would not impact the tight deadline, Hutama Karya simulated the construction with Synchro Software. In addition to testing the construction feasibility of the new design, the application helped them plan the construction process.

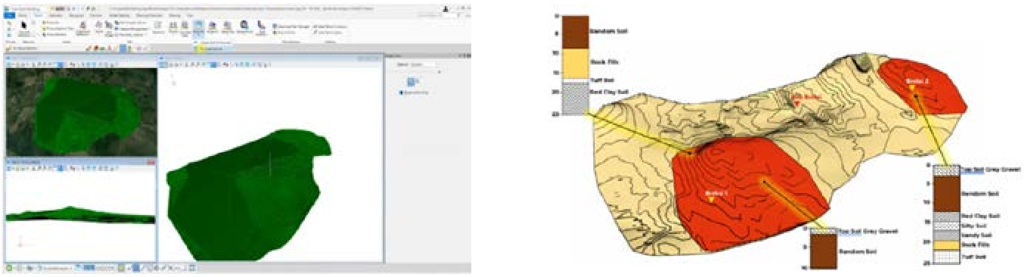

Fig. 6: Quarry BendoAsri & Tritik Classification & Quantification Using OpenRoad Designer

As shown in Figure 6, to ensure the availability of the quarry in that area, the quarry volume was recalculated using BIM to speed up the quantification process. Material take off generated from a 3d model created in OpenRoad Designer Software to help the engineers accurately visualize upon calculation, it was estimated that there is 5.3 million cubic meters of random soil available. Therefore, the first quarry is still utilized, but changes are made to the dam body design so that random soil material can still be used, as indicated in Table 4.

Table 4: Condition After Design Review Using the Random Soil Material at First Quarry

Material	Random Soil in First Quarry after Design Review					
	Volume required (m^3)	Volume Quarry (m^3)	Location	Distance (KM)	Ratio	Availability
Random Soil	2,308,176	5,326,000	Bendo Asri &Tritik	10	2.31	Fulfilled

The first quarry is currently a pine forest owned by Perhutani. When this pine forest is converted into a quarry location, the carbon stock will disappear. Therefore, to comply with existing regulations and to support sustainable project achievement towards the SDGs, Hutama Karya, as the contractor, is obliged to replace the carbon at the quarry site by reforesting after the project is completed and the quarry is no longer in use.

Table 5: calculation of the amount of carbon lost from land conversion.

Area Quarry (m^2)	Area Quarry (Ha)	Type of Tree	Amount of Tree	Carbon of each tree ($KgCo_2$/Pine)	Total Amount of Carbon ($KgCO_2$)	Total Amount of Carbon ($TonCO_2$)
200,000	20	Mercus Pine	141,541	22.60	3,198,827	3,199

According to the data in Table 5, it turns out that by converting a 20-hectare pine forest, a carbon reserve of 3,200 tons of CO_2 will be lost. This loss will be offset by reforestation after the project is completed.

8. DATA PROCESSING

The data calculation begins with the collection of initial data, followed by determining the productivity targets for each case based on the distance and travel time to the quarry, as well as the execution time (work schedule and working hours). The results of these calculations can be seen in Table 6.

Table 6: Comparison Resume of Initial Data & Target Productivity each Case

No	LIST	CASE A		CASE B	
1	Materials	Rockfills		Random Soil	
2	Volume required (m^3)	1,998,934	m^3	2,308,176	m^3
3	Volume Quarry (m^3)	3,107,000	m^3	5,326,000	m^3
4	Location Quarry	Kediri & Blitar		Bendo Asri &Tritik	
5	Ratio Stock Quarry	1.55		2.31	
6	Availability	Fulfilled		Fulfilled	
7	Quarry Type	Existing Quarry		New Quarry	
8	Distance From Project (KM)	85	KM	11	KM
9	Duration Quarry - Project (Minute)	160	Minute	25	Minute
10	Work Hour in a Day	8	Hour	8	Hour
11	Schedule Duration of Work	730	Days	730	Days
12	Target Productivity/day	2,738	m^3/day	3,162	m^3/day

After determining the productivity targets, the next step is to ascertain the equipment needs for each case. To simplify this process, equipment needs are determined for three different locations: the equipment located at the quarry site, the equipment used for construction processes, and the equipment needed for transportation processes.

As seen in Tables 7, 8, and 9, these illustrate the heavy equipment requirements for Case A, calculated based on the work's productivity targets, along with an estimate of fuel consumption for each location.

Table 7: Equipment Requirements & Fuel Consumption at the Quarry Location (Case A)

Equipment	Type	Unit	Fuel Type	Consumption/ Hour/ Machine	Work Hour	Project Duration (Days)	Fuel Consumption		Total Consumption
							(liter/h)	(Liter/ day)	
Excavator 01	Operational Weight 20T	3	Diesel	14	8	730	42	336	245,280
Excavator 02	Operational Weight 30T	1	Diesel	20	8	730	20	160	116,800
Excavator 03	Operational Weight 50T	1	Diesel	40	8	730	40	320	233,600
Excavator 04	Breaker	6	Diesel	25	8	730	150	1200	876,000
TOTAL CONSUMPTION (Liter)									1,471,680

Table 8: Equipment Requirements & Fuel Consumption at the Main Dam Location (Case A)

Equipment	Type	Unit	Fuel Type	Consumption/ Hour/Machine	Work Hour	Project Duration (Days)	Fuel Consumption		Total Consumption
							(liter/h)	(Liter/day)	
Bulldozer	D85SS	5	Diesel	22	8	730	110	880	642,400

VibroSmooth	SD 110	5	Diesel	18	8	730	90	720	525,600
VibroPadfoot	SD 110	5	Diesel	19	8	730	95	760	554,800
TOTAL CONSUMPTION (Liter)									**1,722,800**

Table 9: Equipment Requirements & Fuel Consumption of the Transportation (Case A)

Equipment	Type	Unit	Fuel Type	Travel Speed (KM/h)	Average Consumption		Mileage (Km)	Trip/ DT	Project Duration (Days)	Total Consumption
					(liter/h)	(liter/km)				
DumpTruck	Capacity 30T	72	Diesel	30	50	1.67	84.5	2.3 Times	730	17,025,060
TOTAL CONSUMPTION (Liter)										**17,025,060**

Based on the data above, the total fuel consumption for Case A is 20,219,540 liters.

Next, the calculation of heavy equipment requirements and fuel consumption on Case B, calculated based on productivity targets, can be seen in Tables 10, 11, and 12.

Table 10: Equipment Requirements & Fuel Consumption at the Quarry Location (Case B)

Equipment	Type	Unit	Fuel Type	Consumption / Hour / Machine	Work Hour	Project Duration (Days)	Fuel Consumption		Total Consumption
							(litre/h)	(Litre/ day)	
Excavator 01	Operational Weight 20T	3	Diesel	14	8	730	42	336	245,280
Excavator 02	Operational Weight 30T	1	Diesel	20	8	730	20	160	116,800
Excavator 03	Operational Weight 50T	1	Diesel	40	8	730	40	320	233,600
Excavator 04	Breaker	4	Diesel	25	8	730	100	800	584,000
TOTAL CONSUMPTION (Liter)									**1,179,680**

Table 11: Equipment Requirements & Fuel Consumption at the Main Dam Location (Case B)

Equipment	Type	Unit	Fuel Type	Consumption/ Hour/Machine	Work Hour	Project Duration (Days)	Fuel Consumption		Total Consumption
							(litre/h)	(Litre/day)	
Bulldozer	D85SS	4	Diesel	22	8	730	88	704	513,920
VibroSmooth	SD 110	4	Diesel	18	8	730	72	576	420,480
VibroPadfoot	SD 110	4	Diesel	19	8	730	76	608	443,840
TOTAL CONSUMPTION (Liter)									**1,378,240**

Table 12: Equipment Requirements & Fuel Consumption of the Transportation (Case B)

Equipment	Type	Unit	Fuel Type	Travel Speed (KM/h)	Average Consumption		Mileage (Km)	TRIP / DT	Duration Project (Days)	Total Consumption
					(litre/h)	(litre/km)				
DumpTruck	Capacity 30T	62	Diesel	30	50	1.67	10.5	6 Times	730	4,752,300
TOTAL CONSUMPTION (Liter)										**4,752,300**

Based on the data on Table 10, Table 11 and Table 12, the total fuel consumption for Case B is 7,310,220 liters.

After calculating the total equipment and fuel needs for Case A and Case B, the next step is to convert the total fuel consumption into energy (TJ). This is done by multiplying the total fuel consumption requirements by the specific heat of diesel fuel. The results of these calculations can be seen in Table 13.

Table 13: Conversion the Consumption of Fuel (Liter) to the Consumption of Energy (TJ)

Energy Conversion Calculation	CASE A		CASE B	
Consumption (Litre)	20,219,540	Litre	7,310,220	Litre
Calor Specific (TJ/Litre)	0.000038243	TJ/Litre	0.000038243	TJ/Litre
Consumption (TJ)	**773.255868220**	**TJ**	**279.564743460**	**TJ**

Once all the necessary data is available, the next step is to calculate the carbon emissions generated from each case using the emissions formula (1). The efficiency factor of CO_2 for diesel type is approximately 74,100 (Kg/TJ). The results of the comparison can be seen in Table 14. The table shows that in Case A, there is no additional carbon emission from land conversion, whereas in Case B, the carbon emission is increased due to the land being converted from a pine forest to a quarry. Therefore, the total emissions generated from Case A and Case B are 57,298 Ton and 23,914 Ton respectively. This results in a difference in emissions between the two cases of 33,383.69 Ton.

As a result, Hutama Karya, the main contractor, has chosen Case B, which contains lower carbon emissions than Case A. In response, Hutama Karya will also implement a carbon recovery plan by reforesting a 20-hectare area at the Bendoasri and Tritik quarry sites. This initiative is taken to support the Sustainability Development Goals

13 Climate Action.

Table 14: Emission Carbon Calculation

Emission Calculation	CASE A		CASE B	
Consumption (TJ)	773.255868220	TJ	279.564743460	TJ
EF CO_2 Diesel	74100	(kg/TJ)	74100	(kg/TJ)
Emission (Kg)	57,298,260	Kg	20,715,747	Kg
Emission (Ton)	57,298.26	Ton	20,715.75	Ton
Emission From Land Use Change				
Pine Mercussi to Quarry	-	Ton	3,198.83	Ton
Total Emission	**57,298**	**Ton**	**23,914.57**	**Ton**

9. CARBON RECOVERY PLAN & SUSTAINABLE CONSTRUCTION

Hutama Karya, in its commitment to sustainable development, plays a significant role as a contractor in the construction of the Semantok Dam. As part of their responsibilities, they have implemented reforestation initiatives in response to the conversion of the quarry land. Hutama Karya has planted over 2,000 trees on the former quarry site and an additional 6,000 trees in the surrounding dam area. Additionally, they have planted Vetiver Grass to stabilize the slopes of the spoil bank, which is made of excavation waste material. The project was completed in 2022, and Reforestation efforts continue periodically even today.

Fig. 7: Iriana Joko Widodo, The First Lady, planted date palm trees as a symbol of environmental awareness (Left Side), tree planting and fish hatchling activities by Central & Local Government (Right Side)

In figure 7 (on the left side) during the inauguration of the Semantok Dam, Iriana Joko Widodo planted date palm trees as a symbol of environmental awareness. On the right side of Figure 7, enthusiasm for reforestation also received support from both the central and local governments, who have participated in tree planting and fish hatchling releases into the dam. These efforts are part of a recovery plan intended to replace the lost carbon reserves and support SDG number 15: Life on Land, as Carbon recovery plans often involve afforestation and reforestation initiatives, which help restore land and create wildlife habitats.

The reforestation activities may not be enough to replace the lost carbon completely because this project still produced substantial amount of carbon. However, the benefits of constructing this dam are also substantial, contributing to sustainable infrastructure. When related to the SDGs, these benefits include SDG 2 (Zero Hunger): The dam enhances the planting intensity from 186% to 300%, supplies raw water at a rate of 312 liters per second, equivalent to potable water connections for 28,000 houses, thus driving rapid economic growth and increasing agricultural productivity. SDG 6 (Clean Water and Sanitation): Dams store water and are critical for providing clean water and sanitation facilities. They can also aid in waste management and help improve water quality. SDG 7 (Affordable and Clean Energy): Many dams are utilized to generate hydroelectric power, a form of renewable energy. SDG 8 (Decent Work and Economic Growth): The dam's construction creates new job opportunities, not only in agriculture but also in fish farming and the tourism sector. SDG 15 (Life on Land): The construction of a dam often involves land use changes and can significantly impact local ecosystems and biodiversity. Mitigation measures, such as creating new habitats or corridors for wildlife, can help reduce these impacts. Semantok Dam created a more sustainable infrastructure towards healthier environment, improved human well-being, and boosted economic growth.

10. CONCLUSION

The Semantok Dam Project, identified as one of the National Strategic Projects in Indonesia, is located in the Semantok River Stream in Nganjuk District. It's situated 115 km west of Surabaya City, East Java. With the dam's total length extending to 3.1 km and a height of 31.56 m, it's proudly recognized as “The Longest Dam in Southeast Asia.”

Digital construction technologies such as engineering analysis, digital survey tools, and BIM played a significant role in the project, primarily in acceleration of analysis on design modifications. This acceleration of the decision-making process has resulted in enhanced cost and time efficiency. However, despite BIM's effectiveness as a novel method, it has limitations, notably in computing the impact of carbon emissions on a construction project. This aspect is yet to be fully optimized and requires further development. As a result, a comprehensive analytical calculation is necessary to precisely determine carbon emissions.

In the initial design, rockfills served as the primary material for the dam. However, the quantity available in the existing quarry was insufficient. Consequently, there are two alternatives that emerged to address this problem. Case A proposed sourcing from a new quarry where adequate rockfills were available, but this option posed significant additional costs and potential health concerns for the local community. Case B suggested using the available materials, particularly random soil. However, this would require converting a pine forest area into a quarry, leading to significant land-use change.

Data were collected for both scenarios, including the quantity of materials required according to the initial and revised designs, the dam project's completion schedule, and the distance between the quarry and the project site. This information facilitated the establishment of productivity targets. The productivity targets would, in turn, guide the determination of resource requirements.

The total emissions generated from Case A and Case B were 57,298 tons and 23,914 tons, respectively, resulting in a difference in emissions between the two cases of 33,383.69 tons. The analysis revealed that Case B, which involved transforming a pine forest into a quarry, resulted in lower carbon emissions compared to Case A. However, this land-use change led to a loss of carbon reserves. The project contractor, Hutama Karya, addressed this issue through a carbon recovery plan involving reforestation. More than 6,000 trees were planted around the dam area and at the quarry sites, with an additional 2,000 trees planted on the former quarry land. Vetiver grass was also planted to strengthen the dam’s slopes.

These ongoing recovery efforts demonstrate alignment with SDG 15 - 'Life on Land,' illustrating a commitment to sustainable practices. The dam's construction supports not only SDG 15 but also aligns with other SDGs. These include SDG 2 (Zero Hunger), SDG 6 (Clean Water and Sanitation), SDG 7 (Affordable and Clean Energy), and SDG 8 (Decent Work and Economic Growth). The project has thus far demonstrated substantial benefits, including increased planting intensity, a steady supply of raw water, creation of new job opportunities, and the provision of clean, affordable energy.

SOLAR POTENTIAL AND ENERGY ASSESSMENT DATA IN U-BEM MODELS: INTEROPERABILITY ANALYSIS BETWEEN PERFORMANCE SIMULATION TOOLS AND OPENBIM/GIS PLATFORMS

Carlo Zanchetta, Martina Giorio, Maria Grazia Donatiello, Federico Rossi & Rossana Paparella
Department of Civil, Environmental and Architectural Engineering, University of Padova, Padova, Italy

ABSTRACT: *To evaluate the energy and solar potential of the building stock and address feasibility studies of building retrofit interventions information standards are required to ensure proper data flow from building and urban models to simulation environments. Energy performance data are gathered from different information containers and therefore the result of simulations needs to be shared in BIM/GIS environments to better address energy policies and decision-making processes. Solar potential and energy retrofit estimation, developed by means of urban models (U-BEM) are too rough to support a decision-making process, even if at a feasibility stage. On the opposite, strategic decisions are defined with reference to large building stocks that require a U-BEM approach. To increase the reliability of this kind of simulations the study proposes to integrate U-BEMS with BIM-based data that are aggregated and published at urban scale as average performance indicators of built systems. The interoperability problem is analyzed both for simulation tools that need to manage this kind of data and openBIM/GIS platforms that need to share performance indicators and simulation results.*

KEYWORDS: *Energy potential, Solar potential, IFC, BIM, U-BEM.*

1. BACKGROUND

The necessity to take action in the constructed environment, encompassing both individual structures and entire urban areas, stems from the increasing significance of enhancing comfort levels and energy efficiency. This need arises due to mounting environmental issues and the imperative to reduce energy consumption (Ratti et al., 2005). With urbanization and the increasing impact of buildings on energy demand, there is a crucial demand for accurate predictive models that can guide sustainable urban development (Amado & Poggi, 2012).

Traditionally, urban energy planning and building design analyses have been based on generic models, leading to suboptimal energy performance and inefficient resource utilization (Lan et al., 2022). Due to this reason, it becomes imperative to establish precise information standards that ensure seamless data transfer from architectural structures to urban models, encompassing both geometric and climatic data. These standardized procedures will facilitate, for example, the transmission of initial solar potential assessments within simulation environments. To overcome all the limitations, the development of sophisticated and reliable predictive models has become necessary (Lobaccaro et al., 2019). Such models can provide, in a simulation environment, valuable insights into the solar potential of different urban areas, allowing city planners, architects, and experts to make informed decisions regarding energy-efficient designs, renewable energy integration, and also climate-responsive urban planning (Kabir et al., 2018).

The examination of outcomes from the new solar potential estimation applications, reveals a noteworthy decrease in the computed potential once the feasibility of installing energy production systems like photovoltaics is assessed. Analyzing the solar potential of buildings allows for the swift identification of surfaces significantly impacted by solar irradiation, evaluating the more suitable for incorporating active solar systems. However, if this assessment is conducted on an overly simplistic model, assuming all surfaces possess a uniform level of adaptability, it fails to accurately reflect the true solar potential.

Likewise, concerning the energy retrofit of existing buildings, it is crucial to confirm the practical feasibility of upgrading building envelopes and technological systems with energy-efficient technologies. This verification should occur within a comprehensive information model aimed at identifying transformation barriers that could potentially impact feasibility studies. Such a model would help reference point challenges that might arise during the retrofitting process and ensure a more accurate assessment of the retrofitting potential.

The essence of the issue lies in the requirement for simulations to rely on a dependable information foundation, which necessitates a detailed representation of buildings. However, such detailed data is often unavailable during the preliminary stages of the study. Consequently, it becomes imperative to establish a system that enables the

enrichment of urban models with more accurate values for the subsequent calculation of the solar potential data and the energy retrofit. Such models must integrate irradiation conditions on architectural surfaces depending on their exposure and geographical location with a broader range of factors influencing energy production and transformation to ensure more precise and reliable simulations.

In fact, the building sector lacks a method that makes it possible, in a relatively short period of time, to assess the real renovation potential of an existing building and, therefore, to identify, at a preliminary level, the optimal intervention strategy. The lack of information on the transformation of the existing building, on the one hand, and the enormous potential offered by the development of new technologies, on the other, make it necessary to identify a plan for evaluating the renovation potential of buildings.

The literature analysis revealed that, to date, the only tool for formulating energy efficiency design hypotheses is the energy diagnosis. This is a rather time-consuming process, as well as an economic one. Hence, the need to formulate an expeditious methodology for assessing existing buildings. (Mazzarella & Piterà, n.d.)

Some attempts have been made to propose a method for defining a building potential in Italy, but these go beyond the concept of transformability, which is intrinsically linked to the technological element, and outline intervention scenarios that are compatible with the valuable characteristics of a historic building, such as ENEA method. In turn, the intervention is ranked according to a score determined based on effectiveness, durability, compatibility, and cost-effectiveness (Boriani et al., 2011). Other attempts to propose a methodology to analyze buildings are represented by TABULA project and CRI_TRA method. TABULA focuses on the proposal of a census of building types and their optimization by simulating the effects of possible retrofitting interventions (Corrado et al., 2014), while the CRI_TRA method is very close to what is proposed in the rest of this research activity. It is configured as a study of the criticality and transformability exhibited by the public housing sector through the assignment of a numerical score to the two indices, GDC and GDT (Diana, 2017).

2. METHODOLOGY

To achieve the delineated results, the study proposes to integrate simplified models with "transformability coefficients" that considered the adaptability and potential of various building surfaces and technical elements to harness solar energy effectively. By identifying surfaces that are most susceptible to solar irradiation, the integration of this coefficient with the simulated data offers a more precise representation of the real potential within the urban context.

To establish these coefficients, a representative selection of detailed building models was analyzed. These detailed models serve as a basis for deriving coefficients that reflect the unique characteristics of different surface types and facades. The coefficients were identified inside the entire urban area using characteristics such as the age of the buildings and the architectural similarities. Integrating the coefficients into the subsequent simulation process ensures that the data are based on more realistic and specific information.

The geographic information system (GIS) environment plays a crucial role in this methodology, enabling the integration of various data sources, such as climatic data from terrestrial or satellite weather stations, building geometries, and urban morphologies, in the calculation of the solar potential data. Through this integration, the GIS platform acquires data from 3D simulations that take into account solar irradiance, local weather conditions, and the complex interplay of sunlight with urban elements (Bahu et al., 2013).

Moreover, the simulation outcomes do not only focus on solar potential estimation for photovoltaic installations but also extend to solar thermal systems. This broader perspective enables a comprehensive evaluation of the renewable energy potential available in the urban context, encouraging the adoption of different and integrated renewable energy solutions.

By applying this methodology to the North Piovego University area in Padua, Italy, the study demonstrates its applicability to real urban scenarios. The study area selected for analysis covers approximately 50,000 m2 and it is located in northern Italy. By integrating detailed building data, geographic information, and solar simulation techniques, this approach provides a robust foundation for optimizing energy efficiency, promoting renewable energy integration, and fostering sustainable urban development.

2.1 Source data for modeling

Urban data and weather data are closely related to a geographical location and a determined time. Geospatial data can take different forms: raster, vector, and graph data. Raster data is a gridded matrix, organized in rows and columns. Vector data represent information through points, lines, and polygons. Graph data are represented by edge and node and generally take the form of road networks (Lee & Kang, 2015). Since raster data always have a standard dimension, they are considered more basic than vector data, which, on the contrary, are discrete. The union of raster and vector data makes the geographic database. The sources of these data are manifold and in recent years there has been a radical change in the way the maps are created. While maps were previously only created by national land mapping agencies, in the 2000s, thanks to the elimination of intentional GPS degradation, a new way of creating maps was born (Haklay & Weber, 2008). The accuracy of GPS, introduced in all mobile devices, gives any citizen the possibility of entering information into maps. Numerous studies have named this phenomenon differently. They speak of Volunteered Geographic Information (VGI) (Goodchild, 2007), neogeography (Rana & Joliveau, 2009) and crowdsourcing geospatial data (Heipke, 2010). The peculiarities of this phenomenon are:

- data are much more varied than in official cartographies because anyone can add information to the map;
- data are available for any part of the world even for places subject to legal or technical restrictions.

Main producers of information are the citizens who consciously or unconsciously add information to these databases. the most successful project is OpenStreetMap that up to date, counts 10.729.032 users and 23.604.230.005 GPS points (*OpenStreetMap Statistics*, n.d.). Other VGI projects are Wikimapia, Map Maker, Here Map Creator, Map Share and Waze.

Citizens can actively or passively add information to the map. The active mode is when people are aware of updating the map by participating in some campaigns aimed at updating databases. The passive way, on the other hand, takes place thanks to the GPS inside mobile phones, when georeferencing any post on social media, for example (See et al., 2017). These maps also contain so-called 'framework data', that is the 'most common data themes that users of geographic data need', which can 'typically include seven framework data themes: geodetic control, orthoimage, elevation, transport, hydrography, governmental units and cadastre. These data represent relatively static phenomena and are commonly used for administrative programs, wayfinding, geopositioning, geotagging, and other popular services, so they have been a traditional target of government data production" (Elwood et al., 2012).

Regarding the correctness of data, citizens tend to enter or correct only the data they really know, generally related to the area in which they live. Many institutions that produce geospatial data have espoused the cause of OpenStreetMap, such as for Italy Portale Cartografico Nazionale (PCN), since 2010, makes its images available (*Italy/PCN - OpenStreetMap Wiki*, n.d.). Several studies (Borkowska & Pokonieczny, 2022), (Minaei, 2020), (Dorn et al., 2015) have shown that from a geometric point of view, the information contained in OpenStreetMap databases are quite correct, especially regarding buildings and the transport network. Another important fact concerns the accuracy, which increases proportionally to the urbanization of the area. Accuracy of data is one of the requirements also expressed in ISO 19157:2023 geographic Information - data quality. According to this standard, the quality of geospatial data is based on several characteristics:

- Completeness: presence of values describing different characteristics;
- Logical Consistency: degree of adherence to the rules of the data structure (documented and named);
- Positional Accuracy: accuracy of the measurement between the given position and the position accepted as true within a reference system is. For Global Navigation Satellite System (GNSS), it is within 2-3m.
- Thematic Quality: accuracy of quantitative attributes and the correctness of non-quantitative attributes and feature classifications and their relationships.
- Temporal Quality: the quality of temporal attributes and temporal relationships of features

2.2 Open Street Map as a reliable data source

Due to its large diffusion, the study proposes OpenStreetMap as a reliable and scalable data source. The project started in 2004, so it developed right at the same time as the evolution of crowdsourcing concepts. This study takes all the urban data from OpenStreetMap, which can in fact export part of the whole map. The exported file can also be used as a base map within GIS software. The .osm format is proprietary, but it is written in XML so it is interoperable due to an expandable language (Behr & AGSE. 5 2012 Stuttgart., 2012).

Although the idea is that anyone can insert new information into this map, OpenStreetMap is not included in the more than 70 standards of the Open Geospatial Consortium (OGC). Voluntarily OpenStreetMap does not conform to the standards because its purpose is not to be a standard but only to be a map containing geospatial information.

Despite this fact all OpenStreetMap data can be used and possibly even transformed according to the standards, in fact there is third-party software that allows to read .osm files and transform them into shape files.

OpenStreetMap has its own data structure comprising three geometric features (Nodes, Ways, and Relations) plus an object information feature (Tags) (Vargas-Munoz et al., 2021).
Nodes are the main element in the data structure and represent symbols. A node is a transposition of a point of interest on the earth. Several nodes together form a way, which can be open (polyline) or closed (polygon). An example of a polyline can be a road or a river, while the most illustrative polygon is a building. At least two nodes are needed to create a polyline, while three nodes are needed to create a polygon. It is therefore possible to relate several nodes to create a road, but it is also possible to relate geometric objects with information objects (tags).

Tags consist of two items 'key-value' where the key describes the type or category, and the value is the specification of the key. The insertion or modification of tags is free, in fact although OpenStreetMap has a defined structure of tags, it leaves the user the possibility of adding different tags.

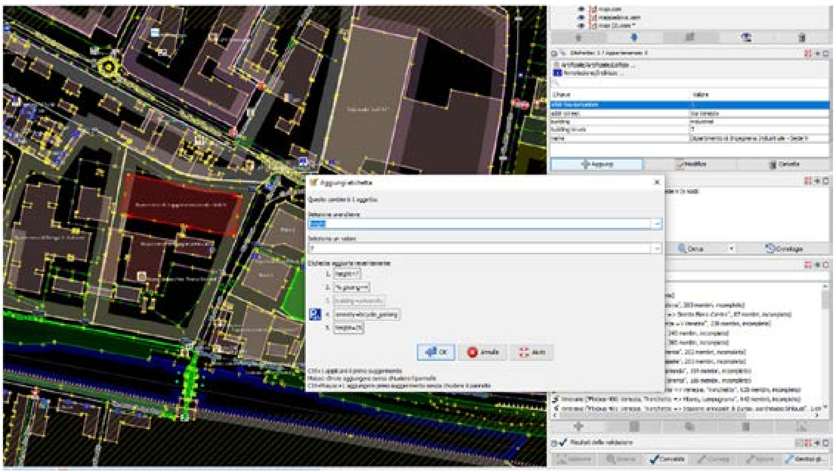

Fig.1: Adding a tag with JOSM.

Unfortunately, the estimates clam that less than 3% of the objects have the height key filled in and very often also wrong. Height is the typical datum that must be entered by the user to be correct, it cannot be taken from satellite orthophotos. Calculating this data could be difficult to obtain especially if the building is tall, which is why the study (Bshouty et al., 2020) of has created an app "OpenStreetHeight" that can calculate the height using a photograph. The height for the buildings, in the selected area, was not present within the .osm file but was visible through the OSMBuildings application. This site, written in Java, shows at the three-dimensional level the 2D map of OpenStreetMap According to what has been said so far, if a data is wrong or missing everyone can change and update it, and that is what has been done. To be able to modify the data there are several editors. There are both computer and telephone applications. The best known and most widely used are JOSM (Java OpenStreetMap) and Potlatch (Neis & Zielstra, 2014), both are computer applications. Through these applications, the map can be viewed and edited. Adding the data, using JOSM, is very simple just import the map and selecting the building polygon add the tag.

2.3 Generation of the model

To create the model of the case study area, the initial step involved the editing of the source OSM file. In fact, certain unnecessary data had to be modified or removed from the starting .osm file. The primary data was generally accurate, except for building heights, which were often incorrect, listed as a default "3 meters" when not available.

To acquire accurate data, several methods were considered, also including LIDAR technology (Manni et al., 2022). LiDAR sensors can gather highly precise and detailed elevation data. These advanced sensors emit laser pulses toward the Earth's surface and measure the time it takes for the laser to return after hitting an object or the ground. By analyzing the return time and the wavelength of the laser, LiDAR systems can calculate the distance between the sensor and the target surface with exceptional accuracy. In any case, it is important to have adequate equipment to carry out these surveys, and for that reason, in this case, building heights were manually calculated by cross-referencing data like the number of floors, using JOSM to modify and delete data. Additionally, two new tags were inserted:

- Transformation coefficient: which represents the percentage of façade or building transformability, indicating the freedom to incorporate new installations on surfaces or interiors.
- % glazing: which represents the total glazed area relative to the total area.

Correct values for these new parameters will be calculated for each building and replaced together with the starting information. Each element in the OSM file has a unique ID number to identify it. The default value is 1 for façade transformability and 0 for glazing.

A generative script developed with Grasshopper's Urban tool generated building volumes starting from OSM metadata and including the urban geometry of roads and external spaces. Each building is represented as an extrusion of its planar geometry. The source file also contains other information, such as the number of levels, function type, and structure identifier, unique to each building.

Climatic and environmental conditions are gathered by .epw file. Ladybug offers a library of data collected from weather stations worldwide, downloadable from their official website (*EPW Map*, n.d.). For the case study, data from the Treviso airport weather station was used due to a lack of specific data for the Padua area. The available data is for year 2020, and the simulations presented focus on the entire month of July 2020.

Before conducting simulations, the presence of greenery and trees must be considered, as they significantly impact solar potential and act as crucial mitigating elements. Therefore, the 3D geometric model was supplemented with the modeling and placement of trees and green elements based on their actual arrangement, height, and leaf density, utilizing a site survey and satellite images for accuracy.

2.4 Solar potential study

Once the basic geometric model is prepared and enriched with additional information, the analysis of solar potential can commence using various available tools, both in GIS environments and beyond. In a comparative study conducted by (Giannelli et al., 2022), five main tools, including GRASS GIS, ArcGIS, SimStadt, CitySim, and Ladybug, were assessed by comparing their simulation data with ground truth data obtained from a weather station (Jakica, 2018), (Peronato et al., 2018). Among these tools, Ladybug was found to be one of the most accurate for solar radiation studies, sky view analysis, sunlight hour modeling, and more (Freitas et al., 2015). Therefore, it was chosen as the basis for the research work in this study.

However, a notable challenge faced by all the tools, including Ladybug, is that the data obtained through simulations are related to simplified surfaces that do not correspond to the real conformation of buildings. Consequently, they may not provide reliable estimates of the exact solar potential, as factors such as surface conformation and the percentage of glazing can significantly impact the results. For instance, certain surfaces may not be suitable for the installation of new energy systems throughout the entire area (Esclapés et al., 2014). The issue arises as simplified models treat all surfaces uniformly, considering them flat and non-glazed facades.

To address this problem, the study aims to introduce coefficients that can account for these specific building characteristics and rectify the results obtained from the simulations. By identifying and incorporating these coefficients into the analysis, the study seeks to obtain more realistic and reliable data with minimal additional complexity. This process involves coding in Grasshopper to automate the identification and application of the coefficients to the simulation results, streamlining the evaluation process (Assouline et al., 2017).

2.5 Energy Potential study

The definition of the energy retrofitting potential of a building is based on the development of a method which allows the cataloguing of technical elements and their subsequent differentiation through the analysis of geometric, aesthetic and technological factors and the relative retrofitting potential. The main objective of this research activity is to develop a simplified type of rapid assessment model about building technical elements, whose horizontality allows the extension of the experimental scheme to the entire building system to evaluate its potential and criticalities and to direct a specific renovation process. The formulation of a percentage score, an indicator of the building retrofitting potential, constitutes the tool for pre-evaluating the effectiveness of its efficiency and for comparing buildings belonging to the same stock to identify a design strategy that is convenient both from an economic and energy point of view.

The structure of the methodology is based on the definition of the upgrading potential, which quantifies the possibility of increasing the performance level of a technical element by implementing specific retrofitting measures. For example, the presence of geometric and aesthetic constraints could significantly limit the building transformability. Although the upgrading potential is directly focused on the element itself, the definition of retrofitting potentials introduces a preliminary assessment of possible interventions.

Once virtual potential for improvement has been defined, it is necessary to introduce the concept of transformability, which indicates the readiness of a technical element or a building to accommodate a technological solution aimed at increasing the energy efficiency. Thus, this parameter represents a tool to moderate the value assumed by the potential according to the real possibility of intervention. The definition of this parameter considers geometric, aesthetic and technological features of each technical element. In fact, the transformability coefficient (T) is the result of geometric mean (Equation 1) of the geometric (T_G), aesthetic (T_A) and technological transformability (T_T).

$$T = \sqrt{T_G \cdot T_A \cdot T_T} \quad (1)$$

Therefore, the combination of the virtual potential and transformability rate into a single index, called effective potential for upgrading, guarantees the moderation of technological element potential as a function of its transformability.

To define effective potential rate, this method involves a careful process of analysis of the specificities that distinguish each item. Both transformability and upgrading potential are subjected to the assignment of a score, a coefficient between 0 and 3 to each index. A coefficient of 3 corresponds to the maximum possibility of intervention to which a technical element can be subjected. On the other hand, a value of zero is determined by the impossibility of intervention: in the case of potential, zero indicates the absence of actions that increase the energy performance of a building component (if it is already particularly performing), while a zero transformability derives from the presence of constraints that inhibit any design strategy. Depending on the type of component, the meaning of the rates changes according to the peculiarities.

The decision to use a classification system with a peer number of coefficients stems from the desire to reduce the possibility of a high percentage of components falling within the median.

At the same time, this research work proposed the decomposition of the building system provided for by UNI 8290 and identifies five technical elements, such as opaque vertical components and windows, opaque horizontal components and heating systems. In addition, the methodology included a census of these elements to determine their profile in terms of energy potential. The entire set of examples is the result of research into sector manuals and direct observation of buildings in nearby cities: in particular, the attempt to grasp the complexity and variety of technical elements is one of the main objectives of this compilation. However, it must be stressed that the definition of building archetypes is a subject that will be further developed to capture the diversity of the building sector.

3. EXPERIMENTATION

The research work, for the solar potential study, involved the analysis of two significant buildings within the study area, focusing on their geometric and solar aspects. The first building, primarily used for offices, had a rectangular floor plan with an overall height of 30m. Its facades featured a series of pilasters, creating a rhythmic pattern of window openings. The second building, with the university department of industrial engineering laboratories, had a rectangular plan with a height of 9m. Its facades were predominantly composed of windows, forming an overlapping grid pattern. The roof of this building had a distinctive stepped pattern.

To analyze the solar potential of these buildings, two models were developed for each, a simplified model, and a more detailed one. Ladybug for Grasshopper was used for the simulations to obtain the solar potential values for each facade. The factors that significantly influenced the actual solar potential were the percentage of windowed and opaque surfaces and the conformation of surfaces susceptible to transformations. The shading factor was already considered by Ladybug, and the presence of elements like balconies would be accounted for in the detailed model.

An equation (Equation 2) was derived to relate the real solar potential value (SP_r) to the simplified solar potential value (SP_s), the percentage of the opaque area ($\%op_{area}$), and the transformation coefficient (T_{coeff}). The simplified solar potential value was obtained through Ladybug simulations on the simplified model. The opaque area percentage was calculated from geometric analysis using software like AutoCAD. The transformation coefficient was derived by using an inverse equation based on the real solar potential value from the detailed model.

$$SP_r = SP_s \cdot \%op_{area} \cdot T_{coeff} \quad (2)$$

The data for the transformation coefficients, opaque area percentages, and glazing percentages were then included within the .osm file to enrich the information for each building. The JOSM software facilitated editing the .osm file to create new categories of parameters and associate their values with each building. For simplicity, a single parameter was associated with each building for the new data categories, taking the average values for each facade and roof to account for varying conformations.

By applying the new coefficients to the data of the simplified solar potential, a more accurate estimation of the solar potential value was obtained, considering the actual building conformation. The additional data calculated using this methodology was inserted into the .osm file for each building using specific identification codes. The file was then exported in .xml format, allowing the GIS environment to read the new data along with the existing data in an open-source format. This approach enables the creation of more realistic territorial models, providing more reliable information on solar potential at a granular level.

The energy potential research activity involves the transformation of the initial qualitative approach, linked to the formulation of a rehabilitation potential index, into a scientifically based methodology. To achieve this, the development of energy simulations made it possible to provide a numerical basis for the initial survey. In this way, the results obtained are crucial to the establishment of the methodology, like the definition of the rehabilitation potential. Specifically, the aim is to quantify the reduction in energy consumption resulting from the implementation of a given retrofitting measure affecting a specific component, leaving the conditions of the other technical elements unchanged. The experimental activity leads to a ranking of the efficiency measures, expressed in terms of energy demand reduction. Thus, it will be possible to relate the actual improvement potential of each technical element to the actual energy footprint assumed by the same. This phase is not an integral part of the methodology, but it is functional to validate its results for subsequent applications.

The verification of the previously assigned virtual improvement potential rates required the development of energy simulations using the EC700 software supplied by Edilclima. Edilclima is one of the main Italian software packages for calculating energy diagnoses. The choice of this calculator is due to the high interoperability between the BIM modelling, carried out in Revit, and the energy simulation software. In fact, the introduction of EC770 (the plug-in provided by the company) makes it possible to derive a large part of the input data for determining the energy performance of a building from the architectural model, speeding up the process.

Moreover, the procedure has introduced a series of energy improvements, each of which is intended for one building component. The decision to use this specific method, which is very different from the usual practice, stems from the desire to be able to calculate the influence of the improvement in the efficiency of a specific technical element on the overall behavior. Several architectural models have been defined in the process to group together the building types studied during the survey phase and, therefore, to evaluate the energy savings percentages by carrying out a considerable number of energy simulations. Specifically, for each macro-category of technical element, a common design state was identified to compare the percentages obtained.

For this purpose, it was considered appropriate to adopt an extremely simplified architectural model. A rectangular building with a side of 10x6 meters, developed on two levels, was implemented in Revit. The floors have the same layout and contain only one room. The construction characteristics are the most common in Italy. It is a load-bearing masonry construction, with brick floors and roofs. The energy performance is particularly poor. To determine the actual impact of a technical element on the overall energy savings, it was considered appropriate to vary the energy characteristics of the considered component, while leaving the other parts of the building organism unchanged. An attempt was made to reproduce the most representative cases of the previous survey.

Four possible types of heating systems were identified: radiators, radiant floors, fan coils, full-air system.

Two boiler variants were associated with each type, such as a traditional boiler and a condensing boiler. The energy retrofit intervention includes the replacement of the central heating system with a heat pump and the installation of a photovoltaic system with a total power of 4.5 kW, while keeping the envelope performance unchanged. The following results were obtained:

Table 1: Schematization of the reduction in energy consumption due to heating system retrofit

Type of plant	Heating generator	EP pre intervention	EP post intervention	Energy saving
Radiators	Boiler	318,86 kWh/m^{2}year	99,00 kWh/m^{2}year	69%
	Condensing boiler	294,06 kWh/m^{2}year	99,00 kWh/m^{2}year	66%
Radiant heating	Boiler	302,93 kWh/m^{2}year	99,00 kWh/m^{2}year	67%
Fancoil	Boiler	305,27 kWh/m^{2}year	118,60 kWh/m^{2}year	61%
	Condensing boiler	281,60 kWh/m^{2}year	118,60 kWh/m^{2}year	58%
Air system	Boiler	319,07 kWh/m^{2}year	67,14 kWh/m^{2}year	79%
	Condensing boiler	290,67 kWh/m^{2}year	67,14 kWh/m^{2}year	77%

Therefore, it can be concluded that the maximum reduction in energy consumption is obtained from the efficiency of the air system, which is over 70%. This result confirms the value of 3 of virtual potential given to the system under consideration. Then, this reasoning was extended to the five technical elements to obtain a complete view of the thermal behavior of a typical building.

Furthermore, the values obtained were used as a tool to calibrate the energy potential values initially assigned based on qualitative assumptions about the energy behavior of each component. This phase was supported by the analysis of the results in Excel. In fact, the formulation of a classification of the reduction in consumption attributable to the improvement of the different types of each technical element made it possible to place the corresponding potential values within four energy saving ranges.

During the experimental stage, the method was applied to a specific case study. The building is one of ATER's buildings of Padua and it is in Ferdinando Coletti Street. It is an apartment block, developed on four levels and divided into three different staircases. Each staircase serves a total of eight residential units, consisting of approximately 45 sqm, whose layout is repeated on all four levels. The size of the typical apartment is rather humble: it consists of a living area with a kitchen and a separate sleeping area, which is served by bathrooms. The building has undergone various renovations over the years, which have not ensured its good state of conservation. In the 1970s, a refurbishment was carried out with questionable results: the total renovation of the facilities allowed the construction of an internal toilet for each flat. Moreover, the energy simulation confirmed its energy-intensive nature. The absence of insulation and technological solutions ensures the veracity of the results.

Established the poor energy performance of the current state, two different intervention scenery could be identified. Specifically, the first is related to maximizing the heating system efficiency, while the second is related to maximizing the insulation of the envelope to reduce dispersion.

The first scenario concentrates almost all resources on the energy retrofitting of the heating system, followed by limited insulation measures. The retrofit action foresees the introduction of renewable energy sources and the installation of a heat pump generator and a radiant floor, after the demolition of the existing flooring with a consequent increase in height, but it is compatible with the functional-spatial characteristics thanks to the high room heights. The autonomous system configurations remain unchanged. The installation of a centralized photovoltaic system on the roof provides a large proportion of the energy required by the new heating plant. Once the retrofit intervention on the installation system had been defined, the discussion focused on evaluating the reduction in energy demand caused by the insulation of the envelope. Thus, it is possible to separate the contribution to the efficiency of envelope structures from the overall behavior. These retrofitting actions include the insulation of opaque components and the replacement of windows to comply with the transmission limits imposed by Italian regulations.

The second scenario focuses attention on increasing the insulation of the envelope and, regarding the systems, replacing the existing generator with a condensing boiler and the existing heating terminals with a radiant floor to ensure proper operation at a lower temperature. The individual system configurations remain unchanged.

4. ANALYSIS AND EVALUATION OF RESULTS

During the final stage, it becomes crucial to evaluate the obtained solar potential data to determine if there are significant differences between the results obtained from simplified models and detailed models, and whether the simplified data is adequate for the evaluation purposes, especially when considering the inclusion of a new system. For instance, upon analyzing the data regarding the total solar potential of some of the buildings present in the area, it was measured a considerable difference corresponding to a potential drop of about 25%. The discrepancies in the results are quite significant, emphasizing the importance of model enrichment to avoid overestimation of solar potential when relying solely on basic models for evaluation. The detailed models provide a more accurate representation of the solar potential, making it evident that the use of simplified simulations alone may not suffice for precise assessments and decision-making regarding the implementation of new energy systems.

The application of the EP method to the case study made it possible to identify its main weaknesses and to optimize its use. In particular, the conversion of the numerical scale with values between 0 and 3 into percentages required various experiments and subsequent adjustments. The initial approach was to proportionally convert the numerical indices of transformability and upgrading potential: however, the implementation of the method highlighted that situations characterized by low transformability were particularly disadvantaged in the calculation of potential for energy redevelopment. The reason can be found in the series of multiplicative operations that lead to the definition of the upgrading potential: in fact, a low potential value is obtained starting from average values assumed by the transformability and the virtual potential. The further multiplication between the effective potential and the technical element weight contributes to a further reduction of the achievable energy savings, making it incompatible with the results of energy simulations. The first attempt to transpose the transformability and the virtual potential was carried out independently of the type of technical element, disregarding the results of the energy model. For this reason, it was necessary to completely revise the entire transformability allocation matrix, calibrating the percentages for each technical element. To facilitate the implementation of energy retrofitting measures, it was appropriate to shift the entire numerical scale to values greater than 70 per cent, thus projecting values in the range between 70 and 100 per cent. The agreement between the results of the fast method and the energy simulations was the basis for the choice of the percentage range.

The graphs below show a comparison between the results obtained by using the methodology, the energy model and the projection of the energy savings obtained by the efficiency of a model type (with construction characteristics very closed to the case study), representing the research building. In the first scenario, the analysis of the deviations shows a maximum deviation of 11%, related to the heating system.

On the other hand, in the second scenario, a maximum deviation of 24% is reported for the insulation of the vertical perimeter walls. The reason for this difference can be found in the proposed interventions: in fact, the walls of the case study have external aesthetic reliefs that are incompatible with the installation of an external insulation system. The insulation is therefore provided internally. On the other hand, the simplified model proposes the external technological solution which, for the same thickness, leads to a better energy performance thanks to the correction of thermal bridge. Where:

- A represents the gap created between the reduction in consumption derived from the methodology and the energy simulations.
- B represents the gap created between the decrease in consumption derived from the methodology and the projected decrease in consumption.

- C represents the gap between the reduction in consumption derived from the energy simulations and the projected reduction in consumption.

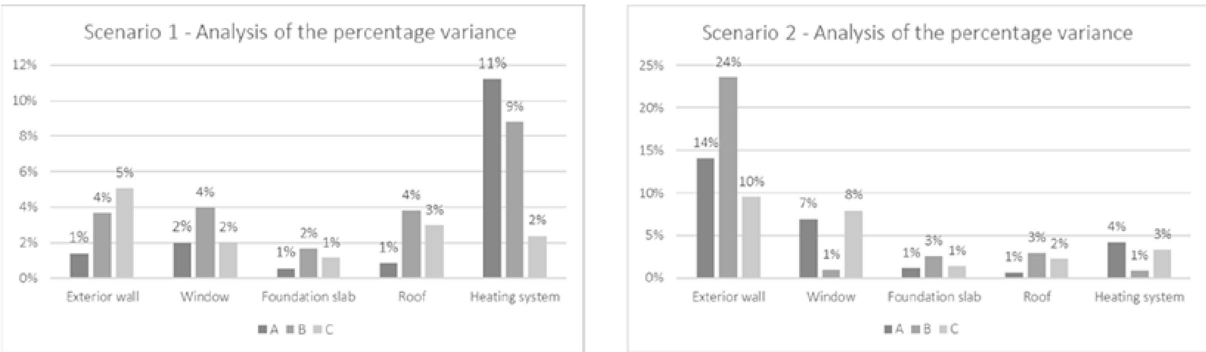

Fig.2: Comparison of methodology results of heat pump systems (scenario 1) and condensing boiler (scenario 2)

5. CONCLUSION AND FUTURE WORK

The innovative aspect of this process revolves around information-related elements, as modern tools process geospatial data that can't be modified based on typological criteria to enhance analysis results. The provided proposal delineates the methods to attain these objectives, approached from two key angles. Firstly, from a disciplinary standpoint, it involves the establishment of transformation coefficients. Secondly, from an informational perspective, it revolves around fostering the interoperability of solar potential reduction factors.

To apply this methodology to various building contexts and urban environments, it becomes crucial to categorize different case studies of typical facades and roofs, examining the similarity between buildings. This allows for the creation of a set of moderating coefficients and parameters associated with the urban environment, considering the structure's form and glazing percentage. For scalability, the process of creating a solar map at the neighborhood level should be as automated as possible to establish urban environment parameterization standards.

One limitation of this approach is that when selecting corrective coefficients on a large scale, it requires more time for context analysis and relies on source materials such as aerial photographs or files that identify the differentiation between glazed and opaque surfaces, which may be challenging to obtain. Moreover, it would be interesting to extend the study further by assessing how much energy could be generated from various PV systems to determine the percentage of energy needs that these systems could cover for the buildings in the area.

The study was conducted in a small area of Padua, but with the necessary adaptations, the data could be replicated across the entire city map. This would enable the integration of the findings into the OpenStreetMap project, expanding the database with valuable information on Solar Potential for the entire city. It is evident that the results show that the methodology is validated by the energy simulations by analyzing energy potential method. In fact, the percentage deviation of the values is around 10%, a percentage that can be considered acceptable in a preliminary assessment. Therefore, the application of the method allows a quick screening within a building stock, identifying the buildings responsible for greater energy savings.

Specifically, it was possible to highlight that heating systems constitutes the most decisive factor in the process of formulating the design hypotheses: thus, it is not possible to disregard the evaluation of plant transformability that, in the first instance, governs the declination of the retrofit intervention. This assumption derives from the fact that, with the same envelope, the replacement of a traditional generator with a heat pump, the installation of a radiant floor system and a photovoltaic system cause a decrease in energy consumption of approximately 70%. The discriminating factor is the possibility of installing renewable energy production systems, which make the thermal behavior of the envelope take second place since the energy produced is largely free. Therefore, it can be said that maximizing plant efficiency is the winning strategy. Where systems are characterized by good performance, it is more convenient to intervene on the envelope insulation.

Mohamed Anwar Fekry & Wessam Hamdy Abbas

Alexandria University, Faculty of Engineering, Department of Architectural Engineering

ABSTRACT: *The construction industry consumes a large amount of raw materials and produces large amounts of carbon dioxide emissions. However, studies have shown that philosophies alone are not efficient in solving problems in the construction industry. They must be supported by new tools and methodologies. Therefore, this study aimed to achieve a more sustainable building field by integrating BIM technology and value engineering principles in the management of building materials. to achieve the highest possible consumption of environmental resources and materials through value engineering. The methodology employed in this study was to develop a material waste management system for construction projects. Starting in the early design phase, develop a decision-making process for selecting the optimum floor tile size according to room dimensions. Some materials, such as floor tiles, wooden panels, and marble, can be used more efficiently using BIM and scheduling tools. Floor tiles are essential finishing materials in the AEC industry. The initial findings outline the benefits that can be obtained by using BIM tools to achieve waste minimization through value engineering principles by creating an automation process to choose the best floor tile size according to the space width and length and minimize the percentage of cut tiles to the total number of tiles that are used in the space. This provides a game-changing solution for construction stakeholders.*

KEYWORDS: *Building Information Modeling, Value Engineering, Sustainable Construction, Material Management, Construction Site Management, Architectural Engineering and Construction.*

1. INTRODUCTION

The construction industry is a critical sector in terms of economic sustainability. This enhances economic growth because it affects other economic areas. Appropriate building material selection and recommended construction details significantly affect the project cost. Moreover, their consumption value is approximately 40% of a project's total cost [3]. The designer ensures that the materials used in the proposed design are chosen accurately.

Floor tiles are major building materials widely used in the Architectural, Engineering, and Construction (AEC) industry. Moreover, it is used in every project with different materials and sizes. is also an essential material in architectural decoration, and its annual consumption worldwide has reached billions of square meters. For example, ceramic tiles, a type of floor tile, require high-temperature firing in factories to produce them, resulting in high energy consumption and significant pollutant emissions., thereby posing a serious threat to human health. The annual consumption of ceramic tiles reached 13 billion square meters by 2020, and more than half were used as floor tiles [6,7]. Improving the efficiency of floor tile application plays a critical role in promoting sustainable development in the AEC industry. Previous studies have shown that improving accuracy, effectiveness, and comprehensiveness may be an effective way to improve project benefits from the design perspective [6].

Compared with refined design, the waste rate difference of building materials caused by different design approaches can be as high as 41% in general architectural construction, and the difference in construction labor resource waste (e.g., rework) also shows a positive correlation [8].

In the architectural project, the architects chose the floor tiles according to the color and design, regardless of the size of the tiles and the wastage of cut tiles. Taking into consideration that Most tile producers and suppliers have different sizes for tiles of the same design and color. In theory, layout design requires architects to accurately plan the laying and cutting of materials. The design should include uncut and cut tiles and provide accurate graphics and figures for the following steps to achieve lean material management [9].

Aya Ali Shihata, Mohamed Anwar Fekry, Wessam Hamdy Abbas, *Implementation of Building Information Modeling (BIM) for Economic Sustainable Construction Minimizing Material Waste in Terms of Value Engineering,* pp. 1033-1041, DOI 10.36253/979-12-215-0289-3.103

Therefore, the main objectives of this study were as follows:

- To optimize the waste of floor tiles in construction projects from the early design phase.
- Choose the best flooring tile size for the room dimensions to minimize the waste ratio of the flooring tiles.
- Create a practical method for selecting the optimum floor tiles.
- To reduce the time required for technical office engineers in the takeoff process.

The optimization process is performed through the integration of the Value Engineering (VE) principles with Building Information Management (BIM) as a tool to input the data and the dimension of the space as parameters, input the different optional sizes of floor tiles, and apply the VE principles and equations.

1.1 BIM and VE integration approach

A project's success and higher market value (fulfilling the owner's specifications) depend on controlling the construction schedule and costs. To reduce the overall costs, stakeholders have increasingly been used in construction projects. The early project phase offers a great opportunity to use BIM to streamline VE. A bibliometric analysis was performed by Baarimah et al. in 2022 to determine the benefits of combining BIM and VE. The findings demonstrate that VE and BIM support rising prominence as mainstream subjects related to the building industry and decision-making around cost-earned value. The evaluation of generated alternatives using predetermined criteria is the most important stage in VE applications. Stakeholders can use multi-attribute criteria to integrate created models by designing an automated method to assess and contrast these options.

1.2 Value Engineering (VE).

Value Engineering (VE) is a proven management approach in the (AEC) industry that is used to improve the functioning of projects and eliminate unnecessary costs. Because the construction industry has faced various challenges in reaching a project's high value on time and within budget, VE has been applied in numerous countries around the world for half a century [9]. VE has become an integral part of the development of many projects' development [10]. Surveys have reported that VE can save as much as 5–10% of construction project costs [11].

The VE study procedure called the VE job plan, is a systematic problem-solving technique comprising the following phases: information, function, creativity, evaluation, development, and implementation. Among these phases, the creativity phase, followed by function analysis, is the most crucial for generating innovative ideas that require existing information and experiential knowledge from past VE projects [12].

Value = Function + Quality/ Cost

Where:

Function = The specific work that a design/item must perform, which must be the same for all the options of floor tiles

Quality = owner’s need, which is the percentage of cut tiles.

Cost = life cycle cost of the product. Moreover, the additional cost of the wastage of the materials

Assuming that the materials are compared, they have the same quality of manufacturing with the same design, color, and materials of different sizes, for example, the same ceramic tile with different sizes only. In this case, the tiles have the same function and quality.

1.3 The current approaches to selectin floor tiles

In most cases, architects choose floor tiles in the conceptual phase of the design by focusing on the type, color, and texture based on design principles, without paying attention to the importance of the floor tile size in the waste management process in the early decision-making stage of the project. Subsequently, shop drawings were drawn without providing the exact tile requirements. Therefore, quantity surveyor engineers estimate the exact number of floor tiles, including uncut and cut tiles manually from shop drawings, which requires considerable effort and time.

For these procedures, it is difficult to produce a different shop drawing for each floor tile option to estimate the number of floor tiles with cut and uncut tiles, and to have a waste ratio to be able to choose the best floor tile size for each space.

As shown in Table 1, for two rooms with the same area and different dimensions, the default most commonly used ceramic floor tiles are 60 × 60 cm. There were different numbers of tiles used in the two rooms.

- The waste ratio for Room 1 was 14% and the total number of tiles used was 30.
- The waste ratio for Room 2 was 14% and the total number of tiles used was 40.

As shown in Fig. 1, the flooring tile layout plan for the default selection is 60x60 cm. There is a clear-cut tile in the two rooms, which can be avoided by using right-floor tiles.

Table 1: Parameters of default selection size.

	Area.	Length.	Width.	Long Ratio.	Total tiles.	Uncut Tiles.	Cut Tiles.	Waste Rate.
Room 1	120000cm2	400cm	300cm	1.3	35	30	5	14%
Room 2	120000cm2	600cm	200cm	3	40	30	10	25%

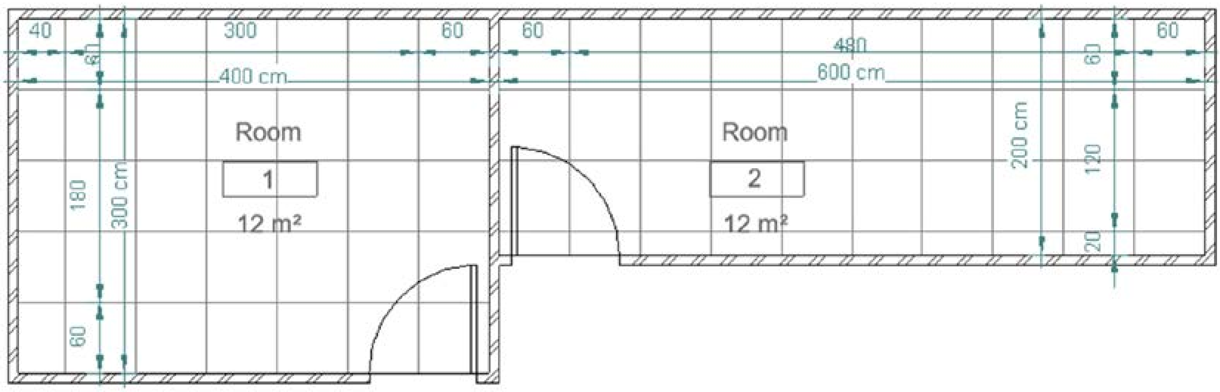

Fig. 1: Flooring tile layout plan for the default selection

2. RESEARCH METHODOLOGY

The purpose of this study is to develop material waste management for construction projects. Starting in the early design phase, develop a decision-making process for selecting the optimum floor tile size according to room dimensions.

As shown in Fig. 2, using a case study plan, this study focused on providing an automation framework according to the BIM model integrated with the VE job plan. The methodology focused on creating decision-making tools depending on the VE. The integration of the VE job plan and BIM into the framework through the optimization of the quantity of waste by applying the VE job plan through BIM tools to reach the optimum value by increasing the quality of the tile floor plan by decreasing the number of cut tiles to have as much space as possible with non-cut tiles, which is very visually comfortable, and decreasing the cost by choosing the optimum size of the tiles.

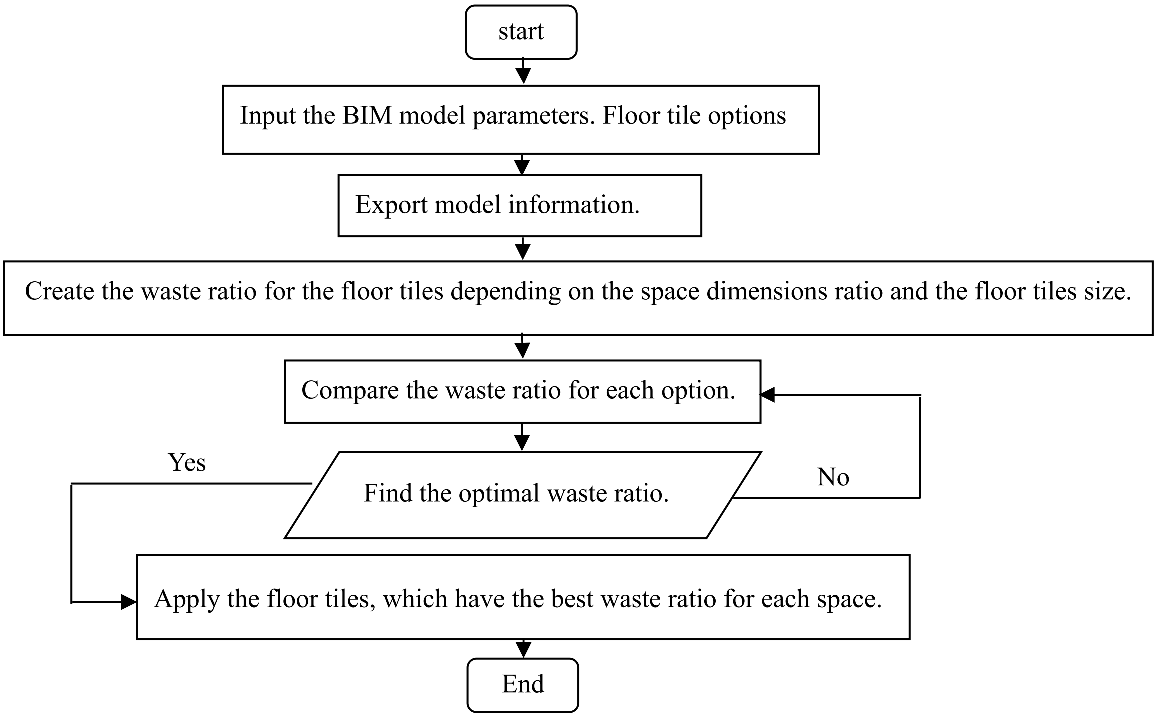

Fig. 2: The flowchart of the design decision-making tool

As shown in Fig. 3, the integration between the VE job plan and BIM optimization framework phase inputs the main parameters required for the floors.

- Function analysis: All the floors that were selected in the process must meet all the function requirements.
- Creativity Phase: Alternative sizer selection options.
- Evaluation phase: start to comprise the alternatives which had been chosen to meet the best quality and assess the risk for each option.
- Development Phase: Finalize the cost and schedule impacts.
- Implementation Phase: Initiate applying the optimum selection choice per quality and cost.

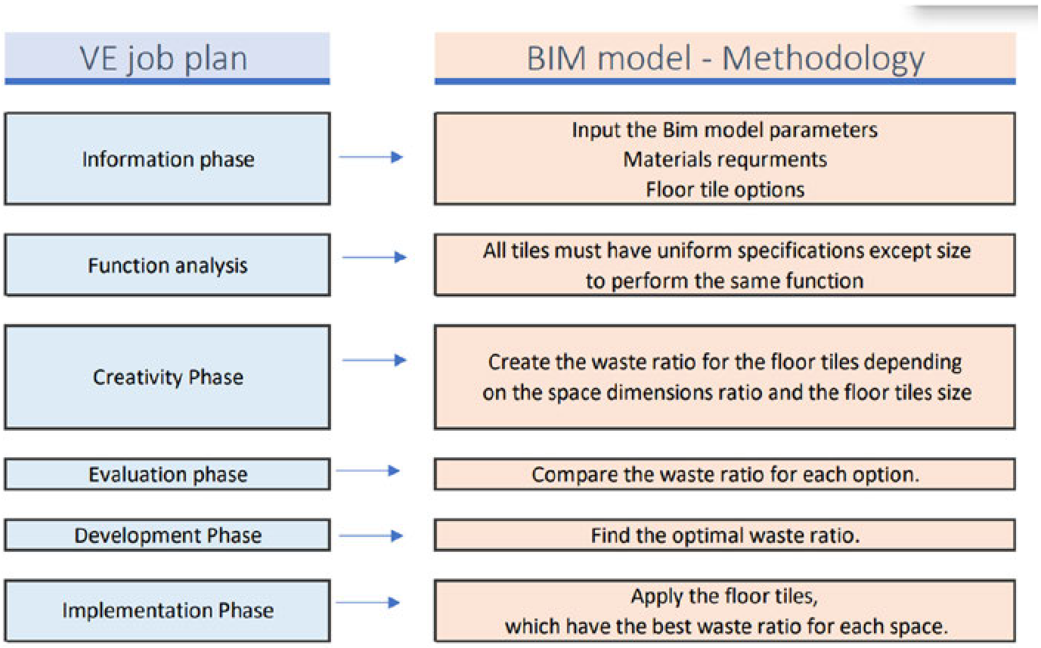

Fig. 3: The integration of the VE job plan and BIM into the optimization framework

3. CASE STUDY

Starting phase: Building the BIM model and inserting the floor tile options as parameters for each room, including the length, width, and dimensions of each floor tile option for each space in the model.

Fig. 4 shows a case study of two different rooms with the same area and different dimensions.

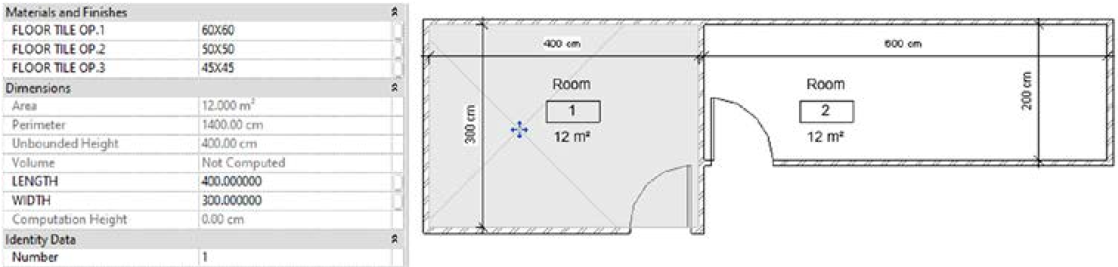

Fig. 4: the model instant parameter for each space

The next step is to create a Revit schedule for the instant parameter for each space, including the area of the room, length, width, and floor tile options. As shown in Fig. 5.

<FLOOR TILES OPTIONS>						
A	B	C	D	E	F	G
Name	Area	LR	WR	FLOOR TILE OP.1	FLOOR TILE OP.2	FLOOR TILE OP.3
Room1	12 m²	600	200	60X60	50X50	45X45
Room2	12 m²	400	300	60X60	50X50	45X45

Fig. 5: the model instant parameter for each space

Then export the Bim model schedule to an Excel sheet to apply the equations for each floor tile option, including the total tiles, uncut tiles, cuts tiles, and waste ratio.

The waste ratio was calculated according to the dimensions of the space and optional tiles, as shown in Fig. 6.

	TILE SIZE		ROOM DIMENTIONS		TILES IN X DIMENTION			TILES IN Y DIMENTION			TOTAL TILES	UNCUT TILES	CUTS TILES	WASTE RATIO
	LT=LENGTH OF TILE	WT=WIDTH OF TILE	LR=LENGTH OF ROOM	WR=WIDTH OF ROOM	UNCUT TILES	LR/LT	TOTAL TILES	UNCUT TILES	WR/WT	TOTAL TILES				
ROOM 1	60	60	600	200	10	10	10	3	3.33333	4	40	30	10	25.00%
	50	50	600	200	12	12	12	4	4	4	48	48	0	0.00%
	45	45	600	200	13	13.333333	14	4	4.44444	5	70	52	18	25.71%
ROOM 2	60	60	400	300	6	6.6666667	7	5	5	5	35	30	5	14.29%
	50	50	400	300	8	8	8	6	6	6	48	48	0	0.00%
	45	45	400	300	8	8.8888889	9	6	6.66667	7	63	48	15	23.81%

Fig. 6: the Excel sheet of the waste Ratio

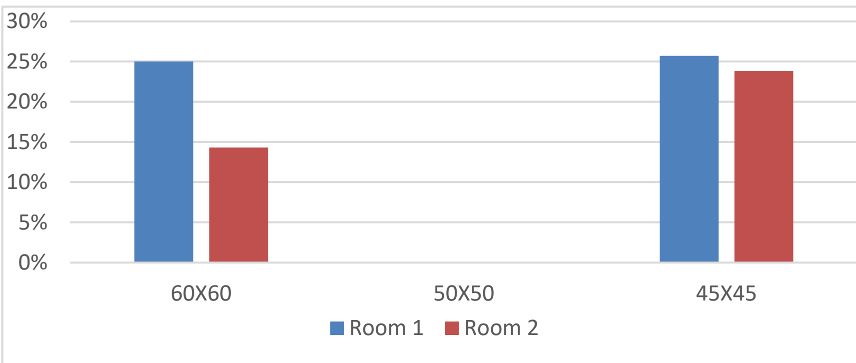

Fig. 7: Chart of waste ratio.

The schedule shows the results of the optional floor tiles, and the schedule shows the results for each space.

- The room 600 × 200 cm shows the following: the waste ratio of the tiling 60 × 60 cm is 25%, the waste ratio of the tiling, the waste ratio of the tiling 45 × 45 cm is 25.71%, and the best ratio is 0% for the flooring tiles 50 × 50.
- The room 400x300cm shows the following: the waste ratio of the tiling 60x60 cm is 14.29%, the waste ratio of the tiling, the waste ratio of the tiling 45x45 cm is 23.81%, and the best ratio is 0% for the flooring tiles 50x50.

Therefore, the optimum selection of the floor tile for the two rooms according to the design approach is 50 × 50 cm, as shown in the chart in Fig. 7.

The next step is importing the sheet excel into Revit using a dynamo script. The minimum waste ratio values were selected. Then, the selected floor tiles were applied to each space.

4. RESULTS AND DISCUSSION

The proposed workflow and decision-making tool for choosing floor tile size by integrating BIM techniques and VE principles generates the waste ratio for alternative floor-tiling sizes.

Rooms 1 and 2 have the same area (12 m2), but different widths and heights, which is used as an example of the current approach to floor tiles. After applying the research methodology and selecting the minimum waste ratio of the floor tile options, the waste ratios for Room 1 and Room 2 were reduced from 14% to 0% and from 25% to 0%, respectively. The total number of cut tiles and unused tiles is clarified in Table 2.

Table 2: Comparison between the default design approach and the optimized selection

	The original design				The optimized selection			
	Total tiles.	Uncut Tiles.	Cut Tiles.	Waste Rate.	Total tiles.	Uncut Tiles.	Cut Tiles.	Waste Rate.
Room 1	35	30	5	14%	48	48	0	0%
Room 2	40	30	10	25%	48	48	0	0%

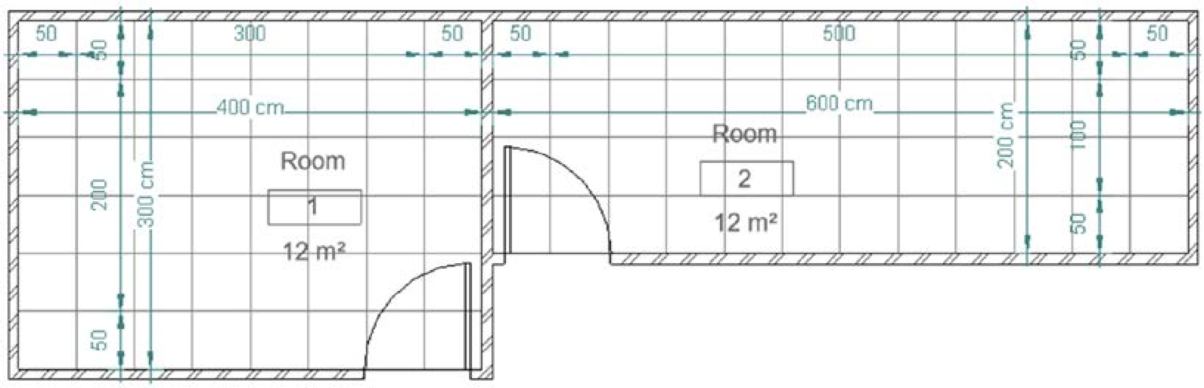

Table 2: Comparison between the default design approach and the optimized selection

As shown in Fig. 8, the floor tiling plan of the two spaces with the size of the selected tiles has a clear number of tiles with no cut tiles as a result of the proposed workflow, which is the optimum design of any space to have clear tiles with no cut tiles for multiple vectors, such as visual design-wise, sustainable to reduced waste ratio, and fast application.

Therefore, this design approach can be applied at different project scales with a large number of rooms to select the optimal floor tile size for each room and calculate the total waste ratio for all rooms that require the same floor tiles. Reducing the overall waste of flooring materials in the project eliminates the time required to apply value engineering principles in the project.

Selecting floor tiles in the AEC industry is a labor-intensive and time-consuming task. Architects often face difficulties in accurately creating shop drawings for floor tiles, owing to a lack of appropriate design tools. Consequently, they struggle to provide design support for subsequent stages, such as procurement and construction. This challenge becomes even more complex when architects need to incorporate waste reduction into their layout design. Consequently, the planning and cutting of floor tiles are typically performed extensively rather than precisely managed. This reliance on experience, rather than accurate calculations, leads to unnecessary material and labor wastage. To address this issue, we developed a workflow for generating accurate and comprehensive material waste rates.

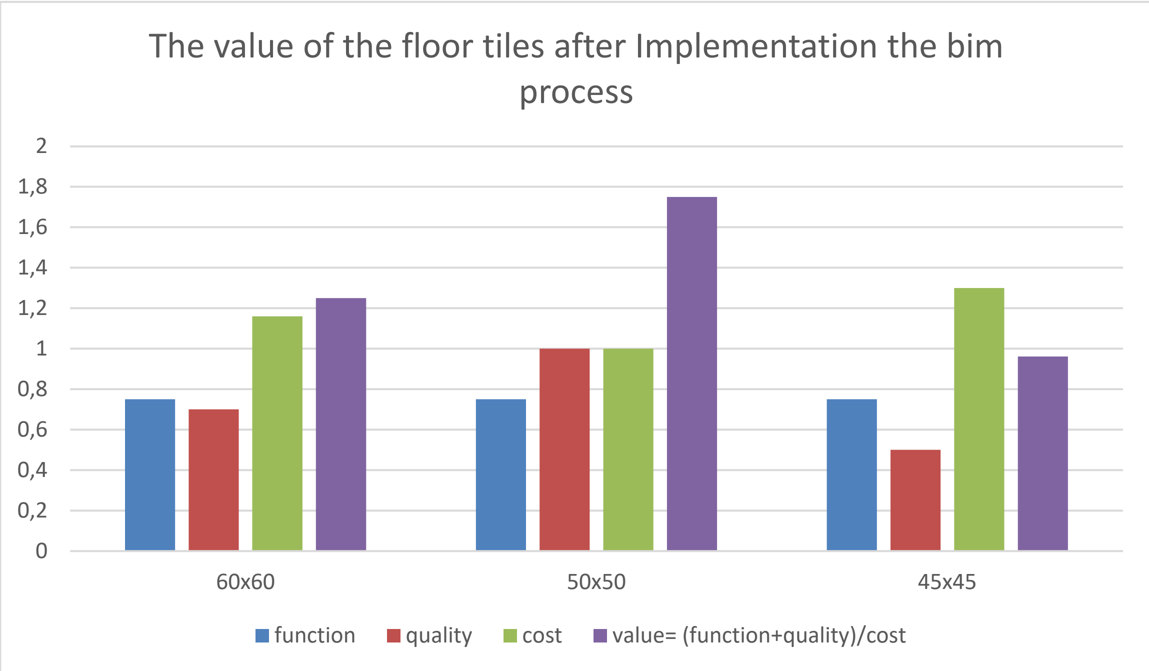

Fig. 9. The Result of the value engineering according to the integration of the Bim framework

5. CONCLUSIONS

This research proposes a workflow for selecting the optimized floor-tile size according to space percentage. The work limitation is on spaces with rectangular shapes with perpendicular angles, which is the most applicable space for material optimization in the VE process. All tiles must have uniform specifications except for size. The automation equation could be updated in future studies for application to regular spaces that are confirmed to have more than one rectangular shape by dividing the spaces into smaller rectangles.

The workflow integrates BIM and VE equations, enabling architects in the early decision-making phase of the project to automatically calculate the waste ratio of each floor tile size option by inserting the optional sizes, outputting the floor selection by the minimum waste ratio for each space individually, which significantly reduces the material waste, minimizing the time wastage of the quantity surveyor engineer surveying the quantity of tiles manually from the shop drawings, and calculating the exact number of uncut and cut tiles to enable the procurement engineer to order the correct amount of flooring tiles. This methodology is a step in waste management research to reduce the material-waste ratio and help technical office engineers to enhance the process of selecting and using flooring materials.

To enhance the entire tile design process, researchers proposed a workflow in the optimization process of floor tile planning to automatically generate the layout design of floor tiles, including uncut and cut tiles, after choosing the best tile size. [28]. Additionally, the two studies can be combined to form an integrated optimization process for the best tile planning.

ABSTRACT: *As climate change intensifies, we must embrace renewable solutions like solar energy to combat greenhouse gas emissions. Harnessing the sun's power, solar energy provides a limitless and eco-friendly source of electricity, reducing our reliance on fossil fuels. Rooftops offer prime real estate for solar panel installation, optimizing sun exposure, and maximizing clean energy generation at the point of use. For installing solar panels, inspecting the suitability of building rooftops is essential because faulty roof structures or obstructions can cause a significant reduction in power generation. Computer vision-based methods proved helpful in such inspections in large urban areas. However, previous studies mainly focused on image-based checking, which limits their usability in 3D applications such as roof slope inspection and building height determination required for proper solar panel installation. This study proposes a GIS-integrated urban point cloud segmentation method to overcome these challenges. Specifically, given a point cloud of a metropolitan area, first, it is localized in the GIS map. Then a deep-learning-based point cloud classification model is trained to detect buildings and rooftops. Finally, a rule-based checking determines the building height, roof slopes, and their appropriateness for solar panel installation. While testing at the National Taiwan University campus, the proposed method demonstrates its efficacy in assessing urban rooftops for solar panel installation.*

KEYWORDS: *Sustainable campus, renewable energy, point cloud segmentation, deep learning*

1. INTRODUCTION

One of the most critical and urgent challenges we face in this century is climate change, resulting mainly from human mass consumption of fossil fuels. Thus, replacing fossil fuels-based energy with renewable energy is a key solution to this problem (IPCC, 2022). Increasing the supply and usage of renewable energy relies on not only efforts by power producers and public sectors but also energy-heavy industries and private sectors. Hence, in recent years, many major corporations worldwide have announced their targets for decreasing carbon emissions and increasing renewable energy usage to fulfill their corporate social responsibility (CSR), and higher education institutions are no exception. Many universities worldwide have also announced their climate targets and planned to increase the usage and supply of renewable energy for their university's social responsibility (USR) (THE, 2022). National Taiwan University (NTU) also announced its carbon-neutral target and pathway in Nov 2021. To achieve this goal, the decrease in building energy usage and the increase in renewable energy are two key strategies. For the latter, how to install more solar panels and smart energy systems on campus is a key question to be explored.

To increase renewable energy supply, using spare spaces on building rooftops for solar panel installation is common in cities worldwide. Various factors affect the effectiveness of solar panel installation on the rooftops, including roof angles, shades created by nearby buildings or penthouses, and obstacles on the rooftops (Lin et al., 2022). To evaluate the potential of solar panel installation effectively, the collection and creation of digital data and models of study objects become critical (Sierra et al., 2022, Chen et al., 2023). Airborne laser scanning is a common practice to capture the basic outline of study objects (Wang et al., 2018). After segmenting the collected point cloud data via deep learning models, large-scale building reconstruction and automated extraction of building instances can be easily achieved (Huang et al. 2022, Feng et al. 2022).

This paper aims to analyze buildings' rooftops for solar panel installation through point cloud segmentation, taking National Taiwan University (NTU) in Taipei, Taiwan, as a study case. As the first university established in Taiwan, more than 100 buildings are on the main campus, built between the 1920s and the present. Large-scale building

point cloud is collected using airborne LiDAR, and a commercial GIS tool, ArcGIS Pro, is used for further analysis. The analysis process and results are presented in sections 2 and 3, along with the challenges encountered. The research outcome can be a good reference for other university campuses which aims to use similar dataset for similar analysis. The main contribution of the paper is as follows:

- It proposes an end-to-end workflow for building rooftop analysis using point cloud data.
- It also proposes a simple and fast methodology for point cloud segmentation using commercial software tools such as ArcGIS Pro.

2. RELATED STUDIES

2.1 Point Cloud Classification for Building Rooftop Analysis

The application of point cloud data obtained from advanced technologies such as LiDAR has significantly transformed geospatial analysis (Dawood et al., 2017). This innovative approach has garnered the attention of researchers tapping into these datasets to extract valuable insights about urban landscapes and, more specifically, to evaluate the feasibility of deploying solar panels on building rooftops (Stack & Narine, 2022). A focal point of this effort lies in utilizing point cloud classification techniques, which can discern various objects and surfaces within the three-dimensional environment. By harnessing these techniques, researchers can effectively identify the detailed contours of building structures, ascertain the orientation of roof planes, and anticipate potential obstructive elements (Sun et al., 2016). This approach starkly contrasts traditional two-dimensional methodologies, allowing for a much more exhaustive and nuanced assessment of the diverse attributes associated with rooftops. Consequently, this three-dimensional perspective empowers researchers and planners to make informed decisions regarding optimizing solar panel placements and leveraging rooftops for sustainable energy generation (Stack & Narine, 2022). The fusion of GIS and point cloud data has opened new avenues for geospatial analysis, enabling researchers to analyze urban environments in three-dimensional detail. However, previous studies hardly integrated point clouds and GIS to check the rooftop suitability for solar panel installation.

2.2 Deep Learning and Machine Learning Approaches

The amalgamation of deep learning and machine learning techniques has marked a substantial leap forward in enhancing the precision and effectiveness of point cloud classification (Pal & Hsieh, 2021). Prominent among these methodologies are convolutional neural networks (CNNs) and other sophisticated deep-learning architectures that have showcased exceptional prowess in deciphering intricate roof structures and discerning the diverse array of rooftop attributes (Yang et al., 2023). These methodologies have emerged as dynamic tools capable of automatically extracting valuable information from point cloud data. This encompassing capability spans identifying building footprints, precisely measuring roof areas, and detecting possible shading elements (Pohle-Fröhlich. et al., 2019). The cumulative result of these advancements is a substantially elevated accuracy and depth in evaluating rooftops' suitability for solar panel deployment (Tan et al., 2019). As these methods continue to mature and evolve, their application within the domain of point cloud classification holds tremendous promise for facilitating increasingly refined and reliable analyses, thus paving the way for more informed and effective decision-making processes related to solar energy integration.

3. METHODOLOGY

The methodology adopted in this study is divided into four steps: data acquisition, preprocessing, classification and analysis, and data aggregation. Figure 1 shows a graphical representation of the proposed methodology. This study uses ArcGIS Pro software for GIS-integrated point cloud classification and analysis. Details of each step of the method are explained in the following paragraphs.

3.1 Data acquisition

A UAV-mounted Light Detection and Ranging (LiDAR) device collects the point cloud data. This process begins with mission planning, outlining flight paths and parameters to ensure comprehensive coverage. Laser pulses are emitted toward the ground, and the LiDAR system calculates the return time to determine distances. The collected data generates a point cloud containing detailed 3D coordinates of terrain, buildings, vegetation, and other features. Georeferencing is achieved through GPS and INS for accurate positioning. Collected point clouds are stored in multiple LAS files of manageable sizes. LAS format is an industry-standard file format developed and managed by the American Society for Photogrammetry and Remote Sensing (ASPRS). It is a widely accepted and published standard for exchanging LiDAR data.

3.2 Preprocessing

In the preprocessing step, the point cloud data is in LAS format imported into ArcGIS Pro software, where the "Create LAS Dataset" tool is employed to establish a structured dataset for subsequent analysis. To accurately register the point cloud data with the GIS map, the map data frame should be in the same coordinate system as the LiDAR point cloud tile. The preprocessing involves aligning the coordinate system, performing initial classification, differentiating ground points, and applying quality checks. The dataset is then clipped to focus on the specific study area, and optional filtering and compression steps are used to enhance data quality and efficiency. This processed dataset is the foundation for various geospatial analyses within the ArcGIS Pro environment, including classification, feature extraction, and terrain modeling.

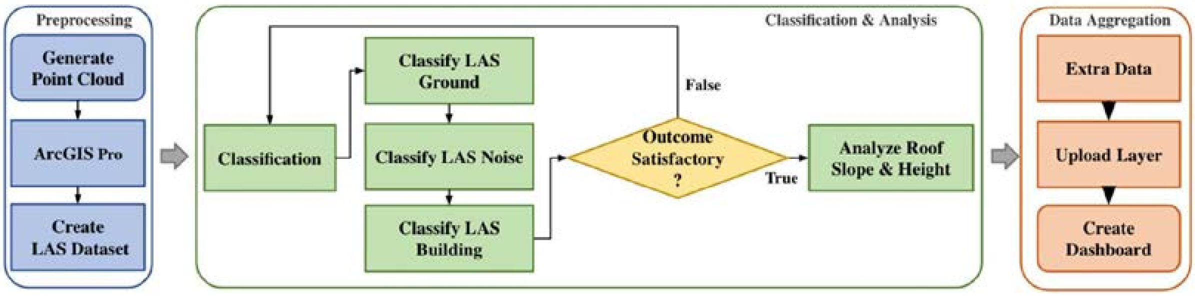

Fig. 1: Overview of the proposed methodology

3.3 Classification and analysis

Once the preprocessing is done, point cloud classification, roof slope analysis, and building height analysis are the next steps. Details of these steps are described below.

3.3.1 Point cloud classification

The point cloud classification is conducted in three steps: (1) using the built-in LAS classification functions such as Classify LAS Ground and Classify LAS Building. (2) 2D shapefile-based classification such as Set LAS Class Codes Using Features, and (3) Classifying a point cloud with deep learning.

First Classify LAS Ground tool is used for the identification of ground points. Ground point assignment is reserved exclusively for LAS points with 0, 1, or 2 class code values. If LAS files employ distinct class code values for unclassified or ground measurements, the Change LAS Class Codes tool can reassign them correspondingly. Next, Classify LAS Building tool is used to classify building rooftops with class code values 0, 1, and 6. Before rooftop classification, LAS data must have classified ground points. This method may not classify points representing walls, vertical facades, and small rooftop features like chimneys. Before building classification, point cloud noises are filtered using Classify LAS Noise function.

The 2D shapefile of buildings is used to enhance the classification quality further. LAS points intersecting the 2D positions of the input polygons are reclassified as buildings. Built-in function Set LAS Class Codes Using Features is used for this purpose. The ArcGIS software uses the American Society for Photogrammetry and Remote Sensing (ASPRS) defined LAS classification scheme. Although this step improves the classification, wall and façade classification is still challenging.

In the final step, a pre-trained deep-learning model, PointCNN, for building classification is used to improve the classification results further. The deep-learning model is inputted as a Deep Learning Package (*.dlpk) in the ArcGIS software. Using the Existing Class Code Handling parameter control over modifications in the target LAS point cloud was achieved. Points already correctly classified (such as grounds) are kept unchanged.

3.3.2 Roof slope and building height analysis

A raster file is created using elevation values stored in the LiDAR points referenced by the LAS dataset for roof slope and building height analysis. Subsequently, a digital elevation model (DEM) of the buildings is created. Next Spatial Analyst function for Slope calculation is used to identify the slope from each cell of the raster file. The Slope tool uses a three-by-three moving window of cells to compute the slope value. The extent of values in the output depends on the measurement units employed. When utilizing degrees, the range of slope values spans from 0 to 90. The analysis can be accelerated using GPU.

Building heights are estimated by comparing the digital surface model (DSM) and the DEM created earlier. The Zonal Statistics tool is used for this purpose. A zone encompasses all regions within the input that share an identical value. The input for defining zones can comprise both raster and feature data types. This tool helps in arithmetic statistics calculations such as Mean, Majority, Maximum, Median, Minimum, Minority, Percentile, Range, Standard deviation, Sum, and Difference. A zonal statistics raster is generated. In this study, the zonal statistics raster represents the building height. Finally, the suitability of the building for rooftop solar panel installation is determined by rule-based checking.

3.4 Data aggregation

During the data aggregation phase, the analysis outcomes, encompassing critical metrics like building heights, mean roof slopes, and evaluations of building suitability, are initially compiled into a structured comma-separated value (.csv) file. This file format aids in organizing the data for seamless processing and interpretation. Subsequently, this collected analytical information is integrated into the university campus's existing Geographic Information System (GIS) shapefile. This incorporation ensures that the analysis outcomes are appropriately aligned with the geographic context of the campus and can be readily accessed for further exploration. Additionally, an additional map layer is generated to enhance the visual representation of these analysis outcomes and promote efficient decision-making. This newly created layer is specifically tailored to present the aggregated results coherently and visually engagingly. The GIS-integrated dashboard within the ArcGIS software serves as a versatile tool for visualizing and interacting with the outcomes, facilitating comprehensive insights and informed actions based on the analysis conducted.

4. RESULTS

The proposed methodology was tested on the expansive 115-hectare main campus of National Taiwan University (NTU) in the Da'an District of Taipei. This sprawling campus hosts a multitude of academic and administrative buildings, exceeding a count of 100. The core objective of this study is to evaluate these buildings' viability for installing rooftop solar panels. To collect the crucial data, an unmanned aerial vehicle (UAV)-mounted LiDAR device was employed, effectively capturing the intricate point cloud representation of the campus. This extensive point cloud dataset was systematically stored in 13 distinct parts, all adhering to the standardized LAS format. Commercial software ArcGIS Pro was used for hosting, processing, and analyzing the point cloud and integrated GIS data. A computer with Intel i7-1370P central processing unit (CPU), 64-gigabyte (GB) random access memory, and 32 GB Intel®Iris®Xe Graphics graphics processing unit (GPU) is used to run the software tool.

In conjunction with this voluminous point cloud dataset, a Geographic Information System (GIS) map showcasing the 2D polygonal representation of campus buildings was prepared. Figure 2 visually depicts the campus's point cloud model and the 2D GIS map. A comprehensive LAS dataset was constructed by amalgamating all 13 LAS files within the ArcGIS Pro software. This amalgamation was executed in accordance with the preprocessing phase described within the methodology. The subsequent phase encompassed applying a three-step classification technique to the compiled LAS dataset, enabling the precise segmentation of building-related point cloud data. The initial stage involved the classification of ground points utilizing the LAS code, following which the 2D GIS polygons facilitated the segmentation of the building point cloud. Eventually, implementing a deep learning model proved instrumental in impeccably classifying and segmenting the points that accurately represented buildings. The outcomes of this segmentation are depicted in Figure 3, which showcases the successful classification outcomes for ground and building points.

Fig. 2: Point cloud (left) and 2D GIS map (right) of NTU main campus

Following the successful classification of building points, a customized DEM raster specific to the campus building was generated. Subsequently, the slope analysis tool was employed to accurately estimate the slope on building rooftops. In this study, the slope measurement unit was defined in degrees, resulting in values spanning the spectrum from 0 to 90 degrees. The ensuing outcome, depicted on the left-hand side of Figure 4, showcases the slope analysis raster. Significantly, the color coding scheme holds informative value: shades of green signify shallower slopes denoting suitability for solar panel installation, while shades of red signify steeper slopes indicating unsuitability. Notably, buildings characterized by substantial rooftop obstructions are prominently indicated in red hues. Furthermore, the color transition observed at building edges is attributed to shifts in slope characteristics, rendering rooftop edges prominently delineated in a striking red color.

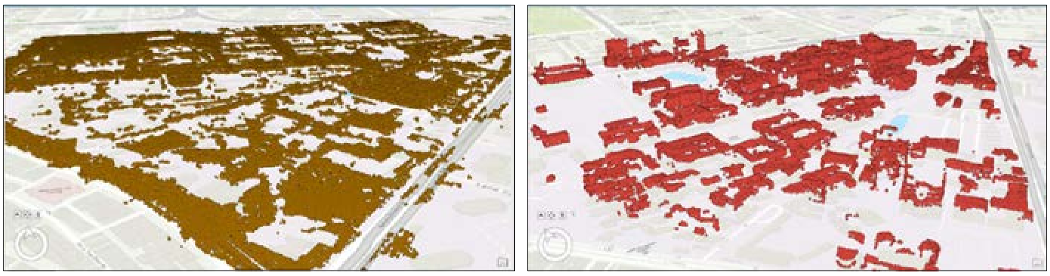

Fig. 3: Point cloud classification results: ground classification (left) and building classification (right)

Building heights were estimated through a comparison between the DSM and DEM rasters, utilizing the Zonal Statistics tool. The outcome of this building height estimation is rendered as a raster, distinguished by color codes corresponding to different heights. This representation is exhibited in the diagram on the right-hand side of Figure 4. Observations indicate that the tool proficiently determined building heights in the majority of cases. However, a few instances (depicted in red) disclosed significant inaccuracies in estimations. Subsequent in-depth analysis established that factors such as noise within the point cloud data, substantial tree obstruction, and inherent point cloud incompleteness substantially influenced the tool's performance.

Finally, the roof slope analysis and building height estimation results were exported into a .csv file, and the existing GIS shapefile was updated. The NTU's GIS dashboard is used to display the analysis results. It can help university administrators to make decisions in a more interactive way. An example of data integration for five buildings is shown in Table 1. The check column of the table shows the suitability of the building for rooftop solar panel installation. The checking result was incomplete for the civil engineering building because of the point cloud incompleteness. The GIS representations of these buildings are shown in Figure 5.

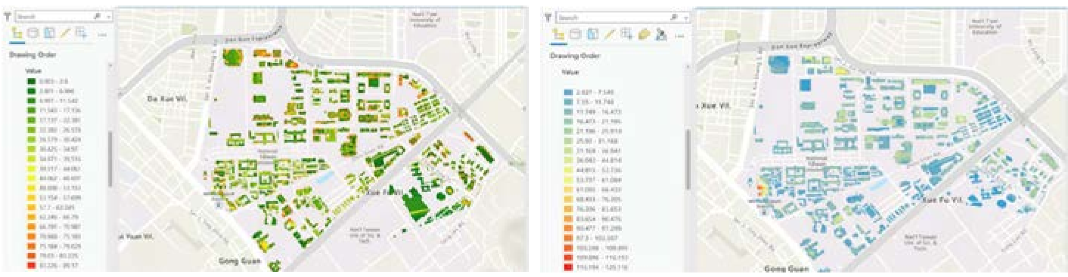

Fig. 4: Results of roof slope analysis (left) and building height estimation (right)

Concluding the process, the roof slope analysis and building height estimation outcomes were transferred into a .csv file, and the pre-existing GIS shapefile was updated concurrently. The integrated results are seamlessly displayed through NTU's GIS dashboard, enhancing the capacity of university administrators to make decisions in an interactive and informed manner. This holistic approach facilitates a more dynamic decision-making process. Exemplifying the integration, Table 1 demonstrates data amalgamation for five specific buildings. Notably, the "Check" column within the table signifies the suitability of each building for rooftop solar panel installation. However, it's essential to underscore that the checking process remained incomplete for the civil engineering building due to inherent point cloud incompleteness. The visual GIS representations of these buildings are depicted in Figure 5. This comprehensive integration emphasizes the analytical and visual richness of the approach.

5. DISCUSSIONS

Although the methodology successfully analyzed building rooftops for solar panel installation, its performance is affected by several factors: point cloud completeness, obstacles from tree leaves, noise in the point cloud data, etc. This method faces a challenge in rooftop analysis of the shorter buildings at the NTU campus because the rooftops of such facilities are often obstruction by tree leaves. Also, the state of these leaves is inherently unstable, subject to growth, pruning, and even shedding, introducing an element of uncertainty into the ongoing analysis. A potential solution could involve implementing filtering criteria during the initial point cloud scanning phase. This strategic approach would enable the retention of essential data points, subsequently alleviating the workload and refining the data for subsequent analysis. Also, the accuracy of the classification methods is subject to several factors, such as the completeness of the existing 2D GIS map data, proper alignment of the map and point cloud data, and the efficiency of the deep-learning model. The incompleteness of the map data and slight discrepancies between map data and point cloud data often leads to manual adjustments.

Table 1: Integration of analysis results in campus GIS map

Building Name	**Area.**	**Mean slope (°)**	**Height (m)**	**Check**
NCREE	13135.83	15.96	21.93	Great
College of Liberal Arts	5980.44	33.23	11.96	Ok
Dept. of Chemistry	11460.91	37.71	27.19	Ok
Floricultural Hall	1381.30	41.26	13.04	Ok
Dept. of Civil Engineering	9686.44	60.05	21.75	Insufficient Data

6. CONCLUSION & FUTURE WORK

In conclusion, this study presents a holistic approach to evaluating the suitability of building rooftops for solar panel installation, contributing to the overarching goal of mitigating climate change through renewable energy solutions. The pressing need to curtail greenhouse gas emissions highlights the imperative to transition away from fossil fuels. Integrating renewable sources, particularly solar energy, is pivotal in this attempt. Rooftops provide an underutilized space for solar panel deployment, offering decentralized clean energy generation. However, the effectiveness of such installations hinges on accurate assessments of rooftop attributes. This research introduces a sophisticated methodology amalgamating Geographic Information System (GIS) techniques with advanced point cloud segmentation methodologies. By harnessing airborne LiDAR technology and leveraging deep learning models, the proposed approach deftly addresses challenges such as rooftop slope analysis and building height determination, ensuring the accuracy and applicability of solar panel placement assessments. The study's application on the National Taiwan University campus confirms the practical viability of the methodology.

As universities and organizations worldwide set ambitious carbon neutrality goals, the methods outlined herein provide valuable tools for optimizing renewable energy integration. Moreover, the interdisciplinary nature of this research, encompassing spatial analysis and environmental considerations, exemplifies the multi-faceted approach required to address complex challenges like climate change. We can advance our understanding of sustainable energy practices through such interdisciplinary endeavors and work towards a greener and more resilient future.

7. ACKNOWLEDGEMENT

The author would like to thank the National Science and Technology Council, Taiwan, for supporting this research through research grant No. MOST 109-2221-E-002 -054 -MY3.

SEMI-AUTOMATIC WORKFLOW FOR AIR-CONDITIONING SYSTEM ZONING AND SIMULATION

Yikun Yang & Yiqun Pan
Tongji University, Shanghai, China

Georg Suter
Vienna University of Technology, Vienna, Austria

ABSTRACT: *Building information modeling shows its potential in the performance driven design, where multiple design solutions are generated and assessed against certain design goals. This paper proposes a workflow for the air-conditioning system design and simulation on thermal zoning level. Thermal zoning plays a pivotal role in the design thinking of engineers, synthesizing load calculation, equipment sizing, and pipe/duct layout. However, it is often done intuitively with its effectiveness and performance unclear at the outset. To make it quantitative, we decompose the zoning process into two levels (control/system) of space aggregation, joining both semantic and numeric characteristics. For the semantic part, space functions are considered through space labeling, accessibility, and adjacency. Regarding the numeric part, spaces are zoned based on their thermal response similarities, using dynamic mode decomposition of the simulated indoor temperature. A two-level hierarchy of duct/pipe network is generated. It connects spaces within each control zone at the second level, and terminal equipment of each zone at the first level, representing typical fan-coil or variable-air-volume systems. For each zoning scheme, the network and configurations are serialized as Modelica scripts for co-simulation with EnergyPlus. The designer can evaluate different zoning schemes in terms of initial cost, energy consumption, and comfort level, based on the simulation result. The entire workflow is implemented in Grasshopper with self-coded plugins.*

KEYWORDS: *BIM, Thermal zoning, Generative design, HVAC system, Performance simulation.*

1. INTRODUCTION

Building Information Modeling (BIM) provides solutions to the design and management problems in the realm of architecture, engineering and construction, as a platform for data and cooperation. The information can be delivered or retrieved by model view definitions (MVD), BIM query languages, or application programming interfaces (API). However, they barely offer model transformation, which involves the insertion, addition of level of detail, or aggregation of objects (Fischer, 1998). In the forward design process, the model transformation expands the room-based model into another space view for analysis (Suter, 2022), such as energy performance or system design.

Zoning is to transform the room-based model (architectural geometry) to a zone-based model, bridging BIM with building energy modeling (BEM), which is also a critical step in the design of an air-conditioning (AC) system. It is more like an "art" for so many factors to consider, such as space function restriction, space load profiles, convenience for ductwork, balance of performance and cost, and even user preference, both semantic and numeric and hard to quantify. The engineers usually solve the zoning problem intuitively by rule of thumb, leading to one solution. How will it affect the system performance or whether there exists an optimum zoning scheme remains unsolved. Back in 2001, Brahme et al. (2001) investigated the generative ducting based on a grid system at the initial stage. Berquist et al. (2017) continued the idea of generative design and experimentally piloted different zoning on several rooms. Bres et al. (2017) examined the zoning effect of the water heating system for residential buildings, with detailed simulation feedback from TRNSYS. With the lower cost of simulation, it is quite possible to automate the system design and simulation at the zoning phase.

In system design, a thermal zone represents the spaces (part or aggregation of rooms) with heating and cooling requirements that are sufficiently similar so that desired conditions can be maintained throughout using a single sensor (denoted as *control unit*). However, in simulation, the thermal zone stands for the spaces that can be lumped together as a single air node (rephrased as a *simulation unit*), where the parameters of air are uniform. The difference is that the simulation unit is scalable, depending on the modeling target (Fig. 1). For example, it should be in line with the control unit when modeling buildings in operation, as recommended by the ASHRAE Standard. When it comes to the building massing, a shoebox model is enough to study how geometric form affects energy performance. Even one thermal zone for a building is acceptable in city-scale simulation and

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)

planning. In the system design, the control unit is the smallest on the building scale, which considers the load similarity. When the building gets larger, more system units emerge with load diversity considered. For example, on a system zoning level, equipment can be downsized by staggering the load profiles of control units. A proper zoning and routing of distribution network can reduce the power of fan/pump. More energy distribution can be regulated on a larger scale, such as the exhibition center that has multiple plants or power stations.

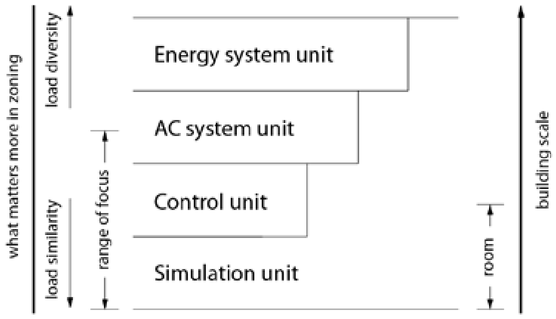

Fig. 1: Different levels of zoning in system design and simulation

Ideally, one should set the control unit exactly the same as the functional space. However, it may have more complex plumbing, ductwork and sensor/equipment installation, increasing the initial cost. There is a trade-off in controlling multiple spaces by a single thermostat since it does cut the cost while causing overheating/cooling. To manifest such an effect, the simulation unit must be smaller than the control unit, or the temperature difference will be evened out during the parameter lumping. Hence, this work takes the functional space as the atomic simulation unit and focuses on the zoning of control unit and system unit.

It is not quite straightforward to evaluate different zoning schemes since it is concerned with the actual system performance and the cost of related equipment configurations. A view model of the distribution network would help with the cost estimation and even the system energy modeling. Bres et al. (2017) pipelined the distribution network generation of the water heating system for residential buildings, by finding the minimum spanning tree (MST) from the potential zone centroids and space boundary vertices. Medjdoub et al. (2018) developed a method for open space fan-coil system layout under specific restrictions. Chen et al. (2022) solved the layout of diffusers and ducts for open spaces with hydraulic balance considered. In related research, the distribution system above the thermal zone level has been rarely visited, especially for non-residential buildings. The problem of distribution network layouts is similar to the design of integrated circuits (Held, 2011) or indoor navigation networks (Fu, 2020).

Following the thread of Bres et al. (2017), this paper details the workflow of thermal zoning and the modeling of air-conditioning distribution systems for office buildings, which can offer multiple zoning schemes in primary design with simulation feedback. After an overview of the methodology, the rest of the paper will be organized into four parts: space view generation, thermal response analysis and zoning, pipe/duct network generation, and model scripting. Each part is exemplified by the same floorplan for reference.

2. METHODOLOGY

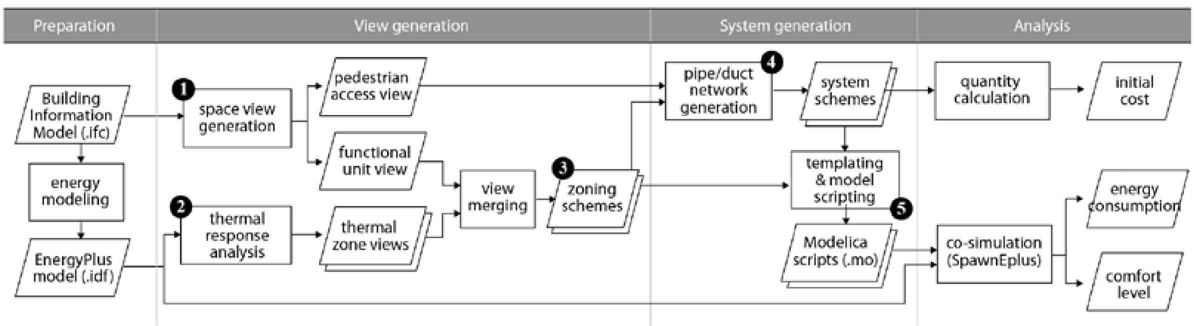

Fig. 2: The semi-automatic workflow of generative thermal zoning toward system simulation

Fig. 2 shows the overall workflow that takes the BIM model (IFC file) as input. In the first preparation stage, the user needs to manually check the integrity of the information model. All spaces must be defined and labeled with their function correctly. All spaces must have boundary components and the 2nd-level boundary defined. To facilitate the testing, templates of construction type, space schedule and load settings are used. The model conversion from BIM to energy model implements IfcOpenShell (Visschers, 2016) and OpenStudio SDK.

The first step includes previous work by Suter et al. (2013), where a method is described to define space views and transform room-based source space data into corresponding space models. Following certain view definitions, the space layout can be selected, aggregated, or decomposed into functional views that are relevant to schematic design (Suter, 2015). The pedestrian space access network is used to identify circulation areas and shafts for plumbing, and the functional unit view for space groups with similarities.

The second step applies Dynamic Mode Decomposition (DMD) (Schmid, 2022) to group spaces with similar thermal responses, similar to the Koopman Analysis application by Georgescu (2015), only more sampler and cost-effective in computation. By tuning the clustering threshold, multiple thermal zone views are generated. The functional unit view and thermal zone views are overlaid as zoning schemes, satisfying both semantic and physical requirements.

The third step implements the potential network that conceptualizes pipe/duct layout in early design, guiding the system distribution network routing. It does not reflect the actual design so the pipe/duct and the equipment may overlay in the schematic diagram. The network first joins spaces of a thermal zone and then connects each zone to the designated shafts. A JSON file collects the geometry and topology of the generated system, with information of peak load, thermostat inherited from zoning schemes.

The fourth step parses the zoning and system into the simulation model. For system simulation, Modelica is used to reflect the control effect across spaces of a thermal zone, which is the temperature bias caused by sharing a thermostat, while EnergyPlus handles the building physics as co-simulation. The workflow is able to reflect the system performance by simulation outputs (energy consumption and comfort level) and quantity takeoffs (equipment, pipe/duct/junction).

Apart from the space view generation (space modeling system, Suter, 2022), the workflow is implemented on the Grasshopper platform with the help of LadybugTools (Roudsari, 2013) and self-coded components. Modularized components make it easier for testing and visualization. The toolkit[1] is written in C# with Rhino core algorithms and CGAL.

3. FUNCTIONAL UNIT VIEW

Although thermal zoning follows clear yet implicit physical requirements, there are more explicit semantic restrictions to it, such as the fire compartmentation forbidding cross ventilation, or the tenant zone for separate energy management. Additionally, designers must consider space functions to avoid serving bathrooms and offices with the same duct system. The functional unit view can depict such a function isolation.

In previous work (Suter, 2022), a data processing pipeline was proposed for defining space views using space ontologies and layout transformation operations. The generated space view model can help with the space layout analysis by offering insights int space function, accessibility, orientation, daylighting or ventilation. In the first step, room-based source data are extracted from BIM by IFC class filters, such as space geometry and related objects. The second step transforms the data to a source space layout, where spaces are labeled automatically or manually. Labels are assigned by default according to the IFC to space ontologies class mapping. Additional labels are inferred by semantic reasoning. In the third step, the source space layout is transformed into a certain space view, by its defined operation sequence (including filtering, selection, aggregation and update).

The functional unit view uses the space access network to identify the cluster in terms of adjacency and function. The space access network originates from a spatial relation network that builds upon centroid nodes of all layout elements (e.g., spaces and doors), with their spatial relations as edges. Such relations include containment, adjacency, proximity, and partial enclosure. A door adjacent to two spaces indicates an accessible path lies in between, while the isolated node with no accessibility proves to be a shaft. Different levels of depth in the space access network tell how important a space functions as a circulation area. Typically, the main circulation space contains the elements accessing each functional unit, which form a node cut-set that partitions a space access network into multiple components. Spaces are then merged as a functional unit with classification (function label) inferred from the spaces within.

Fig. 3 Sample floorplan [2]

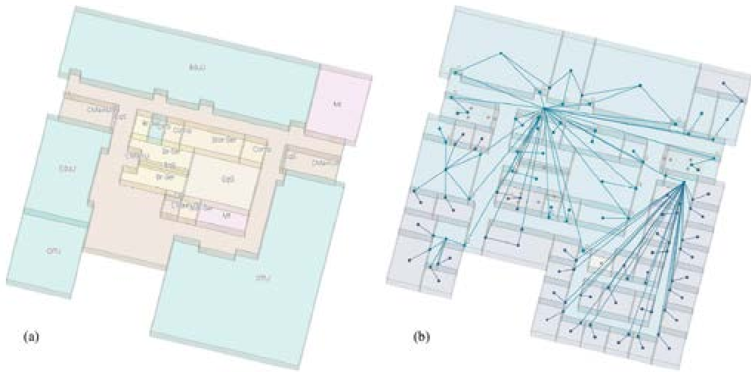

Fig. 4 Generated view of (a) functional unit (b) space access network

Fig. 3 displays the floorplan used for this work, labeled with detail functions. In the example (Fig. 4-a), there are seven major functional units: two marked as educational units (EduU) that include classrooms and affiliated spaces; two marked as office units (OffU) according to their major function; two meeting units (Mt); one circulation unit including the main corridor, stairs and atrium. This view will act as an overlay to the thermal zoning, reflecting function restrictions.

4. THERMAL ZONING VIEW

The control needs for air-conditioning are directly reflected by the thermal responses of all spaces. Taking the whole floorplan as one dynamic system, each space may have different characteristics. The essence of thermal zoning is to apply the same control logic to several spaces sharing similar dynamic characteristics, thus achieving an acceptable control effect with less controller and actuator.

Although many factors are intertwined in this complex dynamic system, such as operation schedule, internal loads, solar radiation, thermal resistance and thermal mass of structure components, the indoor float temperature is one direct externalization of such dynamics. By measuring the time series of temperature waves, we may identify the dynamic characteristics of each space, and aggregate them as thermal zones based on their similarity. Inspired by Georgescu (2015), Dynamic Mode Decomposition (DMD) is used to perform the Koopman Analysis, extracting the dominant modes and their properties based on the free-float temperature data.

The general idea of the Koopman Analysis is to study the time evolution of observables under iteration of a nonlinear system through the Koopman operator U, which is linear but infinite dimensional (Raak, 2016). Considering a dynamic system $\boldsymbol{x}_{k+1} = \boldsymbol{f}(\boldsymbol{x}_k)$ evolving on a manifold M, $\boldsymbol{f}$ is a non-linear map describing how $\boldsymbol{x}$ evolves in discrete time. The operator U acts on the scalar function $g: M \to \mathbb{R}$ (1), which is the selected observable (or the system output), then describes its evolution in a linear, infinite space, along with the system $\boldsymbol{f}$:

$$Ug := g \circ \boldsymbol{f} \qquad \mathrm{Ug}(\boldsymbol{x}_k) = \mathrm{g}\big(\boldsymbol{f}(\boldsymbol{x}_k)\big) = \mathrm{g}(\boldsymbol{x}_{k+1}) \tag{1}$$

Given eigen-decomposition of U (2), we may generally express the vector function $\boldsymbol{g}: M \to \mathbb{R}^n$, in terms of Koopman eigenfunctions ϕ_j and eigenvalues λ_j by (3),

$$U\phi_j(\boldsymbol{x}) = \lambda_j \phi_j(\boldsymbol{x}), \quad j = 1, 2 \ldots \infty \tag{2}$$

$$\boldsymbol{g}(\boldsymbol{x}) = \sum_{j=1}^{\infty} \phi_j(\boldsymbol{x})\boldsymbol{v}_j \qquad \boldsymbol{g}(\boldsymbol{x}_k) = \sum_{j=1}^{\infty} \lambda_j^k \phi_j(\boldsymbol{x}_0)\boldsymbol{v}_j \tag{3}$$

where $\{\boldsymbol{v}_j\}$ is a set of vector coefficients called Koopman modes of map $\boldsymbol{f}$. The set of eigenvalues $\{\lambda_j\}$ indicates the growth rate and frequency of each mode. The practical idea behind this is to collect a set of data, identify observable $\boldsymbol{g}$ of interest, and then express it in terms of Koopman modes and eigenvalues (Chen, 2012). For example, one may take the time series temperature of spaces as observables (data snapshots $\mathbf{X}(\mathrm{n} \times \mathrm{m})$), and analyze the thermal responses of the complex system by eigenvalues and modes.

[2] https://www.angelo.edu/live/news/12569-no-place-like-home

The DMD algorithm approximates the modes and eigenvalues by a finite data set, with a variant of the Arnoldi method described in Chen et al. (2012) and summarized as (Alg. 1). Assuming the dynamic $\boldsymbol{f}$ is linear with $\boldsymbol{f}(\boldsymbol{x}) = \boldsymbol{A}\boldsymbol{x}$, then eigenvalues of $\boldsymbol{A}$ are also eigenvalues of U. Furthermore, if $\boldsymbol{g}(\boldsymbol{x}) = \boldsymbol{x}$, then modes $\boldsymbol{v}_j$ are the corresponding eigenvectors of $\boldsymbol{A}$ (Rowley et al., 2009). However, eigen-decomposition of A is hard to solve directly due to its large dimensions. Alg. 1 further approximates A by projecting it onto one Krylov subspace $\mathcal{K}$ expanded by $\boldsymbol{K}$, then calculating the eigenvalues and eigenvectors with the low-rank operator. Note that in real-world non-linear problems, there must be a bias $\boldsymbol{r}$ representing $\boldsymbol{x}_m$ within $\mathcal{K}$, it is critical to find suitable constant vector(s) $\boldsymbol{c}$ to minimize $\boldsymbol{r}$ in least-square sense (Alg. 1 Line 2). Then, $\boldsymbol{C}$ is regarded as an approximation of the action of the Koopman operator on the associated finite dimensional space $\mathcal{K}$ (Raak, 2016). The resulting empirical Ritz values and vectors (Alg. 1 Lines 7, 8) behave in precisely the same manner as the eigenvalues and modes v of U (1). The theoretical deduction can be found in Rowley et al. (2009).

Algorithm 1 DMD (one variant of standard Arnoldi)

Input snapshots of observable $[\boldsymbol{x}_0\ \boldsymbol{x}_1 \cdots\ \boldsymbol{x}_m]$, $\boldsymbol{x}_k \in \mathbb{R}^n$

Output Ritz values $\{\lambda_i\}$, Ritz vectors $\{\boldsymbol{v}_i\}$

1: $\boldsymbol{K} := [\boldsymbol{x}_0\ \cdots\ \boldsymbol{x}_{m-1}]$, $\boldsymbol{c} := [c_0\ \ldots\ c_{m-1}]^T$

2: $\boldsymbol{x}_m = \boldsymbol{K}\boldsymbol{c} + \boldsymbol{r}$, $\quad \boldsymbol{r} \perp span(\boldsymbol{x}_0 \ldots \boldsymbol{x}_{m-1})$ ▷ find constant $\boldsymbol{c}$ to construct $\boldsymbol{x}_m$ with minimal residual in least-square sense

3: $\boldsymbol{c} = \boldsymbol{K}^{+}\boldsymbol{x}_m$ ▷ one solution by observation

4: $\boldsymbol{K}^{+} = (\boldsymbol{K}^{*}\boldsymbol{K})^{-1}\boldsymbol{K}^{*}$ ▷ when $\boldsymbol{K}$ is not full rank

5: Construct the companion matrix

$$\boldsymbol{C} := \begin{bmatrix} 0 & 0 & \cdots & 0 & c_0 \\ 1 & 0 & & 0 & c_1 \\ 0 & 1 & & 0 & c_2 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & \cdots & 1 & c_{m-1} \end{bmatrix}$$

6: $\boldsymbol{C} = \boldsymbol{T}^{-1}\boldsymbol{\Lambda}\boldsymbol{T}$ ▷ one possible decomposition

7: Output diagonal $\boldsymbol{\Lambda}$ as Ritz values $\{\lambda_1, \ldots, \lambda_m\}$

8: Output $\boldsymbol{V} := \boldsymbol{K}\boldsymbol{T}^{-1}$ as Ritz vectors $\{\boldsymbol{v}_1, \ldots, \boldsymbol{v}_m\}$

There are various approximation methods of $\boldsymbol{A}$ span over the algorithm spectrum, from Koopman analysis (accurate, complex) to DMD (coarse, simple). For example, one can implement a classical Arnoldi algorithm, or by other variants like QR decomposition, SVD decomposition (standard DMD), or Proney-type method (Hankel DMD) (Schmid, 2022). Alg. 1 applies a variant Arnoldi method that takes $\boldsymbol{c} = \boldsymbol{K}^{+}\boldsymbol{x}_m$ as one solution for Line 2 by observation. It is not unique and the result needs cross-verification.

By simulation, a typical school building may yield year-long (8760 hours) time-series data on the free-float temperature, of hundreds of spaces. The space dimension of each snapshot is far less than its time dimension (n ≪ m), where rank deficiency is inevitable. The standard DMD method performs poorly because its SVD process truncates the matrix to n×n with lots of information loss on the time dimension. While, the Arnoldi method gives nice accuracy because it expands the matrix to m×m without truncation. A similar method is applied to the air temperature analysis of a conditioned room (Boskic, 2020), with the data dimension 28×241, and a power system whose data dimension is 7×24~120 (Raak, 2016).

In order to get the free-float temperature and perform the analysis, the following workflow is implemented based on the Grasshopper platform. It includes three steps: 1) build up the energy model by retrieving IFC information; 2) implement the Arnoldi algorithm on the temperature series output by simulation; 3) perform hierarchical clustering and output multiple thermal zoning schemes.

The building floorplan can be manually drawn or transplanted from IFC by IfcOpenShell (Visschers, 2016). The LadybugTools (Roudsary, 2013) helps with the energy modeling based on the geometry and function labeling, by calling OpenStudio SDK. EnergyPlus 9.6.0 performs the year-long simulation without any system, using construction and space function templates from ASHRAE Standard 189.1-200. Because EnergyPlus 9.6.0 does not support thermal zones with multiply-connected region, some corridors are further divided in this case.

Fed with the temperature series, Alg. 1 yields the empirical Ritz vectors and values approximating the Koopman modes $\boldsymbol{v}$ and their eigenvalues λ. If the complex number λ falls near the unit circle, it represents a more steadily evolving mode. Here we name the Growth as $|\lambda|$, the Norm as $|\mathbf{v}|$, and the Frequency as $Im(log(\lambda))/2\pi\Delta t$. Δt stands for the sampling period which, in this case, is 1 hour.

The dominant modes must be selected and cross-validated because the Arnoldi method generates tons of modes (equal to the number of time dimensions). A simple way is to identify the energy-intense frequency bands, then rank all modes by their growth value in descending order, and look up for those modes with the largest norm. In this case, by Discrete Fourier Analysis, the frequency bands of 1/8760, 1/24, and 1/168 take up over 95% energy of the entire system, which corresponds to the year, day and week period, in line with the actual operation schedule. In this way, the dominant modes are highlighted in red in Table 1.

Table 1: Modes ranked by growth

mode	growth	norm	1/frequency
8237	1.000038	9.185662	9656.458
8238	1.000038	13.93669	-9656.458
8418	1.000029	51.34232	168.4023
8419	1.000029	64.30705	-168.4023
5799	**1.000026**	**249.9451**	**23.92526**
5800	1.000026	267.1617	-23.92526
8239	0.999999	82.70703	∞
5845	0.999960	261.9814	24.0553
5846	0.999960	303.0435	-24.0553
5779	0.999950	150.2885	23.9970

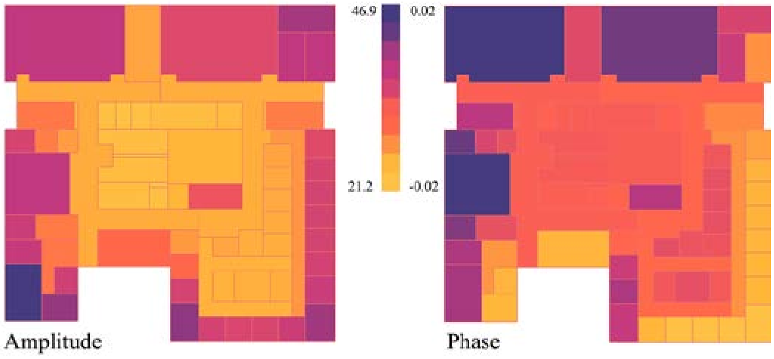

Fig. 6 The distribution of amplitude and phase of mode 5799.

Within the dominant mode, each complex number in $\boldsymbol{v}$ represents the dynamic characteristics of a space. In Fig. 6, each space is rendered by pseudo color based on the calculated amplitude (norm) and argument value as follows. Space aggregation can be identified visually.

$$Amp = \sqrt{Re(\boldsymbol{v}_i)^2 + Im(\boldsymbol{v}_i)^2}, \quad Arg = \arctan\left(\frac{Im(\boldsymbol{v}_i)}{Re(\boldsymbol{v}_i)}\right)$$

To make it quantified, the hierarchical clustering is implemented on the 2-dimensional data space by their Euclidian distance. The hierarchical clustering gradually increases the threshold of cluster distance (e.g., the similarity of dynamic response), and generates multiple layouts (Fig. 7) as the generative zoning process.

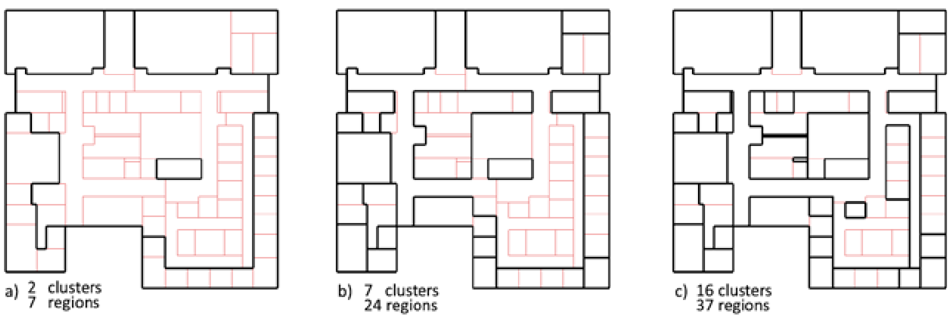

Fig. 7: Different thermal zoning schemes based on different cluster distance.

The final zoning scheme is the overlay of the thermal zoning view and the functional unit view, with all unconditioned spaces ignored. Spaces already grouped in thermal zoning may be partitioned again by the functional unit view.

5. PIPE/DUCT NETWORK VIEW

To better evaluate the effectiveness of zoning schemes, a detailed pipe/duct network view for the distribution system is needed. The designer may grasp a basic idea of system layout and initial cost through the view, even the performance of comfort control and energy consumption via automatic simulation. Similar to the space access network, a pipe/duct network is introduced to describe the path how cooling/heating energy is delivered to each space. Since the zoning process focuses on space aggregation, the terminal ductwork within each space remains unaltered and is consequently not taken into account.

Bres (2017) devised a loop pattern for the water heating system generation, connecting radiators of each zone with pipes around the floorplan perimeter. Due to the buoyancy effect, the radiators are normally located at the baseboard so the water loop should avoid the circulation area. On the contrary, the air-conditioning system incorporates sizable equipment and ducts, making it more cost-effective to distribute cool/warm air through the ceiling void, from core to perimeter. With such a tree pattern, the pipe/duct network starts from core shafts or mechanical rooms and then spreads outward via circulation areas to terminal spaces.

Pipe and duct require dedicated space. Typically, the ceiling void in circulation areas is allocated for the installation of electric wiring, ductwork or plumbing. These circulation areas can be identified based on the space access graph in section 3 (Fig. 4-b). In graph theory, the degree of a node denotes the number of edges incident to that node. Thus, the inaccessible shafts have a degree of zero while the corridor usually has the largest degree. Other spaces (degree > 2), such as waiting rooms, may serve as circulation areas in their own functional unit. The space view in Fig. 8 can be drawn following the methods in section 3.

Algorithm 2 Generate Skeletons

Input rooms as polygon set $R = \{P_0, P_1, \ldots, P_n\}$. Within set P_0 represents the outer boundary while others inner holes. η_{min}, η_{max}
Output list of edge set $list\{S\}$

```
Merge any two set R1 and R2 if R1[0] and R2[0] overlap, then replace R1[0] and R2[0] by the polygon of their Boolean union.
Initiate list{S}
for each remaining R do
    Solve Straight Skeleton by R, build graph G(V, E) from generated inner bisectors, output other bisectors as edge set B
    d ← 0
    for each v in V do
        time(v) ← "time" value of the vertex
        degree(v) ← the degree of vertex
        if degree(v) = 1 then
            if time(v) < η_min then
                remove v from V
            else
                Find edges e1, e2 incident to v from B, then add their bisector as edge to G
            if time(v) > d and time(v) < η_max then
                d ← time(v)
    Get offset polygon set C by Straight Skeleton algorithm from R by inward depth of d
    Break up all edges in S by intersection points with C
    Remove edges from S that are inside the region formed by C
    Merge edges in C with S, then append S to list{S}
```

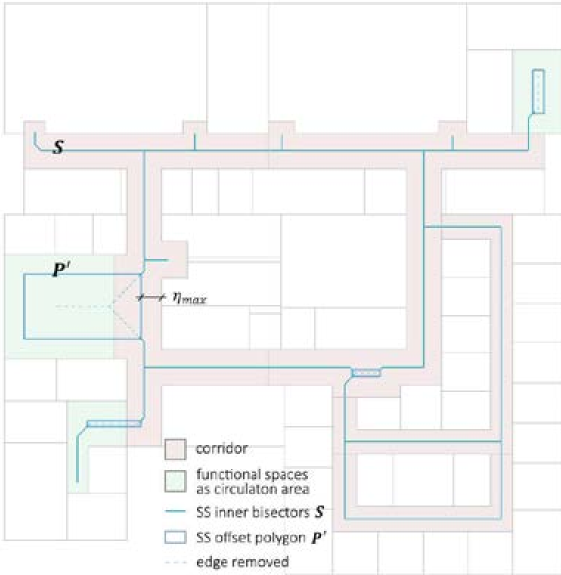

Fig. 8: Circulation areas and the prototype network

Upon the Boolean union of circulation areas, Alg. 2 generates the prototype of potential network by the Straight Skeleton (SS) algorithm. The straight skeleton is defined by continuously moving the polygon edges inwards parallel to themselves at a constant speed. Edges may split in two (split event) or vanish (edge event) due to vertices collision. During this offset process, a set of lines will be traced out by the moving vertices, which is the straight skeleton. It represents the shape well by centerlines, making it suitable for guiding the installation of ductwork. However, for open space such as foyer, the pipe/duct usually walks along the wall (not across the space), which means the offset process should stop at a certain depth. To achieve this, Alg. 2 takes a two-step skeleton generation. Firstly, generate the straight skeleton from the boundary polygon $\boldsymbol{P}$ (Sugihara, 2013), and filter out all interior bisectors as a set $\boldsymbol{S}$. Each vertex in it has a "time" attribute that marks how long it walks during the offset process. Secondly, generate the offset polygon $\boldsymbol{P'}$ by the largest "time" value below the threshold η_{max} (3m, for instance). Thirdly, perform a Boolean subtraction on $\boldsymbol{S}$ using $\boldsymbol{P'}$, and then merge it with $\boldsymbol{P'}$ as the final prototype $\boldsymbol{S}$ (Fig. 8). $2 \times \eta_{max}$ represents the typical width that distinguishes a corridor from a hallway.

In terms of the actual pipe/duct layout, the resulting set of line segments has too many joints, twists and branches. They need further simplification by extension, pruning and alignment. For extension, a vertex generated in an 'edge event' needs to be connected to the mid-point of the edge from which it is collapsed (Fig. 9-b). For pruning, a vertex with too small "time" value below the threshold η_{min} (1m, for instance), as well as the edge incident to it, needs to be pruned (Fig. 9-c). $2 \times \eta_{min}$ represents the minimum width of a typical corridor. Such redundant "branches" are often caused by zig-zag polygon boundaries. For alignment: 1) Considering all prevalent edge directions (edges below length threshold d are ignored), edges in $\boldsymbol{S}$ are grouped by Quality Threshold (QT) clustering with threshold d. The QT clustering takes the maximum cluster diameter as input, finding clusters with guaranteed quality. 2) In each group, an edge can be the alignment baseline only if the total swept area by projecting others to it reaches the minimum. If multiple candidates exist, pick the median. The axis is a line segment that connects all projected vertices along that baseline. 3) The axis will pull the nearby vertices (within the range of d) onto itself while keeping their edge connections. The alignment process aims for the most simplified $\boldsymbol{S}$, by iteratively increasing d until $\boldsymbol{S}$ intersects with any space boundary.

Algorithm 3 Align Skeletons

Input distance threshold d, angle threshold θ, set of edges S
Output set of aligned edges

Initiate $list\langle axis\rangle$
Divide S by Quality Threshold clustering into $\{S_0, \dots, S_n\}$, taking parameter d and θ measuring the distance and angle between two edges. Edges with length smaller than d are ignored.
for each S' in $\{S_0, \dots, S_n\}$ **do**
  $box \leftarrow$ outward offset polygon by d
  Group edges if their box overlap, resulting $\{S'_0, \dots, S'_n\}$
  for each S'' in $\{S'_0, \dots, S'_n\}$ **do**
    $area_{min} \leftarrow \infty$
    $axis \leftarrow S''[0]$
    for each edge e_i in S'' **do**
      $area \leftarrow 0$
      initiate $list\langle point\rangle$
      for each edge e_j in S'' except for e_i **do**
        $area \leftarrow area+$the area of region swept by e_j projected to e_i
        append projected endpoints to $list\langle point\rangle$
      if $area < area_{min}$ **then**
        $area_{min} \leftarrow area$
        $axis \leftarrow$ new edge spanning all points in $list\langle point\rangle$
    Append $axis$ to $list\langle axis\rangle$
Build graph $\mathbf{G}(V, E)$ from S
for each edge $axis$ in $list\langle axis\rangle$ **do**
  for each vertex $\mathbf{v}$ in $\mathbf{G}(V, E)$ **do**
    if distance between $\mathbf{v}$ and $axis < d$ **then**
      Project $\mathbf{v}$ to $axis$
Output E

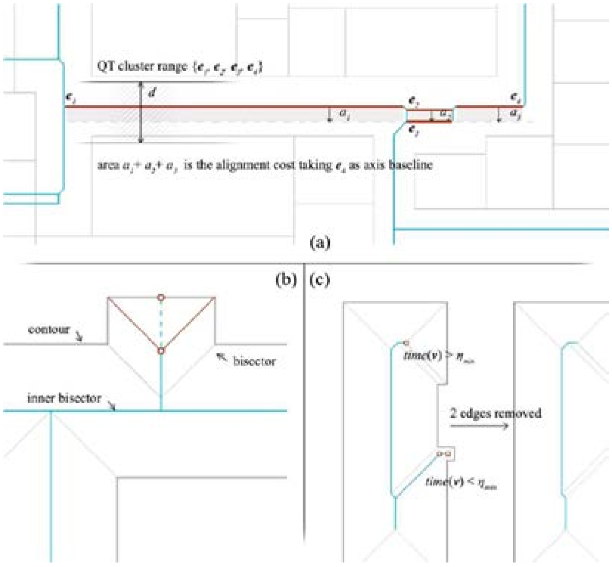

Fig. 9: (a) edge alignment on QT clustering. (b) extrusion of inner bisector with 1-degree vertex. (c) remove vertices with too small "time" value.

In this work, the door locations serve as the entry points to wire in the main network to each space. Such information can be retrieved from BIM (either by IFC or gbXML). If not available (such as a shaft or part of an open space), the centroid of the space region will be used instead. The algorithm finds the Manhattan path between the entry point and the main network by the minimum cost, and then adds them to $\boldsymbol{S}$. Additional penalties will be counted if the path collides with space boundaries. The line segment set $\boldsymbol{S}$ forms a graph $\boldsymbol{G}(V, E)$, serving as the potential network for the detailed layout of pipe/duct system.

According to the hierarchy of zoning outlined in section 1, the terminal nodes (functional spaces) within a thermal zone are connected to a distribution node, representing a variable-air-volume box or air handling unit (AHU). Subsequently, all distribution nodes are connected to the source nodes (shaft or mech rooms). All routes follow the potential network given by an undirected, weighted graph $\boldsymbol{G}(V, E)$. The 2nd-level connection is a Steiner tree problem on terminal nodes $N \subseteq V$ with Steiner points provided as $V \setminus N$. The 1st-level connection can be regarded as the Shortest Path Tree that grows from one source node to all distribution nodes.

Algorithm 4 Get Steiner tree of subset vertices from a graph

Input undirected, weighted graph $\mathbf{G}$, terminal vertices set N
Output Steiner tree graph T

Create the sub graph $\mathbf{H}(V, E)$ by Floyd-Warshall algorithm, making $V \supseteq N$ and E contains all possible path between any $v \in N$
Initiate set V_{del}
Initiate adjacency matrix $A[i, j] \leftarrow e(v_i, v_j),\ i, j \in |V|$
Initiate adjacency matrix $a[i, j] \leftarrow weight(e(v_i, v_j))$
for k from 1 to $|V|$ **do**
  if $degree(v_k) = 2$ **then**
    $v_i, v_j \leftarrow$ neighbours of v_k
    $A[i, j] \leftarrow A[k, i] \cup A[k, j]$, then $A[k, i], A[k, j] \leftarrow \emptyset$
    $a[i, j] \leftarrow a[k, i] + a[k, j]$, then $a[k, i], a[k, j] \leftarrow 0$
    Append v_k to V_{del}
Generate minimum spanning tree $T(V', E')$by Kruskal algorithm based on adjacency matrix $a[i, j]$
for each $e(v_i, v_j)$ in E' **do**
  $e(v_i, v_j) \leftarrow A[i, j]$ ▷ map edges back to H
$V' \leftarrow V' \cup V_{del}$ ▷ bring back relay vertices
Simplify T then output

Algorithm 5 Find centroid of tree

Input undirected, weighted tree graph $\mathbf{T}(V, E)$
Output directed, weighted tree T'

Start form any $v_x \in V$, find the furthest vertex v_0 by Dijkstra algorithm
Start from v_0, find the furthest directed $path = \{v_0, \dots, v_n\}$ by the same Dijkstra algorithm
Locate the middle point v_m on $path$ by length
$V \cup \{v_m\}$, $E \cup \{(v_{m-1}, v_m), (v_m, v_{m+1})\}$
Traverse T from v_m down to leaf node to build the tree T'

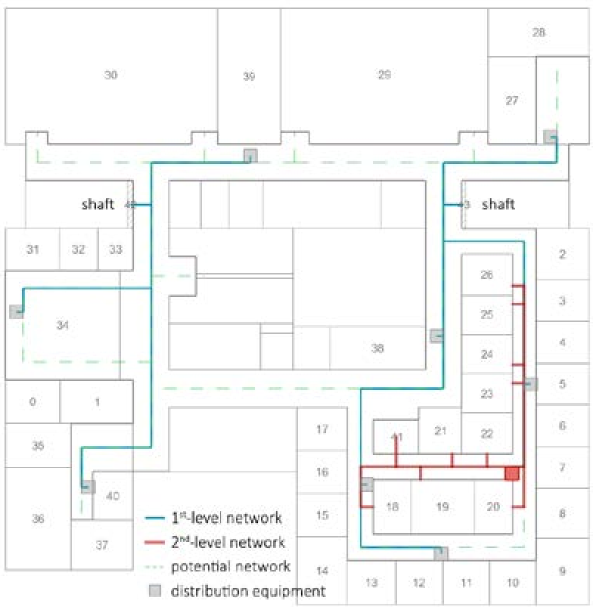

Fig. 10: A sample duct/pipe generation based on the potential network

Alg. 4 describes the steps for solving the 2nd-level connection within a zone: 1) Create the sub-graph $\boldsymbol{H}$ based on $\boldsymbol{G}$, containing the terminals in set N and their possible paths by modified Floyd–Warshall algorithm. 2) Map the graph $\boldsymbol{H}$ to $\boldsymbol{H'}$ by removing relay nodes (degree = 2). 3) Find the MST joining all nodes in the graph $\boldsymbol{H'}$ by Kruskal algorithm, then map it back to $\boldsymbol{H}$. The resulting graph $\boldsymbol{T}$ is the Steiner tree that connects all terminals. To locate the terminal equipment that handles the zone air, Alg. 5 first finds the longest path $\boldsymbol{P}$ by running the Dijkstra furthest path algorithm twice from any node, then adds the mid-point of $\boldsymbol{P}$ as the root node of $\boldsymbol{T}$. The root node minimizes the average path to leaf nodes, implying the minimal cost of distributing cooling/heating air to each space.

All distribution nodes are connected to the source nodes (shaft or mechanical room) along the potential network $\boldsymbol{G}$, in the 1st-level connection. They are clustered by the shortest walk to the nearest source candidate, then get connected by a shortest path tree rooted in that source node (Alg. 4, with Kruskal-MST replaced by Dijkstra shortest-path-tree). It is an edge-weighted breadth-first search that traverses a tree down to every leaf with the same speed.

For simplification, the graph $\boldsymbol{G}$ takes the length of each duct/pipe segment as edge weight. The pressure loss is roughly proportional to the length according to the Darcy-Weisbach equation. Especially in the low-speed ductwork design, a constant pressure loss per unit of duct length is commonly assumed. Moreover, the algorithm ignores many geometric constraints, such as the collision of equipment and ducts in the ceiling void, or the oversized duct that cannot fit in the shaft. Since the generative zoning focuses more on space/system topology than the construction document, it is omitted for our current work.

6. MODEL SCRIPTING

To evaluate the initial cost, energy consumption, and the control effectiveness of zoning schemes at the space level, the co-simulation binding Modelica and EnergyPlus is an ideal choice. *Spawn* (of EnergyPlus) is the latest whole-building energy simulation engine developed by the U.S. Department of Energy, National Labs and industry. It reuses the envelope and daylighting modules of EnergyPlus and couples them with the AC system and control modules from Modelica Buildings Library (Wetter, 2020). This division of tasks optimally leverages EnergyPlus for efficiently solving multi-zone building physics–a task can be time-consuming for Modelica. And, because EnergyPlus takes thermal zone as the basic simulation unit, Modelica is needed for inspecting different behaviors of spaces within a thermal zone.

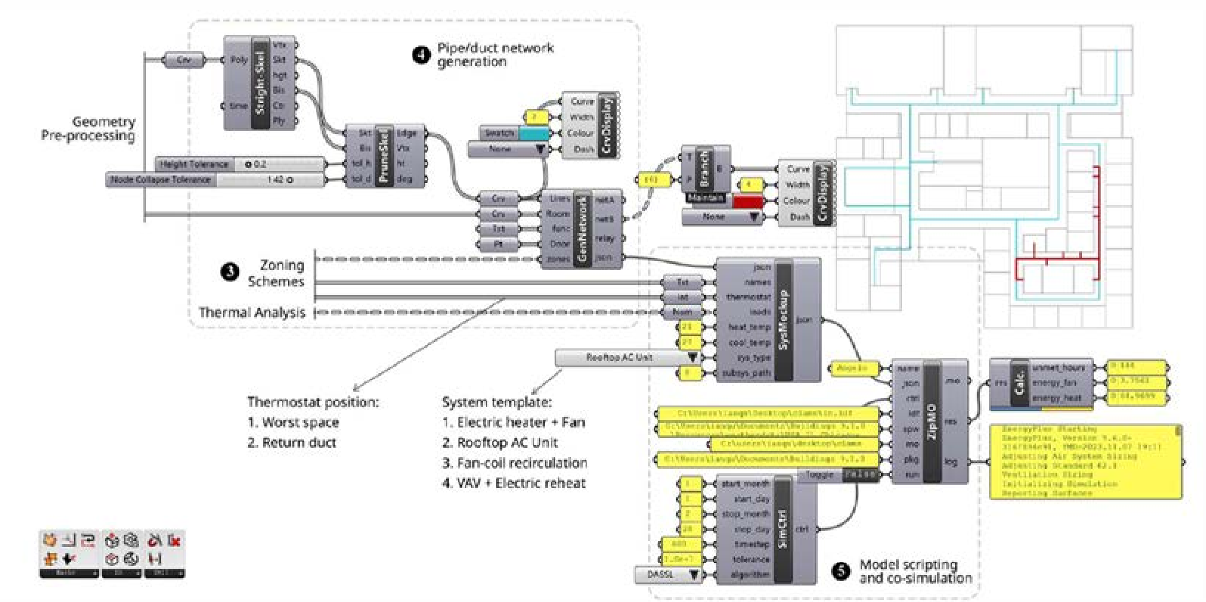

Fig. 11. Workflow of model scripting in developed Grasshopper components.

Based on the typical-day load results from EnergyPlus, the nominal airflow rate is calculated for each space. Then, the algorithm does the equipment and ductwork sizing to meet the nominal airflow. It applies the Equal Friction method to decide the diameter and the pressure loss, which mimics the decision process of engineers.

Following the algorithms in section 2.4, the two-level distribution network, accompanied the functional spaces, is first serialized in a JSON file (component GenNetwork in Fig. 11). Then, joined with the system and simulation configuration, the JSON is further parsed into the Modelica scripts. The user may customize different systems and control templates in the component SysMockup. When component ZipMO is toggled on, the program will call OpenModelica Shell to perform the simulation and analyze the result.

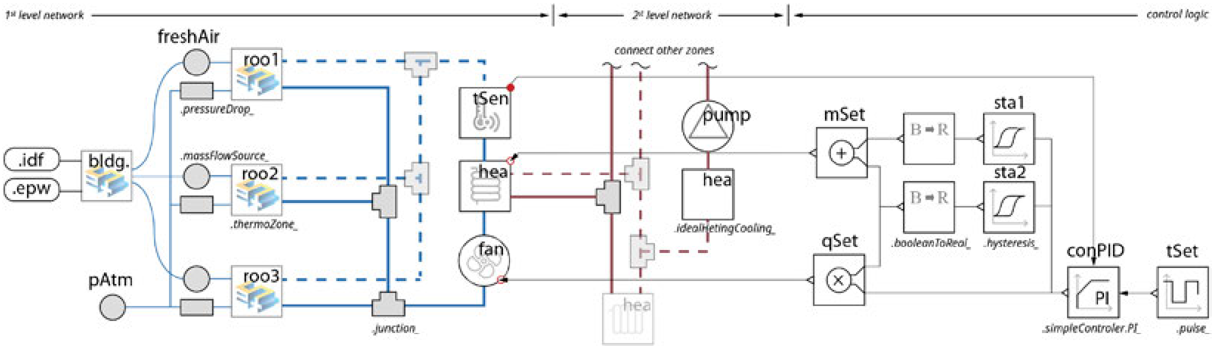

Fig. 12. A sample connection of Modelica model

Fig. 12 gives an example of the generated Modelica model, demonstrated by a recirculation fan-coil system with the water heater and two-speed fan. Each 'thermalZone' component represents a functional space (altogether 43 conditioned spaces), with specific air leakage and fresh air ventilation rate. It exchanges temperature data with the corresponding zone in the EnergyPlus by *Spawn*. The PI controller takes the temperature as input from the sensor mounted on the return duct, and controls the indoor temperature around 21°C during working hours (9:00~18:00). Above the control zone level, a water loop connects all terminal equipment. The fan/pump and heat exchanger are ideal models to give rough estimations. They can be replaced with actual models given detailed parameters, such as performance curves.

Table 2: Simulation results of sample cases

Schemes	Uncomfortable hour (h)	Unmet hour (h)	Fan Power (kWh)	Heat (kWh)	Duct area (m^2)	Pipe length (m)	AHU	Model Equations	Simulation Time (s)
Fig. 4	726	1050	30.82	3317.04	53.60	34.38	9	16857	212
Fig. 7 (a)	1294	1970	35.66	3298.66	78.33	17.54	8	16662	249
Fig. 7 (b)	122	298	33.47	3349.66	24.38	42.67	22	19392	349
Fig. 7 (c)	101	276	34.38	3349.10	17.61	50.75	26	20172	277

The workflow has been tested against 4 zoning schemes for 14 winter days in Chicago. There is a clear trend in Table 2 that the unmet hour decreases along with the increase of control zones. Normally, a control bias of ±1°C is acceptable for comfort conditioning. Hence, the unmet hour accumulates the working hours where the temperature is outside the range of 20~22°C. Similarly, the uncomfortable hour is calculated for temperatures outside the comfort range (20~25°C). In the last case, Fig. 7 (c), 101 uncomfortable hours indicate that one space may get unconditioned for 10 minutes a day on average. However, if 19°C is acceptable, the uncomfortable hour will be zero. Given proper equipment costing spreadsheet, this workflow can offer insights into the advantages and disadvantages of different zoning schemes, in terms of comfort level, initial cost and future energy bills. Such information can facilitate the decision-making process.

7. DISCUSSIONS

This paper introduces a semi-automatic workflow for thermal zoning, the AC distribution system generation, and model scripting. Such a workflow can assist engineers in exploring various zoning schemes and system layouts, taking a step forward toward the generative design driven by simulation. Additionally, it incorporates two unique views into the space view model. One is the thermal response view of spaces (Fig. 6), enabling designers to quickly zone the spaces by color similarity. The other is the potential distribution network view (Fig. 10) that outlines the cost of delivering energy to terminal spaces. However, there are several topics not addressed in this paper, left for future work:

1) The space ontology needs to be enriched, to describe more space relations such as the tenant zone and fire compartmentation. Different tenants must be considered during thermal zoning because their energy

consumption is metered separately. Also, ductwork can be a fire hazard for spreading heat between two compartments.

2) The algorithm for the 1st-level network can be improved, to consider the capacity of terminal equipment and the hydronic balance. It is preferable to evenly distribute the cooling/heating load of zones across multiple risers, ideally making the riser the root node that a tree grows from. If there are outlying spaces in the floorplan with unique load profiles, the algorithm is better to isolate them as distinct system zones (with a direct expansion system for example).

3) More system and control templates are required, for a wide range of system performance comparisons. To a certain degree, the current 2-level network has some universality. Without the 1st-level network, it can be the ductwork of rooftop packaged units. With 1st-level modeled as water pipes and 2nd-level as air ducts, different proportions of water and air can resemble systems from fan-coil (less or no duct) to AHU (more duct). When modeled as air ducts, it suits the constant or variable air-volume system. Each system has specific configurations for model scripting, such as 2-pipe/4-pipe fan-coil, VAV-box reheat, or outdoor air duct.

4) The algorithm lacks the ability to evenly lay out the diffusers and ductwork in an open space. Nevertheless, when the open space has specific function zones allocated, it resembles a multi-room floorplan, with physical partitions replaced by air walls. Under that condition, the pipeline still works given a proper assumption of the airflow rate between spaces (for EnergyPlus modeling in thermal analysis and co-simulation).

GOING BEYOND ENERGY CONSUMPTION: DIGITAL TWINS FOR ACHIEVING SOCIO-ECOLOGICAL SUSTAINABILITY IN THE BUILT ENVIRONMENT

Dragana Nikolić & Ian J. Ewart
University of Reading, UK

ABSTRACT: *Digital twins have attracted much of the attention from the researchers and policy makers as a potent industry-agnostic concept to support ambitious decarbonization goals. Consequently, much of the latest research has focused on computational methods for building and connecting digital twins to monitor and measure energy consumption and resulting emissions from buildings. At the same time, it has been recognized that achieving a truly sustainable built environment goes beyond environmental sustainability and is much more complex, calling for approaches that transcend any single discipline. Initiatives such as the National Digital Twin in the UK and globally, begin to offer a long-term vision of interconnected, purpose-driven and outcome-focused digital twins, grounded in systems thinking. Such approaches recognize the economic, social and ecological layers as critical data components in these digital ecosystems for understanding the built environment as a whole. Yet, social and ecological sustainability will remain difficult to address without involving allied disciplines and those from the realms of sociology, ecology, or anthropology in a conversation about the critical data sitting at the intersections between human behavior and technological innovation. In this paper, we review and discuss the state of the art research on digital twins to identify the disciplines dominating the narrative in the context of a sustainable built environment. We unpack a techno-rationalist view that emphasizes the sole reliance on technology for problem-solving and argue that by going beyond energy consumption and carbon emissions, digital twins can facilitate a more nuanced assessment of sustainability challenges, encompassing social equity, cultural preservation, and ecological resilience.*

KEYWORDS: *Digital twin, socio-ecology, sustainability, smart city, review.*

1. INTRODUCTION

The alarming effects of climate change and environmental degradation have prompted various global policies to set ambitious targets for reducing carbon emission by 2050 (Climate Change Committee, 2019; United Nations Environment Programme, 2022). The urgency of climate change as well as the recent pandemic have raised many questions of what the future of the built environment should look like and how that future can be envisioned and accomplished. Carbon emission targets or achieving "net zero" have thus prompted many digital transformation initiatives as a way to mobilize technology and data science to monitor, simulate and evaluate possible solutions across sectors to meet the decarbonization goals and improve overall performance. In the built environment disciplines and construction specifically, one such initiative that has attracted much attention is the concept of digital twins as a way to connect physical and digital assets to support data-driven decision making in complex environments. In the UK for example, the National Digital Twin Programme (CDBB, 2019), offers a broad vision of connected digital twins across environmental, social and economic spheres driven by an ultimate goal of enabling people and systems to flourish. This shift has also challenged built environment practitioners to consider the long-term consequences of any interventions (Whyte et al., 2020) and has led to a greater focus on outcomes rather than outputs, and a broader digital context within which project data can be situated, for example in the context of 'smart cities'.

Yet, given that the global demands for energy are increasing, the pursuit of carbon emissions reduction has consequently focused efforts on understanding and reducing energy consumption in the contexts of infrastructure and building performance. However, research points out that responding to the climate challenge is far more complex, or a "super-wicked" problem that defies simplistic technological solutions and often prioritizes short-term goals with competing priorities (Levin et al., 2012; Rabeneck, 2008). Achieving a truly sustainable built environment is much more complex, calling for approaches that transcend any single discipline and move away from project-bound methodologies to those where developed models span organizational and jurisdictional units (Whyte et al., 2019). As Rabeneck (2008) argues, any understanding of asset performance demands a systems perspective to better articulate needs within a given context. Initiatives such as the National Digital Twin in the UK and globally, begin to offer a long-term vision of interconnected, purpose-driven and outcome-focused digital twins, grounded in systems thinking. Such approaches recognize the economic, social and ecological layers as critical data components in these digital ecosystems for understanding the built environment as a whole. Yet, social and ecological sustainability will remain difficult to address without involving allied disciplines and those from

the realms of sociology, ecology, or anthropology in a conversation about the critical data sitting at the intersections between human behavior and technological innovation.

In this exploratory paper, we review recent research around large-scale digital twins for the built environment and argue that while promoted as a potent industry-agnostic concept to support ambitious decarbonization goals, the narrative has been dominated by technology-focused methods to meet such goals. We identify literature that raises critical considerations for informing the holistic approaches to developing long-term purpose-driven digital twins for a sustainable environment. We review the relevant literature to unpack a techno-rationalist view that emphasizes the sole reliance on technology for problem-solving and argue that by going beyond energy consumption and carbon emissions, digital twins can facilitate a more nuanced assessment of sustainability challenges, encompassing social equity, cultural preservation, and ecological resilience. We explore a set of underlying assumptions and considerations such as the authority of the data, system complexity and cross-sector boundaries, and the technology landscape and procedures to enable constructive questioning. This approach allows us to understand how digital twin applications are subject to dominating business cases driving their development, which can consequently affect the design and operation of built environment projects. Moreover, we take the view that it is becoming increasingly difficult to sustain the traditional compartmentalized practices, but it is becoming imperative to promote conversations between the allied built environment and social disciplines to avoid single-issue dominance that could lead to unintended consequences, furthered by partially informed policies (Whyte et al., 2020). This has consequences for how digital technologies are used, demanding new and different kinds of data and processes, providing new challenges to the construction informatics research community and to practitioners.

2. THE SOCIO-TECHNICAL LANDSCAPE IN THE BUILT ENVIRONMENT

The pervasiveness of digital technologies across architecture, engineering, and construction practices as seen through a convergence of material science, robotics, 3D printing, sensors, artificial intelligence, and other technologies, presents new digital capabilities that connect physical environments with digital ecosystems. Technological innovation has always been paired with urban development (Quek et al., 2023), although in recent years, the concept of technology has shifted inexorably towards the digital and the view that the world, and reality itself is no longer analogue, but is made up of a digital representation of itself (Ewart, 2018). While the proliferation of low-cost consumer-market technologies paired with big data and Internet of Things has offered an enticing world of opportunities to improve the design, delivery, and operations of physical assets, it has also raised questions about how to make sense of the ever-growing raw and complex data sets to understand how we use the built environment and make informed decisions about its future (Nikolić & Whyte, 2021).

The concept of digital twins in the built environment practice has grown out of the recognition that the delivery of physical assets has become inseparable from the delivery of its digital counterpart and with a potential for an extensive data-capture to understand its use and improve its operation. With real-time asset data enabled, information received can influence future investment decisions, especially for serial clients such as governments, and aim to either change user behaviors or assets in new project interventions (Whyte & Nikolić, 2018). The digital twin idea was first introduced in 2002 in aerospace as a concept for Product Lifecycle Management (Grieves, 2019) and its use remains predominantly in manufacturing. Recent applications in the built environment include smart city initiatives, structural health monitoring, infrastructure planning and management (e.g. power, water, transportation), agriculture, and urban planning and development. In construction, the development of digital twins gained traction only in the last five years (Opoku et al., 2021), though not without challenges (Opoku et al., 2023). Urban infrastructure and 3D city models moving beyond geometry and information have started to become developed around the same time although mostly by linking BIM models with data (Ferré-Bigorra et al., 2022).

Unlike in the aerospace and manufacturing domains, digital twins for the built environment can span greater scales, professional domains and jurisdictional units, with an increasing complexity due to the heterogeneous data sources and sub-system interactions, leading to the difficulty of reliably predicting the system performance. For example, urban planning and management increasingly relies on understanding interactions between natural, cyber-physical and social systems in the form of urban digital twins (UDT) to foster human-centered resilience (Ye et al., 2023). Digital twins at city and urban scales can offer insight into how we use the built environment and inform the decisions for future interventions, yet their development is much more complex compared to DTs at building and component scales. Urban environments and cities are dynamic living systems that constantly evolve (Quek et al., 2023) and any interventions in this complex system will be intricately tied to economic and social sustainability goals as much as environmental. Ultimately, as Grieves (2019) argues, the success of digital twins will need to create value for the users of the systems, generally defined through value propositions or "use cases".

There is a tension between the grand challenge of setting broad sustainability goals and the practical challenge of a system-of-systems approach necessary for addressing them. For sustainable development, some of the recent reviews of digital twin applications and research (e.g. Papadonikolaki & Anumba, 2022) reveal that while holding a promise of a method to mitigate and adapt to environmental changes, the focus has been mostly on the decarbonization efforts in the energy sector and reducing energy consumption across the domains, including buildings. The research on design and delivery of buildings has encapsulated such efforts through increasing energy performance and reducing waste, although under the changing terminology of green, smart, high performance, carbon-neutral or net-zero buildings (Bonci et al., 2019; Gultekin et al., 2013; Korkmaz et al., 2010). A general survey of digital twin applications in design and construction domains, however, reflects rather an engineering approach to meeting decarbonization goals through improved sensing, monitoring, material, and data science, or predicting and simulating occupant behavior; and approach challenged by the view that the building performance is realized over time, rather than predetermined (Green & Sergeeva, 2020). The difficulty of such compartmentalized approaches and domain-specific definition of local carbon targets is that the outcomes may be insufficient to recognize the impact in a larger context and the system within which such interventions operate. As a result, most indicators developed so far have been primarily describing the state of the environment, rather than the relationship between society and ecosystems (Azar et al., 1996).

The dominating narrative around net-zero carbon has prompted predominantly technology-oriented approaches to decarbonization, whether they refer to extending renewable energy technologies or improving the energy performance of buildings and infrastructure. The global quest for smart products, buildings, cities and systems has been met with an ever-growing and more diversified digital ecosystem of software and siloed technological developments, a situation that has prompted calls for the technological dimension to be included in the sustainability trifecta of economic, environmental and social goals guiding the urban planning and development (Quek et al., 2023). However, Waring & Richerson (2011) argued that such environmental challenges are in fact, socio-ecological in nature and therefore, designing effective responses will depend on a deeper understanding of the human-environmental interactions. Socio-ecological perspective emphasizes societal activities that impact the use of resources, rather than on environmental quality indicators with an aim to aid in planning and decision-making processes at various administrative levels (Azar et al., 1996). Ince (2023) further suggests that adopting a socio-ecological approach and systems thinking with a multidisciplinary perspective can offer new models for creating systemic and long-term solutions to sustainability problems. In practice, this would mean thinking and modeling that involves all stakeholders, performing economic and biological analyses of the environment and resources at micro- and macro scales, and participatory approaches to environmental policy design (Ince, 2023). Such perspectives invite dynamic systems thinking approaches that span spatial, temporal and organizational scales and considers a set of critical resources such as natural, social, economic and cultural, all located at the intersection of interdisciplinary collaboration, moving away from short-term narrowly focused technological fixes. In this context, there is somewhat of a paradox of technological optimism where technical fixes are viewed as solutions to all problems, even those that are non-technical in nature, while social and economic factors are viewed as obstacles, rather than essential to designing solutions (Rudolph, 2023). This is further exacerbated by the plethora of isolated pilot studies and the dominance of industry-backed funded research which is unlikely to lead to truly transformative socio-ecological thinking of transdisciplinary work (Rudolph, 2023).

3. METHOD

To explore the current narratives in research associated with socio-ecological systems thinking in the domain of digital twins, we conducted an initial level of a systematic review where we first identified bibliographical sources that focus on urban or city digital twins as we were interested in the broader scale digital twins to understand the system complexity. In the search, we excluded studies that were in the physical science areas, such as mathematics, physics, chemistry or medicine. We conducted a search of the Scopus database to sample articles and studies using the following sampling string:

TITLE-ABS-KEY ("city" OR "urban" OR "built environment" OR "smart city" AND "digital twin") AND TITLE-ABS-KEY ("social" OR "ecolog*" OR "sustainab*" OR "net-zero") AND

(LIMIT-TO (DOCTYPE , "ar") OR LIMIT-TO (DOCTYPE , "cp")) AND (LIMIT-TO (LANGUAGE , "english")) AND (EXCLUDE (SUBJAREA , "phys") OR EXCLUDE (SUBJAREA , "math") OR EXCLUDE (SUBJAREA , "medi") OR EXCLUDE (SUBJAREA , "ceng") OR EXCLUDE (SUBJAREA , "neur") OR EXCLUDE (SUBJAREA , "chem"))

The search yielded 153 publications including journal articles (92) and conference papers (61), all published between 2018-2023 (Fig. 1). Publications in the area of social science are among top five, flanked by those in the areas of engineering, computer and environmental sciences, and energy (Fig. 2). Lastly, it was interesting to observe that the significant funding in this area comes from the European funding schemes, followed by the national science funding programs in the U.S. and China (Fig. 3).

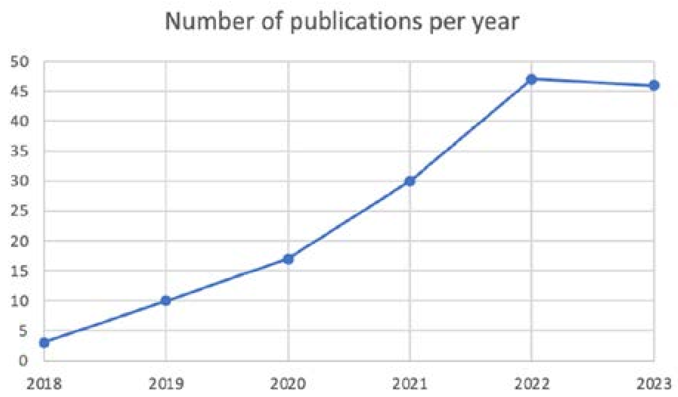

Fig. 1: Number of publications on urban and city digital twins per year

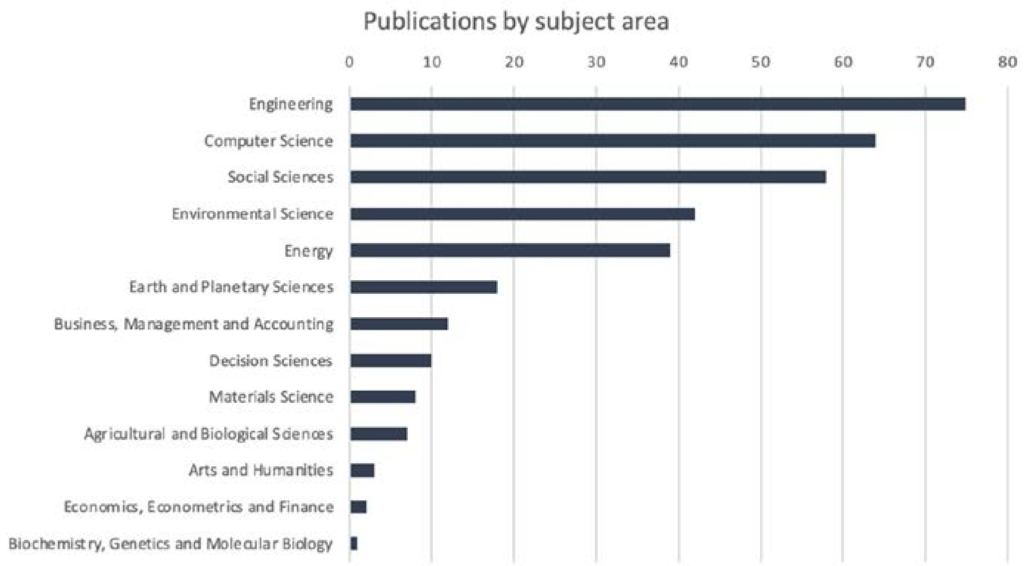

Fig. 2: Number of publications on urban and city digital twins per year

Fig. 3: Publications by funding sponsor

However, the review of abstracts revealed a wide range of approaches and methods with a high degree of varying conceptualization of problems and definition of digital twins, leading to a considerable number of papers being omitted from further review. For example, papers that approached digital twin models from an engineering perspective or conceptualized them as a single system with no links made to either social or ecological issues were out of scope (e.g. water system focusing on flood risks). Similarly, papers focusing only on economic, technological or social aspects were omitted as well. Lastly, papers that only focused on digital models that did not interact with their physical counterpart were not considered to be digital twins as defined. This has led to a list of 25 publications that were selected for further review to identify themes, considerations, developments and challenges for developing complex socio-ecologically driven digital twins (Table 1).

4. EMERGING THEMES AND THE DISCUSSION

The select list of publications demonstrates that the research focusing on large scale digital twins is still in early stages and some of the relevant discussions and debates remain largely embedded within the "smart city" literature. From the select list of publications, we sought to identify the application areas, as well as the indicators of the systems thinking that extend the environmental performance. In doing so, our goal was to establish the extent of socio-ecological and transdisciplinary thinking informing the development of large-scale digital twins and the potential obstacles for their implementation.

4.1 Urban digital twins and smart cities

Digital twins at urban scales have been tightly coupled with the smart city narratives where the focus has been largely on modeling specific infrastructure needs that include forecasting and preventing of floods, increasing the efficiency of power grids, understanding of commuting patterns for transportation, as well as modeling and prevention of epidemics in the public health domain. From the literature, such digital twins have been variably termed city digital twins (CDT), urban digital twins (UDT), or social urban digital twins (SUDT). The greatest challenge, however, is determining how closely the digital twin should be coupled with the real urban environment and whether the abstraction and simplification of social or economic datasets could even qualify such models as digital twins (Ye et al., 2023). While the promise and the potential for city digital twins to not only mirror and interact with the physical counterpart, but also account for social and economic aspects (Wan et al., 2019), fewer studies elaborate on the complexity of developing such models or describe the interactions and dependencies between the heterogeneous data sets spanning spatial and temporal description of environmental, social, and economic factors (Savage et al., 2022). Although digital twins of cities have been developed, it is difficult to discern with consistency what systems have been modeled in each implementation and to what extent, further confusing the understanding of urban or city digital twins (Ferré-Bigorra et al., 2022).

What has also become apparent from the review is that the discussion of city, or urban digital twins is tightly coupled with the smart city narratives. The relationship between city digital twins and smart cities is not yet clear, although the smart city conceptualization as technology-assisted and connected infrastructure and communities through sensors and automation closely resembles that of a digital twin. In that context, both digital twins and smart cities that are deemed to be successful are those that adopt a system of systems approach and balance the sociocultural, geospatial, and institutional perspectives of cities beyond the means of technology solutions (Quek et al., 2023; Yigitcanlar et al., 2019). Yigitcanlar et al. (2019) offer a multidimensional conceptual framework that centers on urban policy to inform urban planning and development where innovation economy, socioeconomic equality, ecological sustainability and (smart) governance, each equipped with their own performance indicators, are all critical for building smart cities.

Some studies expand the use of urban digital twins with sociological approaches by focusing on social issues such as urban aging and gentrification, poverty, or other social disparities, termed as social urban digital twins (SUDT) (Sadowski & Bendor, 2019; Yossef Ravid & Aharon-Gutman, 2023). Such studies exemplify attempts to integrate social fabric with the built urban space, although not without raising ethical and legal questions behind the need to collect social data, currently the focus of the field of Digital Sociology (Lupton, 2015). At the same time, the criticism of such developments is based on observations that corporations tend to reframe urban sustainability challenges that favor narrow economic gains at the expense of socio-ecological sustainability, especially in the context of energy consumption and smart grids (Evans et al., 2019; Quek et al., 2023). Nevertheless, all the city digital twin developments testify to the complexity of replicating such complex and evolving systems, even at the physical levels, which is perhaps one of the reasons for the adoption of technocratic approaches that ignore wider social and environmental factors (Kitchin, 2014; Semeraro et al., 2021).

4.2 Technological optimism and implementation reality

The development of large-scale city digital twins generally involves the integration of 2D and 3D information and data models, such as BIM or GIS, and data sources, such as sensors, Internet of Things, and other solutions that form the physical, network and computing layers (Quek et al., 2023; Semeraro et al., 2021). Research on large scale city and urban digital twins remains more focused on the software side of modeling the physical environment, rather than on participatory planning and policymaking informed by human-centered behavior analysis, an approach that would enable planners and policy makers to understand the knock-on effects of environmental changes on social resilience (Ye et al., 2023). As the complexity of urban systems that need to be modeled and integrated is increasing, so has increased the rate of various siloed technological developments, posing new challenges for the city administrations and governance. It has been widely recognized that city digital twins will require a transition from single institutions to scalable solutions where multiple professional domains contribute the data and inform the relevant analyses (Savage et al., 2022). The technical complexity of integrating various data formats, applications, systems and other sub-system DTs has consequently drawn much more attention to the technological considerations for resolving such issues. The proliferation of various public and private technological research and development efforts have further diversified the digital ecosystem at the expense of knowledge sharing and cross-domain collaboration, leaving the development of city digital twins in their infancy (Shahat et al., 2021).

Though technological challenges remain important to be resolved, the field of smart city and digital twin developments have become progressively critiqued for their heavy reliance on technologies as means to manage urban and environmental crises (e.g. Nochta et al., 2019; Yossef Ravid & Aharon-Gutman, 2023). Advanced smart city initiatives, such as Singapore[1] or Beijing[2] for example, increasingly embed new technologies into city design, retrofitting or upgrading their infrastructure, which presents challenges for the city's phased developments and the pace of technological developments. As Quek et al. (2023) illustrate, cities develop at a much slower pace than technologies, whereby the time projects are completed, the technology solutions may well become outdated. This further exacerbates the existing challenges of integration, interoperability, and compatibility, perpetuating the cycle of pursuing technological solutions to technology-created problems. Some studies have pointed out the challenge of profit-driven corporate interests seeping into the social realm by appropriating and dominating the narrative of urban challenges and technological fixes (Sadowski & Bendor, 2019; Yossef Ravid & Aharon-Gutman, 2023). This complex technological influence on urban governance where social perspective has been largely absent, presents academics, professionals and policy makers with a real challenge of working together to enable outcome-based and value-driven decision making that drives more comprehensive social, environmental and economic values. The ever-growing digital ecosystem of various digital twin technology solutions has consequently raised several practical challenges that extend those of interoperability alone.

4.3 Practical challenges for socio-ecological and systems thinking

The review of studies revealed a number of both technological and strategic challenges facing the development of large scale complex digital twins for addressing socio-ecological and environmental goals. These have been broadly categorized into three categories (Table 2) and described further below.

Table 2: Overview of select hindrances to the development of large-scale digital twins.

Category	Issues	Description
Data	Volume/Quality	Overproduction of unusable data vs. co-production of socially relevant information; data quality; data errors
	Bias	Selection bias or misrepresentation of marginalized communities in the design and deployment of digital twins
	Availability/Ethics	Private, proprietary or other sensitive data, especially social data; security, legal and commercial boundaries
	Heterogeneity	Domain-specific data types and formats; qualitative vs. quantitative; static vs. dynamic; coding and structuring approaches
	Reusability	Lessons learned recorded in a machine-readable form; cross-pollination or knowledge between projects and domains
	Ownership	Enable individuals and communities to envisage and understand data on a human scale; calibration of citizens data
Model	Complexity	Physical, social, ecological datasets; dynamic spatial-temporal and socio-ecological changes
	Optimization	Model assumptions are clear; data are transparent; trade-offs and contradictions between different targets and outcomes
Integration	Siloed development	Within the design, social, and engineering sciences; between research and practice; techno-rationalism and corporatization of technology
	Interoperability	Integrating multiple GIS, BIM, CIM, 2D and 3D data models; individual technology solutions
	Digital divide	DT development and integration bound to the available investments and resources at district, region or country levels

Data is the basis of all digital twins and generating, accessing, filtering, analyzing and using relevant data presents an array of different challenges for the development and usability of digital twins. There is a general consensus across the literature that the overproduction of data, either from the projects or sensors and users, is a problem, prompting an increasing reliance on machine learning and artificial intelligence to process and make sense of the ever growing volumes of raw data. This vast and unfettered production of data also signals the separation between the digital and the human where the suggestion that one of the benefits of the digital revolution is the production of 'big data', becomes dangerous without recognizing our limited ability to make use of it (Ewart, 2018). On the other hand, the needed data may not be easily available due to privacy or proprietary issues.

[1] https://www.smartnation.gov.sg

[2] https://www.beijingcitylab.com/projects-1/43-smart-cities-review/

Most instances of urban digital twins developments are based in 3D models, while the integration of 2D information and non-graphical data is far more sporadic. Ye et al. (2023) in their review demonstrate how multidimensional visualization of integrated social sensing data, land-use change and demand models for example, while essential for planning of future urban landscape, is largely missing. Furthermore, data use is driven by the purpose of their primary users reflecting an inherent bias, even when data are quantitative (Nikolić & Whyte, 2021). In addition, different coding schemes used across the professional domains for describing and structuring the data complicates efforts to automate the querying of data (Peters & Schindler, 2023). Still, planning and design approaches, especially at broad urban, social, and environmental scales, involve consideration of a range of factors, uncertainties, and conflicting goals, all largely part of a decision-making process of which automation is not yet capable (Allam & Dhunny, 2019).

The difficulty of simulating complex systems of systems, such as urban environments has long been debated where some have questioned the value of digital twins in the face of simpler monitoring systems (Ferré-Bigorra et al., 2022). Complexity theory has surfaced as a conceptual framework for studying and designing smart cities (e.g. (Yossef Ravid & Aharon-Gutman, 2023) to help deal with issues of uncertainty, diversity and emergence and inform policies on ways to cope with unpredictable behavior of urban systems. Creating digital twins with a socio-ecological focus necessitates inputs not only from the allied built environment disciplines, but also from the fields of sociology, anthropology, ecology and planning, which still remains short in supply. The importance of such approaches informing policies is illustrated by Savage et al. (2022) where the changes in energy consumption patterns resulting from a combination of measures in carbon tax, technology adoption and land use data would affect social inequality in the UK.

Resulting from the challenges above, the integration of data, models and approaches across domains and scales perhaps remains the over compassing challenge to the development of complex and connected digital twins. Integration of diverse datasets, models and methods that better account for differences in human behaviors further remain underexplored (Delmelle, 2021). It is clear that future tools will have to incorporate different types of data from a variety of domains. This however, does not even account for the computational resources needed to process such large and complex datasets. The remaining controversy is the viability of urban digital twins and whether they can ever truly represent the intra- and inter-social complexity of socio-technical and socio-ecological systems, especially those that incorporate societal elements (Batty, 2018).

5. CONCLUSIONS

The twin urgency of climate change and sustainable development have propelled explorations of large scale urban digital twins as a data-centric, cross-disciplinary platform that could promote better decisions through mutual learning, public participation and stakeholder engagement. The concept of urban digital twins and the value of data sharing across sector boundaries has been recognized in the UK through a National Digital Twin program (CDBB, 2019). Research, however, demonstrates that the urban digital twin conceptualization, development, and implementation are still very much in their infancy, while the narratives intersect with those of smart cities. Urban environments with a complex interplay of spatial, social, environmental, and economic factors have proven challenging for the digital "twinning", leaving most digital twin developments stopping short of modeling socio-ecological and socio-technical systems. When designed well, city digital twins, as other technologies, should support human agency and democratize the decision-making process, shifting the balance of authority away from the experts alone. Yet, despite their great potential and promise they hold, the vast technological bottlenecks exemplified in the issues of data, interoperability, federation, integration, scalability or futureproofing of technological solutions have all focused much attention on resolving such issues and at the expense of exploring and including the socio-ecological dimensions that may impact the planning and development of scenarios.

While sustainability encompasses environmental, social and economic aspects, the literature review demonstrates a predominant focus on the potential of digital twins to achieve decarbonization goals through carbon and energy consumption metrics. In this paper, we began by mapping the latest research on large-scale DT applications across domains to describe the elements of the dominant narratives for informing future changes in the built environment and addressing the challenges of sustainable development and social resilience. Although socio-ecological perspective extends the sustainability trifecta by promoting systems thinking and offering new theory necessitating multidisciplinary management approaches, we illustrated how the urban and city digital twin developments remain largely domain-specific where projects are yet to be seen as interventions within larger complex systems.

Finally, while digital twins offer powerful and novel ways to engage diverse disciplines in shared conversations, fragmented practices are maintained not only within traditional and institutionalized modes of working, but also discipline-specific tools and technologies designed to handle data at different scales and data needs. Integrating such diverse data sets not only requires overcoming issues of interoperability, but also crafting new narratives around salient spatial, social, and ecological features aimed at the users most likely to have a say in decisions with longer term consequences.

ABSTRACT: *Buildings are experiencing tremendous transformation, where Internet of things (IoT) is been used to transform traditional buildings into smart structures. While there are viable IoT techniques, developing IoT applications and operations to fully realise the technology's promise is needed. This may be done successfully by bridging the gaps in the present research to establish a foundation for future investigations. This study analysed extant literature in IoT (between 2008 and 2022) through a bibliometric review to tease out critical measures for their integration and transformation. The study adopted a science mapping quantitative literature review approach and employed bibliometric and visualisation techniques to systematically investigate data. The Scopus database was used to collect data and VOSviewer software to analyse the data collected to determine the strengths, weights, clusters, research trends in IoT. Important findings emerging from the study include recent literature by various researchers on IoT applications in buildings. The shift in recent patterns of research from developed to developing countries. Eighty-nine (89) keywords were analysed and divided into six clusters. Each cluster is discussed to present its research area and associated future studies in relation to Smart buildings. This paper uses bibliometric analysis to unpick recent trends in IoT and its relevant application to buildings. The paper provides a blueprint for future IoT research and practice, needed awareness and future strategy directions for IoT applications in construction. This creates opportunities to transition to more sustainable construction sector.*

KEYWORDS: *Bibliometric review, Energy efficient buildings, IOT (Internet of Things), Literature review, Smart buildings, sustainability, science mapping.*

1. INTRODUCTION

Massive challenges caused by rapid digitalization have greatly increased the demand for energy (Al-Obaidi et al., 2022). Energy consumption around the world is estimated to increase by 56% in 2040 (Energy Information Administration (EIA), 2013). Internationally, there are efforts to reduce energy consumption in buildings and cities such as the EU's 2050 roadmap which aims to lessen energy and gas emissions by approximately 40% (Fragkos et al., 2017). Buildings, both residential and commercial, have played critical roles in human existence by providing convenient, safe, and satisfying venues for emotional, physical, and social requirements. Building inhabitants should constantly feel secure and protected, since this might affect their general well-being and productivity (Lawal & Rafsanjani, 2022). As a result, real-time monitoring, control, and management of a building and its inhabitants, components, appliances, systems, environment, and health is critical (Rafsanjani et al., 2018; Ghahramani et al., 2020). This emphasizes the need of automation in both household and business settings. Smart buildings are unique structures that employ intelligent automation for their operations to provide efficient, pleasant, and secure environments for its users. Building automation utilizing the Internet of Things (IoT), a renowned advanced technology, can provide cutting-edge solutions for strengthening security and safety, remoting appliances/systems, monitoring occupants, increasing efficiency, and improving visual and thermal comfort (Kanan et al., 2018; Saha et al., 2018).

Although there have been various literature on IoT in the context of the buildings (Gholamzadehmi et al., 2020; Al-Obaidi et al., 2022; Wang et al., 2021; Bola et al., 2019; Mataloto, Ferreira & Cruz, 2019; Lawal & Rafsanjani, 2022), only few studies have sought to summarize the existing research using bibliometric techniques. For example, Gholamzadehmi et al. (2020) conducted a review of adaptive-predictive control strategy for heating ventilation and air conditioning (HVAC) systems in smart buildings. However, the scope of their study on smart buildings is focused solely on smart control of building energy services. Al-Obaidi et al. (2022) carried out a systematic review of IoT for energy efficient buildings and cities from a built environment perspective analyzing

literature published between 2020-2022. However, their study scope is too broad and lacks exclusive statistical or quantitative focus on IoT research based on buildings. Bola et al. (2019) presented a critical survey of IoT based automated energy management in buildings. They reviewed various IoT applications in the area of building energy management and energy consumption data were recorded, which they highlight as a very important consideration in system planning and rehabilitation. Mataloto et al. (2019) presented efforts on optimizing energy consumption in buildings by use of an IoT based platform known as LoBEMS (Lora Building and energy management system). They developed an approach that helps local administration entities identify savings from personalized data visualization. Wang et al. (2021) conducted a thorough analysis of the extant literature on IoT and edge computing in different application fields, including smart homes and smart cities. Lastly, Lawal and Rafsanjani (2022) applied a systematic review while exploring the trends, benefits, risk and challenges of IoT implementation in residential and commercial buildings and highlighted that IoT is a crucial driver for the evolution of various types of buildings.

Even though each of these reviews provides a wealth of valuable insights, no thorough and timely review utilizing bibliometrics, focused solely on smart buildings can be found in the literature, which presents an important research gap. Since the academic literature in the field of IoT has had significant growth, the application of a quantitative review approach is required to better understand the knowledge structure of the field (Rivera & Pizam, 2015). Researchers should try to occasionally examine the accumulated body of knowledge as study fields develop and become more complex according to Ferreira et al. (2014), as well as understand new contributions, research trends and traditions, topics being studied and investigative the structure of knowledge and future research directions.

This study analyses extant literature in IOT and its application to buildings (between 2008 to 2022) through a bibliometric review, to tease out critical measures for their integration and transformation. The objectives are to evaluate the global research trends of IOT application in construction based on citation analysis of countries and co-occurrences analysis of author keywords cluster, using Vosviewer document analytic software and Scopus database. The study findings would benefit the academic community as it contributes to (1) providing valuable directions by examining the bibliometric status of IOT in the built environment sector from the existing literature, identifying the knowledge areas with links for their integration and (2) identifying the critical areas needed to advance IOT application in buildings in future studies and to support practical implementation.

2. METHODOLOGY

Researchers commonly employ three approaches to evaluate literature, according to Zupic and Cater (2015): (1) a qualitative approach of a systematic literature review, (2) a quantitative approach via meta-analysis, and (3) science mapping (based on the quantitative approach utilizing bibliometric methodologies). The third technique is viewed as the most suited for assessing the state-of-the-art literature of a research topic and is quickly becoming increasingly popular in numerous disciplines of study (Tavares-Lehmann & Varum, 2021). Science mapping uses bibliometric approaches such as citation analysis to assist academics in identifying trends in the structure and dynamics of scientific subject topics. Using the bibliometric approach in scientific literature reviews enhances rigor and lowers researcher bias (Cavalieri et al., 2021). It is superior to typical literature reviews in that it provides for a more objective and methodical selection and assessment of scientific research on a specific topic (Cobo et al., 2015). To fulfil the study's goals and objectives, we used a bibliometric technique that includes three stages of review: (1) data collecting, (2) analysis and visualization, and (3) interpretation, like a prior study by (Obi et al., 2023).

2.1 Data collection

A search query, selection of relevant database(s), and data screening are all part of the data collecting process (Ari & Cuccurullo, 2017). Employing the correct search phrases in a bibliometric study is important to success (Obi et al., 2023). According to Lawal and Rafsanjani (2022) we followed the search terms for IOT application in buildings. They chose keywords for the IOT research after conducting a thorough review of earlier relevant studies on the definition and application of IOT in various kinds of residential and commercial buildings and they compiled a list of important terms that are used interchangeably. As a result, a mixture of appropriate search phrases was employed, and the whole search code is as follows:

“IOT buildings” OR “Internet of Things buildings” OR “smart buildings” OR “Intelligent Buildings” OR “automated buildings”.

We identified a database that contained bibliometric data. Scopus and Web of Science (WoS) are now prominent databases for retrieving publications (Obi et al., 2023). The Scopus database was used to extract and collect bibliographic data for the study. Scopus is a digital bibliographic platform widely recognized for high quality standards and a frequent instrument for doing construction-related bibliometric research (Patel et al.,2021). Rani and Kumar (2022) conducted bibliographic analyses and identified Scopus as a favored alternative for IOT application review research. Similarly, recent literature reviews in IOT research (Lawal & Rafsanjani, 2022; Al-Obaidi et al., 2022) have employed the Scopus database.

To screen the obtained data, we used a set of inclusion and exclusion criteria (relevance, language, and quality). A total of 26,512 papers were returned because of the search in the Scopus core collection. The publication period was limited to 2008 to present (2022) and was chosen because the classification by year of publication shows a growing trend of articles published in relation to IOT within this period. **Figure 1** shows distribution of articles by year of publication. From this image it can be said that publication on IoT related to building applications picked up in 2005 and had a more significant number of publications from the year 2008. The year 2008 recorded 52 articles whilst the subsequent years recorded a rise in the number of articles published progressively and considering the increasing number of articles over the years, with the constant rise in publications, it can be inferred that literature on IOT application will continue to increase in years to come.

Finally, Papers from subject areas with no strong affiliation to application of IoT in buildings like chemistry and decision sciences were eliminated. Non-English publications in the relevant topic areas were removed to avoid translation difficulties and to decrease ambiguity in essential ideas. Associated keywords presented by Scopus because of searching for relevant documents were skimmed through to identify duplicates and words with no strong link to the research area were subsequently excluded. To ensure the quality of the papers utilized, only peer-reviewed article publications and reviews were included. After that, the author performed further skim readings of the title, abstract, and selected document, resulting in the elimination of papers not connected to IOT application in buildings. Applying the relevance, language and quality criteria resulted to 21,637 papers being deleted during the process, leaving 4,875 articles used for the analysis. These articles were then exported to excel from Scopus (in the order of most cited to least cited documents) to allow the implementation of an analysis software (VOSviewer).

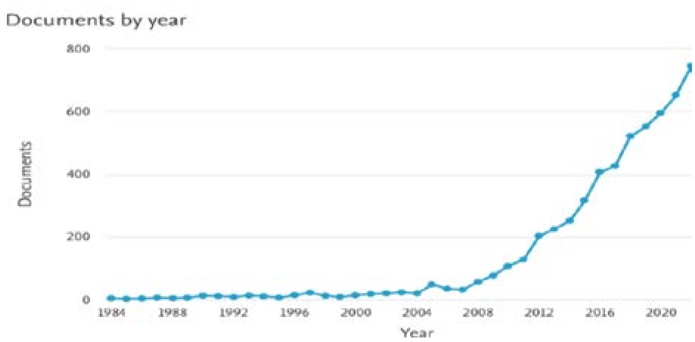

Fig. 1: Showing a growing trend of research on IoT application to construction. (Source: scopus).

2.2 Data analysis and visualization

This paper makes use of citation and co-occurrence analysis. Commonly used bibliometric methodologies, according to Mas-Tur et al. (2021), are:

(1) Co-occurrence analysis which evaluates the conceptual structure of knowledge in the subject, finding relevant keywords and themes related with the primary concepts of research.

(2) Citation analysis estimates the impact of publications, authors, journals, or nations based on citation rates.

The bibliographic information was presented using the visualization of similarities (VOS) viewer software version 1.6.19. VOSviewer allows you to map, visualize, and identify the network structure in research (Leydesdorff & Nerghes, 2017). Because of the ease of understanding, presentation, and visualization of the maps, it was chosen above other regularly used tools such as Pajek and Citespace. The network is composed of distance-based maps, with the distance between two elements reflecting the intensity of their link. A shorter duration often suggests a stronger bond. The size of the item label reflects the number of instances of the phrase discovered. A bigger label size indicates that the related item appears in more publications, while various colours reflect distinct groupings of items aggregated by VOSviewer's clustering approach (Yin et al., 2019).

3. RESULT AND DISCUSSION DATA ANALYSIS AND VISUALISATION

This section presents the bibliometric and network analysis results as tables and networks and a discussion of the various results gotten from the analysis.

3.1 Citation analysis

Citation analysis is used to identify high-impact journals and significant nations in IoT research. The number of publications and citations are used to assess the influence and quality of research in a certain topic (Wuni et al., 2020).

3.1.1 Countries involved in researching the application of IoT in construction.

The minimal number of citations and publications was set at 10 and 5 respectively, using VOSviewer. This was done to guarantee that only nations that are actively engaged in research on IOT application for buildings are chosen. 72 out of the 160 nations available were chosen to meet the criteria; the findings of the analysis are shown in **Figure 2**. There are 10 most productive countries leading in research on IoT in relation to building applications. The republic of China with a total of 730 documents and 35,390 citations. It is followed by United States of America with a total of 716 documents as well as other nations within the top ten as shown in **Table 1.** Among the ten nations China and India are the only developing countries, which is similar to results gotten in a review study by (Al-Obaidi et al., 2022).

Table 1: Top 10 most productive countries involved in the research of IoT application to building construction.

Country	**Document**	**Citation**
China	730	35,390
United States of America	716	21,163
United Kingdom	323	14,280
Italy	260	11,550
South Korea	226	8,480
India	225	6,343
Canada	195	10,701
Australia	182	6,612
Spain	164	5,942
Germany	156	6,450

The closer the colour is too yellow, the recent the investigation is in literature, as seen in **Figure 2,** from countries like United States, Morocco, Nigeria and Pakistan. This demonstrates that recent study patterns are majorly researched by developed nations but are also shifting towards developing countries, particularly those seeking sustainable and energy efficient improvements in their building industry, highlighting the need for more empirical research in these developing countries.

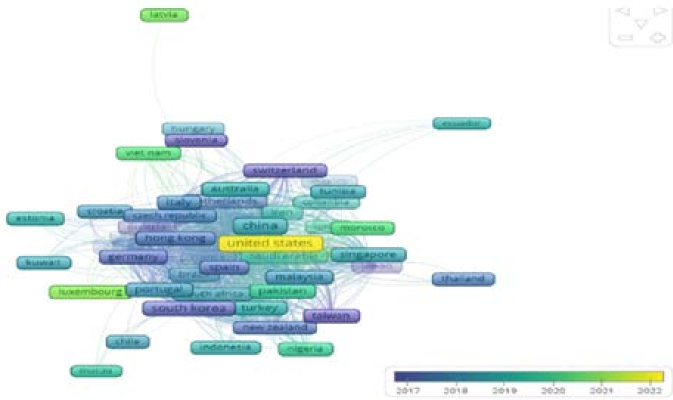

Fig. 2: Vosviewer map of countries associated with the application of IoT in construction.

3.2 Co-occurrence analysis on IoT application in construction

Co-occurrence, highlights keywords and have an important role in bibliometric analysis. According to Van Eck and Waltman (2014), author keywords should be used for bibliometric analysis to show patterns in current research. As a result, author keywords were chosen as the foundation for the current study's co-occurrence maps. The threshold of occurrences of a keyword was chosen at 15 based on recent bibliometric literature review (Baghalzadeh Shishehgarkhaneh et al., 2022). Repeated terms (for example ("smart house" and "smart homes") were eliminated. The criteria for the study were fulfilled by 89 of the 10,008 keywords. The co-occurrence network's large nodes (frames) and colour presentations, as well as the primary linkages, were investigated to analyse the research hotspots and concerns dominating IoT literature. The cluster formation was used in the co-occurrence analysis.

3.2.1 Co-occurrence of author keyword by cluster

The keywords "Smart buildings", "Energy efficiency" and "Internet of Things" have large nodes in the network as seen in **Figure 3**, indicating researchers have been more interested in studying these areas of research and their similar concepts. Six clusters, as shown in **Figure 3** emerge following the analysis.

Cluster 1 (IoT based sustainable construction design): It is in red and the largest cluster with 28 items: building energy efficiency, green building, building information model, thermal energy storage, solar energy are some of the relevant keywords in this cluster. This cluster indicated a strong focus on sustainable construction design in relation to IOT application to buildings. From a design perspective extensive IoT research has focused on Building energy efficiency, especially due to this area of research been one of the main goals of construction design (Lawal & Rafsanjani, 2022).

Cluster 2 (Building automation system): It is green with 17 items; building energy management system, anomaly detection, building automation, model predictive control, building control, hvac, indoor air quality and thermal comfort are some of the relevant keywords emerging from this cluster. This cluster is concerned with IoT based building automation systems and the efficient control and management of building energy services.

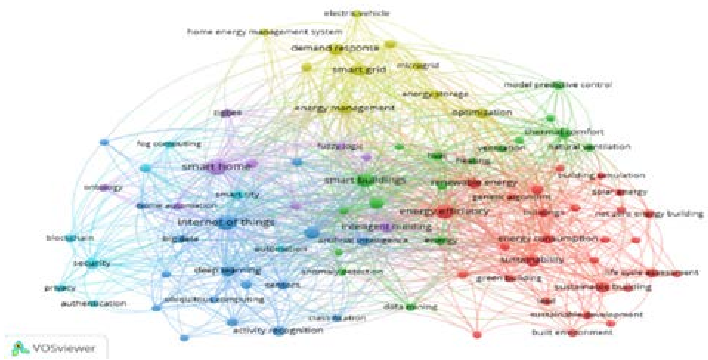

Fig. 3: keyword network visualization by cluster

Cluster 3 (AI in smart buildings): It is in blue and is made up of 17 items: machine learning, sensors, AI (artificial intelligence), internet of things, activity recognition, ambient intelligence, big data are some relevant keywords from this cluster. This cluster highlights the core operational principles of IoT, it explores the concept of AI and its contribution to the realisation of smart buildings.

Cluster 4 (IoT for efficient energy management in buildings); It is yellow and includes 10 items; Energy management, demand response, smart grid, micro grid and home energy management system are some of the relevant keywords. This cluster highlights various technical functions of an IoT system to efficiently manage energy consumption in buildings.

Cluster 5 (Improved quality-of-service in smart buildings); It is purple and includes 9 items; wireless sensor network, neural network and Interoperability are some of the relevant keywords in this cluster. This cluster highlights the improved quality-of-service offered by IoT networks to smart building occupants or smart users.

Cluster 6 (Blockchain in smart buildings); It is light blue in colour and includes 8 items; authentication, blockchain, smart city, privacy and security are some of the relevant keywords in this cluster. This cluster is centered around the use of blockchain in IoT based smart building systems and the role of the technology in protecting user privacy and safeguarding information that flows through IoT devices or nodes.

4. DISCUSSION OF CLUSTERS AND FUTURE RESEARCH DIRECTION

In this section, the six study fields (Blockchain in smart buildings, AI in smart buildings, IoT for efficient energy management, Improved quality-of-service in smart buildings, building automation and IoT based sustainable construction design) emerging from the results of the co-occurrence cluster analysis are discussed. The knowledge gaps and future study directions are also highlighted.

4.1 Blockchain in smart buildings

Blockchain is an emerging concept in IoT based technology with strong links to smart buildings and smart cities. Blockchain has emerged as an important layer of trust (Siountri et al., 2020). as well as a novel approach for improving data integrity and privacy in smart buildings. Blockchain, a type of distributed ledger, can be utilized to reduce the challenges of information sharing and security in smart buildings (Rejeb et al., 2022). Unlike traditional databases, blockchain is built on a peer-to-peer network design in which all network users handle transactions effectively and flexibly rather than being controlled by a trusted centralized authority (Nguyen et al., 2020). It is conceivable to construct and update smart networks in the future, strengthen their resilience, and safeguard a rising amount and diversity of services by relying on blockchain's decentralization, immutability, and accountability. In this regard, blockchain has the potential to address important security concerns while also facilitating smart city operations (Rejeb et al., 2021). Machine learning is utilised to extract vital information from outsourced data and the findings are then stored securely on the blockchain to ease sharing (Rejeb et al., 2022).

The overall effect of blockchain and IoT can be improved with the introduction of 5G. Blockchain technology provides numerous answers to the issues posed by 5G networks. According to Azzaoui et al. (2020), the technology supports AI-powered 5G and leads to the development of a more efficient, and secure cellular network. As a result, 5G will serve as a foundation for IoT, blockchain and mobile edge computing (MEC), enhancing the analysis, collection and exploitation of smart building data (Hemmings, 2020) and making bandwidth less of a limiting factor in overall ecosystem design. With the transition to 5G networks, there is increased interest in investigating the pending issues of a 5G-enabled IoT for blockchain-based smart building applications, as 5G cellular networks are ineffective due to increasingly complex configuration issues in clouds and systems lacking AI functionality (Chen et al., 2020). As a result, future research should look at how blockchain might affect critical elements of IoT-based smart building applications (Rejeb et al., 2022).

4.2 AI in smart buildings

Artificial intelligence (AI) is another key area in IoT systems with strong links to smart buildings. The transition to smart buildings necessitates the collaboration of several technologies to make inhabitants' lives more convenient and inclusive (Ahad et al., 2020). AI is regarded as a critical tool for advancing urban sustainability and building more inclusive and secure settings, as supported by the United Nations' Sustainable Development Goal 11 (Sustainable development goal (SDG), 2015). AI systems rely on massive amounts of data and employ learning algorithms to discover patterns in the data, allowing for event prediction and decision-making tasks (Hariri et al., 2019). This is especially essential when combined with other developing technologies that increase efficiency by automating data collecting and eliminating the need for trusted third parties, hence maximizing profitability Hariri et al., 2019). In the work of Awan et al. (2020), for example, machine learning algorithms used to estimate parking spot availability in smart commercial buildings are thought to benefit from data collected by IoT sensors and devices.

Future research into this cluster may focus on how urban decision-makers might collaborate with residents to develop and create smart cities that meet their expectations. The subject of how to involve all stakeholders in a solution-oriented and citizen-centric manner while solving urban difficulties with IoT and AI approaches is of greater relevance (Brynskov, 2018). Empirical research is also required to better understand the stakeholder-related issues that enable or impede IoT and AI implementation in smart construction (Rejeb et al., 2022).

4.3 IoT for efficient energy management in buildings

Energy management is an empirical function of smart buildings with strong links IoT application to construction. The associated cluster describes how energy management in relation to IoT technology is gaining attention, with numerous sophisticated and ubiquitous smart construction applications, such as smart grids. Smart grids are modern power networks that can change and re-adjust dynamically to offer electricity at a cheap cost and high quality (Alsamhi et al., 2019). Since IoT applications consume a significant amount of energy, smart building solutions must be able to use energy more effectively and implement effective energy prediction systems that reflect the dynamics of the IoT environment (Luo et al., 2019).

The smart grid enables the exchange of energy and information between customers and utilities. Yet, the complexity of utilities to handling real-time data for making business-critical choices remains a difficulty (Alsamhi et al., 2019). Increased data usage improves grid stability and performance while also allowing the utility provider to make better decisions, allowing for efficient demand-side management and demand response. Nevertheless, the massive amount of raw data is incomprehensible or useless without a dependable and consistent capacity to process, analyse, and comprehend the information contained within such a massive amount of data. As a result, before taking action based on the data, the data must be turned into useable information. Such transformation is a difficult procedure since helpful information is not readily apparent from the data. Therefore, further investigation on the challenges faced by utilities to handle real-time data is essential (Syed et al., 2021).

4.4 Improved quality-of-service in smart buildings

Wireless sensor network (WSN) represents an important component of IoT by promoting resource efficiency and increasing smart inhabitants' quality of life (AlSawafi et al., 2020). WSN can handle large-scale installations in any metropolitan setting to perform tasks including real-time monitoring of physical and environmental conditions, routing and load balancing, industrial process monitoring, and energy efficiency optimization (Alsamhi et al., 2019). Researchers have previously focused on WSN-based smart building and city applications for scheduling and routing (e.g., smart grids) that take into consideration the energy efficiency and quality of service (QoS) (Faheem et al., 2019). Nonetheless, the mobility and changing network topologies of IoT nodes continue to pose challenges to the stringent fulfilment of QoS requirements in IoT-based smart building applications. As a result, future research must adapt current routing algorithms in WSN to give QoS guarantee in terms of latency, dependability, bandwidth usage, scalability, and throughput. Moreover, researchers must investigate low-cost methods of connecting IoT equipment and collecting data across the vast number of decentralised WSN in smart cities (Sobin, 2020).

4.5 IoT based sustainable construction design

Building energy efficiency is another key area with strong link to IoTs application to buildings. According to recent studies, tracking energy use in buildings has piqued the interest of many academics interested in IoT and energy saving measures (Xu et al., 2020). Furthermore, the drive towards combining smart buildings with cutting-edge detection techniques has begun to set the framework for seeing IoT as an essential component of smart cities (Al-Obaidi et al., 2022). Recent research has revealed a surge in interest in IoT applications in smart buildings to enhance energy efficiency and decrease environmental concerns. According to other research, if buildings consider effective communication between their systems for operation, they can save a significant amount of energy. As a result of advancements in networking, computing, and sensing technologies, IoT has emerged as a critical component in the design and operation of any smart item in the built (Kumar et al., 2022).

Smart design, smart action, smart control, smart monitoring, smart energy, smart waste and smart water are essential features of an IoT residential/commercial building that should be considered while converting a building to a smart one to make the atmosphere more comfortable not only for the residents but also for the management staff (Lawal & Rafsanjani, 2022).These features necessitate many types of data, and thus the key difficulty might be big data analytics, which arises from the huge, diversified, and time-evolving high-resolution data provided by IoT devices and sensors. The growth of technology has resulted in a dramatic increase in the number of connected IoT devices, resulting in massive data generation and transfer. To improve data flow between devices many different technologies are necessary, which raises the complexity of IoT systems in every kind and size of residential or commercial structure. Based on our analysis of the literature, smart waste and water have seldom been investigated and so additional future research into these aspects is advised to create a completely automated building (Lawal & Rafsanjani, 2022). Furthermore, IoT device batteries consume a large amount of energy and as a result, the rising rate of IoT device deployment has resulted in increased energy consumption making IoT and environmental concern which should be considered in future research (Lawal & Rafsanjani, 2022).

4.6 Buildings automation system

Building automation is yet another integral part of IoTs application to building with strong links to the research area. A building automation control system (BACS) is defined as a computer-based and automated system that analyses the specific needs of a building by controlling the associated mechanical and electrical plants/equipment installed in the building, thereby contributing to energy savings without compromising user thermal/visual comfort. A BACS's major goal is to maintain occupant thermal/visual comfort while maintaining an energy efficient and cost-effective building operation. It incorporates algorithms that replace user demands in directing technological systems depending on various objectives, such as; thermal comfort, Energy savings and cost savings (Gholamzadehmir et al., 2020).

The use of model predictive control, which also has a direct link to IoT application in buildings is a technique in BACS which has recently attracted a lot of interest from the scholarly community (Serale et al., 2018). An advanced control strategy (ACS) with a forecasting function, known as MPC, is necessary to achieve high energy and comfort performance levels by including renewable energy generation, innovative solutions for technical systems (e.g., heat pumps), and energy storage systems (Gholamzadehmir et al., 2020). MPC is commonly used in the building industry to forecast the dynamic behavior of systems in the future and alter reaction by the controller, accordingly, resulting in energy and cost savings while maintaining thermal comfort (Serale et al., 2018).

The evaluation of an accurate prediction horizon based on the system's characteristics is one of the fundamental concerns in predictive control systems (Gholamzadehmir et al., 2020). According to the literature study, the most typical setting for prediction and horizon control is one day ahead (Liu & Heiselberg, 2019). Nevertheless, the tuning of the prediction and control horizons may be influenced by the building boundary circumstances, such as the climate environment and building characteristics (Gholamzadehmir et al., 2020). There is particularly limited data on the link between the prediction horizon and control horizon. As a result, additional research is needed to analyse the relationship between prediction/control horizon and various building boundary conditions for best energy and cost saving outcomes. Because the predictive model is dependent on the quality of the input data, the function of sensor reliability and location are critical. There are just a few publications that report on this crucial issue and therefore research is required to fill this vacuum, which would otherwise be a weak spot for ACS (Gholamzadehmir et al., 2020).

Based on the study findings as discussed, predominant and emerging concepts that can serve as conduits for IoTs application in Buildings and the proposed directions for advancing research and practice are summarized in **Table 2**. Future investigations could pay more attention to the current and emerging concepts in IoT and its application to buildings.

Table 2: Themes, research area and future research direction

Theme	Research areas and concepts with links to IoT application in Buildings	Future research direction

Blockchain in IoT based smart buildings	Blockchain Privacy Smart city Security	Issues of a 5G-enabled IoT for blockchain-based smart building. applications Cost-effective and scalable blockchain solutions.
AI in smart buildings	Machine learning AI Sensors Activity recognition Ambient intelligence	Stakeholder-related issues that enable or impede IoT and AI implementation in smart buildings. How to involve all stakeholders in a solution-oriented and citizen-centric manner while solving urban difficulties with IoT and AI approaches
IoT for efficient energy management	Energy management Smart grid Micro grid Demand response Home energy management system	The complexity of utilities to handling real-time data for making business-critical choices
Improved quality-of-service in smart buildings	Wireless sensor networks Interoperability Neural network	Adapt current routing algorithms in WSN to give QoS guarantee in terms of latency, dependability, bandwidth usage, scalability, and throughput. low-cost methods of connecting IoT equipment and collecting data across the vast number of decentralised WSN in smart cities.
IoT based sustainable construction design	Building energy Efficiency Building Information Model Building envelope Green building Thermal energy storage Solar energy Sustainability	Investigation on smart waste and smart water Negative effects of IoT as an environmental concern
Building automation system	Building energy management system Anomaly detection	Analyse the relationship between prediction/control horizon and various building boundary conditions for best energy and cost saving outcomes

	Building automation Model predictive control Building control Hvac Indoor air quality thermal comfort	Reliability and proper location of IoT Sensors.

5. CONCLUSION

This study conducts a bibliometric review of the extant literature on IoT application in construction from 2008 to 2023 to tease out critical measures for its integration and transformation. In this study, 4875 publications on IoT within the building and construction sector retrieved from Scopus were analyzed using bibliometrics and network analysis in VOSviewer.

The demographic maturity levels and increased prevalence are most notably from China, Italy, the USA and UK Nevertheless, trends in recent IoT research are emerging from developing countries, indicating a surge for sustainable improvements in their construction practices. To enhance IoT research globally, developed and developing countries need to collaborate. The poor collaborative links between IoT researchers across developed and developing countries may be one of the reasons contributing to the slow understanding and uptake of IoT systems in developing economies. Therefore, funding research projects, research hubs and spoke networks and other collaborative research activities as appropriate between developed and developing countries should be highly encouraged. These can facilitate knowledge exchange and transfer on policies and implementation strategies to promote IoT application practice in construction.

Six cluster areas were identified including blockchain in smart buildings, IoT based sustainable construction design, Improved quality-of-service in smart buildings, building automation system, IoT for efficient energy management in buildings and AI in smart buildings. These areas currently seek to optimize energy efficiency in buildings, reduce waste and the environmental impact throughout a building's operation. There are emerging concepts from the cluster and there is the need to expound their links, especially block chain. This is with the view of foreseeing a more strategic approach for improving data integrity and privacy in smart buildings and cities.

This study contributed by highlighting the bibliometric research status of IoT in relation to its application in buildings, identified current gaps in the literature and provided directions for future studies and practice. More importantly, the evidence gleaned from this study would help IoT players and policymakers to develop bespoke strategies, frameworks and policy measures for integrating and implementing IoT practices, creating opportunities to transition to more sustainable systems in the construction sector. However, there were some limitations. One is the use of only Scopus database. Second is the use of only Journal articles and reviews written in English, and third is the exclusion of discussions of other emerging areas because they had no current links to IoT. Future research may use other databases or incorporate data from different sources to enhance generalizability. They can also broaden the sources of documents such as books and include those in foreign languages, to broaden the variety of data. Future research might investigate additional growing sectors where there are presently no linkages to IoT. In addition, expert systems and fuzzy tools can be used to explore a more in-depth quantitative analysis.

ABSTRACT: *The great challenge of global climate change urges world economies to reduce greenhouse gas emissions and promote sustainable development, where the building sector plays a vital role. Carbon tracking technology is one of the keys to capturing carbon emissions for sustainable construction such as net-zero buildings. This paper reviews five key carbon tracking technologies – life cycle assessment (LCA), energy modeling, building operation monitoring, carbon accounting software, and green certification and rating systems. With summarized advantages, beneficiaries, and limitations of the five technologies, we propose a Carbon Tracking 'Cabbage' (CTC) framework that incorporates all carbon tracking tools as inner technological layers for multiple stakeholders at multiple stages of construction management. The main contribution of this paper is the CTC framework that rationalizes the scopes and adoption strategies of carbon tracking technologies by collaborative stakeholders to achieve informed decision-making, implement effective carbon reduction strategies, and subsequently contribute to climate change mitigation actively.*

KEYWORDS: *Carbon tracking; Building sector; Carbon tracking cabbage framework; multi-stakeholder; Technology adoption*

1. INTRODUCTION

Global climate change poses an increasingly severe challenge to human society and ecosystem. Carbon emissions, as a major source of greenhouse gases, have been widely recognized as one of the primary drivers of climate change. In light of this, establishing a sustainable green economy through collective global efforts has become a pressing priority. The building sector plays a crucial role in global carbon emissions, accounting for a significant portion of the global greenhouse gas output (Khalili & Chua, 2013). As society strives to combat climate change and become carbon neutral, addressing the carbon footprints of buildings and adopting sustainable practices in the construction and operation of these structures has become a top priority.

Tracking and monitoring carbon emissions, particularly carbon dioxide (CO_2), reveal evidence and insights into the amount of carbon in the atmosphere, enabling targeted strategies to reduce emissions and mitigate the impacts of climate change (Liu et al., 2020). Carbon tracking, as an essential component of the broader carbon management strategy, has emerged as a powerful tool to measure, monitor, and mitigate the carbon impact of buildings (Liu et al., 2020). Additionally, carbon tracking provides crucial data for setting emission reduction goals, empowering governments, organizations, and industries to establish clear and achievable targets while monitoring progress. Through carbon tracking and reporting, businesses can measure the carbon footprint, identify improvement opportunities, transparently disclose environmental impacts to stakeholders, and showcase the social responsibility. Furthermore, standardized carbon tracking and reporting methods foster global cooperation, which enables international transparency, peer pressure, and collaboration in achieving shared climate goals (Kang et al., 2015). In summary, carbon tracking and reporting are essential tools in combating climate change, providing vital data to empower decision-makers, businesses, and individuals to take proactive action in creating a more sustainable and resilient future.

The significance of carbon tracking technologies in the building sector lies in measurability and interpretable evidence of comprehensive carbon emissions across the entire lifecycle of a building. From the production and transportation of construction materials to energy consumption during building operations and eventual demolition, these technologies offer valuable insights into the carbon impact of each stage, enabling informed decision-making and targeted carbon reduction strategies. Over the years, carbon tracking technologies in the building sector have undergone significant advancements and innovations (Xu et al., 2023). From traditional methodologies to cutting-

Jiajia Wang, Geoffrey Qiping Shen, Fan Xue, *Carbon Tracking in the Building Sector: A 'CABBAGE' Framework*, pp. 1085-1093, DOI 10.36253/979-12-215-0289-3.108

edge digital solutions, these tools have played a pivotal role in quantifying the carbon footprint of buildings at different stages of their lifecycle. By providing a holistic assessment of carbon emissions, these technologies empower stakeholders, including architects, engineers, policymakers, and building owners, to make informed decisions that foster sustainable building practices.

However, current carbon tracking technologies fall short of encompassing the entire building lifecycle in the building sector. Although individual technology is advantageous, carbon tracking as a whole is always fragmented and incomplete. Subsequently, the fragmented and incomplete carbon tracking hinders holistic and effective carbon reduction strategies and leads to missed opportunities for emission mitigation and sustainable practices. Thus, there is a significant research gap in a comprehensive approach that spans carbon tracking to all stages of a building's lifecycle.

This paper embarks on a novel framework that rationalizes the full-lifecycle carbon tracking based on an in-depth exploration of all the carbon tracking technologies in the building sector. By reviewing historical milestones, technological breakthroughs, and real-world applications, we aim to present a comprehensive overview of the evolution of these technologies and their impact on the industry's sustainability efforts. The primary objectives of this study are:

- To provide an in-depth analysis of the historical evolution of carbon tracking technologies in the building sector, highlighting key milestones and breakthroughs that have shaped their current state;
- To examine the existing carbon tracking technology models, methodologies, and tools deployed in the building industry, assessing their effectiveness, limitations, and potential for future enhancements; and
- To explore real-world case studies and successful implementations of carbon tracking strategies, showcasing how these technologies have contributed to carbon reduction goals and sustainable building practices.

2. LITERATURE REVIEW

2.1 Existing carbon tracking technologies

As shown in Fig. 1, there are five main categories of carbon tracking techniques. They are LCA, energy modeling, building operation monitoring, carbon accounting software, and green certifications and rating systems. The associated phases and key technologies are sketched along the of a curved arrow of a typical construction project course in Fig. 1.

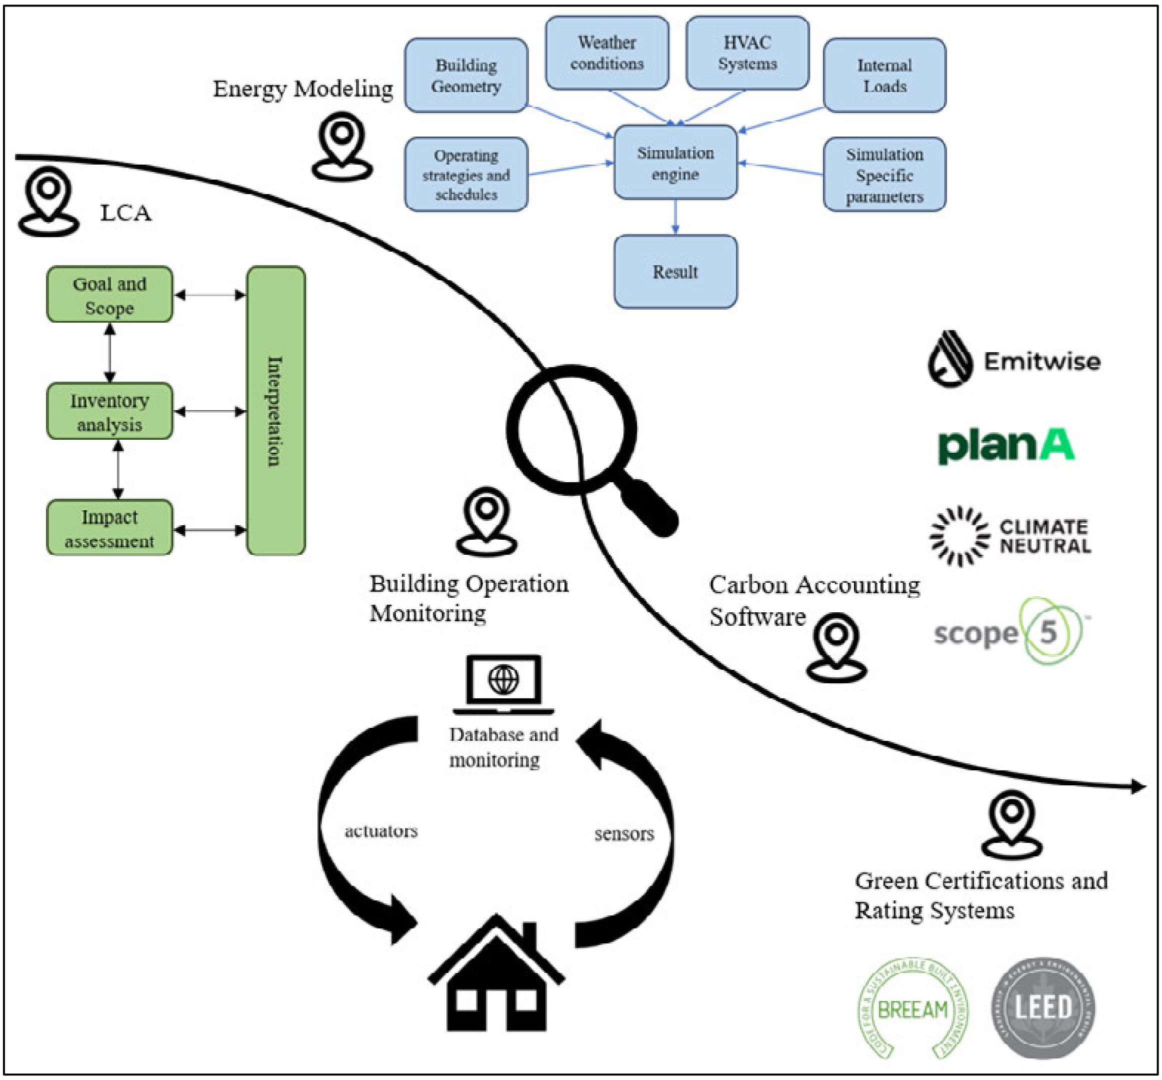

Fig. 1: Conceptual map of existing carbon tracking technologies.

LCA. LCA is a systematic method used to assess the carbon emissions generated throughout the entire lifecycle of a building, including raw material procurement, construction, operation, and demolition (Dodoo et al., 2014). By comprehensively regarding the environmental impacts at each stage, LCA provides comprehensive carbon emission data, guiding design and material selection to achieve sustainable and low-carbon building solutions. The strength of LCA lies in its comprehensiveness, such as material production, transportation, construction, and dismantling, beyond the building's use phase. Thus, LCA offers a more holistic evaluation of the building's environmental impact.

Energy Modeling. Energy modeling is a method that involves simulating a building's energy consumption using specialized software, thereby estimating carbon emissions. These models integrate factors such as building design, energy systems, and climate conditions, providing architects and energy experts with optimized strategies to enhance energy efficiency and reduce carbon emissions (Wang et al., 2021). Energy modeling allows decision-makers to predict a building's energy performance under different conditions during the design phase, facilitating environmentally friendly and energy-efficient choices. Additionally, it enables continuous monitoring and optimization of energy usage during the subsequent operational phase.

Building Operation Monitoring. Building operation monitoring entails the installation of sensors and monitoring systems to collect real-time data on energy consumption and emissions. These monitoring systems help building managers gain better insights into energy usage, promptly identify potential energy waste, and implement measures to reduce carbon emissions (Bilec et al., 2010). Continuous monitoring enables building managers to track energy performance and make timely adjustments and improvements to achieve sustained carbon reduction.

Carbon accounting software. Carbon accounting software is a specialized tool used to track and record carbon emission data for building projects and companies. These software solutions typically offer data collection, analysis, and reporting functionalities, facilitating the formulation of carbon reduction strategies and supporting the realization of carbon neutrality and emission reduction goals (Liu et al., 2019). Carbon accounting software empowers the building industry to efficiently collect and manage carbon emission data, providing support for achieving carbon neutrality and emission reduction objectives.

Green certifications and rating systems. Some countries and regions have introduced green building certification and rating systems, such as LEED, BREEAM, and Green Building Labels. These systems comprehensively assess a building's environmental performance, including carbon emissions, thus encouraging the adoption of more environmentally friendly design and operational practices in the construction industry. Participation in green certifications and ratings allows building projects to gain recognized environmental recognition, enhance market competitiveness, and contribute to sustainable development (Wang, Teng, et al., 2021). These green certification systems provide a clear goal for the building industry, driving the sector towards a more environmentally friendly and low-carbon direction (Chang et al., 2016). By comprehensively applying these carbon tracking technologies and practices, the building industry can play a proactive role in addressing global climate change and collectively create a more sustainable and greener future.

2.2 Advantages, beneficiaries and limitations of carbon tracking

This subsection provides an in-depth examination of the advantages and limitations of different carbon tracking technologies used in the building sector. The technologies discussed include LCA, Energy Modeling, Building Operation Monitoring, Carbon Accounting Software, and Green Certifications and Rating Systems. Each technology's advantages and limitations are summarized for comparison. The beneficiaries are also analyzed to gain a comprehensive understanding of the benefits in sustainable and low-carbon building practices.

Table 1: Advantages, beneficiaries, and limitations of carbon tracking technologies.

Carbon tracking tech.	Advantages	Beneficiaries	Limitations
LCA	• Comprehensive and holistic approach • Enables optimized design and material selection	• Building owners and developers • Government agencies and regulatory authorities • Environmental organizations and NGOs	• Data-intensive and time-consuming • Dependent on data quality and availability
Energy Modeling	• Virtual simulations for energy efficiency • Allows iterative design improvements	• Architects and engineers • Energy managers	• Relies on input assumptions and model accuracy • Real-world performance may differ from predictions
Building Operation Monitoring	• Provides real-time data on energy consumption • Identifies energy wastage and reduction potential	• Building owners and developers • Energy managers	• Requires infrastructure of sensors and data systems • Interpretation may need specialized expertise
Carbon Accounting Software	• Streamlines data collection and analysis • Supports progress tracking and mitigation strategies	• Building owners and developers • Government agencies and regulatory authorities	• Choosing appropriate software can be challenging • Reliability depends on data accuracy and completeness
Green Certifications and Rating Systems	• Offers standardized benchmarks for sustainability • Incentivizes eco-friendly design and practices	• Building owners and developers • Environmental organizations and NGOs	• Time-consuming and resource-intensive certification • Potential gap between predicted and realized outcomes

LCA's strength lies in the comprehensive assessment capability, which takes into account the environmental impact of the life cycle stages of the building. LCA provides comprehensive carbon emission data and other environmental indicators and helps decision makers to fully understand the environmental performance of the building. Through LCA, builders can compare the environmental performances of different design and material options to make more informed choices, optimize building design and material choices, reduce carbon emissions and environmental impact, and achieve sustainability goals (Hong et al., 2015). However, LCA also has some challenges and drawbacks. Its complexity is a significant problem. The implementation of LCA is complex and costly, because it requires a large amount of data collection, analysis and calculation, and has high technical and professional requirements. In addition, the reliability of LCA depends on the quality of the data and the reliability of data source. Therefore, incomplete or missing data can lead to uncertainty in the results and misled decisions. At the same time, conducting LCA also requires a significant investment of time and resources, which may become impractical or difficult to apply to complex construction projects.

Energy modeling can provide architects and energy experts with comprehensive data and information to gain insights into a building's energy use. With the simulation results of a building's energy consumption under different conditions, decision makers can predict a building's energy performance and make environmentally friendly and energy efficient decisions at the early design stage. Secondly, energy modeling integrates factors such as building design, energy system and climate conditions to provide solutions for building projects to optimize energy efficiency and reduce carbon emissions. Therefore, energy modeling can reduce energy costs and environmental impact throughout the life cycle (Li & Chen, 2017). However, energy modeling's reliability depends on the accuracies of both input data and the building model. Inaccurate data or modeling can lead to biased results and ineffective decisions. Secondly, energy modeling requires a high level of technology and expertise, and there may be barriers to learning and application for some builders. In addition, energy modeling also requires a certain amount of time and resource investment, especially for complex construction projects, which may increase the difficulty and cost of implementation.

Building operations monitoring provides real-time and accurate energy consumption data to help building managers get a complete picture of a building's energy use. Through continuous monitoring, managers can immediately grasp the energy consumption of the building, find potential energy waste and problems in time, and provide a basis for taking targeted measures. Secondly, operational monitoring can help optimize a building's energy use and operational strategies to achieve ongoing carbon reduction and energy conservation goals. By aligning operations with actual data, builders can reduce carbon emissions and energy costs and improve operational efficiency (Geng et al., 2022). However, the installation and maintenance of building monitoring systems may require certain inputs and costs. The selection, installation and commissioning of sensors and monitoring equipment require specialized technical support. Secondly, the processing and analysis of large amounts of real-time data may also require certain technical and management capabilities (Geng et al., 2022). For some builders, it may be necessary to train and improve the data analysis and operations management skills of relevant personnel. In addition, the building monitoring system also faces the problem of data security and privacy protection, and it is necessary to establish a reasonable data management and protection mechanism to ensure data security and compliance.

Carbon accounting software enables efficient data collection and management. By automating data acquisition and processing, manual operation and time cost can be greatly reduced, and the accuracy and reliability of data can be improved. Secondly, carbon accounting software provides powerful data analysis and reporting capabilities, capable of turning complex carbon emissions data into intuitive charts and reports to provide clear insight and guidance for decision-makers (Long et al., 2018). This helps to develop carbon reduction strategies and track progress, driving the construction industry in a lower carbon direction. However, choosing the right carbon accounting software for your needs requires consideration of a number of factors, including the software's functionality, compatibility, price, and user-friendliness. Different software may be suitable for different sizes and types of construction projects, so careful evaluation and selection are required. Secondly, it is necessary to ensure the accuracy and integrity of the data during the use of the software, otherwise, it may lead to errors and inaccurate analysis of the results. Therefore, the construction industry needs to establish a reasonable data collection and verification mechanism to ensure that the software output data is reliable and usable.

The Green certification and rating system provides the construction industry with clear environmental standards and targets, driving the construction industry to adopt more environmentally friendly and sustainable design and operation practices. By participating in certification and rating, construction projects can receive recognized environmental recognition, improve their market competitiveness, and attract more environmentally conscious customers and investors. Secondly, the green certification and rating system takes into account the environmental performance of the building, including carbon emissions, energy efficiency, material use and indoor environmental quality, so as to achieve comprehensive environmental benefits and sustainable development (Ma et al., 2020).

However, some rating systems may be too complex and cumbersome, requiring large amounts of data and proof to meet certification standards, increasing costs and burdens for builders. Secondly, the certification and rating process can be time-consuming, affecting the schedule and operation of the project. In addition, sometimes the rating results may only reflect the design and planning stages of the building and do not actually take into account the actual operation and use of the building, and therefore may be biased from the actual environmental performance.

3. THE PROPOSED CARBON TRACKING 'CABBAGE' FRAMEWORK

Fig. 2 presents the proposed Carbon Tracking 'Cabbage' (CTC) framework. The architecture of CTC framework represents the characteristics and beneficiaries of all the five technologies. The integrated framework can enable builders and all stakeholders to get a comprehensive picture of the carbon emissions of buildings. The quantitative carbon tracking results also enables carbon reduction strategies and plans in a data-driven manner, driving the construction industry towards a greener and low-carbon direction in the digital era. Incorporating a multi-stakeholder engagement approach, the CTC framework fosters collaboration among diverse participants, including architects, engineers, policymakers, and environmental experts, creating a synergistic effort to address carbon emissions and advance sustainability within the construction industry. With integrated carbon tracking technologies and evidenced-based multi-stakeholder practices, the construction industry can play an active role in contributing to the global response to climate change and co-creating a more sustainable and green future.

Fig. 2: The proposed Carbon Tracking 'Cabbage' framework in this paper.

3.1 Rationale

Carbon tracking and management becomes distinctly robust and strategic based on the CTC framework. This comprehensive approach stems from the imperative to synergize diverse data streams, resulting in a panoramic understanding of an organization's carbon footprint and the cultivation of a holistic strategy for sustainable practices. By seamlessly integrating techniques like LCA, Energy Modeling, Building Operation Monitoring, Carbon Accounting Software, and Green Certifications and Rating Systems, stakeholders attain a multifaceted perspective on their carbon emissions, uncovering insights that span the entire spectrum of product lifecycles.

Energy modeling serves as a vital supplement to this perspective, shedding light on emissions linked to energy usage, while real-time operational data from building operation monitoring introduces an agile layer of information. Carbon accounting software meticulously quantifies emissions, and green certifications provide benchmarks for measuring sustainability performance. The true power of integration lies in its ability to provide a nuanced analysis of emissions' sources and potential reduction avenues. This comprehensive comprehension empowers organizations to precisely identify processes or lifecycle stages that contribute significantly to the carbon footprint, facilitating the strategic alignment of reduction efforts with broader sustainability objectives.

Furthermore, the incorporation of real-time monitoring and reporting, seamlessly facilitated by building operation monitoring and carbon accounting software, bestows organizations with the nimbleness to make swift, well-informed decisions. The trajectory towards carbon reduction objectives can be closely monitored, enabling agile adjustments in real-time that optimize the efficiency of sustainability initiatives. The integration of esteemed green certifications and rating systems augments the credibility of these endeavors, ingraining transparency and accountability within the organizational approach to sustainability. In essence, this fusion of techniques underscores a sagacious and pragmatic approach to surmounting the intricate challenges of carbon reduction, laying the essential groundwork for a verdant and more sustainable future, fortified by data-driven insights and strategic harmony.

3.2 Adoption strategies

The CTC framework provides actionable strategies for stakeholders to adopt in order to achieve their carbon reduction goals. By facilitating data integration and collaboration across departments, organizations can ensure a seamless flow of information from technologies such as LCA, energy modeling, building operations monitoring, carbon accounting, and green certification. This collaborative approach promotes a comprehensive understanding of carbon emissions, enabling informed decision-making and targeted mitigation efforts. The implementation of advanced technology solutions has become a key strategy. By investing in carbon accounting software, energy management systems, and IoT devices for real-time monitoring of building operations, organizations can improve their ability to accurately quantify emissions and optimize energy use in a timely manner. A continuous improvement cycle is essential, where real-time monitoring data informs regular review and analysis to identify trends and areas for improvement. Over time, this iterative process enhances carbon reduction strategies and optimizes operations.

Transparently communicating efforts to reduce carbon emissions to stakeholders demonstrates a commitment to sustainability, while incentive programs and recognition boost employee motivation and morale. Long-term strategic planning ensures that organizations remain adaptable and resilient in their carbon reduction initiatives. Overall, the CTC framework serves as the foundation for implementing these strategies, guiding organizations toward a more sustainable and environmentally responsible future.

3.3 Application scenarios of the CTC framework

The CTC framework can guide sustainable construction management in different phases of a construction. For example, the framework integrates LCA and energy modeling, enabling design teams to assess the environmental impact of different design options. This enables the selection of materials, systems and technologies that meet carbon reduction targets, creating a solid foundation for sustainable projects. As the construction phase begins, the CTC framework maintains its importance. The integration of real-time monitoring and data-driven insights gives construction teams the means to track energy consumption and emissions in real time. During construction, rapid interventions can be implemented to optimize energy use and reduce carbon emissions, reflecting the immediate utility of the framework.

During the operational phase, the framework facilitates continuous monitoring and ensures the continuous and efficient operation of construction projects. Building operation monitoring ensures sustainable performance, while carbon accounting software tracks ongoing emissions. In addition, a recognized green certification and rating system is used to validate and communicate the sustainable achievements of the project to stakeholders, promoting transparency and accountability. Finally, during the retrofit and retrofit phases, the CTC framework guides informed decision-making by assessing the carbon emissions impact of retrofit choices. By seamlessly integrating LCA and energy modeling, retrofit teams can strategically upgrade systems, materials, and technologies to achieve the best carbon reduction outcomes.

All in all, the CTC framework serves as a comprehensive and adaptable tool for effective and sustainable construction management at all stages of a construction project. By leveraging its integrated technology, stakeholders are able to make informed, data-driven decisions that align with carbon reduction targets, advance environmentally responsible building practices, and contribute to a greener future.

4. DISCUSSION

As carbon emissions continue to be the primary driver of climate change, tracking and mitigating carbon emissions has become a top priority for governments, organizations and industries around the world. The construction sector's significant contribution to global carbon emissions underscores the need to focus on reducing the carbon footprint of buildings throughout their life cycle. Carbon tracking becomes a powerful tool for measuring, monitoring and mitigating the carbon impact of buildings. By tracking and monitoring carbon emissions, policymakers gain valuable insights into the amount of carbon in the atmosphere, enabling targeted mitigation and climate change strategies. Carbon tracking also helps to set clear and achievable emission reduction targets and promotes global cooperation and transparency to achieve common climate goals.

In addition, it is important to standardize carbon tracking and reporting methods to ensure consistency and comparability in international Settings. These technologies enable businesses to measure their carbon footprint, identify opportunities for improvement, and demonstrate to stakeholders their commitment to environmental responsibility. In the construction sector, carbon tracking technology provides a comprehensive understanding of the carbon emissions of buildings throughout their life cycle. From construction through operation to final demolition, these tools provide insights for informed decision-making and promoting sustainable building practices. Throughout the inquiry, the focus remained on the development and advancement of carbon tracking technology. From traditional methods to cutting-edge digital solutions, these technologies continue to improve our ability to quantify and understand carbon emissions, making them indispensable in our fight against climate change.

Overall, carbon tracking technologies enable stakeholders to make informed choices, assess the environmental impact of their actions, and work together to build a more sustainable and resilient future. By providing valuable data and insights, these technologies are transforming the construction industry and moving us closer to a carbon-neutral and healthier planet.

5. CONCLUSION

In summary, this comprehensive review highlights the significance of carbon tracking technologies in the building sector for combating climate change and promoting sustainable practices. The five key technologies—LCA, Energy Modeling, Building Operation Monitoring, Carbon Accounting Software, and Green Certifications and Rating Systems—each play essential roles in understanding, monitoring, and reducing carbon emissions in buildings. LCA provides a comprehensive view of a building's carbon footprint across its entire life cycle, guiding sustainable design and material choices. Energy Modeling allows for energy consumption simulation and optimization during the operational phase, enabling the early implementation of energy-efficient strategies. Building Operation Monitoring offers real-time data collection to understand and reduce energy wastage. Carbon Accounting Software tracks emissions and sets reduction goals, while Green Certifications and Rating Systems incentivize sustainable practices.

A proposed Carbon Tracking 'Cabbage' (CTC) framework integrates all the technologies and empowered stakeholders for data-driven decision-making, carbon reduction strategies, and sustainability initiatives. Collaboration among researchers, policymakers, and industry professionals, as sketched in the CTC framework, is crucial for implementing this framework and achieving a greener and more sustainable future. By embracing carbon tracking technologies under the CTC framework, the building sector can actively contribute to mitigating climate change and creating a resilient and environmentally responsible world.

However, the CTC framework in this paper is conceptual. We require a system platform and pilots in the industry to realize and validate the effectiveness of the CTC framework. Furthermore, the arguments and discussion only flows at the surface of general cases. Fine adjustments are necessary for each construction 'niche' industry to meet construction industrial standards, supply chains, and cultures for carbon tracking of the whole life cycles of buildings.

ACKNOWLEDGEMENT

RETROFITTING OF BUILDINGS TO IMPROVE ENERGY EFFICIENCY: A COMPREHENSIVE SYSTEMATIC LITERATURE REVIEW AND FUTURE RESEARCH DIRECTIONS

Elena Imani*, *Huda Dawood*, *Nashwan Dawood* & *Annalisa Occhipinti

Teesside university,UK

ABSTRACT: *A large body of research has been developed with the aim of assisting policymakers in setting ambitious and achievable environmental targets for the retrofit of current and future building types for energy-efficiency and in creating effective retrofit strategies to meet these targets. The aim of this research is to conduct a comprehensive study to identify the relationship between building type and sustainability, with a particular emphasis on retrofitting and try to identify research gaps in the most effective energy-saving strategies for retrofitting various types of buildings. In this regard, this study conducts a systematic literature review (SLR) utilizes artificial intelligence (AI) and natural language processing (NLP). Sixty relevant papers are selected and reviewed, establishing a comprehensive searching scheme. The research highlights retrofitting strategies for improving energy efficiency in buildings and discuss the limitations of current practises in terms of physical and technical developments, such as utilising new energy systems and innovative retrofitting materials. To overcome these, future studies could focus on in-depth building classification, developing tailored retrofitting alternatives, and establishing an adaptive solution framework. This framework aligns cohesively with diverse typologies, adapting to changing contexts and enhancing long-term performance.*

KEYWORDS: *retrofitting, typology of building, building energy performance, residential buildings.*

1. INTRODUCTION

Buildings account for 40% of the overall energy consumption in the European Union (Ballarini et al., 2017). Improving building energy efficiency is currently considering a top priority by the UK government as a major initiative for accelerating the decarbonization agenda for the building industry by 2050. European policy aims to achieve a 27% increase in energy efficiency by 2030, primarily by improving the energy efficiency of newly constructed buildings. However, the number of new buildings is small compared to the total stock of buildings in Europe, accounting for only 1%. Therefore, the most crucial aspect of energy-saving in Europe is retrofitting of existing residential buildings (Pungercar et al., 2021). Nevertheless, according to (Ortiz et al., 2020), the UK government's main barrier in this regard, tends to be reducing carbon emissions from existing residences. To improve the long-term energy performance of the building stocks and reduce carbon emissions, governments should develop a strategy to invest in building energy refurbishment(Ballarini et al., 2017). A large body of research has been developed to assist policymakers in setting ambitious and achievable environmental targets for converting a certain building type to energy-efficient structures and creating effective strategies to meet these targets (Re Cecconi et al., 2022). However, building regulations are frequently changed, depending on each country's vision, potential, capacity to implement such changes, and the complexity of architectural details and conditions within its building stock (Alabid et al., 2022).

Several variables play a pivotal role in shaping energy consumption within a building, including the building envelope's structure, age distribution among existing building stocks, prevailing climate conditions, building area and type, the building's age, and the efficiency of its system installations (Beagon et al., 2020). In order to promote local or national energy-saving strategies, typical residential building typologies are commonly used to model the energy efficiency of building portfolios (Loga et al., 2016).

Indeed, one crucial aspect that contributes to the complexity of retrofitting residential buildings lies in the fact that each building's characteristics can significantly vary based on the environmental conditions of its location. While previous research, as highlighted by (Kadrić, Aganovic, Martinović, et al., 2022), has delved into the challenges and opportunities of retrofitting different building types, there remains a notable gap in the literature concerning the explicit consideration of environmental factors during the retrofitting process. This research aims to address knowledge gaps by utilizing a novel searching framework that employs an AI algorithm. It seeks to analyse the existing literature concerning the correlation between building types and energy-efficient retrofitting, including the influence of environmental factors on energy-saving strategies according to building's typology. The goal is to identify crucial areas for future research and enhance the understanding of the relationship between building

typology, energy efficiency, and retrofitting.

2. RESEACH METHODOLOGY

Highlighting the most recent developments in many areas of research is essential to ensuring progress and innovation in those areas. However, with an overwhelming number of publications, it becomes challenging to thoroughly read and analyze each one. Ignoring them entirely is not a viable option either, as valuable insights might be missed. Therefore, there is a pressing need to develop a new search scheme that effectively filters publications, ensuring a comprehensive review without overlooking significant contributions. The methodology employed in this research involves a multi-step approach to ensure a comprehensive and robust review of relevant studies (Figure 1).

The research begins by conducting a SLR proceess and develop an algorithmic gap spotting framework, which serves as a fundamental aspect of the process. This framework encompasses the formulation of effective search strategies and the establishment of stringent study selection criteria. By implementing this approach, the research aims to identify and address gaps in existing literature, enhancing the overall quality of the review. Following the development of the framework, the quality of the studies included in the review is thoroughly evaluated. This evaluation focuses on determining the probability of bias and assessing the reliability of the supporting data. By conducting this assessment, the research ensures that only high-quality studies are considered in the analysis, enhancing the credibility and validity of the findings. Based on the results obtained from the algorithmic gap spotting framework and study evaluation, this research aims to identify gaps in the existing literature and design future study. These gaps indicate areas where further investigation is needed to address unanswered questions or explore novel perspectives. By identifying these research gaps, the study aims to contribute to the advancement of knowledge in the field.

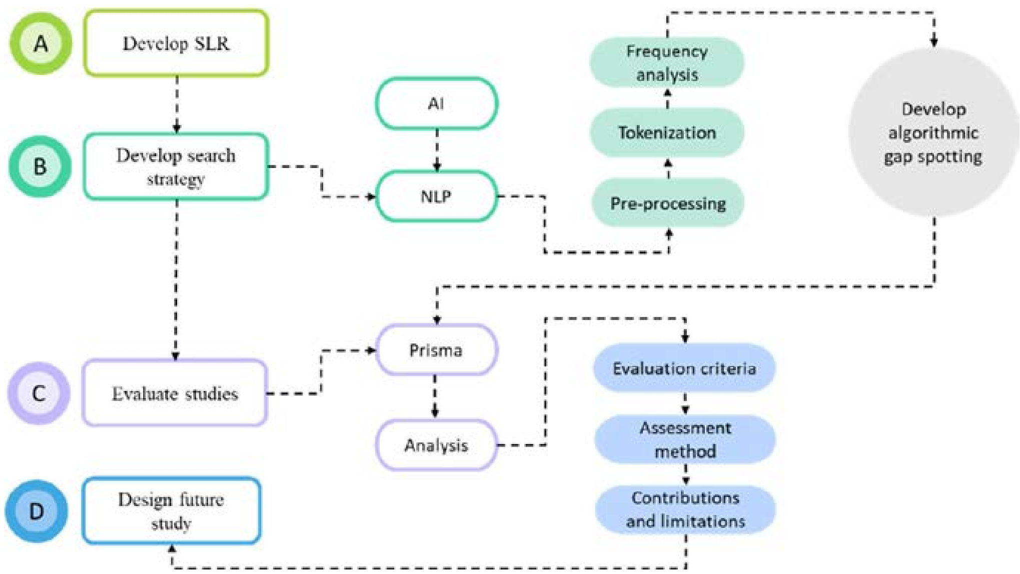

Fig. 1: Research methodology

2.1 Systematic literature review

To fully address a research topic, this study used (SLR) technique. The methodology employed in this publication for conducting (SLR) involves two main steps for defining keywords. Firstly, database selection was performed, and subsequently, a search strategy was developed. This process resulted in the identification of 402 relevant publications that were then selected for evaluation and analysis. The systematic literature review (SLR) process identified 60 relevant papers using PRISMA methodology (Figure 2). This approach provided valuable insights into energy efficiency, particularly building typology's role, crucial for decision-makers and designers.

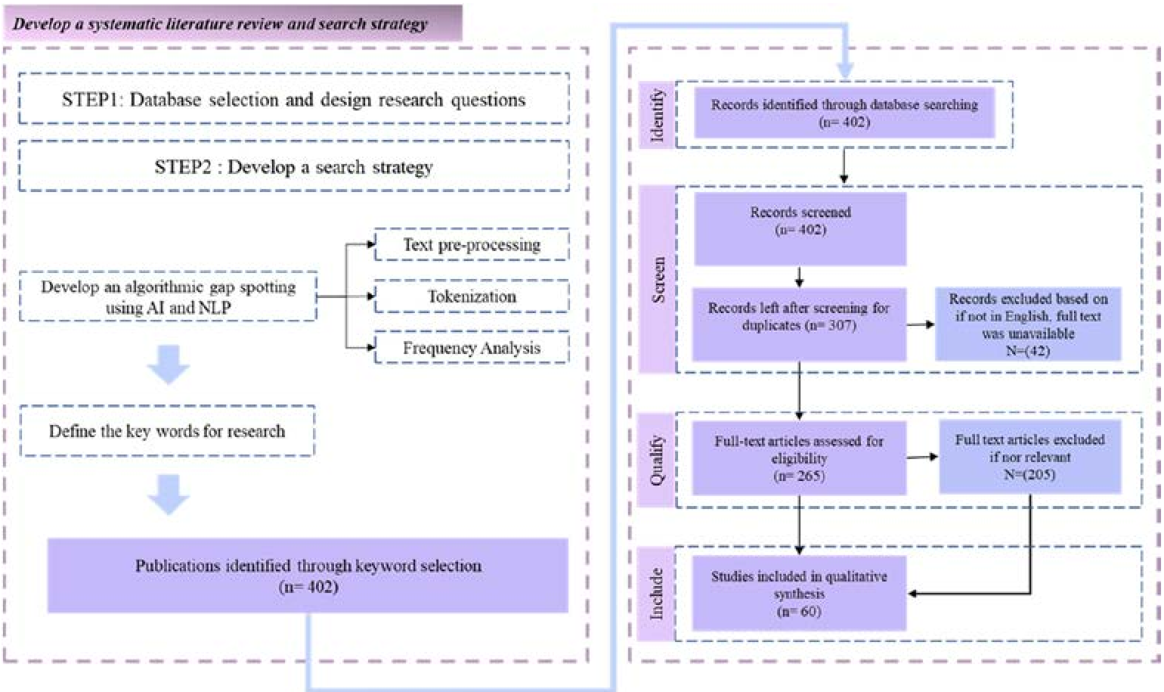

Fig. 2: Search strategy framework

2.2 Algorithmic gap spotting

The research questions addressed in this section are:

RQ1. How much publications have there been about relationship between building type and energy efficiency through retrofitting since 2011?

RQ2. What are the limitations of current research in this area?

In order to answer the research questions, this study reviewed literature related to construction building technology, civil engineering, green sustainable science technology and environmental science fields to catch the most relevant articles. This study introduces a novel approach to addressing the challenge of search strategy for identifying research gaps in existing literature. By leveraging AI algorithms, NLP techniques, and data analysis, a strategy called algorithmic gap spotting (algorithmic gap roadmap) is employed. This method offers an automated and systematic way to identify areas of research or knowledge where there are gaps, enabling researchers to guide future studies, recognize biases and limitations, and foster innovation in various fields (Figure 3).

Algorithmic gap spotting involves the utilization of computational tools to analyse and interpret large volumes of published research papers, articles, and other relevant documents. By applying AI algorithms and NLP techniques, patterns and trends within the data can be identified, such as keyword frequency, co-occurrence of terms, and the distribution of topics across different domains.

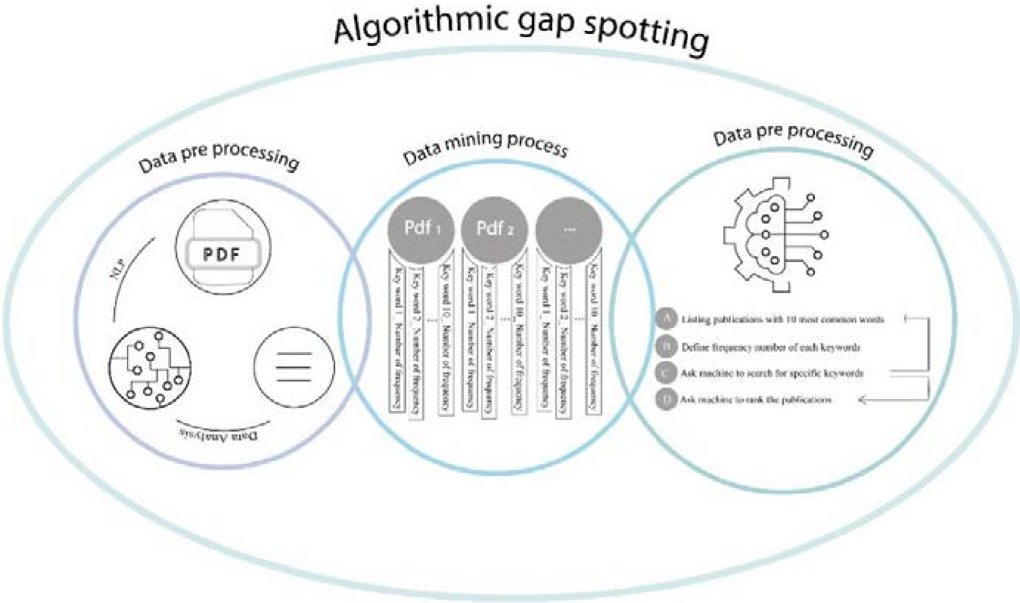

Fig.3: Algorithmic gap spotting design process

3. RESEARCH FINDINGS AND REVIEW RESULTS

As mentioned before, building retrofitting is an effective approach to reducing energy consumption and carbon emissions. However, it is a complex process that requires consideration of various factors. Despite its potential benefits, there is still a lack of information on factors that impact retrofitting solutions. This research aims to address these gaps by conducting a comprehensive literature survey. Reviewed publications in the previous section identified two main areas that remain a gap in the literature, which are building retrofit assessment according to the typology of building and building retrofit assessment according to environmental factors. This paper discusses the importance of addressing these gaps and presents recommendations for future research in these areas.

3.1 Building retrofit assessment according to the typology of building

Building typologies play an essential role in achieving energy performance requirements of buildings. By considering building typologies, a comprehensive understanding of a building stock's energy efficiency can be gained, making it an indispensable tool in ensuring sustainable and energy-efficient buildings (Y. Li et al., 2019).

Numerous pieces of evidence have been identified through the analysis of architectural typologies related to energy in the European Union, at both national and regional levels. Typological data and criteria are being used to develop informational materials and provide energy advice for buildings (Dascalaki et al., 2011a). Moreover, typical residential building typologies are also being employed as tools for modelling the energy efficiency of building portfolios to promote local or national energy-saving strategies (Ballarini et al., 2011a). The main purpose of building typology is to determine the best energy-efficiency techniques to implement in existing structures and quantify the potential energy savings and $CO2$ emission reductions associated with the implementation of energy refurbishment measures in the building stock at various scales (Fernandez-Luzuriaga et al., 2021).

According to (Sugár et al., 2020), building typology also plays a crucial role in determining a building's energy consumption. For instance, the heating energy demand of a building depends on its architectural style, and typology can be used to calculate a building's heating energy requirement. The main objective of this research is to present a study through literature related to the connection between sustainable retrofitting and building typology. The process systematic search method for retrofit decision-making intends to provide thought-provoking insights into the shortcomings and outlines the most important directions for future research.

3.2 Building retrofit assessment according to Environmental factors

The influence of the surrounding environment on building heating energy consumption has been recognized as a critical factor in addition to the physical condition of a building. While the latter factors have been extensively studied, (Song et al., 2020) highlights the importance of urban morphology and climatic conditions in determining the overall heating demand in buildings. There are various global environmental assessment schemes that evaluate the impact of projects on different factors related to sustainability (Del Rosario et al., 2021). This section tries to investigate and comprehend the environmental aspects that influence the energy efficiency of buildings. It highlights a requisite for additional research to advance more precise and comprehensive assessment frameworks that encompass the environmental sustainability of retrofitting strategies.

3.2.1 Building retrofit assessment according to the climate conditions

The classification of buildings varies depending on the climate condition of the region and retrofitting strategies must be tailored to specific climate conditions and building types to ensure their effectiveness (Boardman, 2007). The primary aim of building typology is to create structures that are responsive to their environment while maximizing the use of resources available (Kirkegaard & Foged, 2011) (Tompkins & Adger, 2003). Retrofitting strategies towards energy-efficient buildings in specific climate conditions may have a common target; however, they differ in their strategies. Numerous studies conducted in various locations highlight retrofitting solutions tailored to their specific climate conditions, which might not be applicable to other regions.

The decision-making process for retrofitting buildings can be significantly impacted by the availability of retrofitting alternatives that are specially created for various climate zones (Liu et al., 2022). To increase the adoption of energy-efficient retrofitting solutions and reduce greenhouse gas emissions, it is advised to develop and promote options tailored to local climatic conditions, while considering the typology of the building. By adopting climate-specific retrofitting strategies, energy efficiency can be significantly improved by taking into consideration the unique weather conditions of a region.

3.2.2 Building retrofit assessment according to the surrounding environment

Besides climate factors, there are other environmental factors that are essential for reducing greenhouse gas emissions and improving energy efficiency in cities (Bouw et al., 2021). For instance, the architect must consider solar and daylight availability to optimize solar energy production and minimize environmental impact in design. By integrating sustainable and passive design solutions with active solar energy systems, cities can reduce their reliance on non-renewable energy sources and promote a more environmentally sustainable future (Webb et al., 2016). Many energy models have been developed recently, but they tend to neglect the importance of phenomena that occur at the urban scale, such as the effect of urban geometry on energy consumption (Mirzabeigi & Razkenari, 2022).

In conclusion, the surrounding environment and building design that considers solar and daylight availability are crucial factors in reducing greenhouse gas emissions and improving energy efficiency in buildings. While various energy models have been developed, they often neglect the impact of the surrounding environment on energy consumption. Therefore, it is important to consider factors such as building height, the density of the building in urban design, shape factors and etc, to optimize energy usage and minimize environmental impact. By integrating sustainable and passive design solutions with active solar energy systems, buildings can reduce their reliance on non-renewable energy sources and promote a more environmentally sustainable future. Overall, these findings emphasize the need for integrated approaches to urban planning and building design that prioritize environmental sustainability and energy efficiency.

4. DISCUSSION OF RESULTS

In order to determine the limitations and contributions of building retrofit assessments with regard to building typology and environmental factors, a review of the relevant literature was conducted in this research. This research aims to identify and evaluate the most relevant publications concerning building retrofitting assessments, with a specific focus on their respective key areas. The methodology involves the selection of 60 publications, followed by a thorough analysis of their contents. In this section, this paper selects 27 publications that align closely with its goals and methodology, and delves into their assessment methods (see Table 1). In addition, this paper thoroughly assesses the selected publications, examining their typological and geometrical parameters as evaluated in these studies. Furthermore, it considers other parameters such as the exploration of different climate conditions, cost analysis, CO_2 emissions, as performance metrics and various retrofitting alternatives. These factors are crucial to understanding the assessment of achieving low-energy retrofitting in residential buildings.

Table 1: Summarised Publications for Building Retrofit Assessment based on Focused Parameters

Evaluation criteria	Assessment method	Typology									Retrofitting											Energy performance					
		(Ballarini et al., 2017)	(Coma et al., 2019)	(Ballarini et al., 2011b)	(Dascalaki et al., 2011b)	(Beagon et al., 2020)	(Salehi et al., 2015)	(Kragh et al., 2014)	(Kristensen et al., 2021)	(Loga et al., 2016)	(Ignjatović et al., 2021)	(Bennadji et al., 2022)	(Alavirad et al., 2022)	(Wang et al., 2022)	(Alabid et al., 2022)	(Merlet et al., 2022)	(Carletti et al., 2014)	(Yazdi Bahri et al., 2021)	(Marasco et al., 2016)	(Lee et al., 2019)	(Liu et al., 2022)	(Kadrić et al., 2022)	(Sugár et al., 2020)	(Becchio, 2012)	(Q. Li et al., 2021)	(Aksamija, 2015)	(Xiong et al., 2019)
Architectural features	Geometry	X		X			X					X				X						X	X

	Thermal comfort														x		x	x							x		x

The findings indicate that most of the publications propose retrofitting alternatives as solutions to improve energy efficiency and sustainability in buildings. However, there remains a lack of understanding regarding various metrics and calculation methods for evaluating retrofitting solutions, potentially hindering the development of standardized and readily available approaches. The studies identify that no single retrofitting solution can address all challenges, while also raising awareness about the importance of adoptable retrofitting strategies.

As observed in Table 1, the majority of the publications focus on implementing energy-saving techniques based on specific climate conditions and personalized retrofitting options. Nevertheless, it is crucial to recognize that certain limitations still require attention and resolution. Limitations in current liturature are outlined below:

- Several studies have been conducted, particularly in the last decade, to assess the energy efficiency of dwellings and improve building retrofitting according to their typologies. Although, most have used the "Typology Approach for Building Stock Energy Assessment" TABULA report to provide methods for classifying housing typology in Europe. However, there is still a lack of comprehensive information regarding technical developments, building structures, building layouts, and their relations which could affect energy requirements in buildings.
- TABULA report offers two levels of refurbishment for each typology, usual and advanced refurbishment. According to these refurbishment techniques, there is only one recommendation for each level but no elaboration on other refurbishment alternatives for each typology.
- The physical characteristics of buildings are regularly and significantly altered over time, changing not only the parameters of urban areas but also their physical characteristics and compositions. Therefore, there is a need to develop and amend adoptable retrofitting solutions based on building typologies.
- The energy-efficient building design methods have limitations when applied in regions with diverse climate characteristics. The method may not account for microclimatic conditions, extreme weather conditions or changes in building usage or occupancy patterns. It may not be suitable for regions with different building types or sizes and may require extensive data collection and processing.
- Numerous methods and tools have been created globally for assessing the energy efficiency of buildings. However, each of these methods and tools is different in its own way, and there is no consensus on how to score or weigh them. Furthermore, there is a shortage of building environmental assessment methods for retrofitting stages and approaches for determining carbon emissions and benchmarking are not consistent.

5. FUTURE STUDY DESIGN

In order to address the limitations observed in current liturature and develop more effective energy-efficient building retrofitting, a comprehensive approach is proposed for future studies.

- To address the lack of comprehension regarding the intricate connections among building layouts, technical progress, and energy demands, an in-depth building classification can be undertaken. This entails not only categorizing building typologies but also delving into the details of their structural compositions, architectural designs, and evolving technological aspects.
- Expanding on the predefined retrofitting solutions, a future study could focus on developing retrofitting alternatives tailored to various building typologies. This could involve an in-depth exploration of alternative refurbishment techniques precisely suited to specific building typologies. By considering an array of innovative materials, construction methods, and emerging technologies, researchers could propose retrofitting strategies that cater to the unique characteristics of each typology while also optimizing energy efficiency and sustainability. This approach would provide a richer set of retrofitting solutions for architects, designers, and stakeholders to choose from, ensuring a more adaptable and effective retrofitting process that aligns with diverse building needs and environmental contexts.
- To propose an adaptive retrofitting solution framework that aligns cohesively with diverse building typologies and could respond to their evolving physical features or environmental contexts. By incorporating advanced assessment methodologies, responsive strategies, and a unified assessment framework, the proposed adaptive retrofitting solutions aim to enhance the long-term performance and environmental compatibility of buildings.

6. CONCLUSION

Building retrofitting assessments have recently gained a lot of attention from researchers. Since 2019, the number of published works on this topic has increased significantly. The goal of this study is to thoroughly examine the available literature on the relationship between building typology and energy efficiency, with a particular emphasis on retrofitting. In addition, this study attempts to identify research gaps and plan a future study on the most effective energy-saving solutions for retrofitting various types of buildings while taking specific environmental and physical aspects into account. Based on the review of journal articles (n = 60) between 2011 and 2023, this study summarized: (1) building retrofitting, (2) energy efficiency improvement, and (3) building typology. The main findings of this study include the following: the current body of existing literature on building retrofits has primarily focused on classifying building typologies and tailoring retrofitting solutions accordingly. However, there is a significant gap in knowledge regarding technical advancements, building structures, environmental factors, and their relationship, as well as alternative strategies for executing standard or deep retrofitting and accurately predicting energy savings. The energy-efficient building design method based on climatic zoning has limitations when applied to diverse climates and building types/sizes, which necessitates the development of a comprehensive methodology and tool for transferring knowledge to support adoptable energy-efficient building retrofits. Addressing these deficiencies is crucial for developing responsive and adaptable solutions that are tailored to the unique characteristics of each building rather than relying on a generic approach. It would also facilitate designers and policymakers with relevant information on energy-efficient building retrofits to make informed decisions.

A BIM-BASED APPROACH TO THE MANAGEMENT OF HISTORIC BRIDGES

Carlo Biagini, Alberto Aglietti
Department of Architecture, University of Florence
Andrea Bongini
Department of Civil and Environmental Engineering, University of Florence

ABSTRACT: *Building Information Modelling applied to civil infrastructure has opened up interesting scenarios for integrated management of existing infrastructural works. In the last few years Bridge Management System (BMS) have been increasingly used by infrastructure owners, based on different control systems: from stochastic methods, which make it possible to define a condition ratio (CR) starting from periodic inspections of bridges, to sensors for structural monitoring, which can originate a flow of information exchange between real artifacts and the digital model capable of activating effective reactive or planned responses in the operation and maintenance phase of the asset.*

The paper intends to outline a BIM-oriented process workflow, which from the creation of parametric objects for infrastructural works using Scan-to-BIM acquisition techniques and procedures, arrives at the implementation of information bridge models to manage both static data from scheduled inspections of technicians of defects and their severity according to specific guidelines, and dynamic data from incoming and outgoing sensors placed in the physical asset for real time monitoring towards analysis, supervision and control systems of the facilities owner. The defined process workflow will be applied to some case studies, related to bridges of different characteristics, outlining some directions for future developments. In detail the research showcases the tasks undertaken and the outcomes achieved on four selected bridge case studies, which are real and situated within the geographical area of the Tuscany region, Italy. The studied bridges are all still in use and hold historical significance, as they were constructed between two hundred and one hundred years ago.

KEYWORDS: *Bridge Management System; InfraBIM; HBrIM; Digital Twin, Scan-to-BIM, SHM, IFC.*

1. INTRODUCTION

Generally, users perceive infrastructure projects as safe, and it's uncommon for drivers of regular vehicles to doubt the safety of the bridge they're crossing (Santarsiero et al., 2021). However, factors like extreme environmental conditions, mechanical loads surpassing the design assumptions, extended operational durations, inadequate maintenance, and similar elements can significantly impact and jeopardize the structural integrity of bridges (Saback de Freitas Bello et al., 2022; Santarsiero et al., 2021; Zinno et al., 2022).

After a series of incidents, including the Morandi Bridge collapse (Santarsiero et al., 2021), the Italian Government in 2020 enacted the "Guidelines on risk classification and management, safety assessment, and monitoring of existing bridges" through legislation (Ministerial Decree number 578/2020). The ministerial decree number 204/2022 essentially reaffirmed the aforementioned guidelines, extending their temporal validity to forty-eight months, or until the end of the year 2024. Further complementing the Italian regulatory framework are the "Operational Instructions for the Application of the Guidelines for Risk Classification and Management, Safety Assessment, and Monitoring of Existing Bridges" proposed by ANSFISA and annexed to the ministerial decree number 204/2022.

For the risks that older bridges run and for regulatory issues similar to those described above for the Italian case, in recent years, Bridge Management Systems (BMS) have gained much importance and numerous infrastructure management companies have adopted it. Particularly, those systems based on stochastic methods have gained prominence, allowing the determination of a Condition Ratio (CR) based on regular bridge inspections and on the detection of the defects of the bridges themselves. Bridge Management Systems (BMSs) are modular information systems with designated functions (de Freitas Bello et al., 2021; Woodward et al., 2001), including inventory compilation, preservation assessment, risk evaluation (including load capacity), operational management, cost estimation for maintenance strategies, deterioration prediction and associated costs, socio-economic importance analysis with budget constraints, maintenance priority setting, and multi-temporal budget tracking. BMSs, along with Structural Health Monitoring (SHM) techniques, are employed to assess bridges post-visual inspections by

Carlo Biagini, Alberto Aglietti, Andrea Bongini, *A BIM-Based Approach to the Management of Historic Bridges*, pp. 1105-1116, DOI 10.36253/979-12-215-0289-3.110

specialized technicians.

The majority of current BMSs employ a two-dimensional (2D) approach to record and store information without visual representation and dynamic integration (Li et al., 2023). Building Information Modeling (BIM), which involves creating and managing a comprehensive 3D model embedded with informative data for the entire lifecycle management of a specific asset (Kaewunruen et al., 2022), emerges as the most natural source of information and data storage for next-generation BMSs.

In the field of the SHM it is now common practice to place sensors on the bridges that it is believed to have to check or monitor for what has emerged from inspections on the same. The type of sensors that can be installed varies according to the phenomenon to be monitored but also with respect to its purpose: it is possible to install different sensors for short, medium or long-term monitoring or to install sensors capable of sending an alarm when a certain threshold value is reached. Enhancing finite element method (FEM) analyses with continuous sensor data can bolster the reliability of studying degradation. Artificial Intelligence (AI), especially Machine Learning (ML), offers transformative potential for Structural Health Monitoring (SHM). ML techniques automate pattern recognition in sensor data, aiding defect detection and risk assessment (Malekloo et al., 2022; Zinno et al., 2022).

Considering AI as a predictive technology that utilizes data and "experience" to formulate forecasts, which in turn serve as inputs for the decision-making process, it can be asserted that the initial solutions conceived and applied to date across various fields, including Structural Health Monitoring (SHM), have been “Point Solution” where AI has replaced previous predictive tools (Agrawal et al., 2018, 2022). However, it is reasonable to anticipate a substantial paradigm shift in the medium term within this sector, as well as others. Stemming from the concept of reducing the cost associated with forecasting, a principal economic facet introduced by contemporary Machine Learning (ML) algorithms, a complete reorganization of SHM is foreseeable. Referring to this form of AI-based solution as a “System Solution” is appropriate.

The Italian Guidelines also envision the utilization of digital technologies for their "intelligent" administration, achieved by integrating sensors into SHM systems and constructing informative models of structures. This is regarded as a step towards the realization of the National Digital Archive of Public Works (AINOP).

A digital model integrating geometric and performance data aids SHM and aligns with the "Digital Twin" concept of Smart Manufacturing and infrastructure research. In the AECO sector, the Digital Twin concept is tied to Building Information Modelling (BIM). In the realm of bridges, the term "BIM" is often replaced with: InfraBIM (Osello, 2019), BrIM (Barazzetti et al., 2016; Saback et al., 2022), HBIM (Barazzetti et al., 2016; Borin & Cavazzini, 2019; León-Robles et al., 2019; Murphy et al., 2011; Stavroulaki et al., 2016), HBrIM (León-Robles et al., 2019).

In the field of built heritage, surveying plays a crucial role in comprehending structures. Contemporary techniques such as laser scanning(Boardman et al., 2018; León-Robles et al., 2019; Pritchard et al., 2017) and photogrammetry (Ioli et al., 2022; Jáuregui et al., 2006; Mohammadi et al., 2021) are widely employed, utilizing both ground-based tools and UAV systems. These methods generate datasets in the form of point clouds (PC), which then require further processing to create Building Information Models (BIM). Known as Scan-to-BIM, this process is well-documented in the literature(Croce et al., 2023; Roggeri et al., 2022; Sing et al., 2022; Wang et al., 2019).

The surveys and consequently the point clouds can serve at different stages in the useful life of a bridge:

- They can form the database foundation to create a BIM model if it doesn't already exist.
- They can be work an AS IS representation of the structure.
- In the capacity of AS IS, they can be used for comparisons with a BIM model representing a situation prior to the survey.

When a Building Information Model (BIM) of an existing bridge is being developed, several factors come into play that strongly affect the modeling process. These factors include the bridge's characteristics, how easy it is to access the bridge for data collection, and the availability of detailed design plans or information about the bridge's original construction and its current state. All of these elements have a significant impact on how the BIM model of the bridge is created and how accurate and comprehensive it can be. The process of creating a Building Information Model (BIM) from scanned data is easier for bridges with massive components like masonry structures. On the other hand, this process is more complex for bridges made of metal trusses. The complexity arises because metal truss bridges consist of many intricate elements with edges and corners that are difficult to accurately capture using laser scanning and photogrammetry techniques. It's easier to model massive bridges using scan-to-BIM methods compared to complex metal truss bridges due to the challenges of capturing detailed data.

With the widespread adoption of BIM as a methodology for building modeling, the IFC data schema, Industry Foundation Classes, has gained importance. Leveraging the principles inherent in Object-Oriented Programming (OOP), IFC presents a novel shared language across the entire Architecture, Engineering, Construction, and Operations (AECO) sector. IFC is not a replacement for the language of technician draw nor an evolution thereof; rather, it serves as a schema enabling the transmission of comprehensive information about a construction. This logically structured data extends far beyond mere geometric representation. As described above, IFC has become an essential component of knowledge incorporated into all leading university programs within the sector. With the upcoming version of IFC, the schema will expand into the domain of infrastructure, which until now has been only partially representable or represented using non-conventional methods.

The topics addressed by this research are relevant to Cluster 3 of the Horizon Europe 2021-2027 program and also dealt with in the 2021-2027 National Research Plan (PNR), in line with the objectives of Goals 9 and 11 of the 2030 Agenda of United Nations Organization.

2. MATERIALS AND METHODS

In recent years, the intersection of engineering, digital technology, and heritage preservation has paved the way for innovative approaches in the study of historic structures. This research article presents a comprehensive examination of the digital documentation and structural monitoring of four distinct historic bridges. By employing Building Information Modeling (BIM) techniques, each bridge was meticulously captured in a virtual environment, enabling a detailed analysis of its architectural and structural features. Furthermore, this study explores diverse strategies for the digital representation of these historic constructions and the implementation of structural monitoring solutions.

The preservation of historic bridges holds significant cultural, historical, and engineering value. Through the integration of BIM methodologies, these bridges can be accurately documented and analyzed, facilitating the development of effective strategies for their maintenance and conservation. The four selected case studies serve as tangible examples of this interdisciplinary approach, shedding light on the challenges and opportunities that arise when dealing with the intricate balance between preserving heritage and ensuring structural integrity. By examining the challenges and successes encountered in the digital documentation and structural monitoring of historic bridges, this study aims to inform best practices and inspire further advancements in the field.

Fig. 1, 2: Masonry bridge over Masera Ditch | Laser scanner survey.

2.1 Case Study 1: Masonry Bridge over the Masera Ditch

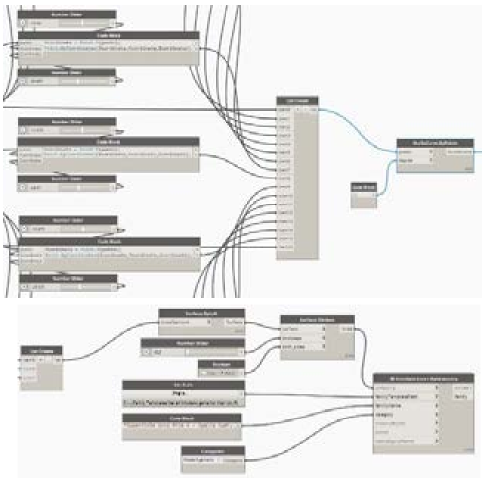
The masonry bridge over the Masera Ditch is situated in the Crespino over Lamone-Biforco section of the railway line connecting Borgo San Lorenzo to Faenza. The “Faentina” Railway is a state-owned railway line that connects Florence to Faenza via Borgo San Lorenzo (fig. 1). Its construction took place between 1880 and 1893, with the idea originating as far back as the 1840s. This railway was closed for an extended period due to significant damage sustained during World War II. Traffic resumed partially in the 1950s, but the line experienced another closure in 1971. The gradual reopening began in the 1990s and was completed in the early 2000s. Essentially, it’s a sparsely utilized line, hence its lack of electrification and the presence of a single track.

The bridge over the Masera Ditch is a masonry structure with five arches, situated on a curved path. At its highest point, the structure stands 40 meters above the ground. Adjacent to the bridge, both upstream and downstream, are two galleries manually excavated from the rock.

2.1.1 Documentary research and survey campaign

No original bridge designs have been found, nor have any other technical drawings of any kind been located. Near the bridge, there is an access point to regular road traffic, and it's also possible to ascend the mountain to reach little clearings at the bridge's height, away from the rail track. Given the scenario described in the preceding paragraph, a significant portion of the survey was conducted without the presence of surveillance personnel. However, this did involve a temporary suspension of railway traffic.

The survey campaign was conducted using a Z+F IMAGER 5016 Laser Scanner, which also captured RGB data (fig. 2). Additionally, photographic documentation was captured using a Sony H300 Camera with 35x optical zoom. The point cloud datasets were captured in .fls format and subsequently imported into Autodesk Recap® software.



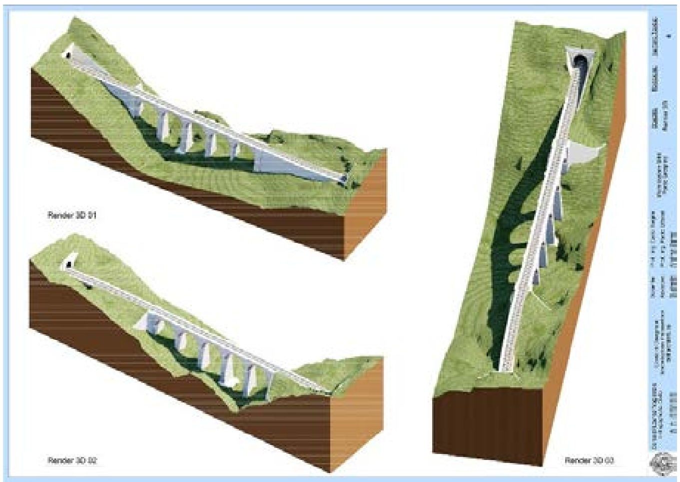


Fig. 3, 4: VPL script for arches modelling | Views of the BrIM model

2.1.2 BIM Modeling and Implementations

Given the absence of technical drawings for the bridge, in the case study of the Masonry Bridge over the Masera Ditch, a BIM modeling was carried out using a conventional Scan-to-BIM workflow.

The initial step taken towards modeling the viaduct involved refining the provided point cloud data. This was achieved by removing portions of the surrounding vegetation and segmenting the point cloud into three parts, aimed at reducing the file size to expedite the modeling process. Subsequently, these three segments of the point cloud were integrated into Revit to initiate the modeling process. The bridge has been decomposed into its constituent elements based on the methodologies employed by the management company of the Italian railway line, similarly to what was done for the case study of the metal girder on the Osa river. The three segments of the point cloud were successively integrated into the Revit environment, and reference grids were generated from them. These grids were then utilized to position individual components in subsequent stages.

Chronologically, the first elements that were modeled are the viaduct piers. For the BIM component describing the piers, the parameters that have been made parametric include the height, dimensions of the upper rectangular base, and the various inclinations characterizing the short and long sides of the pyramid. Based on these dimensions, the dimensions of the lower rectangular base were then defined. Furthermore, the material with which the piers were constructed has been made parametric and based on observations of images and the point cloud, masonry was chosen as the material. The arch surface was generated using the Dynamo platform, as the represented form exhibits a complex double curvature that is challenging to model otherwise (fig. 3). Initially, commands were implemented in Revit to select the edges on which the arch relies. Subsequently, median points of the segments were placed to create a central line. Alongside two other lines positioned at the ends of the selected segments, these components facilitated the creation of the arch surface.

The subsequent step involved establishing control points on the previously generated lines. Each control point was defined with its respective height relative to the arch springing level and the setback. Following this, a curve was constructed. Finally, after executing these procedures for the three segments that define the curve, the surface was generated and assigned a thickness. Ultimately, the thus-formed geometry was incorporated into the Revit project. The abutment and backfill were modeled using the "Generic Models" category. Both components were initially modeled as solid forms, and subsequently, the shape of the arch was subtracted using an empty arch model. For these elements, in addition to the parameters defining their shapes, a material attribution parameter was introduced. For the abutment, the material is masonry, while for the backfill, it is railway crushed stone (fig. 4).

2.2 Case Study 2: Giorgini Bridge over the Bruna River

The presented case study revolves around the "Giorgini Bridge" in Castiglione della Pescaia (Grosseto, Tuscany Italy), build from 1827 to 1828 as part of the Maremma reclamation works (fig. 5). Designed by mathematician and civil engineer Gaetano Giorgini, the bridge was constructed across the Bruna River. The bridge featured three floodgates, aimed at preventing the intermingling of Bruna River's freshwater with the saline seawater. The construction, initiated in 1827, aimed to address the belief that this mingling caused malaria, belief of the time which later proved to be scientifically unfounded. The bridge, 26 meters wide and 12 meters high, is composed of lateral shoulders, lowered round arches, and pylons. Positioned between these pylons were three floodgates enclosed in oak and framed with metal. These floodgates rotated on iron pins, closing manually or automatically via high-tide currents, preventing seawater intrusion into the marsh. During low tide, the force of the lake water facilitated the opening of the floodgates, discharging water into the sea.

Fig. 5, 6, 7: View of Giorgini Bridge | Digital photogrammetry from drone | Views of the BrIM model

2.2.1 Documentary research and survey campaign

The investigation involved multiple methodologies: a laser scanner was utilized for acquiring geometric data, and a drone facilitated a photogrammetric survey. This was further supplemented by a topography network (polygon) for survey phases. The approach encompassed a sequence of steps, starting with a total station and GPS survey, followed by drone-based photosets creation, and concluding with the generation of a point cloud through a laser scanner.

The instruments employed in the survey campaign are: a SOKKIA SET3 130-R3 total station, a TOPCON GR-3 GPS receiver, optical prisms, a DJI 3 Phantom UAV, and a FARO FOCUS CAM2 laser scanner. The drone flight was organized using the Altizure® application, enabling the definition of the GPS-coordinated flight path. Subsequently, the photographic dataset was post-processed with Agisoft PhotoScan® software to generate a point cloud. Meanwhile, the laser scanning dataset underwent processing using Autodesk Recap® software (fig. 6).

The comparison in terms of "deviation of the cloud of points", to evaluate the difference between the two clouds generated using different data acquisition technologies, was performed with Cloud Compare open-source software. The original design drawings were retrieved, and their accuracy was subsequently verified during the BIM modeling process. This validation was achieved by comparing them with the point clouds obtained from the previously described survey campaign.

2.2.2 BIM Modeling and Implementations

To develop the H-BIM model representing this unique historical infrastructure, a semantic deconstruction was required. This involved defining individual BIM components ranging from primary structural elements to intricate detailing components (fig. 7).

Both point clouds were imported into the chosen BIM modeling software, Autodesk Revit®. By concurrently utilizing the point clouds and the original design drawings, each component of the structure was meticulously modeled one by one. The metal components of the bridge were primarily modeled using the original design plans, whereas the masonry components were predominantly elaborated based on the point clouds.

2.3 Case Study 3: Metal Truss Bridge over the Osa River

The subsequent case study pertains to a dual-track metal truss railroad bridge that dates back to the early 1900s. This bridge remains operational, spanning the Osa River in Italy as part of the Albinia-Talamone railway section on the Rome-Grosseto line, which is managed by RFI (Rete Ferroviaria Italiana), an Italian railway company (fig. 8). The metal bridge boasts a 42-meter span and features abutments constructed using a composite material of masonry and concrete. Notably, a diverse array of components deviating from standard commercial metal profiles can be observed. These elements consist of a combination of "plate" profiles, each implemented with distinct configurations, and they incorporate supplementary reinforcement plates in the areas subjected to the highest stress levels. The connections between disparate components were forged using plates and secured with hot-riveted nails.

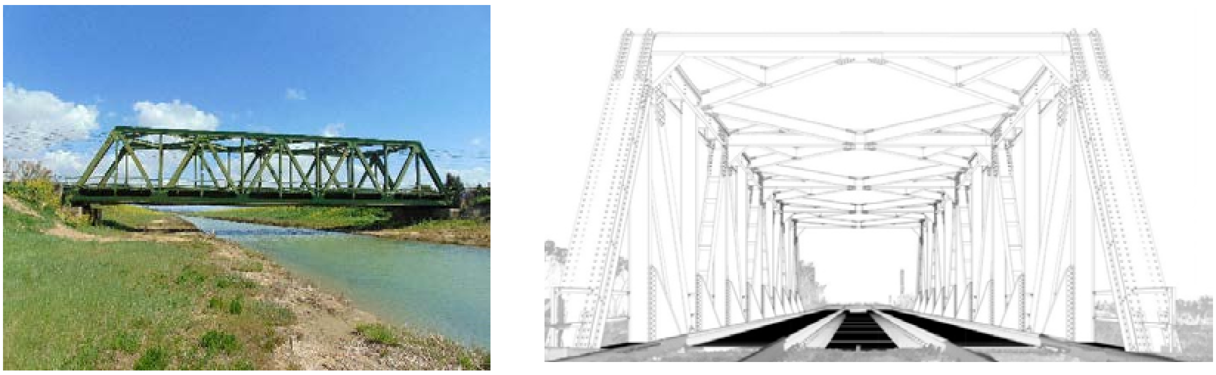

Fig. 8, 9: View of metal bridge over OSA River | Perspective view of the BriIM model

2.3.1 Documentary research and survey campaign

The original design documentation for the metal bridge has been retrieved, comprising seven technical drawings. Additionally, there are documents pertaining to the materials used in the bridge, the conducted load tests, and other activities related to the construction phases. The survey campaign was executed utilizing the Faro® Focus 3D x 330 Laser Scanner. The survey operations were meticulously scheduled to coincide with intervals when train traffic was absent. At the time of the survey, the riverbed exhibited cleanliness and optimal condition. The point cloud datasets were captured in .fls format and subsequently imported into Autodesk Recap® software. This software facilitated the alignment procedures for the distinct scans acquired during the campaign.

2.3.2 BIM Modeling and Implementations

The bridge has been conceptually broken down into constituent elements following the procedures utilized by the management company of the Italian railway line. Given the presence of detailed original designs, the BIM modeling of the various bridge components was based on these drawings. The point cloud obtained as a result of the survey campaign was used as an "AS IS" comparison for the modeled components. The comparison was possible with the Cloud Compare open-source software (fig. 9).

The chosen modeling workflow was partly influenced by the availability of the original technical drawings and partly dictated by the complexity of the metal truss. This truss comprises a high number of components that include edges, vertices, perforated elements, and other geometric intricacies, making its survey using a Laser Scanner challenging and difficult, along with the subsequent generation of a point cloud representation. The software used for BIM modeling was Autodesk Revit®. Given the uniqueness of the bridge components, a family was created for each type of element, and a report was produced for each of them.

The concept underlying the breakdown into "elements" logic, as provided by the Italian railway company, aligns with the D.O.M.U.S. Software. This software aids maintenance engineers in the railway infrastructure sector in evaluating the condition and preservation status of bridges. A dedicated master dataset is employed for cataloging both the structures and their identifiable defects. These defects are linked to corresponding indices, facilitating the algorithm in forming assessments.

During the inspection visit, engineers identify and photograph each defect present on the bridge, utilizing official catalogs and documenting the specific bridge component affected by each defect. Based on the previously mentioned data encompassing the geometric configuration of the bridges and inspection outcomes, the algorithm computes some indices. These indices are associated with a particular level of defectiveness, aligning with the established protocol for inspecting railway structures. Through assigning level of defectiveness, the bridges, infrastructure management gains the ability to ascertain priority interventions and make well-informed choices concerning measures for mitigating risks.

The operationalization of the management software functionalities was achieved through a synthesis of Python code scripts utilized within the visual programming environment (VPL) Dynamo. These scripts were integrated with Excel spreadsheets and an Access database, encompassing various tables and numerous queries, the latter of which were scripted directly in SQL language. The Dynamo-developed algorithm is composed by several interconnected node clusters in groups, each of them serving distinct functions. These functions include querying the BIM model for crucial input, exporting datasets to Excel, enabling automated interactions between Excel and Access, reading and importing externally processed data, and ultimately recording achieved results – or macro-outputs – within pertinent fields in BIM environment (fig. 10).

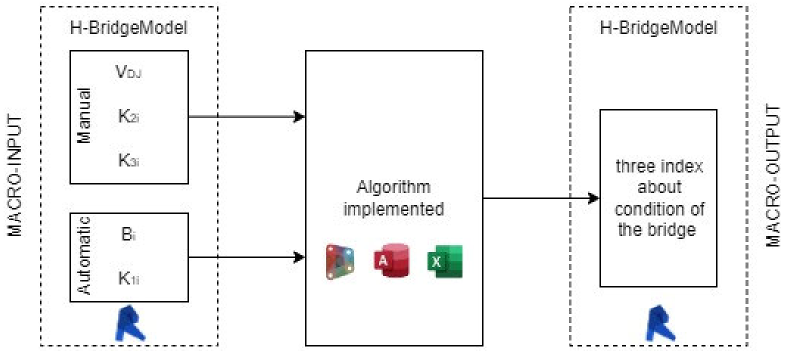

Fig. 10: Data flow. From macro-inputs to macro-outputs

The implemented management functionalities within the BIM environment enable railway engineers to record bridge defects directly in the BIM environment, execute the Dynamo algorithm, and access the calculated indices in the same software. Finally, an IFC model of the metal truss over the Osa River was generated in accordance with the IFC4 standard. In this model, bridge components were categorized as follows:

- all beam-like components have been converted into IfcBeam instances;
- flat metal profiles have been translated into IfcPlate instances;
- bolts have been categorized as IfcMechanicalFastener instances;

- masonry abutments are classified as IfcBuildingElementProxy instances;
- supports have been transformed into IfcBuildingElementProxy iinstances.

With the upcoming release of IFC 5 and its corresponding implementation by commercial software, it will be possible to more accurately map the elements of an infrastructure.

2.4 Case Study 4: Toppoli Bridge over the Arno River

The presented case study pertains to the Toppoli Bridge located over the Arno River near Bibbiena in the Province of Arezzo (Tuscany, Italy) (fig. 11, 12). This bridge, originating from the early 1900s, was constructed using traditional building techniques. The structure comprises a substantial masonry construction featuring a dual arched span. Each arch possesses dimensions of 19.60 meters in length, 3.00 meters in height, and 5.00 meters in width. The piers and abutments are constructed using square stone masonry, while the arches are composed of brick masonry. In the approximate timeframe of the 1960s, a noteworthy event involves the expansion of the road deck. This expansion entails a reinforced concrete slab measuring around 7.50 meters in width and 0.25 meters in thickness. This slab extends out as a cantilever from beneath the masonry arches.

Fig. 11, 12: Views of Toppoli Bridge over the Arno River

The bridge was part of a 2019 experiment in multilevel methodology, conducted through a collaboration between the Tuscany Region Administration and the Regional Federation of the Orders of Engineers of Tuscany. This initiative aimed to analyze and inspect priority bridges efficiently. The experience prompted the authors to develop an innovative BIM-centered approach for bridge risk management and monitoring.

2.4.1 Documentary research and survey campaign

No archival records of Toppoli Bridge original design have been discovered. The acquisition of geospatial data was achieved through a laser scanner survey, facilitating the creation of point clouds compatible with the chosen BIM authoring software, Autodesk Revit®. Prior to importing, the point clouds underwent necessary adjustments within Autodesk ReCap® software. This included aligning the scans into a unified model and reducing the point count to eliminate redundancies and the noise. The point cloud was then stored in .rcp format for seamless integration into Autodesk Revit® software.

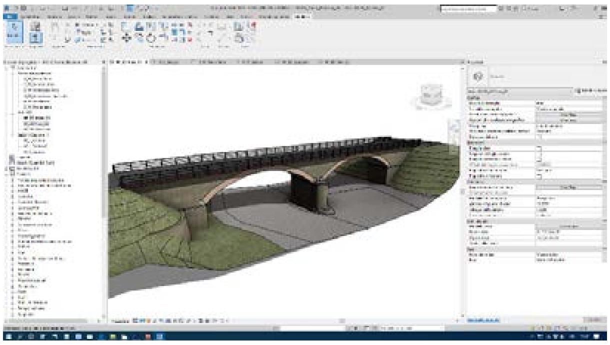
2.4.2 BIM Modeling and Implementations

The preliminary BIM model was established utilizing system families, followed by the development of customized loadable families to represent specific components. Throughout this process, the aim was to adhere to the classification structure outlined in the CNR classification of masonry bridges. To model individual components, the point cloud was segmented, component by component, using the open-source software Cloud Compare. Each point cloud segment was then employed for BIM-based modeling of the corresponding component, either directly or by extracting sections in .dxf format (fig. 13).

Utilizing the DB-Link plug-in, model information from the Toppoli Bridge BIModel was exported and integrated into Microsoft Access software. This facilitated real-time updates reflecting any alterations made to the model. Any changes made in either Revit or Access were synchronized seamlessly between the two. Moreover, modifications to the database could be propagated back to the BIM model in Revit.

A BIM-centric system was established to manage sensor data, with a focus on accelerometers. In the case study, a WIT-type accelerometer sensor capable of capturing angle, acceleration, angular velocity, and magnetic field along the 3 XYZ axes was employed. The acceleration measurements exhibit an error rate of approximately 1%, with a capacity to record accelerations up to 16g. Extracted data can be exported in .txt format and imported into spreadsheets for generating graphs that depict accelerations along the three axes (fig. 14).

Building on the earlier described implementation process, the default information model in Autodesk Forge® software was substituted with the Toppoli Bridge HBrIM model, functioning locally. This model integration includes all essential tools for querying and editing the model. Additionally, it offers a comprehensive view of both the overall model and individual elements. Reference "sprites" are created within the model, i.e. icons that simulate the position of the sensor in the artefact. The setting then of a "sprite" within the model allowed the visualization of data obtained from the sensor directly on the screen. Notably, the study's scope primarily concentrated on optimizing the workflow process and did not delve into the technical and operational management of sensors installed on the bridge.



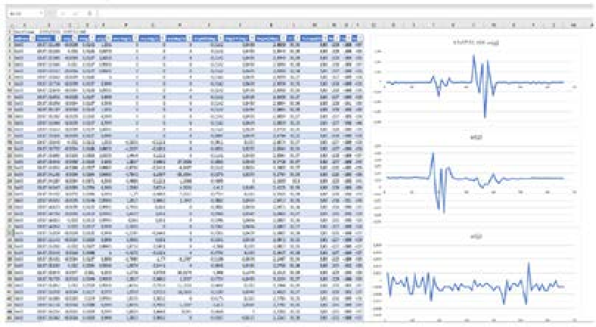


Fig. 13, 14: View of BrIM model | Representation of data by sensor device in a data sheet.

3. RESULTS AND DISCUSSION

3.1 Results

The results of the topographic survey campaigns and experiments conducted for each distinct case study are presented below.

1) Masonry Bridge over the Masera Ditch - The laser scanner survey campaign yielded excellent results, partly owing to the bridge's composition of easily distinguishable massive elements. RGB data was acquired. The workflow in this case was forced given the absence of technical documents. Using the Dynamo platform, a dedicated tool was developed to model elements characterized by double curvature, in this specific case the arches of the bridge. The tool described above produced the desired results and can be reused in similar situations, which are often encountered in the study of the heritage of Italian historic bridges.

2) Giorgini Bridge over Bruna River - The point cloud generated by the laser scanner comprise a total of 19 million points, while the one generated by UAV photogrammetry reached the size of 14 million points. The comparison in terms of standard deviation between the two point clouds, conducted using Cloud Compare, yielded optimal results.

3) Metal Truss Bridge over the Osa River - The survey campaign on the metal truss proved to be challenging due to its complexity. Given its numerous components and the sharp angles that define them, acquiring the bridge's geometry using laser scanners is hindered by the inevitable presence of "shadowed areas" in the acquired dataset. The chosen modeling workflow was partly influenced by the availability of the original technical drawings and partly dictated by the complexity of the metal truss described above.
The implemented management functionalities within the BIM environment enable railway engineers to record bridge defects directly in the BIM environment, execute the Dynamo algorithm, and access the calculated indices in the same software. In the generated IFC model, bridge components were categorized as follows:
- all beam-like components have been converted into IfcBeam instances;
- flat metal profiles have been translated into IfcPlate instances;
- bolts have been categorized as IfcMechanicalFastener instances;
- masonry abutments are classified as IfcBuildingElementProxy instances;
- supports have been transformed into IfcBuildingElementProxy instances.

With the upcoming release of IFC 5 and its corresponding implementation by commercial software, it will be possible to more accurately map the elements of an infrastructure.

4) Toppoli Bridge over the Arno River - The laser scanner survey campaign produced outstanding results, in part due to the bridge's makeup of clearly distinguishable large components, similar to what was previously noted for case study 1). A two-way connection between the BIM model in Revit, viewed as a collection of elements, and a dedicated database created in Microsoft Access has been developed and tested, yielding satisfactory results. A workflow was tested and optimized to connect a sensor, specifically an accelerometer, with the BIM model of the Toppoli Bridge. The objective was to visualize the sensor's output on the Autodesk Forge platform. Historical sensor data was used in the test; nevertheless, it is possible to achieve the same result with real-time data using a more powerful software version and a connected sensor.

3.2 Discussion

The present study aimed to offer a contribution to the development of Structural Health Monitoring systems in the context of transport infrastructures and bridges in particular, in line with the recent orientations of the technical-scientific community, both at the national and European level, on risk management and assessment.

The application of Building Information Modelling tools and methodologies was the first step in the information management of bridge knowledge. The obtained BIM models for the various studied bridges demonstrate the reliability of the scan-to-BIM methodology for modeling both infrastructure and bridges, just as it is for buildings. The conducted survey campaigns vary in terms of the instruments used and the surrounding conditions. Consequently, these experiences are valuable for identifying common factors that have influenced them: the intrinsic nature of the bridge and the materials of which it is made, the ability to suspend bridge usage, the size of the river or obstacle crossed by the bridges, the overall accessibility of the structure, and the economic and time costs associated with potentially repeating the survey campaign.

The most significant factor influencing the choice of BIM modeling workflow is the presence or absence of reliable design documentation. In the case of historical bridges, a survey campaign is essential. However, for some cases, the survey results become the primary or sole dataset for modeling, while in others, they serve only as a comparison. The processes of implementing bridge information models from the geospatial data acquisition phases conducted with laser scanning or 3D image surveying techniques show an adequate level of maturity for the intended and foreseeable uses in bridge control and monitoring activities. In particular, the use of scripts created in Visual Programming Language (such as Dynamo) into the BIM authoring software allows for the effective handling of complex shapes, which are derived from the geometric-constructive rules used in the design of railroad tracks and artwork in the late 1800s.

At the interoperability level, it has been demonstrated that translating a BIM model of a bridge into the IFC schema is already feasible, although currently, there are occasional challenges in classifying certain elements. Geometric data, however, is readily translatable into the IFC data schema. On the contrary methods of managing data from bridge monitoring can vary widely depending on the criteria set by the owner, which based on its strategic goals and internal organizational structure may define different approaches in terms of Asset Management System and related supporting technological infrastructure.

An initial strategy for enabling a "smart" approach to bridge risk assessment has been developed in the fourth study case, involving the implementation of a continuous data acquisition process through sensors installed on the physical structure. This approach leveraged the cloud-based Autodesk Forge platform, seamlessly integrated with BIM authoring software for information models. The functionalities of the corporate software assisting engineers in evaluating the safety and maintenance condition of railway bridges have been replicated within the BIM environment in the third case study. It was possible to provide information necessary to support decision-making regarding prevention and mitigation of natural and anthropogenic hazards, that pose a threat to the stability of the examined bridge and the integrity of the infrastructure network.

4. CONCLUSION

The conducted studies demonstrate the benefits achievable through the approach 'BIM - first of all', which prioritizes the use of BIM models at the core of bridge management processes for these infrastructures.

The approach used in the proposed experiments, can be attributed to the economic concept of a "Point Solution", whereas the more desirable approach for Bridge Management Systems (BMS) is certainly a "System Solution". This implies a comprehensive rethinking of BMS within the context of BIM and AI integration, aiming for a comprehensive and holistic solution.

The topics covered occupy a prominent place in the National Research Plan 2021-2027, particularly in the areas related to security and digital innovation. This is in line with Cluster 3 of Horizon Europe 2021-2027 and supports goals 9 and 11 of the United Nations Agenda 2030, which focus on resilient infrastructure, innovation and sustainable urban development.

AS-BUILT DETECTION OF STRUCTURES BY THE SEGMENTATION OF THREE-DIMENSIONAL MODELS AND POINT CLOUD DATA

Nobuyoshi Yabuki & Tomohiro Fukuda
Osaka University, Japan

Ryu Izutsu
Kajima Corporation, Japan

ABSTRACT: *At construction sites, as-built management is generally conducted by taking pictures or surveying with total stations and comparing the images or survey data with design drawings or Building Information Modeling (BIM) models. Since this work is time-consuming and error-prone, more efficient and accurate methods using advanced Information and Communication Technology (ICT) are desired. Therefore, this research proposes a method that can efficiently capture the progress of construction by detecting each constructed structural member, such as beams, columns, connections, etc. In this proposed method, construction engineers first take many pictures of the construction site and conduct automatic image segmentation using a pre-trained Convolutional Neural Network (CNN) model. Next, point cloud data is generated from taken pictures by using Structure from Motion (SfM). Then, the point cloud data is semantically segmented by overlapping the segmented images and point cloud data using the pin-hole camera technique. Finally, the design BIM model and segmented point cloud data are overlapped, and constructed parts of the BIM model can be detected, which can be reported as as-built parts. A prototype system was developed and applied to an actual railway construction project in Osaka, Japan for testing the accuracy and performance of the system.*

KEYWORDS: *Construction progress management, Instance segmentation, Point cloud, Building Information Modeling.*

1. INTRODUCTION

Construction site management involves inspecting the completed parts of a construction project to ensure that the work is within specifications and contractual requirements. This task requires construction workers to compare the actual construction with the provided drawings and documents. The goal is to ensure that the construction is performed correctly and to calculate the corresponding contract price. Traditionally, construction management relied on drawings, but the use of 3D models has become more prevalent. These models enable better visualization and consensus building among stakeholders. While image data and laser scanners have been used in previous studies to create 3D models, large-scale structures and deep learning techniques have not been fully utilized for construction site monitoring. The succession of technical skills in the construction industry has been identified as an issue, prompting the need for changes in the construction production system. Leveraging technology advancements, such as 3D models and sensor information, has improved efficiency and contributed to various aspects of construction, including design, management, and maintenance. Building Information Modeling (BIM) is a lifecycle management system that facilitates efficient building maintenance. However, the process of collating 3D models with 2D drawings is time-consuming and prone to human error. Structure from motion (SfM) is a method used to acquire 3D data of existing structures, but converting point cloud models to polygon models presents challenges such as removing unnecessary details and setting appropriate thresholds. Efforts are needed to develop more efficient methods for capturing the current 3D model of a structure.

Recent advancements in deep learning and object detection technology have automated tasks such as construction site inspections, including identifying deformations and damages from images. The availability of large image datasets, such as ImageNet, has greatly improved object recognition accuracy using deep learning algorithms. In addition, recently, much research has been done for classifying point cloud data using deep learning (Charles et al. 2017). However, much research is required to classify civil infrastructure members.

Thus, this research has adopted a more simple 2D object detection method using deep learning and a pin-hole camera method and combined it with 3D BIM models to reproduce the construction situation on a 3D model and calculate construction costs. A training dataset specific to construction members was created to fine-tune existing deep-learning models. The proposed method enables efficient shape detection and attribute identification of construction elements and should contribute to the integration of detection information into 3D models, facilitating the creation of as-built models.

2. RELATED WORKS

Before the advent of deep learning-based object detection, selecting features for object detection was challenging, especially in complex construction sites with various members and intricate structures. Past research in the field of construction has focused on automating tasks such as progress and productivity management using deep learning. One study proposed a system to automatically recognize completed parts in construction site images, but the detection results were not applicable to other systems, and accuracy was limited for complex-shaped structural members (Fathi et al., 2015). Research combining automation technology and BIM has aimed for efficient work (Kropp et al., 2018; Park et al., 2018), but perfect automation remains elusive due to the need for human intervention.

Another study developed a management system using a 3D model and proposed a method for constructing original models by detecting structural members in existing bridges from point cloud data (Lu et al., 2019). However, the method faced challenges in detecting complex geometric structures such as concrete or truss bridges. A laser scanner is used to create detailed BIM models of existing facilities but encountered difficulties with complex structures and occlusion (Tang et al., 2010). Various approaches have been attempted to create 3D models of existing buildings (Bosche et al., 2009; Brilakis et al., 2010).

Recent advancements in computer vision technology have enabled the automation of tasks performed by the human visual system. One study developed a system that automatically detects construction members in a room using 2D image data (Hamledari et al., 2017). Other studies have attempted to capture construction status and shape from image data (Gidaris et al., 2015; Khaloo et al., 2015). Perez-Perez et al. (2021) developed a method for the segmentation of indoor point clouds via joint semantic and geometric features for 3D modeling of the built environment. Pan et al. (2022) proposed geometric digital twins of buildings with small objects by fusing laser scanning and AI-based image recognition. However, the detection of different material members and multiple structure types for outdoor civil infrastructures remains challenging. Therefore, this research aims to fill this gap to improve the performance of as-built detection of civil infrastructures under construction for better construction site management.

3. PROPOSED METHOD

The proposed method aims to recreate the construction status in an as-built 3D model by incorporating the shape information from the detection result images obtained through a deep learning model. This allows for cost calculations without the need to match 2D drawings with the construction progress. The positional relationship between the detection result images, the completed 3D model, and a point cloud model generated using Structure from Motion (SfM) are matched.

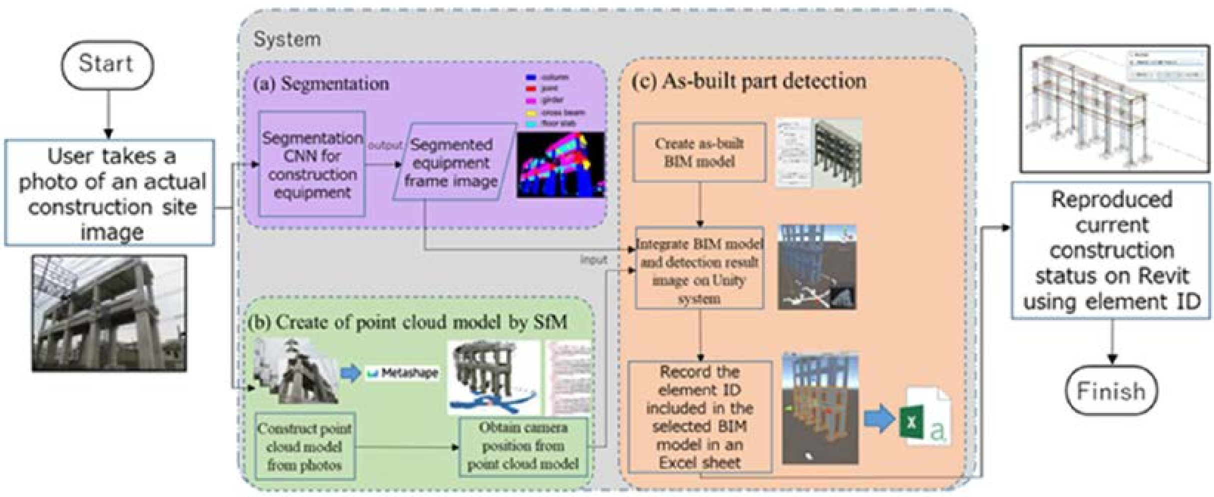

Fig. 1: Method overview.

As shown in Fig. 1, the method consists of three main steps: (1) performing segmentation detection using a fine-tuned deep learning model to identify structural members in the construction images, (2) creating a point cloud model using Agisoft Metashape to determine the 3D positions of the images, and (3) integrating the completed 3D model, detection result images, and point cloud model in a volume detection system using the Unity game engine. The positional relationship is established, and the identified structural members are recorded in an Excel sheet. Finally, the construction status is reproduced in BIM software (Revit), and the attribute information of the structural members is used to calculate the construction cost at the time of shooting.

3.1 SEGMENTATION

In this study, the weights of a U-Net model trained on the Cityscapes Dataset (Cityscapes Dataset, n.d.) were adjusted to distinguish structural members and the background. By updating the weights of the 37 layers, the positions and attributes of the structural members in the captured images could be identified. These detection results were treated as the finished form, providing insights into the construction site's situation. Since there were no published trained models for construction members such as columns, beams, and ducts, a training dataset was created using interior photographs of buildings under construction. The dataset was manually annotated using Adobe Photoshop CS4, creating mask images for each target member. The existing trained model was then fine-tuned using the mask images and the corresponding color changes in the original images.

In this study, a U-Net model trained on the Cityscapes Dataset was fine-tuned and used as a CNN for object detection to detect construction structural members from images, specifically targeting the five main structural members (Fig. 2).

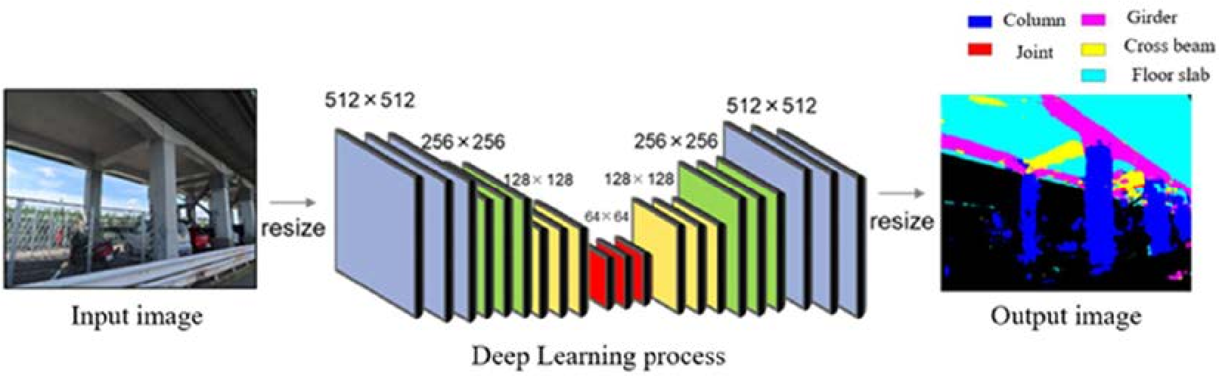

Fig. 2: U-Net-based CNN structure and learning results (example).

Meanwhile, a three-dimensional model representing the real space, including the camera position and target structure, was created using Structure from Motion (SfM) and Agisoft Metashape, a software for photogrammetric processing and 3D spatial data generation. Fig. 3 shows the results of fine-tuning U-Net using the created training dataset, where IoU stands for Intersection over Union.

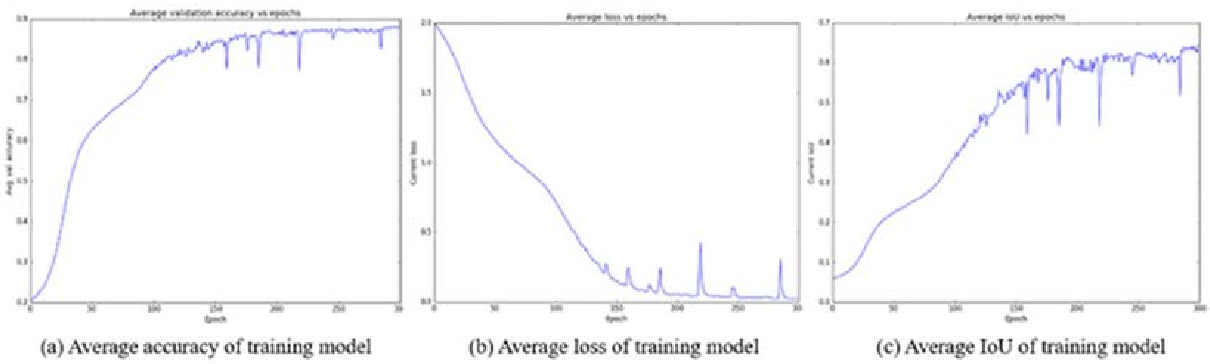

Fig. 3: The results of fine-tuning U-Net using the created training dataset.

The deep learning model in this study does not exhibit over-learning. The average accuracy for the training dataset increases, but the average loss for the test training dataset does not decrease. The detection accuracy of the fine-tuned model is evaluated using the average IoU value, which is 0.6428 at the 300th epoch. The IoU value measures the overlap between the correct answer area and the predicted area, indicating the model's performance. The evaluation index IoU indicates the numerical value obtained by dividing the overlapping part of the correct answer area and the prediction area by the union part of both areas, as explained in equation (1).

$$IoU \text{ (Intersection over Union)} = \text{(Intersection of detection areas)}/\text{(Union of detection areas)} \quad (1)$$

3.2 POINT CLOUD MODEL CONSTRUCTION

It is difficult to reproduce the positional relationship of the construction status when each image and model is imported into the game engine Unity in the lack of coordinate information. Therefore, we use SfM and Agisoft Metashape software to create a three-dimensional model that replicates the camera position and target structure in virtual space. Metashape allows us to process digital images and generate 3D spatial data, enabling the scanning of both small objects and large buildings. By analyzing the overlapping shooting locations in the photographs, we can calculate the distance to the subject in each photo.

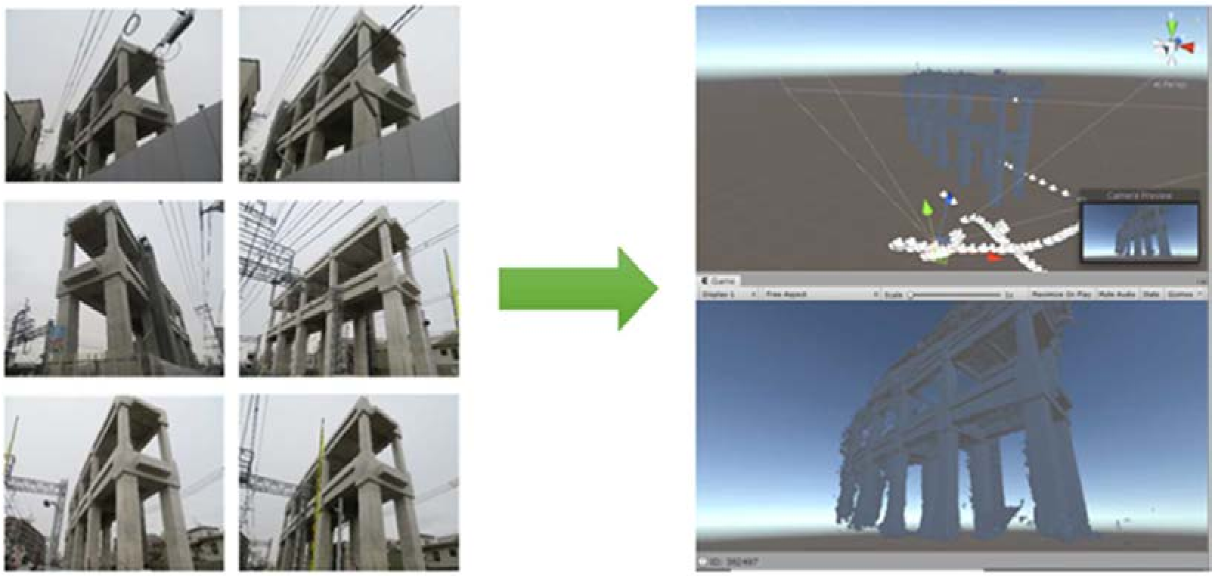

Fig. 4: Transfer from real frame to SfM model.

The gray model consists of a mesh overlaying a point cloud model created in Metashape, while the white object represents a virtual camera. As shown in Fig. 4, we can confirm the accurate reproduction of the camera's position and the target structure in Unity. Valid values for camera parameters such as position and rotation were confirmed in Unity, indicating successful reproduction of the real-world positions of the target structure and the camera in the game space. By overlaying the SfM model with the expected BIM model, a work detection system was created. The deep learning model performs object detection using the created mask image, adjusting the position and rotation coordinates of the virtual camera based on the mask image's parameters. The field of view on the virtual camera side is also adjusted to match the mask image. These preparations enable the replication of the construction situation in the game engine and the reflection of the deep learning model's detection results onto the BIM model.

4. EVALUATION

A case study was conducted on a building under construction at Osaka University to verify the proposed method. The system was tested by creating a BIM model from construction drawings and capturing photographs at the construction site, allowing for the verification of volume detection using a point cloud model. The system was implemented and tested using Unity on a standard PC with an Intel Core i7-3770K CPU and 32 GB RAM.

The detection result image from the deep learning model is utilized as a filter to extract and choose the completed portion from the generated BIM model. By aligning the aspect ratio of the Unity camera with the actual image size, the system excludes the undetected background area that is still under construction, ensuring only completed members are selected such as shown in Fig. 5.

In order to apply the image filter to the application, multiple angled frames are captured and went through a deep learning model with different weights. Fig. 6 shows part of the detection results

Fig. 7 shows the generated model in Unity and Revit. The detection results on the left if it indicates the accurate detection of completed ducts. However, upon examining the member model based on element ID, it was found that four beams on the front side of the third-floor slab were missing. Additionally, low detection accuracy is observed for elements not included in the learning dataset, such as overhead poles, scaffolds, and multiple electric wires, depending on the viewing angle of the target structure. On its right, the screen displays the selection of the element ID obtained from the viewpoint, with the selected member highlighted by the blue wireframe line and the unselected part shown by the black wireframe line.

Table 1 displays the results of member detection from multiple viewpoints in the case study, including detection accuracy for each member and overall detection accuracy calculations.

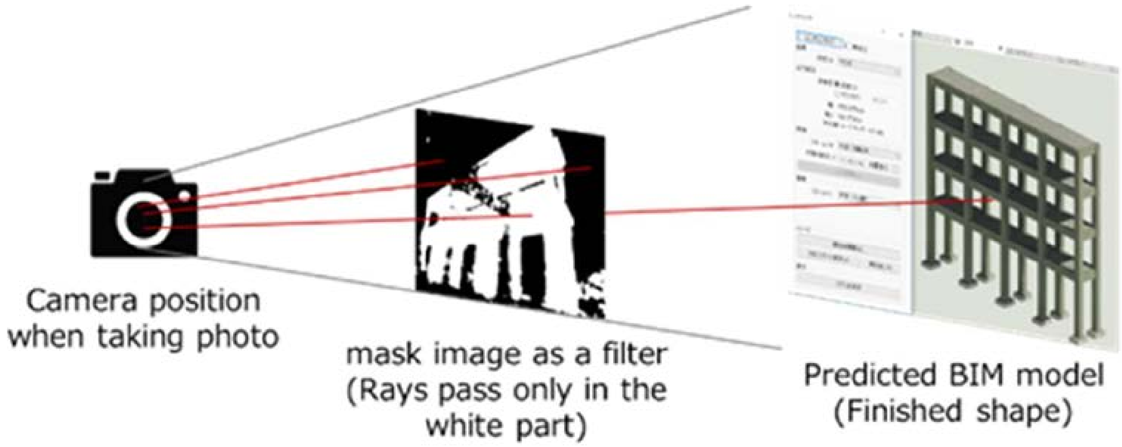

Fig. 5: Image filter in BIM model construction.

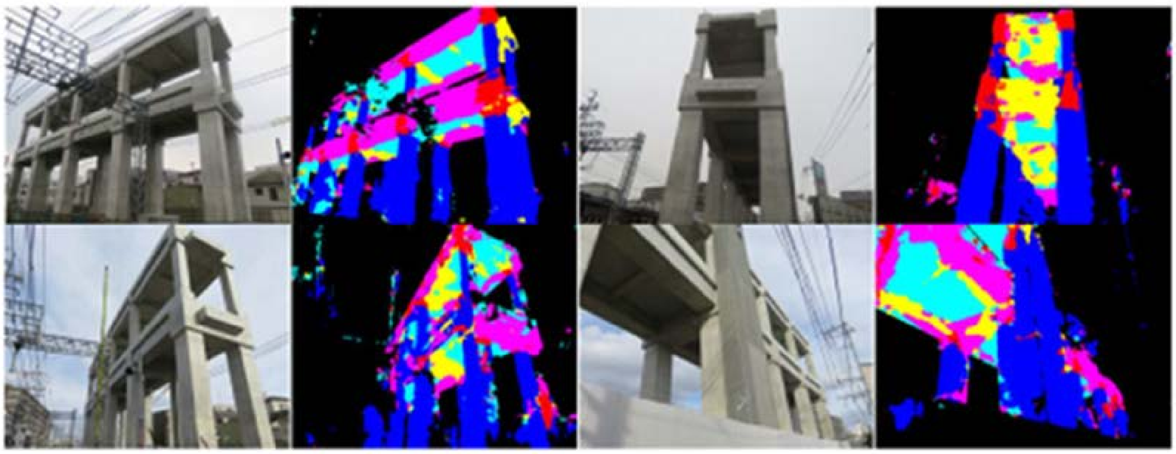

Fig. 6: Part of the results in image processing.

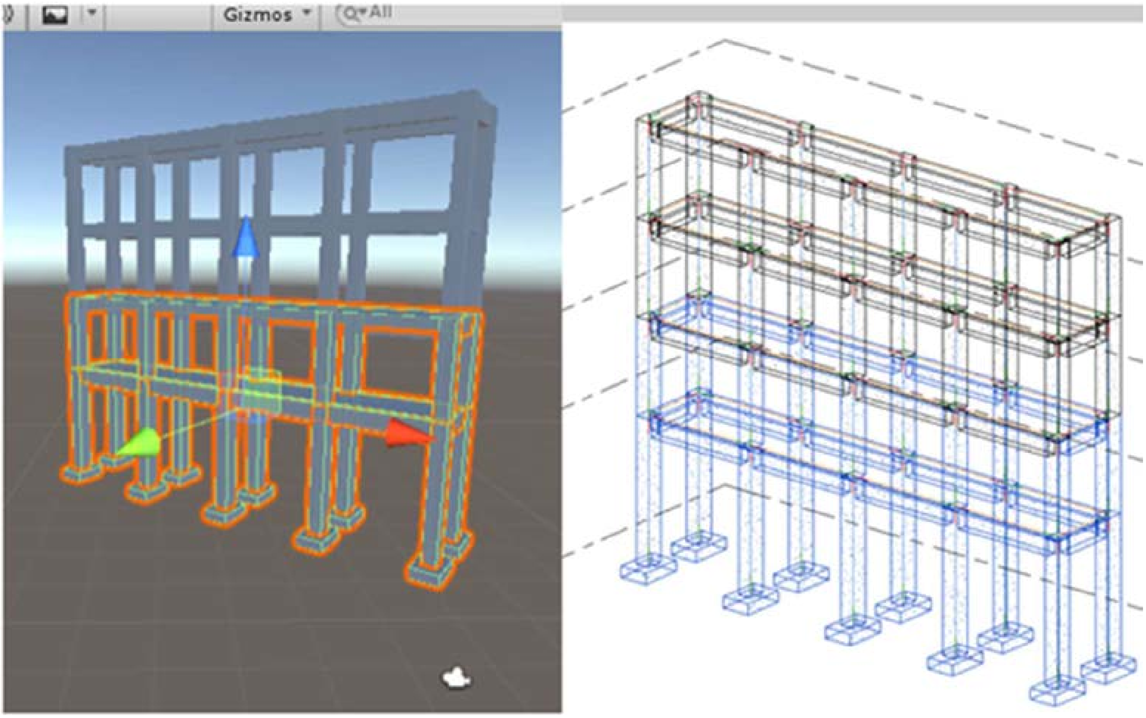

Fig. 7: Generated 3D model in Unity and Revit.

Table 1: Structure member detection accuracy.

Shooting viewpoint	Overall detection accuracy (%)	Column detection accuracy (%)	Floor slab detection accuracy (%)	Foundation detection accuracy (%)	Beam detection accuracy (%)
Viewpoint 1	92.31	100	100	100	80
Viewpoint 2	98.08	95	100	100	100
Viewpoint 3	83.33	90	100	100	75
Viewpoint 4	86.79	90	100	100	80

5. CONCLUSION

This study aimed to verify the effectiveness of using deep learning for detecting structural members and construction equipment at a construction site. To overcome the limitation of existing training datasets, a verification experiment was conducted using images created from photographs of other construction sites. The existing convolutional neural network (CNN) was fine-tuned with different learning weights to detect structural members from actual construction site photos. The following results were obtained:

- The shape of the target structure could be detected from the construction site photographs by considering the detection result image.
- A volume calculation system was constructed using the deep learning model's segmentation results, enabling volume calculation on a three-dimensional model based on the shape information from two-dimensional images.
- The 3D model that reproduces the construction site was displayed on BIM software like Revit by acquiring the element ID from the 3D model using the Unity game engine.

- The recall of the constructed 3D model at each viewpoint showed an average of 90%, demonstrating high accuracy by combining detection results from multiple viewpoints.
- By assigning attribute information of construction unit prices to each member, it was possible to calculate the work volume based on the work form.

To improve the accuracy of the volume detection system, the deep learning model's detection accuracy needs enhancement. The training dataset should include information on detecting obstacles in front of the target. The applicability of the proposed method to other structures and the diversification of the system needs further investigation.

FIRE SAFETY ENGINEERING: THE COMPUTATIONAL SIMULATION OF THE ESCAPE IN A HISTORIC BUILDING IN BOLOGNA

Ing. Stefano Tagliatti & Prof. Ing. Marco Alvise Bragadin
University of Bologna, Italy

ABSTRACT: *In the field of Fire Safety Engineering (FSE), virtual reality has increasingly assumed an important role, especially for the simulation of fire and escape.*

The present work aims at comparing the potential of virtual simulations of the escape of occupants in case of emergency to simulations based on traditional calculations. Above all, the goal is to highlight the greater adherence to reality of the simulations that use behavioural models compared to those that use hydraulic models.

Simulations are performed for the case study of a listed historic tower in Bologna city centre and calculate the Required Safe Escape Time (RSET) in various evacuation scenarios using the innovative Pathfinder® software which, in addition to using flow-based models, is "agent-based", as it manages the variables related to behavioural factors and can model complex escape scenarios faster than hand-made calculation.

Case study results show that RSET times calculated with the behavioural steering mode in the virtual environment are 15-19% higher than the hydraulic mode (SFPE) and therefore demonstrate that the Steering mode is more realistic, as human behaviour significantly influences the evacuation process.

Anyway, all the realistic simulations return safety margin times above 100% of the RSET as asked by national law, highlighting that it is possible to guarantee the safety of the occupants in a particular historical building using innovative Fire Safety Engineering (FSE) approaches, even if the prescriptive rules are not respected.

KEYWORDS: *FSE, Virtual reality, Emergency Escape, ASET/RSET.*

1. INTRODUCTION

Optimizing the fire prevention of a human activity means to identify technical solutions aimed at achieving three primary objectives: the protection of human life, the protection of assets and the protection of the environment. Therefore, in Fire Safety Engineering the chosen escape strategy, i.e., the one that ensures that the occupants can reach a safe location, independently or with assistance, before the fire causes incapacitating conditions, represents one of the most important and most complex designing strategies.

The international legislation as well as the Italian one is increasingly moving from a prescriptive approach (with defined rules to be strictly applied), towards a performance approach with Fire Safety Engineering (FSE) which better allows to deal with the most complex situations.

This new and innovative FSE approach is certainly more suitable for a specific assessment of the individual case under study, and it allows greater flexibility and gives greater autonomy and responsibility to the designer on the basis of rigorous scientific modelling.

Scientific modelling brings a new responsibility to be taken on by the designer and this requires a greater knowledge of FSE processes and having new modelling skills. Virtual reality becomes very important as the scientific-predictive simulation software of the movement of people during the escape manages to model complex escape scenarios and gives data output quickly and efficiently, therefore a better understanding of the phenomenon is achieved even if environmental and specific conditions vary.

The research work under this paper deals with the problem of escape in case of fire in listed historic buildings and in particular compares the results returned by an innovative simulation software with those obtained with other traditional calculation methods.

The case study concerns the museum part of a historic tower in Bologna, the eighteenth-century Astronomical "Specola" Tower, in Bologna, built inside Poggi Palace, which is a historic building listed since 1911. Simulations of the escape were carried out assuming different emergency evacuation scenarios using the Pathfinder® software.

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Stefano Tagliatti, Marco Alvise Bragadin, *Fire Safety Engineering: The Computational Simulation of the Escape in a Historic Building in Bologna,* pp. 1125-1136, DOI 10.36253/979-12-215-0289-3.112

In the case of historic buildings, the second objective of fire prevention, i.e., the protection of assets, assumes particular importance and it can be said that among the most complex situations that a designer has to face there are certainly those of protected historic buildings. In these buildings it is very often difficult, or maybe even impossible, to comply with the safety requirements established by the fire regulations due to their particularity or uniqueness and to the constraints to which they are subjected, constraints that are of an artistic, historical, cultural nature and refer both to the building itself and to the context in which it is built. In many cases, the needed structural and MEP renovations could be unsustainable, both in terms of impact and in terms of cost. In fact, many time happens that the minimum dimensions prescribed by the regulations for escape routes are not respected (widths often less than 80 cm, heights less than 1.80 m), or the number of exits is inadequate, or the escape paths (unidirectional and otherwise) are too long, or it is impossible to build external stairs, and so on.

With these situations, for which it is impossible to apply the measures provided for by the national technical rules, it is allowed to turn to the Fire Safety Engineering method (FSE) as considered by the New Italian consolidated Fire Prevention Code (Decreto del Ministero dell'Interno - DM - 2015, 3 August, updated by DM 2019, 18 October) and as presented by the ISO international standards (ISO/TR 13387:1999). Therefore, the designer can use the FSE-based performance approach, which is aimed at the purpose of safety rather than at the rules to achieve it and can apply alternative solutions well-adapted to the specific case that create an equivalent safety level of performance.

Given to the complexity of the application rules of FSE, the support of an escape simulation software such as Pathfinder® is needed. The software application allows the translation of simulation constraints into quantitative values, which can be inserted within a mathematical model of evacuation. In this way, not only the physical and geometric aspects of the structure, but also the qualitative, behavioural and physical aspects of the occupants (children, elderly, disabled, with their own speed and specific decision-making processes, etc.) can be modelled.

2. METHODS

The case study concerns the Specola Tower Museum (Fig.1, 2, 3) which develops entirely inside the tower, from the fourth to the eighth floor (47 m altitude), while the first three floors are included in the structure of Poggi Palace (Fig.1 right). The work involved numerous inspections in collaboration with the museum managers to carry out all the necessary surveys including measurements and identification of all the components of fire safety system.

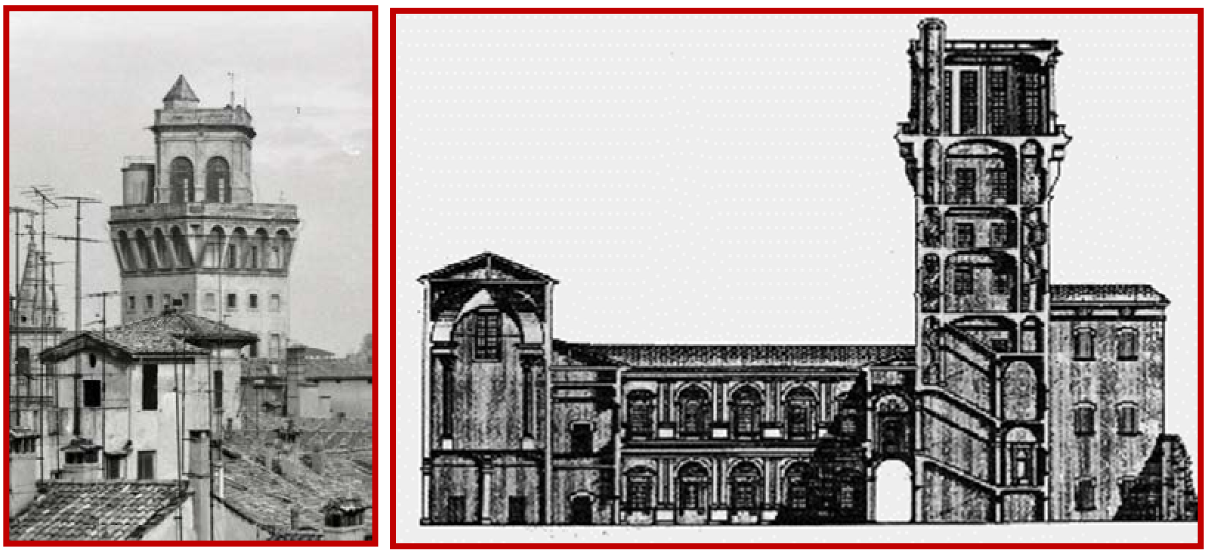

Fig. 1: Picture by Monti P. (1974) of the Specola tower (left) and an 18th century reproduction in section (right)

Fig. 2: Staircases: from the ground floor (left); access to the museum area from the 3rd to the 4th floor (right)

Fig. 3: Spiral staircase from the 4th to the 7th floor of the tower

2.1 The fire safety compliance solution in application of the rules

It should be noted that the New Italian consolidated Fire Prevention Code provides for rules valid for all human-based activities (the so-called "Regola Tecnica Orizzontale" RTO or "Horizontal Technical Rules") and specific rules for historic buildings (the "Regola Tecnica Verticale" or "Vertical Technical Rules" RTV10 and RTV12).

The analysis of the case study was based on the life risk profile, R_{vita} (given by the characteristics of the occupants and the rate of growth of the fire), as well as on the maximum crowding of each room of the structure. The designers found that the rigorous application of the compliance solution for evacuation was not possible, as the prescriptive rules of the Code (RTO) and of the RTV10 specific for museum activities in buildings subject to protection, were not all fulfilled.

• the heights and lengths of escape routes and dead-end corridors comply with the requirements.

• each floor is a specific fire compartment (there are two activities that are not pertinent to each other: museum and offices/services, which are not in separate compartments).

• the stairway area, with annexed landings and corridors, essential for emergency evacuation, is correctly compartmentalized and would constitute a temporary safe area; however, since it is a multi-storey building of considerable height (47 m), the standard requirement is that the current single compartment of the stairwell delimited by REI fire doors is divided into at least three compartments in order to be able to be considered as a temporary safe location (maximum 18 m for the RTV10).

• the width of some horizontal escape routes (Fig.4 on the left) is not compliant with the law (72-73-75 cm, while the limit is 80 cm for the RTV10) and also the width of the spiral staircases (Fig.4 on the right) from the fourth to the eighth floor is not compliant with the law (71-75 cm, while the limit is 80 cm for the RTV10).

• there is only one way out, which, although admitted, is problematic due to the physical characteristics of a part of it, being a spiral staircase, 5 floors long and rather narrow and steep.

compartment	R_{VITA}	width per person (mm/pers)	crowding (persons)	minimum width L_0 (mm)	minimum width (RTV10) (mm)	real width (mm)

2.2 The alternative FSE-based solution in application of Section M (Fire Prevention Code)

As the compliance solution is not fully applicable, the designers have switched to the performance approach as proposed by FSE and an alternative solution, provided for by section M of the Code, was proposed to calculate the escape time.

By using the FSE-based performance approach, the designers can propose alternative design solutions that provide an equivalent fire safety level of performance and are sustainable both in terms of architectural and environmental impact and in economic terms.

The alternative solution involves comparing the Available Safe Escape Time (ASET), i.e. the time available for the escape guaranteed by the building, and the Required Safe Escape Time (RSET), i.e. the time actually taken by the occupants for the escape, from the moment the fire is triggered to the moment they reach a safe location to save themselves. The established engineering criterion is that ASET > RSET and that the difference between the two, i.e. the safety margin (t_{marg}), is greater than or equal to 10% of the RSET, and in any case not less than 30 seconds, in the event that the ASET derives from a reliable calculation (obtained by using fire simulation models such as FDS, for example, which is one of the most used software), or is greater than or equal to 100% of the RSET, otherwise. In the case study presented, the reference is the latter, because the ASET was not simulated, but data from examples relating to listed buildings taken from the literature were used.

To calculate the escape time, it is necessary to obtain the RSET time.

The international standard ISO/TR 16738 of 2009 (implemented in the Fire Prevention Code - Fig. 5) defines the RSET as the sum of 4 components:

$$RSET = t_{det} + t_a + t_{pre} + t_{tra}$$

where

- t_{det} is the detection time
- t_a is the alarm time
- t_{pre} is the pre-travel activity time, PTAT
- t_{tra} is the travel time

Of these 4 components, only the calculation of the movement time, Time of travel (T_{tra}), was carried out because the other 3 components of the RSET time are calculated with the European standard (ISO/TR 16738:2009) and were assumed equal respectively to: 60 seconds the T_{det} (*which is considered cautionary since in the museum there is the presence of an automatic fire detection and alarm system-IRAI*), 0 seconds the T_a (as there is an automatic *IRAI with optical-acoustic panels*) and 30 seconds the T_{pre}, which is a low value, because it is due to the *presence of awake occupants, without motor disabilities and trained guides who always accompany visitors to the Museum and who help them with wayfinding*.

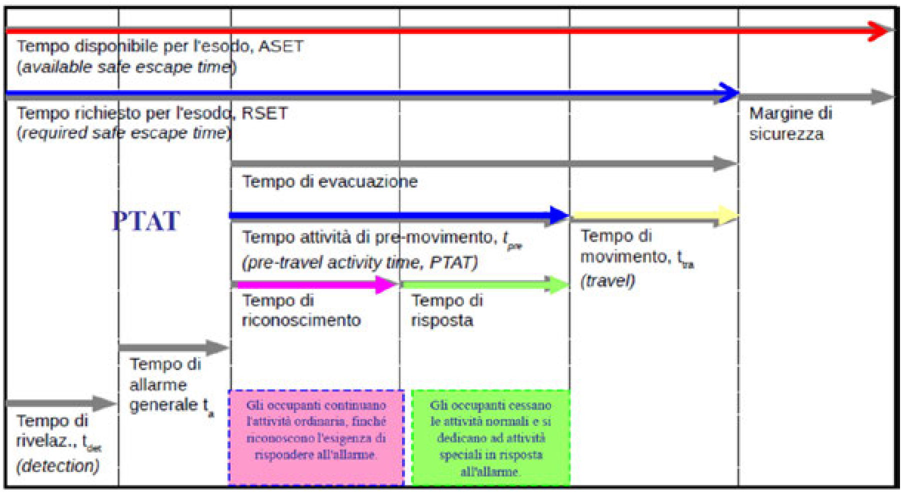

Fig.5 - Comparison between ASET and RSET (Illustration M.3-1 of the Code DM 2019, October 18, modified)

For the calculation of the movement time (t_{tra}) two alternative methods can be used:

1. *flow-based models (hydraulic): they are macroscopic models that represent people as a homogeneous group and in which the movement of the crowd is considered similar to the flow of a fluid.*
2. *ABM agent-based models (behavioural): they are microscopic models that take into account human behaviour, as well as movement, and in which the occupants are considered individually.*

2.3 Escape simulation software and Pathfinder®

Simulation software are essential for the development of behavioural models because they are able to manage a multiplicity of factors: technical, physical and geometric considerations are accompanied by many components connected to the human behaviour of the individual occupants.

These software have been categorized from each other by NIST - National Institute of Standards and Technology (E. Kuligowski, *et al*. 2010) based on the different characteristics: modelling method, model purpose, type of structure, model view of the occupants, behaviour of the occupants, type of movement of the occupants, ability to enter fire data, ability to import CAD data, visualization and validation methods.

The software chosen for the case study is Pathfinder® by Thunderhead Engineering, an agent-based simulator. In addition to being based on the hydraulic models that describe the movement, Pathfinder® manages the behavioural variables, describing complex behaviours and reciprocal interactions. Each occupant is defined by a set of parameters which determines its behaviour during the evacuation phase and the interactions with the other occupants. Pathfinder® is designed to simplify the input phase of the many information managed, but what is more important is that it has *a powerful 3D graphical interface that shows the filmed sequence of the virtual evacuation in a very realistic way.*

Pathfinder® uses a three-dimensional geometry model, however, for simulation purposes, the elements considered are only of the two-dimensional type, to reduce the calculation complexity. The Pathfinder® movement environment (3D continuous space model) is automatically transformed into a 2D navigation triangular mesh (represented by adjacent triangles) on which the occupants are free to move. The use of triangular meshes for the geometric representation allows the software to discretize even curved surfaces quite effectively. Obstacles (up to 1.8 meters away from the floor) are represented in the navigation mesh as empty spaces, which prevent the occupants from being able to move in spaces that house walls, furnishings, objects and therefore in fact they can only move on the navigation mesh. The navigation geometry is organized into irregularly shaped rooms, with boundaries that cannot be crossed by the occupants. The passage from one room to the adjacent one can be done through *connecting doors*. A door that does not connect two rooms and is placed on the outside boundary of one room is defined as an *exit door*. See Figure 6 as an example of a navigation mesh, where occupants are indicated with blue dots, doors with orange lines, and the exit door with a green line. Any mesh zone can be classified as one of four types: open space (room or ramp), staircase, connecting door and exit door, each with a different effect on the occupants' behaviour.

In the user interface, *each person can be assigned their own profile and behaviour*. The profile defines the fixed characteristics of the occupants (i.e., maximum speed, size, colour). The behaviour defines a series of actions that the occupant performs in the simulation (for example moving to a room, waiting time, exiting, route stops). Based on individual characteristics, each occupant makes autonomous decisions on which path to take. It is possible to define groups of occupants with the same behavioural properties who look for each other and who maintain a minimum distance between them (such as families, colleagues, students), associating them with a leader profile (for example a tour guide in a museum).

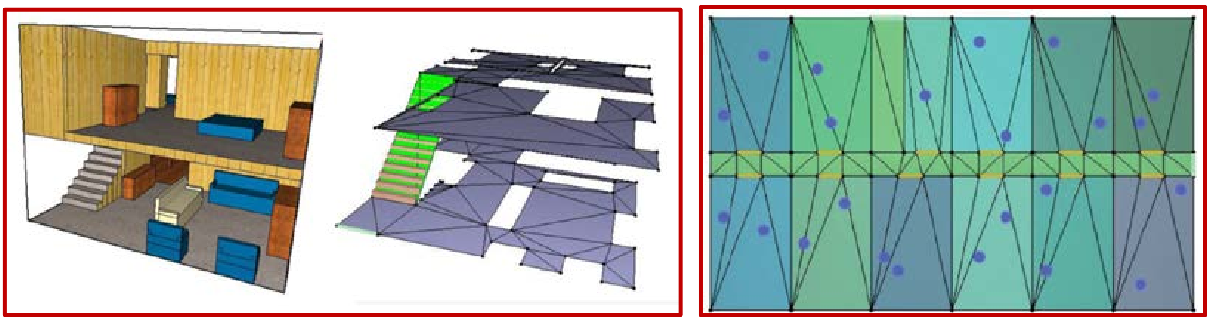

Fig. 6: Example of 3D geometry and related 2D navigation mesh with evidence of rooms, doors and exit doors (Pathfinder Technical Reference Manual, 2022)

Pathfinder® provides two modes of occupant movement simulation:

- *SFPE (hydraulic model)* which reproduces the concepts and calculations defined in the "SFPE Handbook of Fire Protection Engineering, 2016" and in the "SFPE Engineering Guide: Human Behavior in Fire, 2019" and considers the movement of the occupants as a flow model where walking speeds are determined by the density of occupants within each room and flow through doors is dictated by their width. In SFPE mode the occupants do not attempt to avoid each other but may overlap. The main parameters used in SFPE mode are the following: maximum occupant density for the room, effective width of the door (Boundary Layer), specific flow through the doors, movement speed of an occupant.

- *Steering (behavioural model)* which reproduces human behaviour and movement as much as possible and is based on the studies carried out for the first time by C. Reynolds ("Steering behaviours for autonomous characters - 1999"): through a combination of guidance and collision management mechanisms (with people, walls or objects), it allows each occupant to proceed towards his goal while avoiding other occupants and obstacles along the way, proceeding in lanes in the case of counter-current occupants, following other faster occupants, etc. The movements of each occupant in the different possible directions are evaluated and the optimized direction is then determined. The main parameters used in Steering mode are the following: maximum speed of each occupant, maximum acceleration and occupant density.

2.4 The calculation of the T_{tra} with Pathfinder® in the case study

Firstly, *hand calculation* for escape time computation was carried out with a hydraulic model and then Pathfinder® was used to develop the simulations in the two methods provided: SFPE and Steering.

The simulations were carried out to determine how the evacuation time varies according to the different hypothesized scenarios, which differ from each other in terms of the number of occupants, their type and their location.

The working procedure was as follows:

- Setting the geometric characteristics of the building by importing the *3D DWG files* into the software (Fig.7 on the left)
- creation of *5 occupant profiles* (guides, adults, elderly, children and staff) with specific characteristics (travel speed, shape, size, reduction factors, etc.). In Fig.7 on the right the input interface of the "child visitors"
- assignment of a *behaviour* (choice of exit, priority, initial delay, assistance to others, waiting for assistance, etc.) for each profile
- choice of *10 scenarios* (see list in Fig.9):
  - *5 "realistic" scenarios* with 28 occupants (different in type and location), of which 20 visitors admitted at the same time, 2 guides and 6 office workers (in Fig. 8 on the left, the simulation for scenario II in which the mixed visitors - children in yellow, adults in red, elderly people in green and guides in black - they are partly on the 8th floor and partly on the 7th and the office workers, in blue, are all on the 4th floor)

- *1 "theoretical*" scenario with 126 occupants, maximum occupant density admitted by Code (in Fig.8 on the right)
- *4 intermediate "theoretical" scenarios* (with 90, 74, 56 and 29 occupants)

* Calculation of T_{tra} for each simulation with analysis of the speed of the occupants and any critical situation.

10 simulations in Steering mode and 2 in SFPE mode were performed: Fig.9 shows the results obtained.

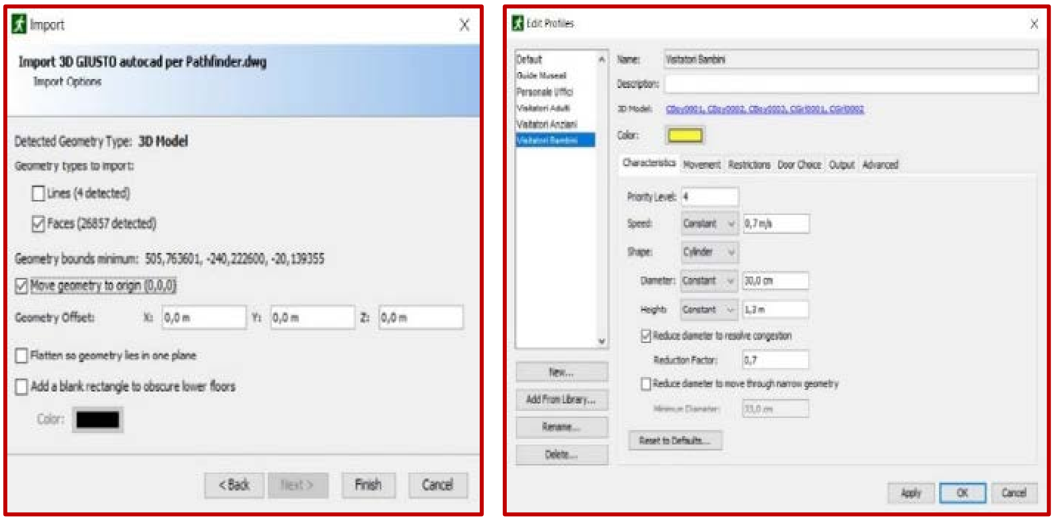

Fig. 7: Pathfinder® user interfaces for importing the 3D DWG file (on the left) and for the characterization of the "Child Visitors" occupants (on the right)

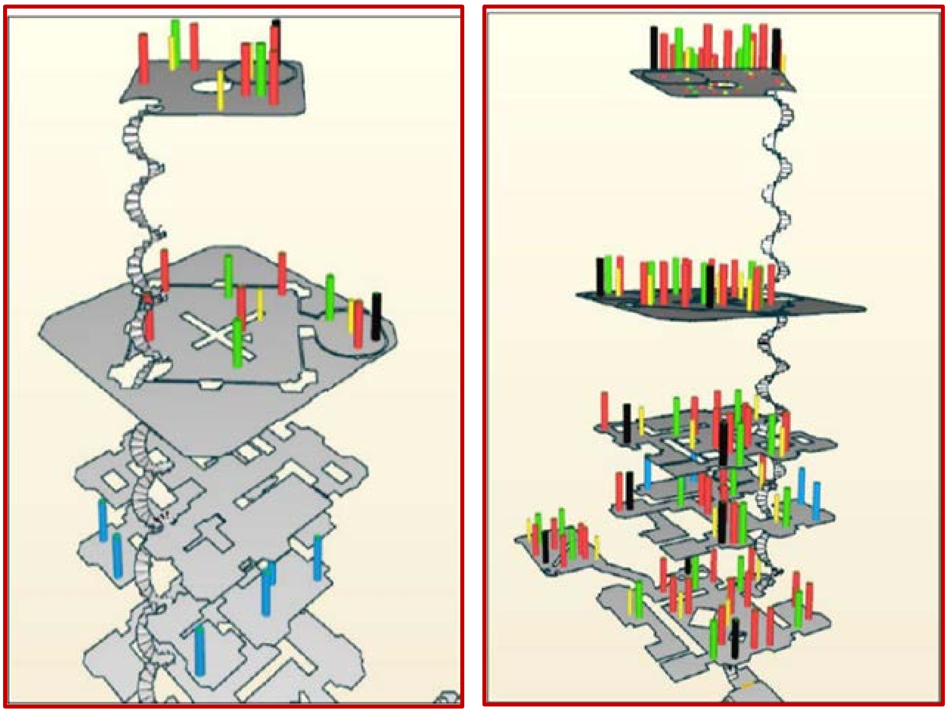

Fig. 8: View of the occupants in simulation II (mixed typology) and in VI (126 people)

The *main outputs* of the software consist of *realistic 3D graphic elaborations and 2D graphics* that allow to reproduce the evacuation and to analyze, even with video still images, any critical situation (queues, high density areas) and the speed of the occupants (see by way of example Fig. 11 and Fig. 12).

Particularly effective in terms of clarity for understanding the phenomenon are the video that reproduce the entire sequence of the evacuation with all its critical points in a very realistic way and with effective times.

scenario (Pathfinder "Steering")		total crowding (persons)	guides (persons)	adult visitors (persons)	elderly visitors (persons)	children visitors (persons)	office workers (persons)	pre-travel time (PTAT) (sec)	travel time (sec)	evacuation time (sec)	RSET (sec)
I	low crowding mixed typology visitors all on the 8th floor	28	2	10	5	5	6	30	272.5	302.5	362.5

3. RESULTS AND DISCUSSION

3.1 Effectiveness of the alternative solution in the case study

The calculations and simulations carried out demonstrate how it is possible to guarantee the safety of the occupants in a particular historical building using alternative measures, even if the prescriptive standards are not respected.

Therefore, it was possible to evaluate the efficiency of the design system and to show that the fire safety measures adopted in the case study are sufficient to guarantee an adequate level of protection of life and assets. All "realistic" simulations, in fact, return safety margins higher than 100% of the RSET time.

It must be said that concerning the case study, an historic tower museum, some important management fire protection measures have been adopted by the museum organization, that help to increase the safety margin, reducing the RSET:

- the non-simultaneity of the two activities carried out inside the building (museum and offices/services).
- the limitation of the maximum crowding of museum visitors, divided in no more than two groups (one for each of the two museum guides).
- the ineligibility of visitors with motor disabilities.
- the access of visitors only accompanied by properly trained guides, who lead people who otherwise would not be familiar with the place.

In addition to these safety measures, an important role is played by the preventive and protective measures adopted by law, i.e. the presence of an automatic fire detection and alarm system (IRAI); the entire active protection system for extinguishing the fire (fire extinguishers and internal fire hose reels) built in all the museum spaces; a clear signal that facilitates the wayfinding process; the compartmentation of the escape routes (staircases and corridors on the ground floor) open to the public, with the insertion of suitable REI fire doors; the limitation of the fire loads in these paths (because of this they can be considered as temporary safe locations). In consideration of the above fire protective measures, it can be said that the overall safety is excellent, as the horizontal paths in the various floors are very short.

However, as already mentioned, the ASET time taken as a reference would require a more precise calculation using fire simulation models, i.e., deterministic models based on the principles of physics and chemistry. For this reason, in this study, a safety margin equal to 100% of the RSET was always considered, as required by the international and local regulations. Furthermore, again to play on the safe side, not all the management fire protection measures mentioned above and actually adopted, were considered as present in the simulations.

3.2 Utility of the escape simulation software

The simulations (Fig.9) show that the movement time obtained with the SFPE mode (181.3 sec) is more or less equivalent with the one obtained with the hand calculation with the hydraulic model (184.3 sec). Therefore, using the software in SFPE mode, which uses the hydraulic model, there is no significant qualitative improvement of the results compared to the hand calculation, but only a greater computing speed.

The simulations carried out with the Steering (behavioural) mode, on the other hand, show a significant difference compared to the simulations in SFPE mode (hydraulic model). It emerges, in fact, that the calculated times are 15-19% higher than those of the SFPE mode. This occurs because the SFPE mode admits the physical overlapping of the occupants in the queues that form in the exits and does not properly consider the interactions between the occupants themselves, which makes this mode clearly less adherent to reality (see Fig.10).

Fig. 10: Occupant overlay at stair entrance using Pathfinder® SFPE mode

Furthermore, with the behavioural steering mode, some critical situations clearly emerge which strongly affect escape times. Queues are created in emergency escape and gatherings near the access sections from the floors to the stairs, i.e., at the intersection (so-called "converging nodes") between the evacuation flows of the occupants who come from the floors and those who come from the spiral staircases. This demonstrates how the Steering mode is much more realistic, as human behaviour significantly influences escape times. The Pathfinder® software has various ways of representing these critical situations. Firstly graphs with the progression of the evacuation (Fig. 11 on the left) and secondly the flow rates in the reduced access sections (Fig. 11 on the right); then the 3D graphic elaborations with crowding densities (Fig. 12 on the left) and the graphic elaborations that represent the so-called Level of Service (LoS), that is the criticalities in the queues, in the walkways, and in the movement on the stairs (Fig. 12 on the right).

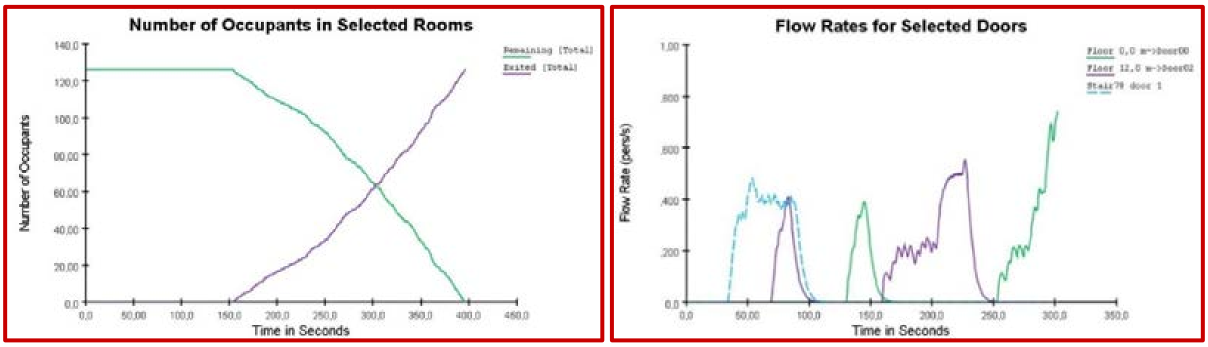

Fig. 11: escape simulation times in scenario VI (left); flow rates at the significant gates in scenario I (right)

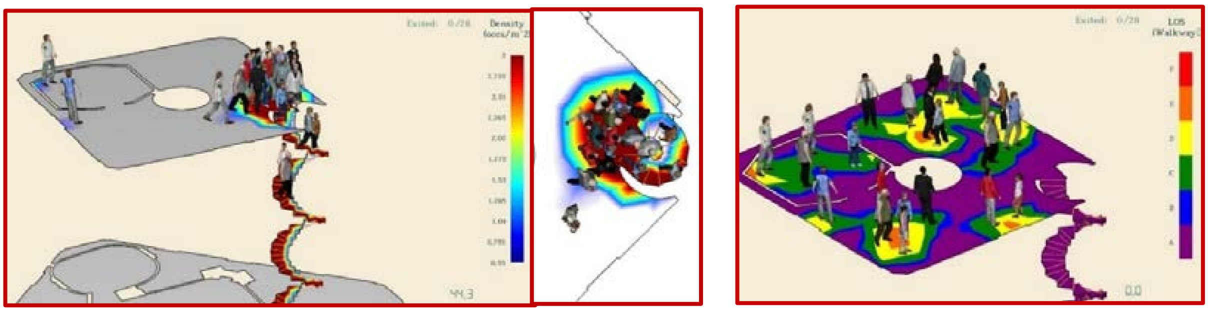

Fig. 12: Scenario I - on the left occupant density in the critical section of the stairwell at the exit of the 8th floor - on the right Service level (Walking LoS) in the most critical location on the 8th floor

These simulations also show that the presence of visitors with reduced travel speed (children and the elderly) strongly limits the evacuation from the building (times longer by about 30%, as shown by the comparison between scenarios IV and V - Fig.9).

Even the most critical simulation among the realistic ones (scenario V - school group of 20 children all on the 8th floor) appears to be in compliance with the prescription of the alternative solution of the FSE (safety margin must be greater than 100% of the RSET). The comparison of the assumed ASET and RSET gives as results the following equation:

$$ASET - RSET = 106\%\ RSET.$$

For the sake of completeness, an unrealistic hypothesis was also developed. This hypothesis foresees the maximum crowding allowed by the compliant solution, equal to 126 total occupants (scenario VI). In this case, due to the numerous queues and gatherings that are created above all on the 6th and 7th floors in the access door to the stairwell, the criterion provided for by the Code is not respected, but there is still a wide time margin:

$$ASET - RSET = 71\%\ RSET.$$

Another interesting evaluation uses simulations IX and X in order to estimate the maximum crowding which allows, with the assumed scenarios, compliance with the criterion t_{marg} = 100% • RSET = 390 seconds. The number of occupants is obtained by interpolation of the linear function referred to the two simulations IX and X and is equal to an estimate of 54 people (see the graph in Figure 13).

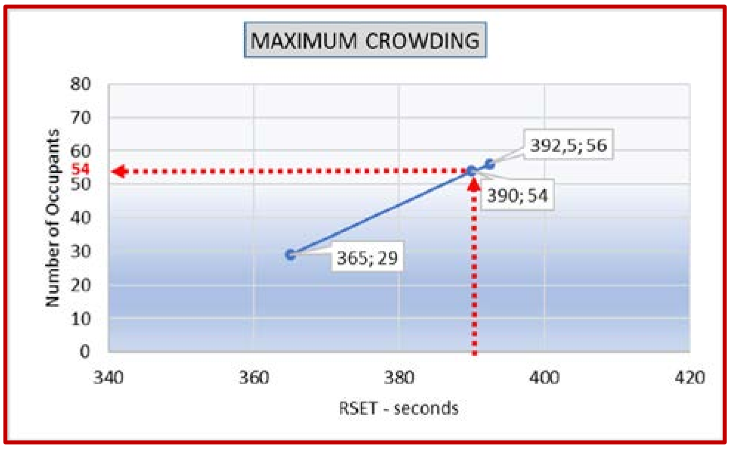

Fig. 13: Estimate of maximum crowding using the escape simulation times of scenarios IX and X

In Figure 14 there are two screen shots of the VI simulation with 126 occupants, taken from the video made with the simulation software, which shows the entire evacuation and gives an idea of the power of virtual representation of reality that Pathfinder® has.

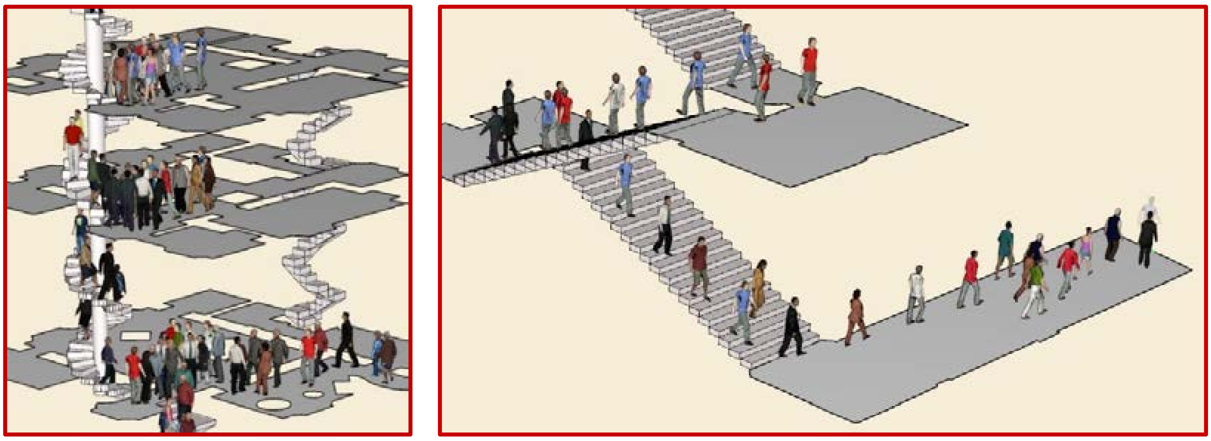

Fig. 14: Examples of 3D graphic visualization of the occupants in the escape simulations processed with Pathfinder® (Steering mode) in the case study

4. CONCLUSIONS

The most innovative escape virtual modelling software, such as Pathfinder®, are able to return high-quality results by means of video based visualization techniques that perfectly simulate reality and give an absolutely real perception of what can happen in the hypothesized situation. This software is used as a planning tool of the evacuation dynamics of an environment and allows to explore different evacuation cases and scenarios, varying the parameters of the simulation and the properties of the occupants. This makes possible to calculate the evacuation times in the various scenarios and to highlight the most critical ones.

The research work under this paper clearly shows hydraulic models are less in adherence to reality than behavioural models that are more reliable by using a scientific-predictive simulation software of the movement of people during the escape such as Pathfinder®.

Behavioural models are able to demonstrate how human behaviour significantly influences evacuation times and are able to give quantitative outputs, evaluated from a series of assigned parameters.

Due to their greater flexibility, these software bring out critical issues that otherwise could not be considered in the fire safety design phase, as for example delays in time due to congestion and queues in areas of restriction or intersection of multiple flows.

Anyway, the use of virtual simulation requires new skills and greater caution, as they are highly sensitive to some input parameters, but they contribute to a better understanding of the phenomena as they give quickly new results with the variation of the individual conditions.

Due to their characteristics, they can therefore also be of great use for simulating the evacuation of occupants in other emergency situations, such as earthquakes, terrorism or other cases in which people's safety is threatened.

QUANTIFYING THE CONFIDENCE IN MODELS OUTPUTTED BY SCAN-TO-BIM PROCESSES

Shirin Malihi, Frédéric Bosché & Martin Bueno Esposito
School of Engineering, University of Edinburgh

ABSTRACT: *3D spatial data is increasingly employed to generate Building Information Models (BIMs) by extension digital twins for various applications in the architecture, engineering, and construction (AEC) sector such as project monitoring, engineering analyses, retrofit planning, etc. The outputted models of Scan-to-BIM processes should satisfy pre-defined levels of quality. In the case of emerging automated Scan-to-BIM solutions, users however currently need to check all generated geometry manually, which is time-consuming. What would help users is if the automated systems could also provide a level of confidence in the detection and modelling of each element. In this paper three generic indicators are defined for analysing the reliability of the generated 3D models:* $I_{coverage}$ *estimates the portion of the surface of the modelled element that can be explained by the input point cloud.* $I_{distance}$ *defines the closeness of the generated element models to the input point cloud. The confidence of the generated 3D local models can be computed by combining the two aforementioned indices. The proposed indicators are assessed using actual examples and comparisons are conducted between automatically generated 3D BIM models and 3D models generated manually by a BIM modeler.*

Keywords: *BIM, point cloud, confidence, indoor modelling, wall, digital twin*

1 INTRODUCTION

Digital twinning of built environment assets is a modern data-driven process with benefits to improving performance and productivity within the Architecture, Engineering, and Construction (AEC) industry. It affords a multi-dimensional view of how an asset will perform by simulating, predicting, and making decisions based on real-world conditions (Boje et al., 2020). At the information (or data) level, it represents the information in a useful, structured form of description. At a higher level, it applies tools that make use of that information to provide diagnostics of why something might be happening, predict the possible future outcome, and decide the action based on the objectives. Optimising construction project execution (Akula et al., 2013; Bueno et al., 2018), building energy usage (Valero et al., 2021), and space utilization (Pan et al., 2022) are some of the numerous use cases of digital twins in the built environment. A built environment digital twin is commonly built from a Building Information Model (hereafter `BIM model'), which contains geometric and some semantics (such as element materials) that can be used to support the envisioned use cases (I. Giannakis et al., 2015).

The generation of BIM models of new buildings is done during the delivery process with an as-design BIM model created during the design phase that should then ideally be updated into an as-built BIM model that incorporates any change made during construction. But, BIM models also increasingly need to be created for existing buildings, for example to plan refurbishment or enhance operation.

In a 2020 survey conducted in 78 countries 2020, professionals asserted major benefits that BIM brings to the construction process from a geometric viewpoint (Rocha et al., 2021). However, the generation of BIM models is challenging due to the complexity and diversity of building geometry, and the possibly high levels of clutter existing in occupied buildings. New technologies, such as Terrestrial Laser Scanners (TLS) or photogrammetry (PG), now enable the acquisition of dense and accurate 3D geometric data, in the form of point clouds. Scan-to-BIM is the process to produce the as-built model of an asset from laser scanned or photogrammetric point clouds (Bassier & Vergauwen, 2020; Bosché et al., 2015a). It includes segmenting the data and generating a final semantically-rich 3D model (Rashdi et al., 2022). Despite the benefits afforded by those new sensing technologies, the generation of BIM models remains challenging due to the complexity and diversity of building geometry, and the possibly high levels of clutter existing in occupied buildings.

Although Scan-to-BIM is generally a manual process in current industrial practice, there is extensive research in academia and industry to develop automatic Scan-to-BIM algorithms (Nikoohemat et al., 2019; Thomson & Boehm, 2015; Valero et al., 2021). For example, a Scan-to-BIM solution based on deep learning is developed in (Perez-Perez et al., 2021) for semantic segmentation. It classifies beam, ceiling, column, floor, pipe, and wall elements using two convolutional neural network and one recurrent neural network.

Referee List (DOI: 10.36253/fup_referee_list)
FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Shirin Malihi, Frederic Bosche, Martin Bueno Esposito, *Quantifying the Confidence in Models Outputted by Scan-To-BIM Processes*, pp. 1137-1146,

Some researchers (Bassier & Vergauwen, 2020) have gone beyond the problem of object detection in scan-to-BIM, and presented results producing BIM models in IFC from semantic information extracted from point clouds (IFC is an open data schema described as in ISO 16739-1:2018 (BuildingSMART, n.d.)).

However, (Rocha et al., 2021) reported that Level of Accuracy was used in 9.2 % of the research reviewed from the literature, which shows a big room for development and using this concept. Guaranteeing the completeness and accuracy of BIM models generated through Scan-to-BIM processes (manual or automated) is an important issue. In previous research, authors have mainly done this manually. For example, in (Skrzypczak et al., 2022) the authors compare the lengths from total station measurements and the BIM model generated from Scan-to-BIM approach. But, comparisons like this are established to check quality manually for the purpose of academic assessment.

In practice, however, the user would need to know to what extent it can be confident that a scan-to-BIM algorithm has produced a correct model from the input point cloud data. Without any such information, the user will need to check every reconstructed element against the input data and gauge correctness manually, which is a time-consuming, and error-prone process that partially undoes the benefits afforded by automated scan-to-BIM algorithms.

Reducing this manual work could be achieved if the scan-to-BIM algorithm could also report some level of confidence for the modelling of each element in the outputted model. In this paper, we explore two such generic metrics (and a third one combining them) to automatically assess the quality of the model generated by a Scan-to-BIM algorithm, focusing on geometrical fitness.

The proposed indicators of the confidence are introduced in section 2. Section 3 then reports experimental results on their evaluation using some real case studies. Finally, the results are discussed and avenues for future work suggested in Section 3.

2 METHOD

This section presents the method proposed to calculate the level of confidence in BIM models outputted by Scan-to-BIM processes. Two different indices are defined $I_{coverage}$, $I_{distance}$, and *their combination* that can be computed for any element in the outputted model. They are detailed in the following sub-sections.

2.1 $I_{coverage}$

$I_{coverage}$ is the principal index and aims to capture how much of the modelled 3D surface of a given element in the outputted model is explained by the input point cloud data. One quantitative measure of this consists in homogeneously discretizing the element's surface and check if some points from the input point cloud lay in the neighbourhood and describe that discrete surface.

A practical way to implement this is to use space voxelization. First, for each modelled element, a voxelization is performed in its bounding box, with a resolution δ (e.g. $\delta = 2.5$cm). The set of voxels intersecting the element mesh is then found (we use the method described in (Open3D)); we call this set γ_m . Then, we identify the subset of voxels in γ_m that also contain points from the point cloud. Points are searched inside the voxels. The centre of each voxel is the base of this search. KD tree structure is used to partition this space and efficiently search the set of points falling within each voxel. We call this second set γ_c. We then define $I_{coverage}$ as:

$$I_{coverage} = \frac{|\gamma_c|}{|\gamma_m|} \tag{1}$$

where $|.|$ is the cardinality operator. $I_{coverage}$ takes values between 0 and 1, with 1 indicating that the entire surface of the element’s mesh has matched scanned point in its vicinity, i.e. within δ distance.

2.2 $I_{distance}$

$I_{coverage}$ captures how much of the modelled surface is explained by a point cloud in a somewhat coarse way, and considers neither how closely the modelled surface matches the point cloud nor the local orientation of the points and the modelled surface. The metric $I_{distance}$ aims to complement $I_{coverage}$. For this, we take the set of point cloud that are in the voxels in γ_c (called n), calculate their closest (orthonormal) distance to the element mesh, and then compute $I_{distance}$ as follows:

$$I_{distance} = \frac{1.0\,.n_1 + 0.5\,.n_2 + 0.25\,.n_3 + 0.125\,.n_4 + 0.0625\,.n_5}{n} \tag{2}$$

where n_1 is the number of the n points that are within $\left({}^{1}\!/_{5}\right)\delta$ distance to the mesh, n_2 is the number of the n points that are between $\left({}^{1}\!/_{5}\right)\delta$ 1 and $\left({}^{2}\!/_{5}\right)\delta$ distance to the mesh, n_3 is the number of the n points that are between $\left({}^{2}\!/_{5}\right)\delta$ and $\left({}^{3}\!/_{5}\right)\delta$ distance to the mesh, n_4 is the number of the n points that are between $\left({}^{3}\!/_{5}\right)\delta$ and $\left({}^{4}\!/_{5}\right)\delta$ distance to the mesh, and finally n_5 is the number of the n points that are between $\left({}^{4}\!/_{5}\right)\delta$ and δ distance to the mesh.

Calculation of the distance between a point of the point cloud and a triangle of the mesh satisfying two conditions that are the projection of the point on the plane, formed by the triangle, should be located inside this triangle, and additionally the distance between the point and the mesh triangle should be less than the buffer size. Afterwards points inside this buffer are used to compute the $I_{distance}$ using the weighted average formula in Equation 2. $I_{distance}$ also takes values between 0 and 1, with 1 indicating that all the points are very close to the mesh (within $\left({}^{1}\!/_{5}\right)\delta$ distance).

3 EXPERIMENTAL VALIDATION

The validation of the proposed method is conducted using an example Scan-to-BIM algorithm, but the method is applicable to the use of any other algorithm. The employed Scan-to-BIM solution was developed as part of the EU-funded Horizon2020 BIMERR project (Valero et al., 2021). The whole solution is semi-automatic and aimed at producing as-is models that contain as much information as possible to support the efficient (automated) development of an energy model that can be used to conduct simulations for refurbishment planning. This solution is divided into three components (Valero et al., 2021):

1. The *Structural Scan-to-BIM* component that automatically generates an IFC model containing the main architectural elements (floors, walls, openings, spaces) as well as second level space boundaries;
2. The *Mechanical, Electrical and Plumbing (MEP) Scan-to-BIM* component that automatically enriches the IFC model with elements such as radiators, HAVC units and sockets (Bosché et al., 2015b); and
3. *Scan-to-BIM Editor* to manually enrich the model with wall layers, materials, material properties and MEP properties.

The modelling confidence metrics proposed herein could be employed in each component, but are assessed here in the context of the first component of the solution, the Structural Scan-to-BIM component.

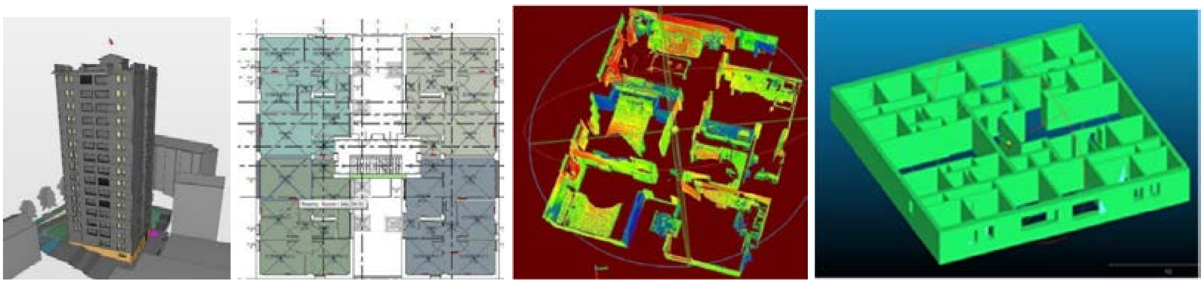
3.1 Experimental Data

One of the pilot sites of the BIMERR project is the two-story Kripis House located in Thessaloniki, Greece. A coloured point cloud of the whole house (exterior and interior) was captured using a terrestrial laser scanner Faro Focus 150s, and subsequently subsampled to a density of 1 pt/cm^2.

This house is furnished, however the interior is not much cluttered. The *Structural Scan-to-BIM* component automatically delivered a 3D model of the house in IFC format from that point cloud alone. A second pilot site is located in Bilbao, Spain. This is a multi-story apartment building, with essentially the same layout on all floors. Each floor contains four flats. A storey of the building was captured fully by terrestrial laser scanning. In contrast to the Kripis House, the Bilbao environment is cluttered because the building was scanned when fully inhabited. It contains wardrobes cupboards and other pieces of furniture and personal belongings inside rooms, resulting in significant levels of occlusion, which challenge Scan-to-BIM processes.

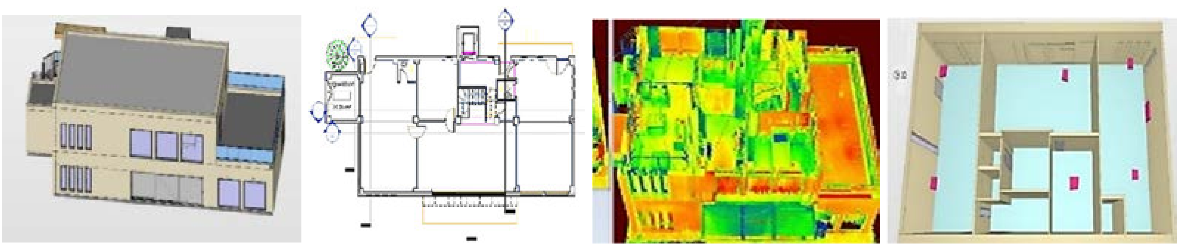
To assess the value of the proposed confidence metrics to report Scan-to-BIM confidence levels, manual scan-to-BIM was conducted by architects using standard commercial software and the resulting models exported in IFC. While those models may contain errors, they are generally good and can serve as ground truth. The validation then focuses on the walls, as walls are the most frequent elements in the models. The walls modelled manually and with the automated process are compared.

Figure 1 shows the Spanish dataset and the corresponding output IFC model generated by the *Scan-to-BIM* tool. Figure 2 shows the same information for the Greek dataset.



(a) (b) (c) (d)

Figure 1 : Spanish dataset and Scan-to-BIM output. The 3D model generated manually by the BIM modeller (a), plan view of one floor (b), the point cloud of one apartment (c), and 3D IFC model outputted by the Scan-to-BIM component for one floor (d).



(a) (b) (c) (d)

Figure 2: The 3D model generated manually by the BIM modeller (a), plan view of one floor (b), the point cloud (c), and 3D model outputted by the Scan-to-BIM (d). Stuff of indoor spaces are displayed in the point clouds.

3.2 Results and Discussion

First of all, we report on the overall wall detection performance of the Scan-to-BIM component. In an IFC model, correctly detected walls are counted as true positive (TP), non-existing detected walls are counted as false positive (FP), and missing walls are counted as false negative (FN).

Table 1 summarizes the performance obtained by the automated Scan-to-BIM algorithm. The results bring to light the challenges faced in the case of the Spanish dataset. While the automated Scan-to-BIM tool detected most walls (despite the clutter, noise and furniture of the rooms) but many walls modelled by the tool that actually do not exist, and four walls missed. In the case of the Greek project, 100% recall is achieved and 96% precision. Two FPs are reported, but these include a protruding beam confused as a wall and two columns modelled as a wall. These can in fact be considered acceptable because the automated Scan-to-BIM algorithm assumes that the structure of residential buildings is composed of walls and slabs only, and thus does not explicitly look for and model columns and beams.

Table 1: Wall detection performance of the Scan-to-BIM tool.

	TP	FP	FN	Recall	Precision
Spain dataset	60	14	4	94%	81%
Greece dataset	45	2	0	100%	96%

Figure 3 and Figure 4 show some of the modelling errors made by the automated algorithm with both datasets.

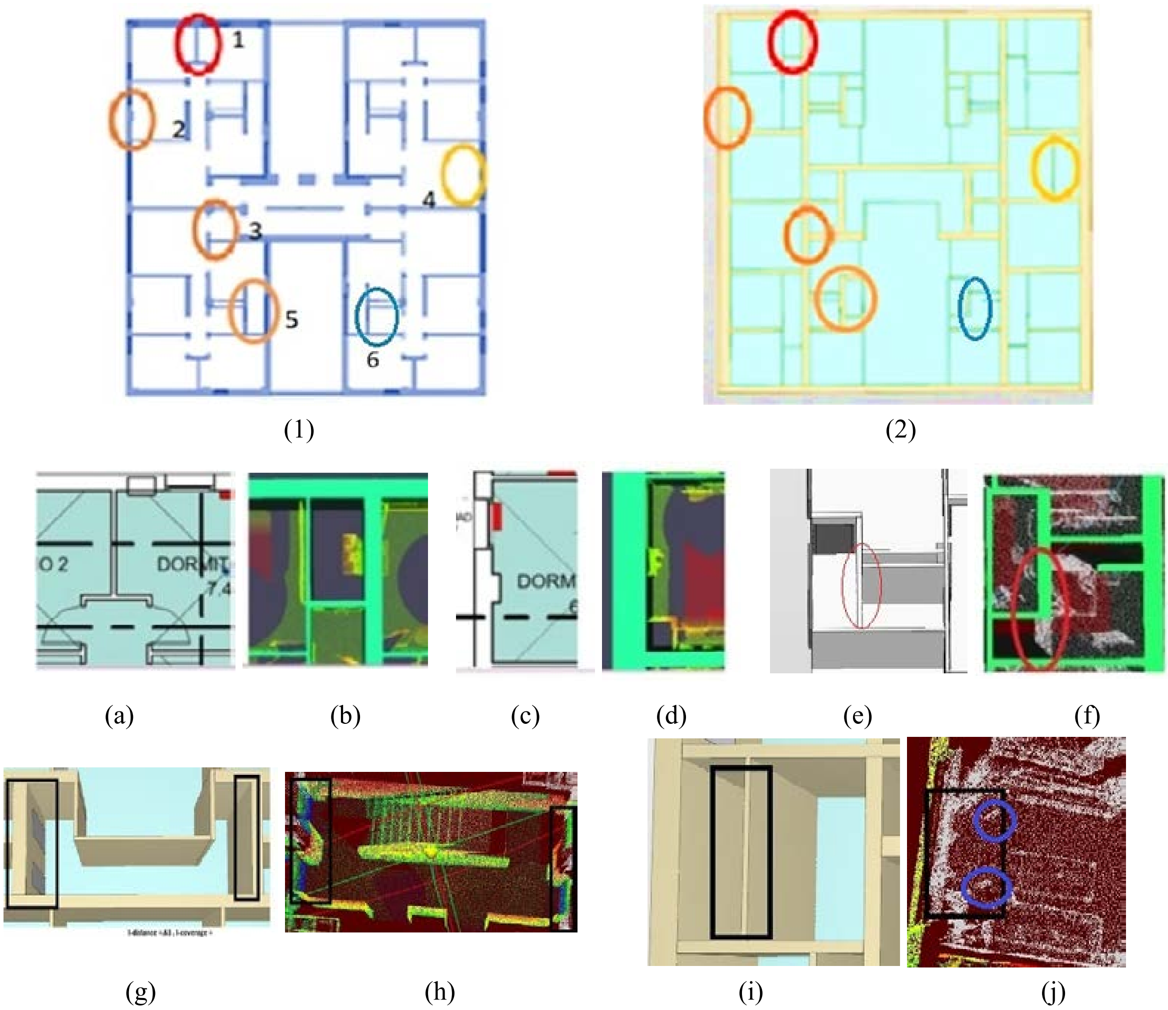


Figure 3: Modelling errors in the Spanish dataset. Errors in the manually-generated BIM model and the automated Scan-to-BIM algorithm are shown in (1) and (2) respectively. (a) and (b) show a wall which is modelled as a room with walls due to the presence of wardrobes inserted in the spaces on both sides. (c) and (d) depict a wall which is modelled as thick the column that is embedded in it. (e) and (f) demonstrate FN wall examples. (g) and (h) display an error in the modelling of thickness of walls. (i) and (j) show FP walls due to clutter in the room near the wall.

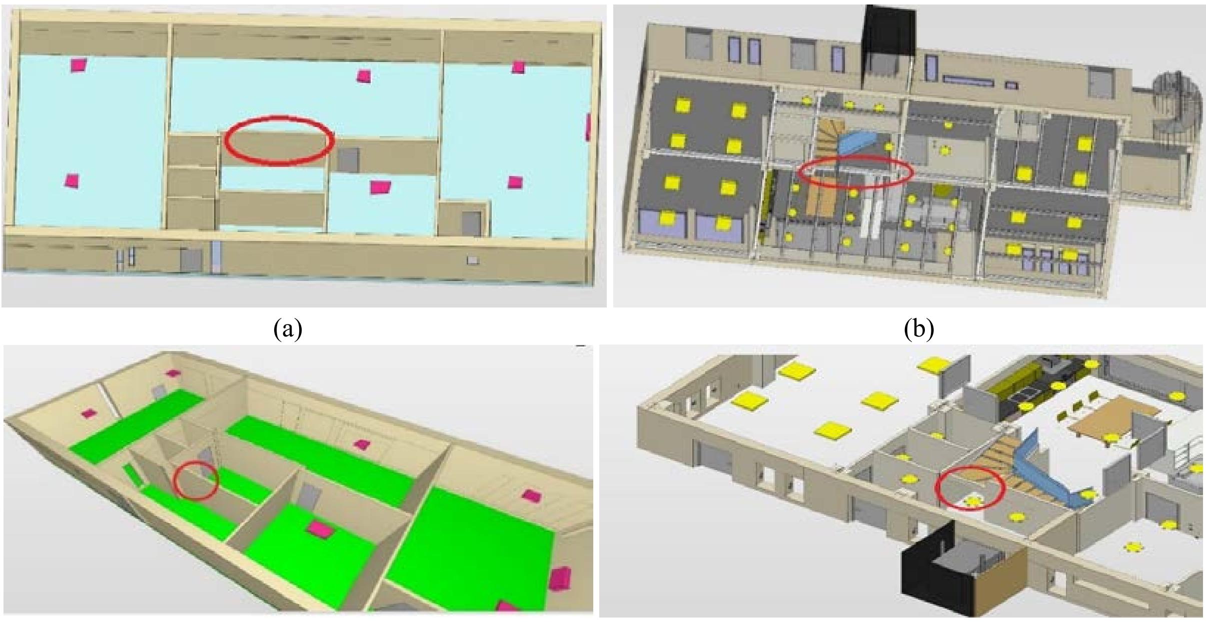
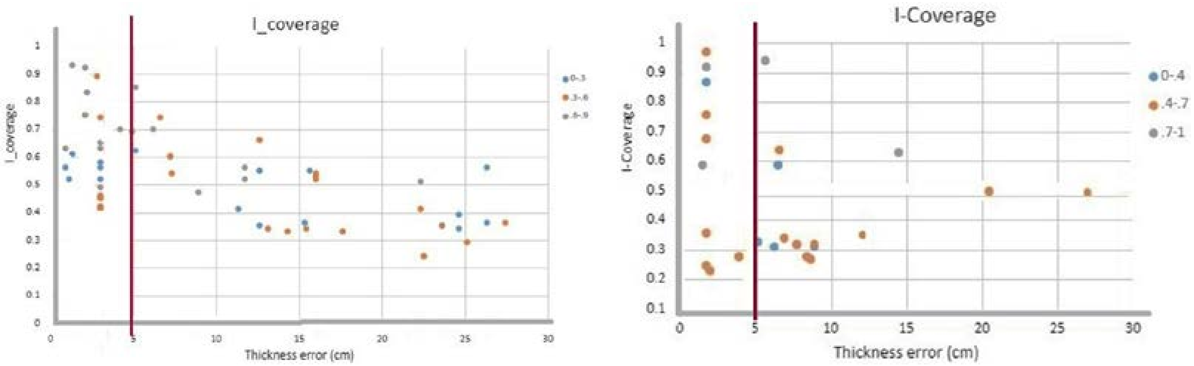


(a) (b)

(c) (d)

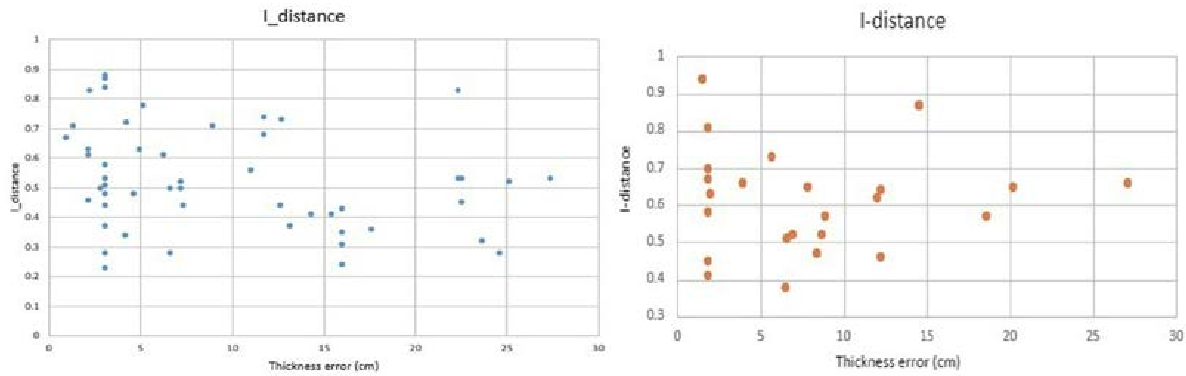
Figure 4: modelling errors in the Greek dataset. (a) and (c) show the model generated by the automated algorithm, while (b) and (d) show the model generated manually. In (a) and (b) a wall is modelled instead of two columns and a beam. (c) and (d) show a wall modelled instead of a beam.

Figure 5 reports the $I_{coverage}$ values obtained for each wall in the Spanish and Greek datasets. This figure plots the $I_{coverage}$ against the difference between the thicknesses of a given wall modelled manually (ground truth) and the same wall modelled automatically by the Scan-to-BIM algorithm. Note that in this experiment we use δ = 2.5 cm. The red vertical lines in Figure 5 are inserted on the distance of 2δ . This line is important because, if the wall is modelled at the right location but with a thickness error larger than 2δ, than the number of points within δ of each wall side, and a result the value of $I_{coverage}$ should be much lower. Figure 6 shows the $I_{distance}$ against the wall thickness error for the two datasets.



(a) (b)

Figure 5: $I_{coverage}$ and thickness errors for two datasets of Spanish (a) and Greek (b). They are coloured based on their corresponding $I_{distance}$ and split into three groups. The red vertical lines are inserted on the distance of 2δ.

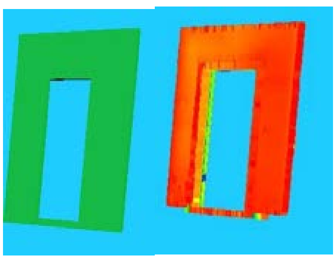


(a) (b)

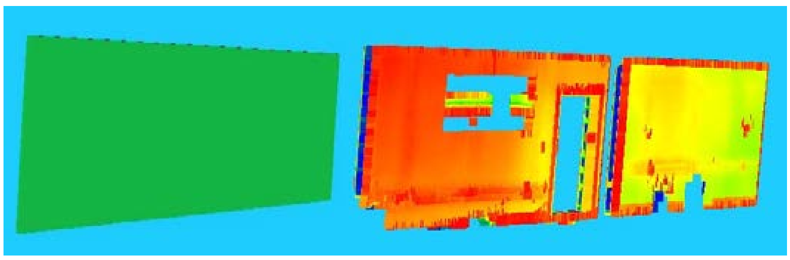
Figure 6: $I_{distance}$ and thickness errors for two datasets of Spanish (a) and Greek (b).

Looking at Figure 5, one can see a trend where $I_{coverage}$ is lower for walls with greater thickness error (in particular $>2\delta$). This implies some correlation between $I_{coverage}$ and the confidence in the modelling quality. Nonetheless, some outliers do exist and good confidence seems to be only achieved for very high values of $I_{coverage}$ For $I_{distance}$ (Figure 6) a similar, but less positive trend can also be observed, as more obvious outliers can be observed.

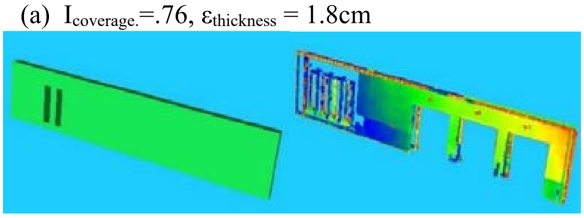
Figure 7 shows coverages and thickness errors of seven sample walls which were selected from different parts of Figure 5. (a, b) show examples where $I_{coverage}$ >0.5 and thickness error < 2δ. (c, d) show example for which $I_{coverage}$ is lower with values closer to 0.5, with one wall having thickness error >2δ and the other just below 2δ. The average value of $I_{coverage}$ in both cases are due to the fact that one of the faces of the walls is detected correctly, but the other one is wrongly detected. In the case of (c) this is due to a structural column (which the algorithm fails to detect) that leads to a gross over estimation of the width of the wall which subsequently leads to only very few points being matches to that face of the wall. The two large undetected windows also impact $I_{coverage}$. In (d), the second face of the wall is also wrongly modelled because the algorithm wrongly selected the curtains as the boundary for that wall. This results in lower (although not insignificant) thickness error which is still high enough to impact $I_{coverage}$. The conclusion is that, in both cases, $I_{coverage}$ rightly represents some level of error (for one face of the walls). (e, f) show walls for which $I_{coverage}$ <0.5 and thickness errors > 2 δ. These walls similarly have one face of the wall that is wrongly modelled, which is the source of the thickness error and implies that $I_{coverage}$ couldn't be higher than 0.5, as in the examples (c, d). But, (e, f) additionally contain undetected large windows and many occlusions due to desk, frame and mirror. Finally, (g) shows a wall that has a very low $I_{coverage}$ value (0.23) despite a small thickness modelling error. This may first appear to show a weakness of the proposed $I_{coverage}$ index. But, actually, in this case, while the wall is modelled with only 2cm thickness error, both faces of the wall are wrongly modelled and the wall end up looking like it was modelled at a location 4cm away from its true location. Therefore, $I_{coverage}$ rightly responds to this important modelling error.



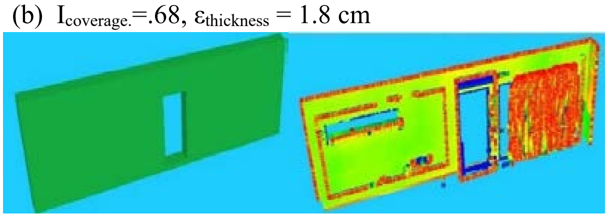
(a) $I_{coverage.}$=.76, $\varepsilon_{thickness}$ = 1.8cm



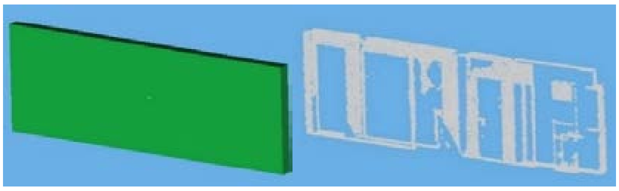
(b) $I_{coverage.}$=.68, $\varepsilon_{thickness}$ = 1.8 cm



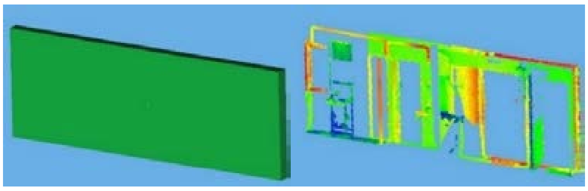
(c) $I_{coverage.}$=.51, $\varepsilon_{thickness}$ = 27.1cm



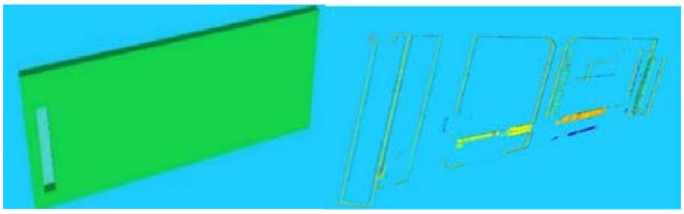
(d) $I_{coverage.}$=.63, $\varepsilon_{thickness}$ = 4.5 cm



(e) $I_{coverage.}$=.41, $\varepsilon_{thickness}$ = 11.3 cm



(f) $I_{coverage.}$=.35, $\varepsilon_{thickness}$ = 12.6 cm



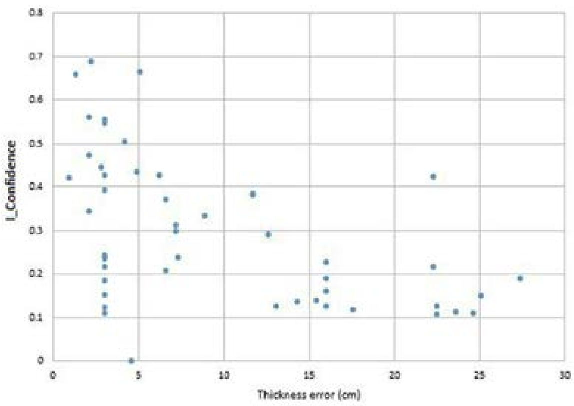
(g) $I_{coverage.}$=.23, $\varepsilon_{thickness}$ = 2.0 cm

Figure 7: $I_{coverage}$ and thickness error of sample walls

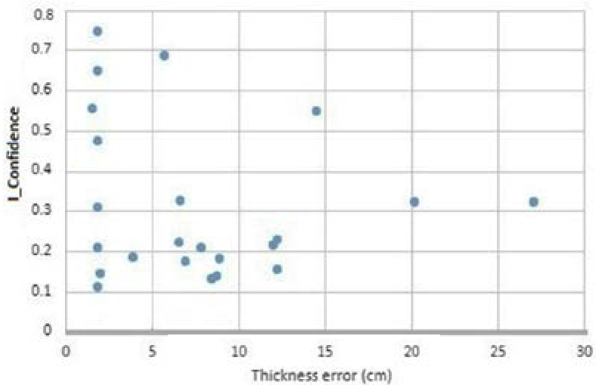
Overall, higher $I_{coverage}$, and to a lesser extent $I_{distance}$, show some level of correlation with smaller thickness modelling errors. However, in the presence of occlusion and obstruction from items such as cabinets, wall decorations, or curtains, $I_{coverage}$ is less reliable as a determinant factor for confidence of the automated Scan-to-BIM tool. To has achieve a higher correlation with the confidence of modelling, we can first look at combining these indices as:

$$I_{confidence} = I_{coverage} * I_{distance} \tag{3}$$

The results for $I_{confidence}$ are shown in Figure 8. This shows that $I_{confidence}$ has a slightly improved correlation with the confidence level of modelling.



(a)



(b)

Figure 8: $I_{confidence}$ against the thickness errors for two datasets of Spanish (a) and Greek (b).

A second observation is that, since many of the modelling thickness errors arise from the presence of pieces of furniture or decoration in close proximity to the walls as well as the confusion of the algorithm between walls and columns, it is suggested, for future work to explore the use of some point cloud semantic segmentation algorithm (e.g. (Armeni et al., 2016)), which could provide further support during the modelling as well as to refine the confidence index by ensuring that wall elements are indeed modelled with points that are mostly labelled as being in the “wall” category.

4 CONCLUSION

Users of Scan-to-BIM algorithms and generally digital twins should be provided with reliable metrics of confidence for geometric modelling; hence they do not need to check everything manually to ease quality control and corrective works.

For this purpose, we introduce indices related to coverage and distance. These indices use information to analyse estimate confidence of the modelling tool. Coverage and distance information of the point cloud and IFC models are used to determine the consistency of the modelling. The major indicator is defined based on the coverage. Information of coverage provides local qualification of the modelling. The coverage index shows the best results, but, However due to obstruction, and the presence of furniture and decorative items in close proximity of or onto walls, only fairly high values of this index (>0.8) can be used to have high confidence in modelling. The distance index can be combined with to it and to improve its results, but still further work is necessary to improve the reliability of these indices. Semantic segmentation could be employed to detect different elements such as desk, mirror, frame, cupboard, as well as distinguish columns from walls, which would then be removed before modelling and/or accounted for in the calculation of a confidence index.

ABSTRACT: *The objective of this paper is to develop a semi-automatic method for constructing a practical finite element model from point cloud data of an entire span of a through-type steel truss bridge. In the first step, we introduced practical finite element models for truss bridges based on structural experiments and numerical analyses of a sway bracing located at the end support. We also proposed a basic method for semi-automatically constructing a finite element model of a sway bracing using point cloud data. This method was then extended for an entire of steel truss bridge. The point cloud data is converted to individual data structures which, in turn, are connected to construct a whole structure. The main members, such as upper chords, lower chords, and diagonals, are converted to fiber-based models by automatically creating central axis lines and cross-sections from the point cloud. The slab is converted to shell models by obtaining surfaces and thickness from the point cloud. The effectiveness of the proposed method was confirmed by comparing the analysis results from the finite element model manually created from the design drawing (drawing-model) with those obtained from the model generated by this method (point-cloud-model). The proposed method is more efficient than reading drawings and creating the models manually, and it was confirmed that the point-cloud-model shows response values close to those of the drawing-model within the design load. However, the reproducibility of the response values with more than the design load remains an issue, which can be solved by tuning plate thickness.*

KEYWORDS: *Point Cloud, Fiber-based model, Steel Truss Bridge, Structural Analysis Model, Semi-Automatic Method*

1. INTRODUCTION

A vast number of existing bridges are rapidly aging. Since it is not practical to rebuild all of them at the same time, strategic renewal through life cycle extension is required. To extend the life cycle of bridges, quantitative evaluation of the residual load capacity is being promoted through numerical analysis. The accuracy of the analytical model, such as finite element model configuration (dimensions, materials, and boundary conditions) has been verified through structural experiments and is now being realized with high reproducibility (Magoshi et al. 2014), but the efficiency of the generation method still remains an issue.

Construction of a finite element model requires acquisition of member dimensions of a target structure. However, in cases of old bridges, as-build drawings are often unavailable. In addition, conditions of bridges inevitably changed since its construction due to various factors. Therefore, it is necessary to construct a finite element model based on dimensions data instead of relying on drawings, but manual measurement is time-consuming and prone to various human errors.

Therefore, a method to efficiently construct a finite element model from point cloud data, which can efficiently reproduce the 3D shape of an object, has begun to attract attention. Some existing methods (Suzuki et al. 2019 and Nakamizo et al. 2022) convert point cloud data to a finite element model by shell or solid elements, but the shell or solid element models are not practical because of their computational burdens. In addition, such methods are only applicable to simple structures like simple beams and not to usual structures consisting of multiple members. Therefore, it is necessary to apply structures with multiple members connected to each other and to convert to fiber-based models used in practice. Fig. 1 shows a type and outline of finite element models.

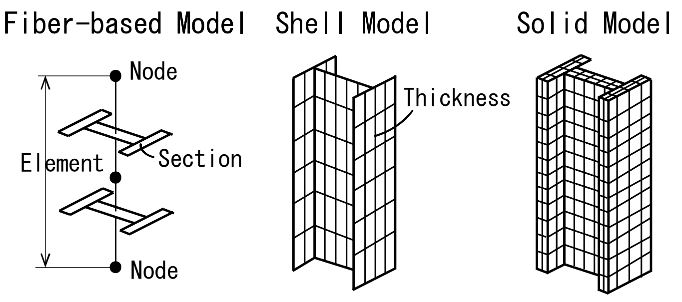

Fig. 1: The types of finite element models used in structural mechanics

The authors have developed a method for constructing a fiber-based model from point cloud data and applied a case of sway bracing located at the end support of a steel truss bridge in the structural experiment (Hidaka et al., 2023). The numerical result based on the fiber-based model constructed by the proposed method reproduced the experimental result very well. It is interesting to note that the model yields a better result than an analytical model manually constructed from the drawings. The point cloud based model can reflect accurately the state of a structure as it is. A real structure cannot avoid initial imperfections within tolerance.

In this paper, the modeling method is extended to a whole truss bridge. A semi-automatic procedure is proposed and developed to construct a finite element model from the point cloud data of the entire side span of a through-type truss bridge. To verify the validity of the model, a model created manually from drawings was also prepared, and the response values were compared under the same loading conditions.

2. CASE STUDY

A two-span continuous through-type truss bridge in Aichi Prefecture, Japan, was measured in March 2023. A photograph of the bridge is shown in Fig. 2(a). The bridge length is 136.9m with a span length of 2@67.9m. A full width is 14.3 m with sidewalks on both sides. The effective width of the roadway is 7.5 m and that of the sidewalk is 2.0 m without width widening. A slab thickness is 200 mm with a pavement of 80 mm thickness (roadway) and of 30 mm thickness (sidewalk). In addition, the bridge is straight and has a symmetric cross slope. A general bridge drawing is shown in Fig. 2(b).

In acquisition of point cloud data of the entire P4-A2 span, the stationary laser scanner (Leica RTC360, resolution: 3mm@10m, accuracy: 1.9mm@10m) was used from the beneath of the girder and from the road surface. The number of points in the point cloud was about 1 billion. Furthermore, the handheld laser scanner (HandySCAN BLACK™ Elite, resolution: 0.05 mm@30 cm, accuracy: 0.025 mm@30 cm) was used to measure the detailed geometry of the parts of lower chords, braces, main girders, and lower lateral bracing. The lower chord, main girder, and lower lateral bracing were measured for the member closest to the abutment due to on-site restrictions, and two braces (two different cross-sectional shapes) were measured for the member closest to the pier (fixed bearing). The number of points in each point cloud was approximately 0.3 to 1.5 million. The point cloud data is shown in Fig. 2(c). The total measurement time was approximately 3 hours. The coordinate system was set so that the x-axis is along the longitudinal direction, the y-axis is transverse direction, and the z-axis is along the height direction. Table 1 shows the dimensions of each member components. Measured values, data in the as-built drawings and data by the handheld laser scanner are given.

The bridge is a two-span continuous bridge, but due to on-site restrictions, only P4-A2 span were measured; to interpolate the parameter of P3-P4 span, the altitudes of fulcrum at both ends were measured with a total station.

3. PROPOSED METHOD

A computer program is developed to generate fiber-based models for numerical analysis from point cloud data obtained in Chapter 2. To construct a fiber-based model, nodes along an axis passing through a center of each member, elements connecting the nodes, a cross-sectional geometry of each element, and other material and loading conditions are required.

3.1 Creating nodes and elements for a fiber-based model from a point cloud

In the first step, nodes and elements are created from point cloud data. In this step, taking advantage of the fact that braces of the truss bridge are connected to many members (such as upper and lower chords, upper and lower lateral bracings, and cross beams), nodes, the central axes of the braces are extracted from the point cloud data of the entire bridge, and the nodes and elements of the fiber-based model are created by making the points of intersection between the central axes of adjacent braces as grid points.

First, point cloud data of the entire bridge (Fig. 3(a)) is sliced along a longitudinal direction (in this case, the x-axis direction) from an abutment position at small intervals. A cross-sectional point cloud is obtained as shown in Fig. 3(b). By grouping points in the cross-sectional point cloud based on the Euclidean distance (Ester et al., 1996), point groups of cross sections of each member (such as upper and lower chords) are separated. Centroids of these cross sections correspond to a center axis of each member, and if continuing to slice, candidate points for the center axis of the members are created as shown in Fig. 3(c). If location of centroid is obtained by a simple average method, it is biased by the density of point cloud data. To avoid the bias, cross-sectional point cloud is converted to polyline with the convex hull (Preparata and Hong, 1977) method and a centroid is obtained using an image processing algorithm.

Next, central axes are obtained from the candidate points for the center axis using the RANSAC method (Fischler and Robert, 1981). In the above procedure, however, central axes of other members than braces are inevitably included. The central axes of braces can be extracted by using a threshold value method based on the fact that they extend in the x- and z- directions. To create intersections of the central axes of the adjacent braces, the central axes are sorted as x-coordinates of the center points in the axes. When the two lines are in a twisted position, the intersection is defined here as a midpoint of a line segment that is orthogonal to two lines and has the shortest length. After creating the grid points, nodes are sampled at equally spaced intervals along the line segment connecting the two grid points, with the specified number of nodes. For the upper lateral bracing, its grid points are located at the center of the upper chords.

Since grid points, nodes, and elements of main girders cannot be created from grid point of braces, they are created additionally. Fig.4 shows a summary to create grid points of main girders. A cross-sectional point cloud perpendicular to longitudinal direction at a location of a cross beam is obtained. Points within 1 m of the upper side of a line connecting grid points of lower chords (bottom horizontal line in Fig. 4) are extracted and divided point groups of main girders and others based on Euclidean distance. To extract main girder lines, the divided into point groups are converted into direction vectors by using principal component analysis and only the z- direction vectors are extracted as main girder lines (blue vertical lines in Fig. 4). Intersections of main girder lines and a line connecting grid points of lower chords are grid points of the main girders. To account for the possibility that grid points cannot be created at a few of cross beam positions, the average value of the created grid points was calculated. After creating grid points, if there is a cross beam position where the grid points cannot be generated by the above procedure, the calculated average value is applied.

3.2 Obtaining a cross-sectional geometry of each member for a fiber-based model from a point cloud

In the second step, once the nodes and the elements have been created, the next step is to obtain a cross-sectional geometry to be applied to the elements. In finite element models, a cross-sectional geometry is represented by a collection of rectangles as shown in Fig. 5. The rectangle is defined by the coordinates of a start and an end point and its thickness. The coordinate system of the cross section must be converted to a two-dimensional coordinate system (such as u-v coordinate system) with the origin at the position through which the element axis lines pass.

Cross-sectional geometry is obtained using cross-sectional point cloud perpendicular to a direction vector of the element passing through the midpoint of the element. Because point cloud measured by the stationary laser scanner (accuracy: 1.9mm@10m) is difficult to ensure accuracy of plate thickness, representative cross-sectional geometry is obtained from the point cloud data measured by the handheld laser scanner (accuracy: 0.025 mm@30 cm), and is applied to all the elements of the corresponding member. In addition, for the upper chords, the upper lateral bracing, and the cross beams which could not be measured by the handheld scanner due to on-site restrictions, the vertical and horizontal scales of cross sections of other members with similar shapes were adjusted. Specifically, the cross-sectional geometry of the upper chords is a vertically inverted that of the lower chords, the upper lateral bracing applies the I-section of the braces, and the cross beam applies to the cross-sectional geometry of the main girder. Table 2 shows the relation of them. For members whose entire surface could not be measure by the handheld laser scanner due to on-site restrictions, the symmetric center point of the cross-section at the same position was obtained from the point cloud data collected by a stationary laser scanner. Subsequently, the cross-sectional geometry was determined by duplicating the measured portion through rotational symmetry, utilizing the point symmetry of the cross section. In the following, the methods of obtaining cross-sectional geometry are explained according to the type of geometry.

Table 2: The relation of applying cross-sectional geometry of members that could not be measured by the handheld laser scanner

Unscanned member	Upper chord	Upper lateral bracing	Cross beam
Referenced member	Lower chord	Brace (Tension)	Main girder
Cross section			
3.2.1 Open cross-section (I-shape and T-shape)

Midpoints of all point pairs in a cross-sectional point cloud are created (Fig. 6(a)), and the midpoints that are not on the cross-sectional point cloud are extracted as points of candidate centerlines. These are converted to straight lines by using RANSAC (Fig. 6(b)), intersection points of these lines and the cross-sectional point cloud are starting and ending points (Fig. 6(d)), and its thickness is obtained by doubling an average of the shortest distances from the cross-sectional point cloud (Fig. 6(c)).

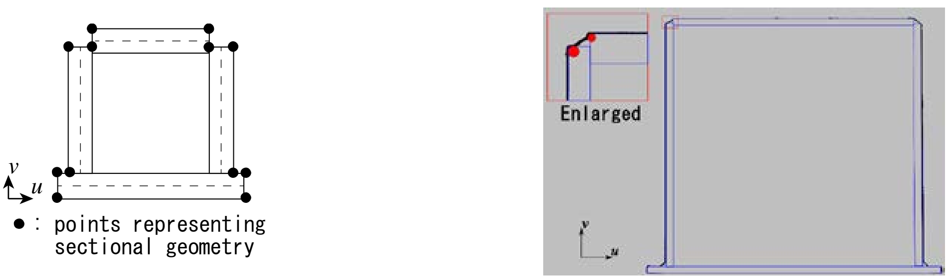
(a) Finding midpoints (b) Creating center lines from (a)

(c) Calcurating plate thickness (d) Calcurating starting and ending point

Fig.6: Obtaining parameters of open-cross section

3.2.2 Close cross-section (quadrangle-shape)

The algorithm in 3.2.1 cannot be applied to a square cross section because back sides of plates cannot be measured. Therefore, as shown in Fig. 7(a), cross-sectional geometry is constructed by finding points at corners. Since corner points and joint positions are rounded, as shown in Fig. 7(b), corner points can be found by taking a local area at all points of the cross section and extracting the area where the radius of the circle is smaller when fitting it to a circle. For areas where thickness cannot be measured, such as the web and the upper flange of the lower chord, general plate thicknesses are used.



(a) Cross-sectional geometry of quadrangle-shape (b) Finding corner points by fitting to circles

Fig.7: Getting parameters of close-cross section

3.3 Creating a slab model as a shell model

Only in a case of modeling for a slab, to reproduce load sharing of live load accurately, a shell model is constructed. It is connected to main girders and cross beams in the fiber-based model with springs. As shown in Fig. 8, a position of a slab is determined by finding the difference in z-coordinates between the main girder grid points and a centerline of the slab, and offsetting the z-coordinates from the main girder grid points by that value. In the same way as in Sec. 3.2.1, a centerline of a slab is obtained by finding midpoints of all point pairs in a cross-sectional point cloud of a slab and extracting points of a candidate centerline that are not on the cross-sectional point cloud. This is converted to a straight line, and the average of the shortest distances from the cross-sectional point cloud of the slab is doubled to obtain the slab thickness. As the slab thickness obtained in the above procedure includes the pavement portion, the thickness after substracting a typical pavement thickness of 80mm is used.

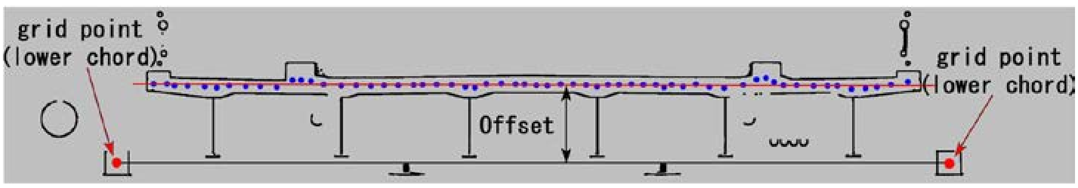


Fig. 8: Obtaining offset and thickness parameter of a slab

3.4 Implementation

The proposed methods were applied to the point cloud data in Chapter 2. Due to memory limitations, the point cloud data measured by the stationary laser scanner was down-sampled from approximately 1 billion points to approximately 200 million points (3 mm pitch). Only the nodes and elements in P4-A2 span were created from the point cloud data, and those in P3-P4 span were extrapolated by duplicating the linearly stored height of the grid using the altitudes of fulcrum difference. Table 3 shows the development environment.

The program that implements the proposed method is divided into several phases because it requires several manual operations in the process. The program flow is shown in Fig. 9.

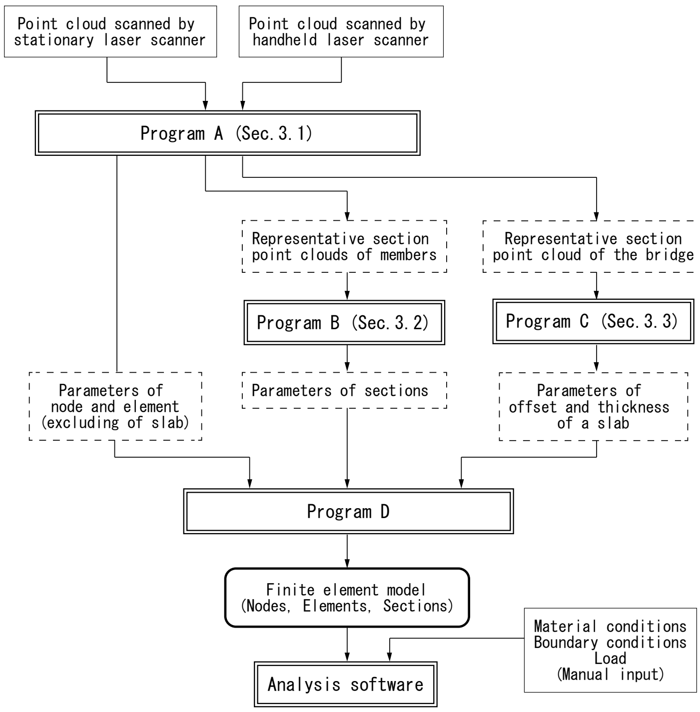

Fig. 9: The flow of implement for the proposed method

First, the nodes and the elements excluding for slab are obtained by inputting the point cloud measured by the stationary laser scanner and the handheld laser scanner into Program A, which performs the procedure described in Sec. 3.1. To obtain the cross-sectional geometries, the representative cross-sectional point cloud of each member is output. Furthermore, to obtain the nodes and the elements of the slab, the representative cross-sectional point cloud of the bridge perpendicular to longitudinal direction is output.

Next, in order to obtain the cross-sectional geometry, the missing part is manually compensated, and the scale is adjusted to apply to other members. After that, they are input to Program B, which performs the processing described in Sec. 3.2.

After the slab points are manually extracted from the cross-sectional point cloud data, they are input into Program C that performs the procedure described in Sec. 3.3.

Finally, the output results of Programs A, B, and C are input to Program D, which outputs the finite element model. Once the nodes, elements and cross-sections are obtained in this way, the material and boundary conditions are manually specified and entered into the analysis software.

Excluding manual operations such as preliminary down-sampling and correction of missing points in the cross-sectional point cloud, it took 35 minutes to input the stationary laser scanner point cloud, create the KD search tree, slice the cross-section in the 100 mm pitch in the longitudinal direction, divide them using the Euclidean distance, and obtain the centroid of each member cross-section. In addition, it took 1 minute to extract the central axis of the braces from the point cloud of the centroid, 6.5 minutes to obtain the grid point position of the main girder, and 1 minute per section to obtain the end point and plate thickness of the cross section. The remaining processing was completed in less than 1 second.

The generated finite element model is shown in Figs. 10. (a) is the framework element, and (b) is the cross-sectional geometries reflected on it.

4. RESULTS AND DISCUSSION

4.1 Results of repeatability analysis

The response values of nonlinear analysis were analyzed by applying progressively increasing dead and live load according to the Japanese Specification for Highway Bridges (Japan Road Association, 2017). Dead load is loaded to whole of the bridge and live load is loaded as Fig. 11. The material conditions and reinforcement of the slab were set based on actual bridge design experience. To verify the validity of the model, the same loading conditions were applied to a model created manually from drawings. Hereafter, the finite element model generated by the proposed method will be referred to as the "point-cloud-model" and the model from the drawing as the "drawing-model".

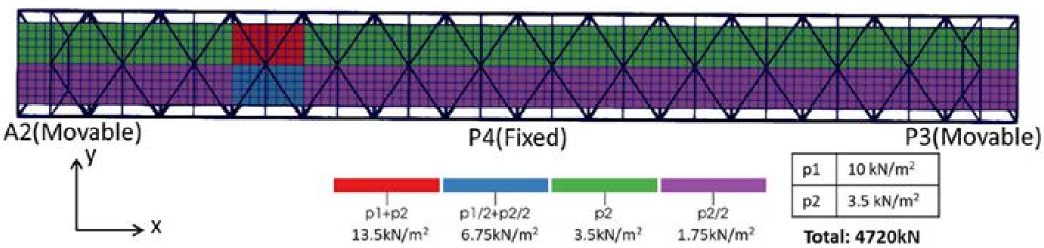

Fig. 11: Live load

The displacement of the point-cloud-model was close to that of the drawing-model within the design load that is the sum of dead and live load. Additionally, when examining the strain contour and deformation diagrams for the design load (Fig. 12), the deflection of the bridge exhibited a nearly identical behavior between the two models. However, with a load larger than the design load, the response value of point-cloud-model was different to the drawing-model (Fig. 13(a)). As the deformation diagram of the point-cloud-model for the 1.3 times of the design load (Fig. 13(b)), one upper chord at left-side in the center span of P4-A2 was extremely deflected. Consequently, a discernible variance arose between the response of the point-cloud model and that of the drawing model.

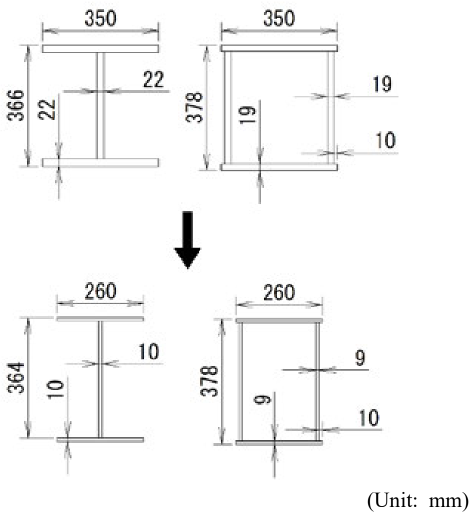
4.2 Discussion

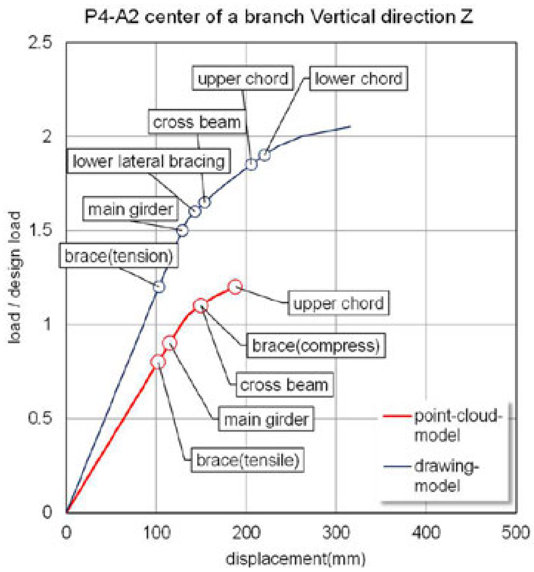
To improve maintenance efficiency, a method was developed to semi-automatically construct a fiber-based model (the slab is a shell model) that reproduces the structure of a truss bridge from point cloud data. When the drawing-model was created manually from drawings, it took several days to read the dimensions and connections of the members and input them into the software. In particular, the most time-consuming step was the input of cross-sectional geometries due to variations in plate thickness. The point-cloud-model, on the other hand, took about three hours to measure the point cloud data and less than one hour to generate the model from the point cloud data. Other manual work, such as processing noise and filling missing portions in the cross-sectional point cloud, can still be completed in 12 to 24 hours. The proposed method is expected to contribute to efficient maintenance and management.

However, there are several issues related to the accuracy of elemental axis construction and the limits to applicable structures.

The point-cloud-model demonstrated a response closely aligned with the drawing-model under the design load. However, deviations emerged with a load larger than the design load. One plausible explanation stems from the inherent variability in plate thicknesses and member dimensions among upper chords, lower chords, braces, and lower lateral bracings unlike the brace panel in the previous research (Hidaka et al., 2023). The point-cloud-model encompasses disparities in cross-sectional geometries, as the stationary laser scanner's limited measurement precision and the handheld laser scanner's constrained range preclude the complete capture of all such geometries. Notably, the upper chord's cross-sectional geometry, pivotal for truss bridges experiencing significant forces, eludes handheld scanner measurement and significantly influences analytical outcomes, as evident in Fig. 13(b). Furthermore, the substitution of a representative, thinner cross-sectional geometry for the braces at the span's center, as described in Fig. 14(a), led to a marked reduction in overall bridge stiffness (Fig. 14(b)). These findings underscore the notion that a uniform approach to determining cross-sectional geometries across members with varying plate thicknesses sacrifices precision. Thus, an enhanced methodology is imperative to refine cross-sectional geometries and achieve heightened accuracy.



(a) Cross-sectional geometry



(b) Load-displacement curve (open circles represent the yield points of individual members)

Fig. 14: The case of braces with thinner cross-sectional geometry

In the previous research (Hidaka et al., 2023), the fiber-based modeling approach was employed for simulating sway bracing. This involved adjusting node positions to accurately replicate member bending by utilizing centroids within localized regions. The incorporation of this technique successfully accounted for initial irregularities, resulting in a response that closely aligned with the actual structural behavior. However, in the present case, this method couldn't be employed due to its limited accuracy in centroid generation. This limitation stemmed from numerous factors, including the presence of numerous gaps in the point cloud data as well as the inclusion of extraneous points within local regions intended for centroid calculation. As such, there exists a pressing need to enhance the methodology in order to effectively surmount the aforementioned challenges. The proposed method is based on an algorithm that uses advantage of the fact that the bridge is a straight and has no widening and same truss spanning. It is required to improve the method to extend to curved or width extension bridges. A longitudinal direction of curved bridges and width widening may be obtained by tracing line of curb stones and white lines, for example. In addition, it may be effective to supple missing geometries and dimensions by using information of similar bridges.

5. CONCLUSIONS AND FUTURE WORK

In this paper, a method is proposed to semi-automatically generate a finite element model for practical use from a point cloud data for the entire of steel truss bridge without using drawings. The findings are as follows:

- The method to accurately obtain the geometry and member dimensions of the entire bridge was proposed by using stationary and handheld laser scanners.

- A program to construct a finite element model from a point cloud data was developed and its usefulness was demonstrated.
- The proposed method showed the response value is close to the drawing model within the design load, but it is required to improve detailed analysis results with more than the design load. A possible reason for this is that the representative section was uniformly determined for members although they have non-uniform thickness.

In the future, we will address the issues of dealing with various plate thickness and curved bridges, and interpolation of unmeasured points using other dimension data and other parameters, such as road alignment. In particular, for applying appropriate cross-sectional geometries, the following two proposals are seen to be effective and will be implemented.

- A method to determine appropriate members for measurement by using a handheld scanner will be developed. It is useful to estimate the members that are subjected to large cross-sectional forces according to the structural characteristics of a bridge type and span. Additionally, numerical analysis enables us to determine the members whose cross-sectional dimensions require high accuracy, such as the upper chords and diagonals in this particular project.
- We are in the process of devising a methodology to extrapolate cross-sectional geometries from point cloud data measured by a stationary laser scanner. Despite the inherent precision limitation to a few millimeters associated with the stationary laser scanner's point cloud, it facilitates the extraction of crucial details concerning member classification, cross-sectional profiles, and member lengths. Leveraging this data, an effective approach to determine the suitable plate thickness can be formulated.

A BIM-BASED FRAMEWORK FOR FACILITY MANAGEMENT DATA INTEGRATION IN HERITAGE ASSETS

Carlo Biagini, Alberto Aglietti & Luca Marzi
Department of Architecture, University of Florence

Andrea Bongini
Department of Civil and Environmental Engineering, University of Florence

ABSTRACT: *The operational phase of a real estate asset accounts for approximately 80% of the overall investment and management costs throughout the entire life cycle of the building, and the activities of space management and monitoring of building components and systems play a crucial role in ensuring the well-being and health of users. The AECO (Architecture, Engineering, Construction, and Operation) industry is transitioning towards a new framework governed by data-driven processes. In this context, Building Information Modeling (BIM) can support the utilization of big data generated throughout different stages of the building's life cycle, thereby establishing itself as a dynamic repository of information at the center of a constellation of systems used by a Facility Management body to achieve specific objectives (such as CAFM, ERP, BMS, etc.).*

The proposed study aims to define a processing framework for the collection and management of data aimed at the implementation of DT of existing real estate assets, created based on the integration between BIM platforms and IoT technology oriented to subsequent developments of big data analytics and AI applications. The objective is to support in the operational phase of buildings the decisions of the various operators involved in planning scheduled and/or corrective maintenance actions and to generate content, recommendations, best practices by formulating predictive analysis on managed assets. In particular, a critical analysis is made of the various approaches available for the definition of an IT architecture to support IoT reference models, which will find application in the monitoring of some existing assets of the University of Florence's real estate managed by the Building Area, digitally implemented on a BIM platform. The contribution is part of a broader research activity carried out as part of the PNR Project, "BIM2DT. BIM-to-Digital Twin: information management to support decision-making in the building life cycle."

KEYWORDS: *Facility Management; HBIM; Digital Twin, IoT.*

1. INTRODUCTION

For several years now, the digitization of the construction process has been a primary objective of governments, organizations and in general stakeholders in the AECO sector (Daniotti et al., 2022) to reconfigure a production sector that, with different graduations in different countries around the world, lags historically behind the manufacturing sector in gathering the benefits that technological and process innovation through Information Technology can return in terms of efficiency, competitiveness and economic, environmental and social sustainability.

In particular, the introduction of regulations at the national and international level regarding the information management of the construction process with Building Information Modeling (BIM) tools and methodologies in public supply, service, and works contracts has necessitated the redefinition of structured and planned flows of data and information exchange between the various stages of the delivery and operation process of real estate assets. More recently and in line with the Industry 4.0 approach, many organizations and business operators are orienting their decision-making processes toward data-driven strategies especially in the management of complex estate assets (Mêda et al., 2021). In fact, the operation phase engages about 80 percent of the total investment and management costs of a building's life cycle (Volk et al., 2014), and the management and monitoring activities of spaces, building components, and facilities play a decisive role in ensuring the well-being of users and health and safety in living and working places. The use of BIM in Facility Management for an organization therefore becomes a key step in improving and optimizing the operation and maintenance activities of managed assets and, in a broader perspective, in contributing significantly to achieving the goals set by the European Green Deal and Sustainable Development Agenda 2030 (Ciribini et al., 2016; Mirarchi et al., 2018).

Currently, information management of an existing asset in the operation phase is conducted through different tools and platforms, including Computerized Maintenance Management System (CMMS), Computer-Aided Facility

FUP Best Practice in Scholarly Publishing (DOI 10.36253/fup_best_practice)
Carlo Biagini, Alberto Aglietti, Luca Marzi, Andrea Bongini, *A BIM-Based Framework for Facility Management Data Integration in Heritage Assets,* pp. 1159-1170, DOI 10.36253/979-12-215-0289-3.115

Management (CAFM), Building Automation System (BAS), Integrated Workplace Management System (IWMS). However, there is a lack on creating an integrated system to manage multiple information distributed on different databases. In this context, BIM can act as a centralized repository that can hold all the information about the building and its surroundings (Qiuchen Lu et al., 2019). In fact, much of the information produced in the design and construction phases is lost and only a small portion is passed on to the next operation phase usually in the form of spreadsheets with 3D information added according to client specifications. This loss of information can be avoided, or at least reduced, through the use of standardized and shared practices and procedures among the different actors in the supply chain, but also through open and interoperable exchange formats (Patacas et al., 2015). This type of information, which we can define as "static", can also be combined with "dynamic" information from the collection of heterogeneous data, both in terms of protocols and formats, during the use and management phase of the real estate.

In particular, the rapid spread of the Internet of Thing (IoT) in daily activities has made available real-time data and information on many aspects of the operating conditions of buildings and their surroundings, which can be usefully employed by facility managers to improve building performance management, reduce energy consumption, optimize routine and extraordinary maintenance operations and increase user satisfaction and well-being. All this leads to the creation of a "digital twin" (Boje et al., 2020) of the building aimed at the management of existing assets, enabling a two-way exchange of information between the physical and digital worlds.

This contribution represents a first outcome of a wider research activity within the PNR Project, *"BIM2DT. BIM-to-Digital Twin: information management to support decision-making processes in the life cycle of buildings"*, which intends to define an operational framework for the collection and management of data aimed at the implementation of DTs of existing real estate assets, created on the basis of the integration between BIM platforms and IoT technology oriented to subsequent developments of big data analytics and AI applications. The objective is to support the decisions of the various operators involved in the planning of scheduled and/or corrective maintenance actions in the operational phase of buildings, and to generate content, recommendations, and best practices by formulating predictive analyses on managed assets. In particular, it is proposed a critical analysis of the various approaches available for the definition of an IT architecture that supports an IoT reference model, which is structured according to protocols parallel to those that today support the Internet infrastructure. The IoT model thus identified, will find application in some existing assets of the University of Florence's real estate managed by the Building Area, digitally implemented on a BIM platform.

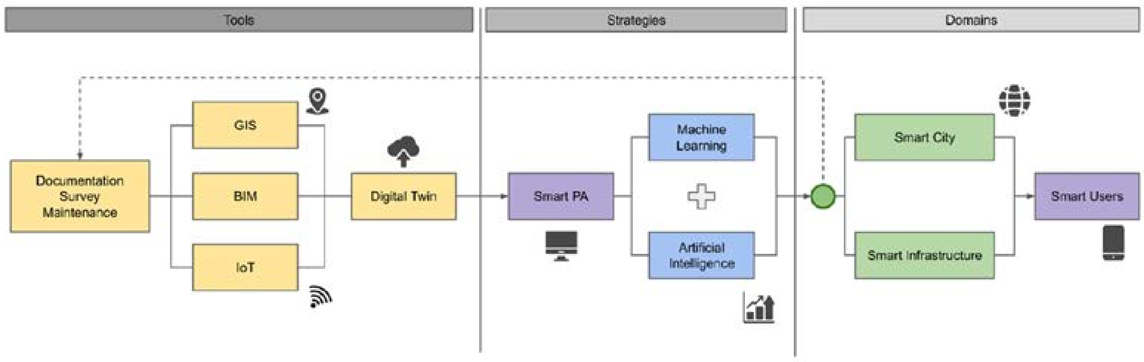

Fig. 1 – Conceptual outline of the BIM2DT research project theme

2. INTERNET OF THINGS FOR THE MANAGEMENT OF BUILT ASSETS

Buildings are complex systems, from which a large amount of data (environmental, comfort, security, ...) can be collected by Building Management Systems (BMS). This data, which until now was stored locally, is moving to a cloud environment, increasing the adoption of IoT solutions. The BIM methodology itself is evolving with web-based and data-driven solutions. A major problem is the heavy reliance on native solutions that confine facility managers to proprietary platforms and do not provide the opportunity to develop evaluations across multiple systems. The information associated with BIM elements is also usually unusable outside modelling environments, and only a few applications have started to integrate data from different types of sensors. With the increasing demand for smart buildings, there is therefore a need to develop applications capable of accommodating heterogeneous data, which are transmitted according to different formats, protocols and languages. The starting point, however, must be an understanding of the infrastructure that revolves around the world of the Internet of

Things and how this can be used to improve and implement the semantic content of information models produced using BIM methodology.

2.1 Internet of Things Model

The term Internet of Things (IoT) was first coined in 1999 by British engineer Kevin Ashton, co-founder of the Auto-ID Center at MIT (Ashton, 1999). In 2001, the MIT Auto-ID Center presented its vision on the topic of IoT, which the International Telecommunication Union (ITU) later drew on in its 2005 Internet Report. The latter defines the term IoT as *"a global infrastructure for the information society, enabling advanced services by interconnecting (physical and virtual) things based on existing and evolving interoperable information and communication technologies"* (Overview of the Internet of Things, 2012). The Internet Society instead speaks of IoT technologies as *"scenarios where network connectivity and computing capability extends to objects, sensors and everyday items not normally considered computers, allowing these devices to generate, exchange and consume data with minimal human intervention"*. Beyond the definitions, of which there is still no universal one (Rose et al., 2015), we can conclude that around the topic of IoT, new scenarios are developing concerning the tools and methods of digital management of building assets.

When we speak of the Internet of Things, we are referring to any type of smart object capable of connecting to the Internet via a wired or wireless connection (through a dual communication capacity: M2M, machine-to-machine, and M2H, machine-to-human), and consequently having an active role within the communication processes. In order to be able to define a smart object, however, we need certain fundamental characteristics: the sensing component, i.e., the ability to gather information from the real world or to perform an action following an input, a unique identifier to identify the source from which the data is received, a connection to the Internet, for communication and notification of the information, and finally, one or more software platforms for the analysis and processing of the data collected

The term IoT, in its simplest form, can thus be considered as the intersection between the internet infrastructure, objects and data. Other more complex definitions, however, lead to the inclusion of standards and processes, as these technologies make it possible to connect objects to the internet in order to exchange data according to industry standards that guarantee interoperability and enable the execution of mostly automated processes. We thus find ourselves having to manage not only an exchange of information between individuals but also between single devices. The potential applications of this technology are many, from smart home to smart cities, smart healthcare, smart retail or even connected cars.

The main question to be asked is therefore how it is possible to achieve this type of interaction between very often heterogeneous systems and tools and to provide a simple and immediate service for the end user, both in the working environment and in everyday life actions. To address these problems, communication standards were created for specific areas, corresponding to the heterogeneous application areas of the IoT. We may, for example, have the need to have efficient communication with minimum packet loss but at the same time have a latency that allows communication to be defined almost in real time, or we may have the need for a less reliable protocol but with the peculiarity of operating on low performance and low power hardware. Each protocol offers certain functionalities or combinations of functionalities that make it preferable to others. Recurring factors that determine the preference of one protocol over another include geographical location, power consumption, physical barriers and hardware cost.

The inapplicability of classical communication protocols even in the context of IoT devices depends on the minimal requirements in terms of hardware and power consumption required by these devices. It has therefore become necessary to develop new technologies that do not require complex computational efforts for sometimes very simple devices. The fundamental objective of an IoT architecture is to connect the physical world with the digital one, and over the years many entities, both international organizations and individual developers, have implemented new communication mechanisms, leading us today to have a wide choice of protocols at our disposal. Protocols that, however, were not designed to interact with each other, as they are based on different concepts and ideas. International organizations therefore, in order to prevent the vertical fragmentation of different commercial solutions, have set themselves the goal of defining open communication standards and mapping the traditional IP-based stack to the new IoT concept, understood as a network of heterogeneous devices connected to each other. Cisco, IBM and Intel have proposed an IoT reference model (fig.2) to standardize the concepts and terminology used in the IoT world based on seven levels. These levels are represented by:

1. physical devices and controllers: these are terminals that send or receive information;
2. connectivity and communication between objects and networks: information must flow both horizontally between objects within the network, and vertically between different networks; gateways may be introduced for older devices not equipped with IP;
3. edge/fog computing: is the data processing layer closest to the network with minimum latency from the data collection point;
4. data accumulation: is level of data collection and storage; converts data-in-motion to data-at-rest;
5. data abstraction: level of data aggregation from multiple devices and simplify data access to the application by creating schemas and data views;
6. applications: provide the desired output through the interpretation of available information;
7. collaboration and processes: level of involving people and business processes to make IoT application useful.

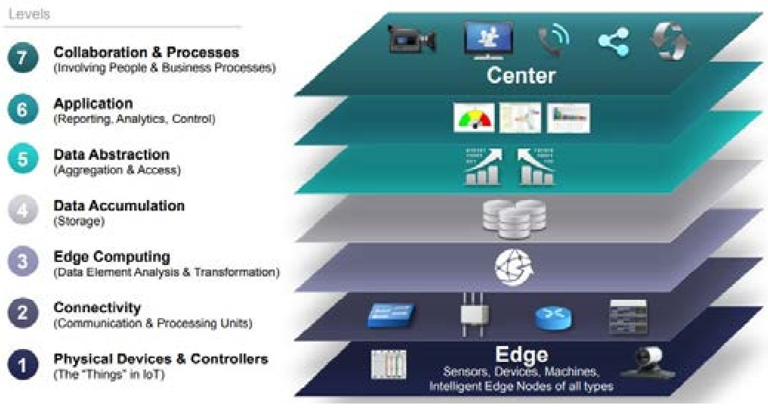

Fig. 2: IoT Reference Model presented at IoT World Forum by Cisco, IBM and Intel

This reference model follows the subdivision already used for the Internet, namely the OSI (Open Systems Interconnection) model, which consists of seven layers grouped into three media layers (physical layer, link layer and network layer) and four host layers (transport layer, session layer, presentation layer and application layer). Technologies such as Bluetooth and Wi-Fi use the lower communication layers while DDS or MQTT use, for instance, the application layer.

2.1.1 IoT Devices

The first elements that make up an IoT network are the devices themselves, which can be grouped according to their characteristics. According to the ITU, hardware platforms can be classified according to their computational and connection capabilities into three classes (Bormann et al., 2014):
a) class 0, devices very limited in memory and information processing capabilities that sometimes do not even have the necessary resources to communicate directly with the internet in a secure manner and therefore rely on other devices such as proxies, gateways or servers;
b) class 1, devices with certain limitations and that cannot talk to other nodes on the internet that use "a full stack protocol as HTTP, TLS and related security protocols and XML-based data representation". However, they are able to use a specific protocol stack for limited nodes such as COAP and participate in the conversation without the use of gateways;
c) class 2, less limited devices capable of supporting the same protocol stack as servers or notebooks. They can still benefit from the use of lighter and less energy-consuming protocols. Devices such as Arduino and Raspberry microprocessors fall into this class.

From this classification, it can be seen that not all devices are able to connect to the Internet or process the collected data in situ. To facilitate the transit of information to the end platforms and to reduce the computational load, gateways are introduced, i.e. elements used, not necessarily, to establish communication from one device to another or to connect IP-based devices, which are not able to connect directly to the cloud environment. The data collected by IoT devices is in this case transmitted to a gateway, processed in the perimeter devices and then transmitted to the cloud. The use of gateways reduces latency and transmission size and also offers a higher level of protection to data-in-motion. When data is processed locally by the same device that collects it, it is called *edge computing*; when it is sent to a gateway for peripheral processing, it is called *fog computing*; and when it is sent and processed within a cloud-based repository, it is called *cloud computing*. IoT applications can then be integrated with a data analytics engine for analyzing and customizing the output.

2.1.2 Protocols and connectivity

The concretization of the IoT concept has been made possible by the introduction of communication protocols, the most significant of which are: WSN (Wireless Sensor Networks), used in particular for sensing operations (environmental sensors); RFID, a system based on the use of radio-frequency waves, consisting of tags, readers and a back-end system that allows each ID to be associated with the corresponding physical object and any information relating to it; the NFC protocol, produced by Philips, Sony and Nokia, used to transfer data from one device to another over short distances.

From these communication protocols, all the new standards we use today have developed, which we can group into two main classes, one short-range and one long-range. The short-range, low-power category is usually used for smaller environments such as homes or offices, which can be defined as Personal Area Networks (PAN). It includes technologies such as Bluetooth, NFC, Wi-Fi, Z-Wave and ZigBee. The long-range network category, on the other hand, allows communications up to 500 m with a minimum amount of energy. Within this category we find technologies such as LPWAN, from which proprietary solutions LoRaWAN and SigFox derive, as well as cellular IoT technologies such as NO-IoT, LTE-M and EC-GSM-IoT proposed by 3GPP.

Within a specific network, devices communicate according to a particular type of protocol, i.e. a set of rules that work on different layers of their reference model and according to which data is transmitted and received along Internet backbones. The IoT is thus to be understood as a network that lives in parallel to the traditional protocols used, for instance, for the web (fig. 3)

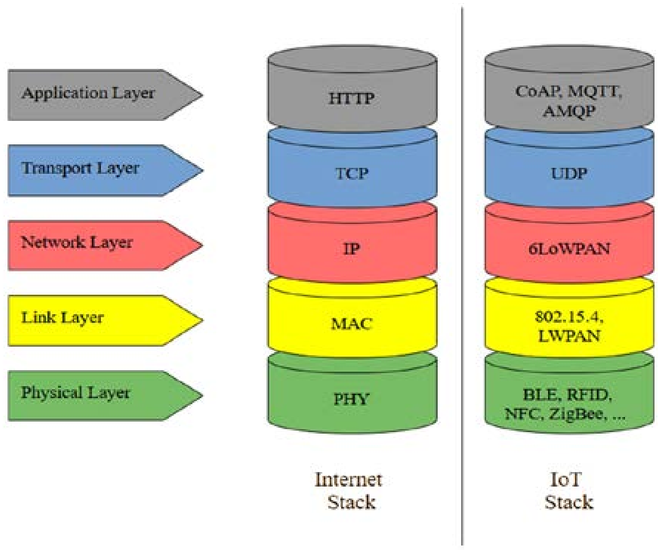

Fig. 3: IoT and Internet architecture

At the **application level**, that is, at the interface between user and device, we find the following protocols:

- CoAP (Constrained Application Protocol) (Shelby et al., 2014), a bandwidth and network constrained protocol designed to bring web functionality to devices with limited capacity. It uses a binary format rather than a text format like HTTP, for whose integration it requires the use of an intermediary (proxy);
- MQTT (Message Queue Telemetry Transport) (Banks et al., 2019), a messaging protocol designed for lightweight computer-to-computer communications, used primarily for low-bandwidth connections to remote locations. It uses an author-subscriber crtiteria and is ideal for small devices that require bandwidth efficiency and battery usage;
- AMQP (Advanced Message Queuing Protocol) (Godfrey et al., 2012), a specification for interoperable messaging for message-oriented middleware (MOM), creates interoperability between messaging middleware. It allows a wide range of systems and applications to interact, creating an asynchronous messaging system complementary to the http protocol.

The **transport layer** enables and protects the communication and transmission of data between different layers; within it we find:

- TCP (Transmission Control Protocol) (Eddy, 2022), the dominant protocol for most Internet connectivity. It provides host-to-host communications by splitting large data sets into individual packets and resending and reassembling packets as needed;
- UDP (User Datagram Protocol), a communication protocol that enables process-to-process communication and runs over IP. UDP improves data transfer rates over TCP and is optimal for applications that need lossless transmissions of information.

The **network layer** helps individual devices communicate with the router; in this layer we find:

- IP (Internet Protocol), many IoT protocols use IPv4, while newer implementations use IPv6. This recent IP update routes traffic over the Internet and identifies and locates devices on the network.
- 6LoWPAN (IPv6 over Low Power Wireless Personal Area Networks) (Kushalnagar et al., 2007), is an IoT protocol conforming to the IEEE 802.15.4 specification that works optimally with low-power devices with limited processing capabilities. It allows the creation of wireless networks with devices that use the IP protocol for communication, through an intermediate layer placed between the MAC and network layers.
- BACnet (Building Automation and Control Network), is a protocol developed by ASHRAE, and reported within ISO 16484-5, for managing building automation systems. Its goal is to create application protocols adaptable to all building control needs and transportable from one of the existing physical network technologies.

The **data layer** (MAC) is the part that transfers data within the system architecture, identifying and correcting errors found in the physical layer; within it we find:

- IEEE 802.15.4, an IEEE standard based on radio waves for a low-power wireless connection. It is used with Zigbee, 6LoWPAN and other standards to create embedded wireless networks;
- LPWAN, networks allow communication between distances of 500 meters to more than 10 km in some locations. They arise to meet the special needs of the many applications that require wider coverage but do not need high bit-rates. The LoRaWAN network, developed by the LoRa Alliance, is an example of an LPWAN network optimized for low power consumption.

Table 1: Most common IoT protocols

Protocol	Standard	Frequency	Distance
NFC	ISO/IEC 18092, ISO/IEC 21481, ISO/IEC 28361	13.56 MHz (universal frequency)	Max 10 cm (with other frequency you can obtain different distances)
Wi-Fi	802.11n (2009) – 802.11ac (2014)	2.4 GHz – 5GHz	50 m (indoor) – 100 m (outdoor)
BLE	Bluetooth v.5 (based on IEEE 802.15.1)	2.4 GHz	50 m
ZigBee	ZigBee 3.0 (based on IEEE 802.15.4)	2.4 GHz	10 – 100 m
Z-Wave	Z-Wave Alliance (proprietary technology)	800 – 900 MHz	10 m (indoor) – 100 m (outdoor)
6LoWPAN	Based on IEEE 802.15.4	Multiple physic support	20 m
LoRa	LoRaWAN (ITU-T Y.4480)	ISM 868/(915) MHz	10 km

The **physical layer** is the communication channel among devices in a specific environment; part of this layer are:
- Bluetooth, developed by Ericsson in 1994 and defined by the IEEE 802.15.1 standard, is an alternative to wireless information exchange using radio waves. It is optimal for high-speed data transfer up to 10 m. BLE (Bluetooth Low Energy) is a newer implementation that significantly reduces power consumption and cost while maintaining a connectivity range similar to that of classic Bluetooth;
- Ethernet, a wired connection that provides a fast data connection with low latency;
- LTE (Long-Term Evolution), a wireless broadband communication standard for mobile devices and data terminals. The LTE standard increases capacity and speed of wireless networks and supports multicast and broadcast streams;
- NFC (Near Field Communication), a set of communication protocols using electromagnetic fields that allows

two devices to communicate at a maximum distance of 4 cm. When the two devices are brought close together, a peer-to-peer network is created that allows both to exchange information. They are typically used for contactless payments for mobile devices, ticket creation and smart cards;
- PLC (Power Line Communication), communication technology that allows data to be sent and received over existing power cables. It allows an IoT device to be powered and controlled over the same cable;
- RFID (Radio Frequency IDentification), uses electromagnetic fields to track otherwise unpowered electronic tags. Compatible hardware provides power and communicates with those tags, reading their respective information for identification and authentication;
- Wi-Fi, standard 802.11, is a standard in homes and offices. It does not always fit all scenarios because of limited range and 24/7 power consumption;
- Z-Wave, mesh network that uses low-energy radio waves for appliance-to-appliance communication. Being a proprietary technology, it is based on a different architecture on all layers;
- Zigbee, developed by the ZigBee Alliance, now Connectivity Standards Alliance, IEEE 802.15.4-based specification for a suite of high-level communication protocols used to create personal local area networks with small, low-power digital radios. It is typically used in the context of the smart home where we find battery-powered devices. The total uptime is limited and most of the time the device is in a power-saving state (sleep mode);
- Thread, developed by Nest and other companies, is based on the 6LoWPAN protocol for a mesh connection;
- Matter, an open standard for the Smart Home developed by the Connectivity Standard Alliance with the aim of improving the compatibility and security of IoT devices.

2.2 BIM and IoT

In recent years, the massive development of digital technologies for acquiring data from variously deployed sensors for a multiplicity of uses and purposes, both within buildings and in the urban environment, has necessitated an expansion of the traditional semantic domains of the construction industry with particular reference to BIM-based information management processes (He et al., 2021; Tomalini, 2022). Created initially as a method for exchanging data between different silos, BIM today is increasingly being approached with concepts such as big data, IoT, and AI, which are seen as potential solutions for automation and inclusion of broader environmental contexts. The evolution of interoperability solutions, from ISO STEP to IFC to IFCOWL, is leading to the transformation of a static BIM to a new web-based paradigm.

In fact, the information model must be able to accommodate and store not only data-at-rest, produced in the survey and/or design phases, but also to manage data-in-motion, coming in real-time from devices for monitoring the environmental quality of architectural and urban spaces. However, the inclusion of IoT sensors within an asset should only be considered as a starting point for the implementation of a Digital Twin (Sacks et al., 2020). Indeed, there is no single DT solution, as this may vary from time to time based on specific needs, just as its implementation is subject to evolve over time.

Thus, the use of BIM methodology, and its extension to the Digital Twin concept, can bring enormous benefits for those involved in FM as it allows: planning of asset management systems and effective cost estimation; prediction of operational problems and improvement of maintenance activities; increased accessibility and security of information; reduced waste; and more reliable documentation (Singh et al., 2021). On the other hand, for IoT devices, many communication protocols and semantic models are available to support information exchange between devices but there is only partial integration with the IFC schema for the building.

For example, some studies have focused on integrating open protocols such as BACnet and the IFC schema, creating specific MVDs to represent BAS information within BIM models at different stages of the building process (Tang et al., 2020). Even the use of extensions to the IFC schema, however, is still an immature process and provides only limited support for the integration of this information (Wang et al., 2022). In addition, the IFC format is designed for transferring data from one tool to another and is therefore not meant to be dynamically modified or transformed. The definition of Linked Data (LD) and the Web Ontology Language (OWL) has recently tried to address these issues.

Given the limitations of the IFC schema some organizations have begun to develop alternative or complementary data schemes such as the Brick Schema, which provides a semantic description of the physical, logical, and virtual assets within a building and their relationships. This schema is defined using the Resource Description Framework (RDF) and is thus integrable with Semantic Web standards and Linked Open Data. Within it, classes such as sensor or plant-type equipment find broader description, and since version 1.3 the schema also includes support for linking Brick models and the sensor network with communication protocols such as BACnet, facilitating the achievement of a digital twin. An IFC model can contain within it a link to the Brick model via a unique identifier contained within the *IfcLibraryReference* instance, so that an external platform can retrieve information from both schemas.

3. A FRAMEWORK FOR APPLYING DIGITAL TWIN TO BUILT ASSETS

A processing framework is defined for the collection and management of data-in-motion from IoT and subsequent integration with data-at-rest allocated in a BIM-based common data environment, aimed at the creation of a Digital Twin of existing real estate assets, oriented to subsequent developments of big data analytics through AI applications. It is thus intended to support the decision-making processes of the different operators, owners, facility managers, technicians and experts involved in the operational phases of buildings and to be able to plan planned and/or corrective maintenance actions, generate content, recommendations, best practices and formulate forecasts on managed assets. Particular insight will then be conducted for the optimization of integration processes between BIM and IoT in relation to interoperability and data-set exchange issues in the creation of DTs, and to enable real-time visualization of monitoring data from BIM models for Facility Management.

The proposed approach involves the implementation of BIM models from the data and information held by the owner, which manages the real estate assets, whether of geometric (2D/3D), alphanumeric or documentary type, enriched with the additional semantic content useful for the subsequent management phases. Upstream of this operational phase, however, an in-depth analysis must be developed of the activities carried out within the same estate property concerning the maintenance and functionality of the assets in terms of actions carried out, resources and available infrastructure, aiming to define the organization's information requirements (OIR), to which all the information exchanges that will govern the various management processes must be informed. This should converge in the compilation of a BIM Guide for the implementation of the organization's asset information models, which can standardize their delivery processes among the various internal operators, or external suppliers, following specific standards and best practices adopted by the company.

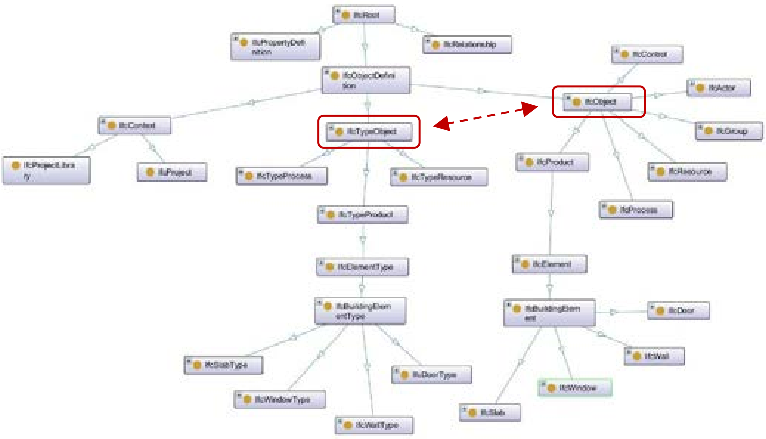

Fig. 4: Derivation path of IfcObject and IfcTypeObject inside IFC schema

The addressee of this research is a public institution and consequently it is necessary to think not only in terms of proprietary formats but how the various building elements and their information should be modelled and delivered to the maintainer. After compiling the OIRs the next step is therefore to draw up matrices based on the Level of Information Need concept that allow us to catalogue all the assets within individual buildings so that we have a complete technical record of the minimum information to populate our models. This also allows us to begin to create a library of general BIM objects that can be used in any building, and associate to each of these the relative class of the IFC schema with the appropriate psets necessary to convey the required information. A first reasoning must be made on the naming convention to be adopted for the creation and use of such objects, since if we look at the proprietary Revit software, for example, we find the distinction between family name and type name, while within an IFC model we can observe many instances of the same object (*IfcObject*), each with its own name, typically distinguished by a progressive number, and different types (*IfcTypeObject*) which instead perform the function of template for the assignment of homogeneous parameters for that grouping of objects (fig. 4). Types and instances in this case are both derived from the superclass *IfcObjectDefinition* and therefore have a horizontal relationship with cardinality [1:N] and not a vertical dependency as proposed by proprietary software. This entails the assignment of different names as the former must be understood in a generic context regardless of the project (*IfcProject*) in which they are placed, while the latter have their own identity when placed within a floor (*IfcBuildingStorey*), or a room (*IfcSpace*), and consequently are assumed to require, in a management type environment, a code capable of representing this position and not being generic for the whole building. The second reasoning must then be done on the parameters relating to these entities. Finding a correspondence between the parameters already in use by an organisation and those prepared by the IFC schema is not always trivial or easily represented by the tools in use today. Where it is not possible to find this relationship, in fact, custom psets created within the BIM authoring software will be used to meet the needs of the client, knowing that they may be subject to change over the years as a result of future changes to the schema proposed by buildingSMART.

In parallel, a data environment will be set up to collect, index and process data from a number of IoT devices deployed within the assets (Fig. 5). These devices are to be chosen based on the observations presented in the previous chapters and will need to enable real-time collection of environmental, or other designated, information. There will then be a breakdown by layers, where the physical layer will be represented by the device itself; the latter will send the collected data to one or more gateways, or directly to the cloud, for indexing and aggregation of the information (Data Storage Layer). Then the data, depending on the type, can be integrated within appropriate databases (Data Integration Layer) and retrieved through appropriate processes or APIs within software applications for real-time analysis and querying.

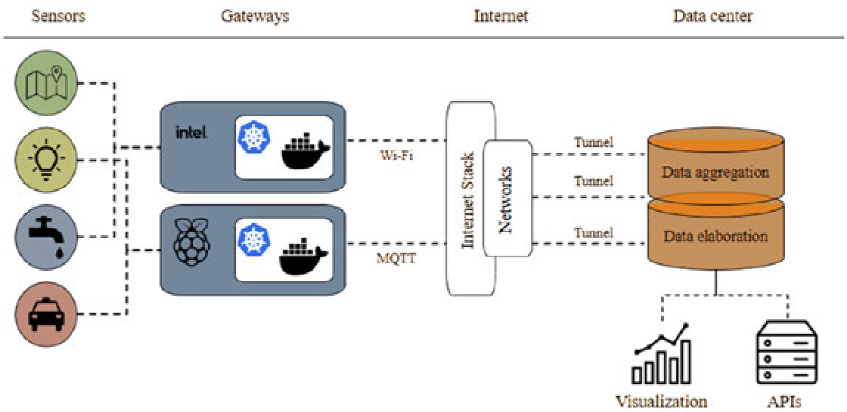

Fig. 5: IoT framework

Aware of the impossibility of directly integrating dynamic information within a BIM model, and in particular within the IFC schema, it is necessary to adopt an intermediate platform that acts as a collection and processing point for all the data collected. The workflow envisages the inclusion within the BIM models of digital representations of the sensors (*IfcSensors*) that will be inserted into the real environment with a series of parameters describing their characteristics and the use of a unique identifier (*IfcTag*) that can be used as a key for association with external DBs. This reference must necessarily be the same as the one present in the DB created from the data collected by the various sensors. The use of a cloud-based platform finally allows us to combine these two databases, representative of two different semantic domains, for the creation of customised queries and dashboards useful for the maintenance of an entire portfolio of assets.

3.1 The case studies

A PNR EU Next Generation research project, entitled *"BIM-to-Digital Twin: information management to support decision-making in the building life cycle"*, has been initiated as part of a collaboration with the University of Florence's Building Area, with the aim of developing information management of built assets belonging to the university's real estate stock through the implementation of BIM information models aimed at facility management.

The Building Area is divided into three Process Units - Real Estate, Building Plan, Ordinary Maintenance - in addition to Administrative Support, to which are added two specialized services called "Fire System Management (GSA)" and "Control and Maintenance of Asbestos Containing Materials". In particular, the tasks of the Ordinary Maintenance PU are those of planning and scheduling of ordinary maintenance interventions, coordination of technical referents allocated in the various territorial offices, monitoring the need for programmable maintenance interventions and requests for urgent interventions, and coordination with the Property and Logistics Services Area in cases of integrated interventions.

Facility management operational services managed by Ordinary Maintenance UP are divided into: 1) Maintenance services, 2) Cleaning and environmental hygiene services, and 3) Reception and porterage services. Each operational service includes various activities that are divided into: ordinary activities (predefined or supplementary) or extraordinary activities (breakdown or on-demand). Maintenance Services include all activities aimed at maintaining the functional state and preservation of the building's systems and construction components. Specifically, the categories of systems managed as different maintenance services are the following: Electrical system, Water system, Heating system, Air-conditioning system. Elevator system, Firefighting system, Security and access control system, Networks, Minute building maintenance.

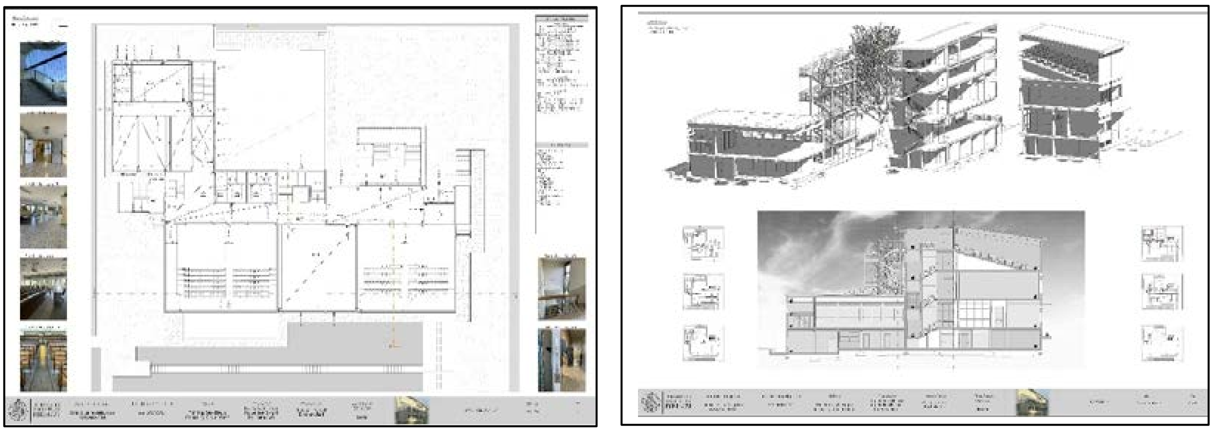

Fig. 6: Layout from BIM model of an asset of University of Florence

The managed real estate portfolio is characterized by numerous assets, different both in terms of function, construction, system, etc., and historical-architectural value, which require different intervention methodologies and maintenance systems from case to case. Precisely with regard to management and maintenance processes, the University has been equipped for some years now with a dedicated IT tool for the management of its real estate assets, namely Infocad.FM by Descor s.r.l., a corporate partner in this research. The backbone of this tool is the centralized and standardized Technical Registry within which all the information (documents, data sheets, CAD plans, photos, etc.) used, by those who interact in various capacities with the properties, converge.

The buildings in the archives are subdivided by municipality and geographical area. Each building is also currently accompanied by all the patrimonial and urban planning documentation that distinguishes it (cadastral extracts, property titles, lease or loan contracts, etc.). Despite this rationalization effort there are still many difficulties in the information management of these assets mainly due to the heterogeneity of the available data and information, since in many cases these documents are still in paper format. Therefore, there is a need to move to an information management using BIM tools and methodologies, so that data and information about the building are produced, managed, stored and exchanged in a secure, reliable and consistent way within a CDE, which allows not only the uploading of files but also the writing of metadata related to them (Paparella & Zanchetta, 2020).

The launch of the research project saw the selection of pilot cases and the implementation of a number of built asset information models, which will serve as the test bed for the testing of IoT models and the subsequent development of Business Intelligence (BI) to support facility management activities. Specifically, the asset model of each building is organized into federated models related to the different disciplinary domains-architectural, structural, and systems to facilitate the management of the model's information content in the subsequent stages of data extraction for technical performance simulation (fig. 6). The various modeling stages are developed depending on the type of geospatial data available through CAD-to-BIM and/or Scan-to-BIM processes and through the use of Autodesk Revit BIM authoring software, which will be followed by export to IFC format, mapping all elements to the correct schema class.

A phase of analysis of the history of the maintenance actions carried out by the Ordinary Maintenance UP and the related costs incurred for each building investigated is also underway, in order to define strategic lines of improvement in the FM of the managed assets to be conducted through the preparation of an IoT model for environmental monitoring, energy consumption and in general the efficiency of the facilities. In particular, this will make it possible to identify those spaces within the buildings that, in relation to their conditions of use, can be a source of useful data to be acquired by sensors (temperature, humidity, pressure, air quality, movement, brightness, etc.).

4. CONCLUSIONS AND FUTURE DEVELOPMENTS

The use of BIM tools and methodologies in the information management of the operational phases of a built asset with its extension to the Digital Twin concept can bring enormous advantages from an economic and management perspective for the owner entity and more specifically for facility managers.

The "BIM-to-Digital Twin" research project, to date in its start-up phase, aims to implement a Decision Support System (DSS) within Facility Management activities through the integration of BIM platforms and IoT technology, geared toward subsequent developments of big data analytics and AI applications. The system should accommodate different types of structured and unstructured data from different sources and enable integration with the IoT model identified for the specific experimentation conducted in the various case studies identified.

This contribution aimed to develop a broad survey of the various approaches available and the problem still open for defining an information technology architecture, which supports the implementation of IoT sensors that can be integrated with the BIM information models of built assets for more efficient management of maintenance and operation activities implemented by owners. Despite the wide variety of communication protocols and semantic models for information exchange between IoT devices there is still only partial integration with the IFC scheme for building classification. Extensions of the IFC schema still provide immature and limited support processes in integrating this type of data. In fact, the IFC format was not designed for data-in-motion transfer from one tool to another and thus to be dynamically modified. The definition of Linked Data (LD) and the Web Ontology Language (OWL) has recently tried to address these issues.

Promising developments can be recognized in the Brick Schema where within it classes such as sensor or plant-type equipment find wide description, and connections between Brick models and the sensor network with specific communication protocols are also included, facilitating the implementation of Digital Twins.

COMBINING LARGE-SCALE 3D METROLOGY AND MIXED REALITY FOR ASSEMBLY QUALITY CONTROL IN MODULAR CONSTRUCTION

Wafa Bounaouara, Louis Rivest & Antoine Tahan
École de Technologie Supérieure (ÉTS), Montréal, Quebec, Canada

ABSTRACT: *The quality control (QC) of assembled modules is an essential process when constructing modular buildings such as hotels and hospitals. Defects that go undetected during module assembly may result in lost productivity in the form of unnecessary transportation, rework or project delays. QC has traditionally been performed using specialized tools and carried out a posteriori in an inspection station dedicated solely to this task. Nowadays, large-scale 3D metrology technology provides a more efficient alternative since it enables accurate measurements to be taken* in situ*. Additionally, mixed reality (MR) supports the immersive projection of information and guidance instructions. This paper introduces a proof of concept of a framework that combines industrial photogrammetry with the HoloLens 2 MR headset to assist with assembly and QC during the off-site construction phase of modular construction. Many tests were conducted in a laboratory and a factory setting to evaluate the system's user-friendliness and possible challenges associated with its future implementation. The experiments conducted confirmed that combining 3D metrology with MR offers an interesting solution for integrating QC into the assembly process. However, further work is needed to enhance the measurement workflow and optimize the measurement system's accuracy.*

KEYWORDS: *3D Metrology, Augmented Reality, Mixed Reality, Modular Construction, Photogrammetry.*

1. INTRODUCTION

In modular construction, volumetric building units, or modules, are factory-built with almost complete interiors including plumbing, electricity, insulation and even furniture. They are then transported to the construction site for final building assembly, which basically involves stacking the pre-assembled modules together. The modules' structure can be made of wood, steel or a combination thereof depending on the customer's requirements and the final height of the assembled building.

During module assembly in the factory, the control of key characteristics (e.g., overall dimensions, squareness error, parallelism of the ceiling and floor) is essential to ensure the module complies with the specifications and estimate the adjustment shims needed when stacking modules on-site. Traditionally, this process has been carried out manually using tools like measuring tapes and levels in the assembly stage and controlled *a posteriori* at an inspection station dedicated solely to this task. If necessary, adjustments and corrections are then made, which leads to lost productivity in the form of unnecessary transportation, rework or project delays.

The advent of contactless 3D metrology provides a valuable alternative since it makes it possible to take accurate measurements *in situ,* while building information modeling (BIM) provides a 3D digital representation of as-designed buildings. This combination of technologies thus automates inspection and digitalizes QC information. QC automation in the prefabricated construction industry has been addressed in recent research. Bae and Han (2021) proposed a vision-based approach to off-site quality inspection that reconstructs 3D point clouds using a projector camera system and computes how much scans deviate from the virtual model to generate quality assessment error maps. Kim et al. (2019) proposed to use a registration-free mirror-aided laser scanning approach to inspect the dimensions and geometric requirements of planar prefabricated elements. Xu, Kang, and Lu (2020) used laser scanning reconstruction technology to inspect surface defects in prefabricated concrete elements. The information they collected during QC was then stored in accordance with the Industry Foundation Classes (IFC) standard and integrated in a BIM platform.

In industry, advances in 3D measurement systems have made it possible to incorporate inspection in the assembly process, which is referred to as measurement-assisted assembly (MAA). The term MAA is used to describe any process that involves measurements being used to guide assembly and QC (Muelaner, Kayani, Martin, & Maropoulos, 2011)

MAA was first introduced as a paradigm shift for the assembly of high-quality large-scale complex structures like aircraft frames to eliminate the monolithic jigs and manual specialized tools that were usually involved in large

Wafa Bounaouara, Louis Rivest, Antoine Tahan, *Combining Large-Scale 3D Metrology and Mixed Reality for Assembly Quality Control in Modular Construction,* pp. 1171-1180, DOI 10.36253/979-12-215-0289-3.116

flexible-component assembly (Maropoulos, Muelaner, Summers, & Martin, 2014). This paradigm shift was motivated by advances in large-scale 3D metrology systems that made it possible to take measurements during fabrication or *in situ.* This is particularly beneficial because large-scale structures are often too big to fit into conventional measuring devices or be transported to calibration laboratories (Schmitt et al., 2016). While the construction industry requires less accuracy than the aerospace industry, the same concept can be used to integrate QC in the assembly process of modular and prefabricated structures.

On the other hand, workers need to keep their hands free during assembly to move around and carry their tools. Augmented reality (AR) and mixed reality (MR) technology can make a significant contribution here. They merge computer-generated information with real-world sensations using a device (e.g., a head-mounted screen, a projector, or a tablet) that provides an immersive user experience and eliminates the need to constantly look at fixed screens for information. In the case of MR, the user can interact with the virtual objects (Peddie, 2017). MR can be seen as an evolution of AR that has been made possible by technological advances in sensors and imaging techniques (Park, Bokijonov, & Choi, 2021).

Various studies have evaluated applying AR and MR to assembly tasks and inspection processes. Qin et al. (2021) investigated whether it was possible to use head-mounted AR displays for wood frame assembly tasks. Ahn, Han, and Al-Hussein (2019) proposed to use a projection-based AR system to provide workers with visual guidance during manual panel assembly. Their system projected as-designed models (panel drawings) into the assembly station. Kwiatek et al. (2019) demonstrated that using a mobile AR application in conjunction with 3D scanning during pipe section assembly and inspection improved productivity, reduced the amount of work that needed to be redone, and enhanced workers' spatial skills. Talamas (2017) evaluated using MR interfaces to automate the metrology process flow for in-line assembly process inspection and found that each volunteer made fewer errors when using the MR interface than paper or laptop instruction guides.

The aim of this paper is to propose a proof of concept of a framework that combines 3D measurement technology and MR to integrate QC in off-site module structure assembly. The purpose is to enhance productivity during the assembly process, provide more accurate measurements, and ensure quality output traceability.

2. MATERIALS AND METHODS

2.1 Measurement Equipment

In this research, we focus on assembling a cuboid wood frame structure formed of a floor, four walls and a ceiling. We suppose that the quality of these six parts was previously controlled. To control the quality of the assembly process, we measure the 3D position of a set of points that will make it possible to control the key characteristics, (KCs) the overall dimensions, squareness error, parallelism of the ceiling and floor, etc. These positions will then be compared to the data represented in the computer-aided design (CAD) model. Fig. 1 illustrates the wood frame structure and the set of control points.

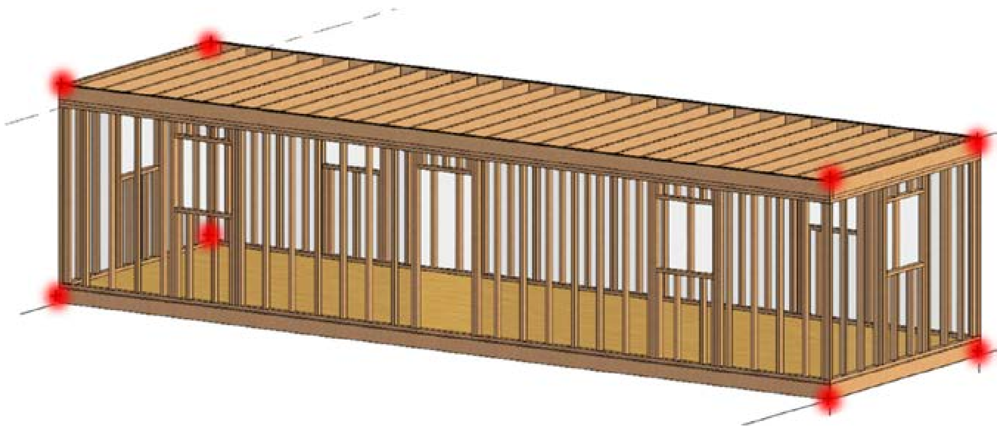

Fig. 1: Wood frame structure

Photogrammetry is a technology that is based on the principle of optical triangulation. An element is positioned in 3D space by at least two cameras that are used to identify targets from different viewpoints. The targets reflect infrared light. The cameras can then capture the position of the targets and position them in relation to the measurement system reference. Multiple targets can be perceived simultaneously, and their positions can be determined dynamically for real-time target tracking (≥ 10 Hz). Photogrammetry is used in many sectors for dimensional inspection. In our research, we use its tracking capability to provide 3D measurement data to assist with the assembly process. C-Track is a photogrammetry device from the company Creaform® that has a measurement volume of up to 16 m^3. Its measurement range can be extended by combining up to four devices to form a measuring system around assembly stations. This eliminates the need to transport measuring equipment from one station to another. Additionally, C-Track can be integrated with portable scanners to probe or scan specific geometric elements as required.

However, the retroreflective targets that are commonly used with C-Track, such as stickers and magnetic artifacts, are unsuitable for wood framing and cannot be accurately calibrated in the CAD model. To address this limitation, customized artifacts have been developed. The artifacts are designed to be easily attached to a wood frame. Each artifact is composed of three retroreflective targets (C1, C2, C3) to locate a point in 3D space. The targets have different spacing to be able to easily differentiate them. Fig. 2 shows a sample artifact developed for tracking the upper corner of a wall.

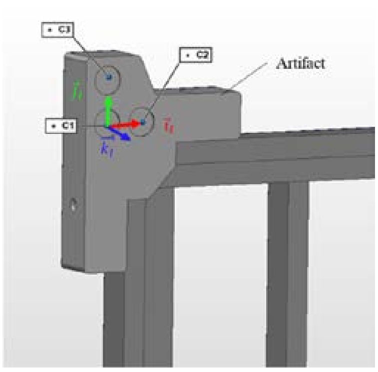

Fig. 2: Sample artifact

2.2 Measurement System Setup

Prior to initiating the inspection process, certain preliminary operations must be conducted to prepare the measurement system. These operations are: environmental referencing, alignment (or registration), and tracking model creation.

Environmental referencing: This step serves to establish a frame of reference for C-Track within the real environment. The working environment is identified using retroreflective targets (the targets shown in blue in Fig. *3* (a)). These targets are then registered using the primary C-Track (if multiple C-Tracks are used) and exported as a reference file. Once this has been done, measurements can be taken by moving C-Track within the referenced environment.

Alignment: To be able to compare measured point coordinates with the CAD model, the C-Track needs to be aligned within the 3D CAD volume. This involves creating reference entities that align the instrument in the metrology software workspace with the real-world instrument. We utilized the floor as a centerpiece. Three perpendicular planes were probed and used to define the measurement coordinate system (as illustrated in Fig. *3* (b)), which was then aligned with the CAD model. Creaform's HandyPROBE portable probe was used with C-Track for this alignment process.

Tracking model creation: The tracking model refers to the collection of retroreflective targets that the C-Track system dynamically tracks. To create this model, the targets comprising the tracked artifacts are registered using the C-Track. Fig. *3* (c) illustrates this process. The acquired targets are then exported as a text file for future use during the inspection process.

(b) Aligning the measurement coordinate system with the CAD model

(c) Creating the tracking model

Fig. 3: Measurement system setup

2.3 Data Processing

The raw data collected by C-Track has to be processed and interpreted in order to extract KCs and interpret the measurements in line with the technical specifications. VxElements® software was used with C-Track for data acquisition. For data post-processing, inspection software offers a wider range of tools. In this project, PolyWorks Inspector® was used to extract dimensions from a CAD model, import measurement data and compare the measurement data with the CAD data. Moreover, macro scripting was used to automate the dynamic measurement process workflow.

For each artifact (see Fig. 2), C-Track provides the (x, y, z) positions of the three targets (C1, C2, C3). It is thus possible to create a local coordinate system (ℓ) attached to the artifact. Once the geometry of the artifact is known, the position of a point of interest (for example, an upper corner of a wall) can be determined in the local coordinate system. Geometric transformation makes it possible to determine the point of interest's position in the global coordinate system (the measurement coordinate system). This logic is computed via macro scripts in PolyWorks Inspector®. The detailed method is explained below.

The first step is to identify the targets, which involves associating them with each point of interest and distinguishing each artifact's different targets. To identify the targets that correspond to each artifact, we calculate the Euclidean distances between the nominal position of the corresponding point of interest and the targets. The three targets that lie within a sphere of radius 10 cm around a point of interest are considered the targets associated with the relevant artifact. If one or more targets are missing, an error message is displayed. This approach is based on the assumption that the part (the wall, for example) is positioned roughly at its nominal (CAD) position. Once the three targets associated with each artifact have been identified, the three targets are distinguished by comparing the distances between the targets based on the artifact's geometry. Equation 2.1 provides the vector calculations for creating a local coordinate system $\ell(\vec{\imath}_\ell, \vec{\jmath}_\ell, \vec{k}_\ell)$ around each artifact using the positions of the three targets (C1, C2, C3).

$$\vec{\imath}_\ell = \frac{C_2 - C_1}{\| C_2 - C_1 \|}; \ \vec{\jmath}_\ell = \frac{C_3 - C_1}{\| C_3 - C_1 \|}; \ \overrightarrow{k_\ell} = \vec{\imath}_\ell \wedge \vec{\jmath}_\ell \qquad 2.1$$

The position of the point of interest in the global coordinate system g, $P_g = (x_g, y_g, z_g)$, is calculated by geometric transformation from the position of the point of interest in the local coordinate system ℓ ($P_\ell = (x_\ell, y_\ell, z_\ell)$). This transformation is represented by Equation 2.2:

$$P_g = \mathrm{T}_{g/\ell} \cdot P_\ell \quad 2.2$$

where $T_{g/\ell}$ is the transformation matrix from the local coordinate system (ℓ) to the global coordinate system (g). To represent this transformation using homogeneous coordinates, Equation 2.2 is equivalently expressed as Equation 2.3:

$$\begin{Bmatrix} x_g \\ y_g \\ z_g \\ 1 \end{Bmatrix} = \begin{bmatrix} r_{11} & r_{12} & r_{13} & t_x \\ r_{21} & r_{22} & r_{23} & t_y \\ r_{31} & r_{32} & r_{33} & t_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{Bmatrix} x_l \\ y_l \\ z_l \\ 1 \end{Bmatrix} \quad 2.3$$

Equation 2.4 donates the rotation matrix:

$$\begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} = \begin{bmatrix} x\vec{\imath}_g & x\vec{\jmath}_g & x\vec{k}_g \\ y\vec{\imath}_g & y\vec{\jmath}_g & y\vec{k}_g \\ z\vec{\imath}_g & z\vec{\jmath}_g & z\vec{k}_g \end{bmatrix} \quad 2.4$$

The translation vector corresponds to the coordinate of the origin of the local coordinate system in the global coordinate system as donated by Equation 3.1:

$$\begin{Bmatrix} t_x \\ t_y \\ t_z \end{Bmatrix} = \begin{Bmatrix} xc1_g \\ yc1_g \\ zc1_g \end{Bmatrix} \quad 2.5$$

2.4 User Interface

As mentioned above, this project uses MR to project dynamic measurements for a user during wood frame structure assembly. The HoloLens 2 headset is a completely standalone head-mounted display (HMD), which means that it doesn't need to be connected to a separate computing device. In addition, it is MR-based, which means that it enables users to interact in real time with digital content that is superimposed on the real world. The content takes the form of holograms, and the holograms interact simultaneously with the user and the real world. Furthermore, HoloLens 2 enables users to interact with holograms using voice commands, hand gestures or eye movement. What's more, the technology makes it possible for two users in different locations to see what the other sees, which enables one to guide the other through a process or simply interact with the world the other sees. This feature has the potential to make remote collaboration easier, more efficient and far more interactive. In addition, an MR plug-in exists for PolyWorks Inspector that makes it possible to manipulate an inspection project directly on HoloLens 2. Macro scripting can also be used to customize the user interface displayed by HoloLens 2.

The user interface must provide the operator with the values of the KCs measured to guide the adjustments to be made and ensure the geometric quality of the assembly. In addition, it must enable the operator to perform certain control commands, such as exporting results and navigating between different inspection stages.

The user interface proposed has two components (Fig. 4): (i) the menu or toolbar, which is composed of three buttons that are each associated with a command Button 1 launches dynamic measurement, Button 2 exports the measurement results, and Button 3 shows or hides the CAD hologram; and (ii) annotations to display the measured value's deviation from the nominal value along the x, y and z axes. The annotations are displayed at the nominal position of the corresponding point of interest and change color depending on whether the measured value is within or outside of the tolerance interval. Note that the functionalities of the PolyWorks AR plug-in for HoloLens 2 were used to align the CAD hologram with the real environment.

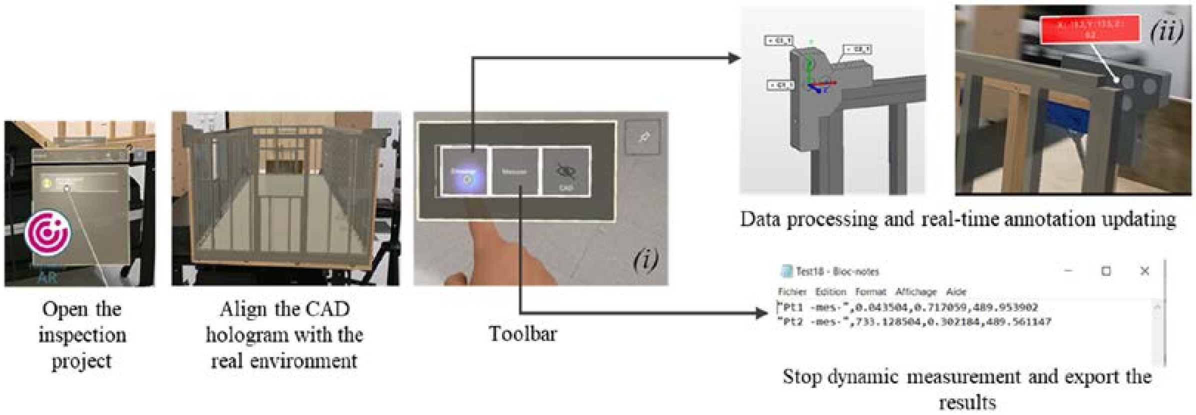

Fig. 4: User interface created for the HoloLens 2 headset

3. LABORATORY TESTING

In order to conduct tests in a laboratory setting, a scaled-down module had to be constructed that adhered to spatial and ergonomic limitations. The scaled module replicates a typical wood frame structure and is around 1/8th the size of an actual module. The module was designed using CAD software. Dimensional and geometric data was present in the CAD model and served as reference information for the nominal (as-designed) model. The measured data was subsequently compared with this nominal data.

3.1 Experimental Setup

The floor was placed on a granite surface plate and secured to the table with a weight to prevent it from moving (see the picture on the right in Fig. 5). Next, we acquired the reference targets, performed alignment and acquired the tracking model as explained in § 2.2.

In an industrial context, adjustable braces are used while assembling walls. A turnbuckle system was built to replicate this for the experiment and allow the operator to easily adjust the position of the wall while tracking the position of the point of interest (see the picture on the left in Fig. 5).

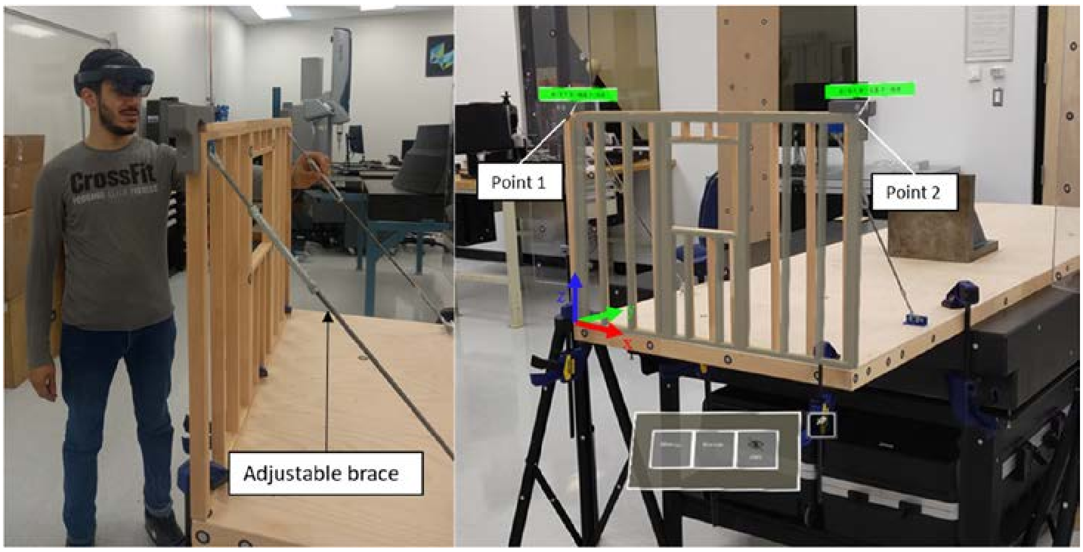

Fig. 5: Experimental setup

3.2 Gage Repeatability and Reproducibility Study

A measurement may be influenced by various sources of variation during the inspection process, which results in there being uncertainty associated with each measurement result. Measurement uncertainty is a quantitative assessment of the unreliability associated with a measurement result based on probability distributions. The dispersion of a set of measurements of a quantity can be characterized using the estimator of its standard deviation, which is also known as standard uncertainty (σ).

Studying the overall uncertainty of the measurement system and evaluating whether the system is able to accurately detect quality defects requires more in-depth study that is beyond the scope of this project. In this study, we intend only to evaluate the amount of variation in the measurement data that is attributable to the measurement system in the configuration proposed. Measurement system variation consists of two important factors, repeatability and reproducibility (R&R). Repeatability is related to equipment variation, whereas reproducibility is related to inspector or operator variation. Measurement system variation can be assessed by conducting a Gage R&R study, which involves data being collected by having multiple operators measure the same set of parts in a random order. Several methodologies can be used for statistical analysis of the data obtained from the Gage R&R study. We chose to use the ANOVA method, which breaks down the sources of measurement system variation as follows:(1) part-to-part: variation originating from the parts being studied; (2) reproducibility: variation originating from the operator(s); (3) operator/part: variation arising from the operator(s) interacting with the parts; and (4) repeatability: variation that originates from the measuring system and cannot be attributable to other sources of variation. The purpose of measuring multiple parts is to evaluate manufacturing method variation, which is also beyond the scope of our research. Therefore, only one part is measured in this study and, thus, variation sources (1) and (3) listed above (which are usually provided by ANOVA) are not taken into consideration in our analysis results.

3.3 Test Sequence

Two operators were asked to repeat the positioning of a wall while tracking the position of the wall's two upper corners. An operator begins by wearing the MR headset and opening the project. The interface displays a hologram of the CAD file with the wall in its nominal position along with a three-button menu, the latter of which is described in § 2.4. The operator then positions the wall approximately in its nominal position and attaches it to the floor and the adjustable assembly brace system. They then fasten the artifacts to the top corners of the wall. Afterwards, they start dynamic measurement by pressing Button 1. The annotations are displayed to indicate each point of interest's positioning error on the x, y and z axes.

The operator begins by adjusting the wall's position along the x-axis in accordance with the deviation values displayed in the annotations for Points 1 and 2 (see Fig. 5). Once the x coordinate is within tolerance, the operator adjusts the position of Point 1 along the y and z axes by adjusting the adjustable brace. When Point 1's position is within tolerance along all three axes, the annotation changes from red to green. The operator then moves on to Point 2 and adjusts its position along the y and z axes. Once both annotations are green (see Fig. 5), the operator stops dynamic measurement by pressing Button 2, which automatically exports the values to a text file. Each operator repeated the sequence 37 times, with six measurements captured each time: *Point1_x*, *Point1_y*, *Point1_z*, *Point2_x*, *Point 2_y* and *Point2 _z*.

3.4 Results and Discussion

The data collected was analyzed using the ANOVA method. Table 1 indicates the repeatability and reproducibility standard deviation of x, y and z for Points 1 and 2. The precision-to-tolerance ratio P/T is expressed by Equation 3.1:

$$P/T = \frac{6\sigma}{USL - LSL} \qquad 3.1$$

where USL is the upper specification limit, LSL is the lower specification limit, and σ is the standard deviation of the measurement error.

Table 1: Gage R&R results

	Point 1			Point 2		
	x	y	z	x	y	z
$\sigma_{\text{repeatability}}$	0.335	0.487	0.152	0.325	0.413	0.089
$\sigma_{\text{reproducibility}}$	0.000	0.019	0.028	0.000	0.237	0.029
$\sigma_{\text{R\&R}}$	0.335	0.487	0.154	0.325	0.476	0.093
P/T	33.5%	49%	15%	33%	48%	9%

The results show that the maximum total standard deviation is 0.487 mm. This means that 95% of the time, the measurement value varies by no more than $4\sigma_{\text{Total}}$ = 1.948 mm ($\pm 2\sigma_{\text{Total}}$ = ±0.974 mm), which is below the maximum allowed tolerance range of 6 mm (±3 mm) indicated in the technical specification. However, for a measurement system to be considered “good”, its precision-to-tolerance ratio must be ≤10%. (Note that 10%<P/T≤30% is borderline, and P/T>30% is unacceptable).

It should be noted, however, that system variation is influenced by the fact that the operator is asked to position each point within an interval of ±1 mm. This can be confirmed by the fact there is less variation along the axis-z since this value is the least impacted by the positioning interval. In fact, when the operator adjusts the braces, the wall’s position along the z-axis almost doesn’t change. In addition, given the experimental setup, the y-axis corresponds to C-Track’s depth axis. A study of the effect C-Track’s depth of field has on measurement system variation showed that the depth of field has a significant effect on system repeatability (Émond-Girard, 2022). In all cases, the system repeatability error is greater than the reproducibility error, which means that the greatest source of variation is the measurement system itself, not operator manipulation.

4. FACTORY TESTING

In order to assess the user-friendliness of the proposed system and to highlight potential constraints linked to its use in an industrial environment, a test was carried out under real working conditions. Below is a description of the experimental setup and test procedure used, as well as the findings and observations noted following the test.

4.1 Experimental Setup and Test Sequence

A near-real-size module was designed to perform factory testing. The artifacts were also adjusted to a true scale. All system setup steps, including referencing the environment, aligning the measurement system with the CAD model’s global coordinate system, creating the tracking model, and aligning the CAD hologram with the real environment were first completed by the research team. Then, we explained to the operators assigned to take part in the tests how the system worked. Three (3) operators then worked together to pre-assemble the module and add the adjustable wall braces. One operator attached the artifacts and put on the MR headset to begin positioning the wall beginning with Point 1. Since the annotation displayed on the MR headset was small, the operator had to climb a ladder to read the value. The other two operators adjusted the position of the wall following the instructions given by the operator wearing the MR headset. The process was repeated until the position of Point 1 was within the desired tolerance range. The process was then repeated for Point 2 following the same procedure. Fig. 6 shows the test sequence.

Fig. 6: Factory testing sequence

4.2 Observations and Discussion

The preliminary actions involved in referencing the environment can be quite demanding in an industrial context. The referencing targets that C-Track requires to locate itself may move due to vibration and operator movement. In addition, during the assembly stage, the floor often moved (drilling of the floor to fix the adjustable wall braces, operator movement, etc.), which made the proposed registration method (alignment of measured data and CAD data) not well suited to the real context. The operator who used the HoloLens 2 headset reported that it was easy to use and comfortable to wear and work with. However, during the test, some drawbacks were noted with the user interface, such as the size of the annotations, which was deemed to be too small. Also, we had to explain to the operator the orientation of the axes and how to interpret the values displayed in the annotation because the coordinate system axes and displacement vectors were not indicated.

5. CONCLUSION

In this research, we were able to achieve a proof of concept of a system that combines industrial photogrammetry and MR to assist operators during the assembly of a wood frame structure. Points of interests were tracked and compared to the nominal data presented in the CAD model. The deviation between the nominal value and the measured value was projected on the real assembly through the MR headset. The proposed solution also supported the documenting of measurement results.

Although the Gage R&R study results showed that the measurement system varied less than the allowed tolerance range indicated in the technical specification, its precision-to-tolerance ratio is still higher than what is recommended. The error associated with artifact fabrication can contribute significantly to the system's variation; thus, further research should work on optimizing the artifact and using the artifact's as-manufactured geometry when computing the measurement data to minimize the amount of variation generated by the artifacts. Further research must be done to evaluate the measurement system's overall uncertainty and validate the system's ability to detect nonconformities.

The test completed in the industrial context helped to identify some drawbacks related to the proposed solution, and, thus, this research serves as a guideline for potential future implementation of a quality control system that combines 3D metrology and MR for integration in an assembly process.

The proposed measurement setup was complex and time-consuming, and keeping the reference targets stable seemed to be a struggle during factory testing. In order to use photogrammetry in *in situ* measurement-assisted assembly, fixed reference entity has to be integrated in the plant layout. Other large-scale technologies like indoor global positioning system (iGPS) could be investigated as an alternative type of measurement equipment. Also, improvements could be made to the user interface to provide the operator with more visual guidance and a more ergonomic way to display the measured values could be sought.

BUILDING'S TWIN RECONSTRUCTION

Cecilia Maria Roberta Luschi & Alessandra Vezzi
University of Florence UNIFI, Department of Architecture DIDA, Florence

ABSTRACT: *The work shows a process that starts from the digitization of cultural heritage and through analysis arrives at the subsequent diachronic holographic representation. The object of the study was the creation of two holograms of historical buildings: the church of St. Maria in Sovana with an interesting subsoil and the ruin of church of St. Francesco, attributed to Sangallo il Giovane in Pitigliano. However, the theoretical setting of the research is placed at due distance from the twin term. It has implications and meaning that are not matched by producing a digital copy, even a very high resolution one. The use of different cognitive technologies and the assembly of the various inputs in a digital model can never be defined as a twin of the original. Bearing in mind what has just been specified, the work was organized according to different levels of acquisition of cognitive data. Obtained from the survey and from historical studies the shape of the original state, a historical narrative interweaving of digital models has been created. The hologram is a three-dimensional and dynamic representation, which in the case of the church of San Francesco shows the reconstruction of the ancient architectural complex, visualizing the evolution of the studies of historical documents, up to the vision of today's ruin. For the church of S. Maria, the underground area is reconstructed through the geoelectric analysis of the subsoil and of the urban composition. Use of high detection technologies (GPR and HVNSR). The holographic of the artifact, promotes scientific divulgation and its dissemination sharing experience, it is not realized through device indeed, but thanks a holographic display.*

KEYWORDS: *Digital twining of cultural heritage, hologram technology, scientific divulgation, dissemination - Diocesan Museum Palazzo Orsini of Pitigliano (GR).*

1. INTRODUCTION

The research activity concerning the case of the church of St. Maria in Sovana (GR) and the ruins of the church of St. Francesco in Pitigliano (GR) starts by questioning the real possibility of making a digital twin of any object or structure especially in relation to the concept of cultural heritage. Starting from the awareness that nothing can be perfectly reproduced, both in structure and texture, even more we find ourselves in the impossibility of being able to observe any artifact divorced from its concrete and real contextualization.

The highest resolution survey and the most advanced technologies can never produce the real in the sense of the twin as we would like it to be. Much less can digital reproductions be correlated with the originals of which they are a partial copy. The theoretical setting of the research thus identifies in the term *twin*, incongruence between signified and signifier; twins in fact have a usual nature, it would instead be more appropriate to speak of digital copies to already have in mind the intrinsic limitation of the action. The misunderstanding, evidently intended, may not seem foundational, but we think at the level of scientific setting it is.

To return to the question of architectural research having clarified the position, albeit in a consciously non-exhaustive way, the paper proposes a twin action of architectural study and composition. That is aimed at identifying the usual nature of the project idea starting from artifact, investigating it according to the compositional rules of architecture referring to different historical periods. Therefore, if the idea has a usual nature, we can research its premises according to the regulative logics of architectural design and here plausibly offer a digital twin of the project idea, which is then confronted with the nature of the artifact, or the cognitive process given by the physical survey and the historical documentary study. In this case then the result shifts to making the project visible from the object.

The structures that are virtually duplicated remain of the usual nature at the ontological level of idea, and the effect of this operation is an architectural image and form that mediates the direct study work on the object and the design process that preceded it. On the one hand, we are in the sphere of the late Renaissance, and we are confronted with a pragmatic architect by profession such as Antonio da Sangallo il Giovane, who in the service of the Medici family, engaged in urbanistic actions of profound transformation in that of Pitigliano, a contested episcopal city and a border town right between Rome and Florence. This area that today is called a minor interior area is characterized by castles, fortified towns and monasteries or convents, and the town of Sovana connected today with Sorano is one of these centers that supplied travertine and valuable mineral resources to Rome. The operation

carried out in Santa Maria Sovana is trying to represent an evolutionary diachronicity of a site that is resemantized within the urban grid.

2. THE DHOMUS PROJECT, MATERIALS AND METHODS

In the framework of the research described above, the DHoMus project, conducted in collaboration between the Department of Architecture (disciplinary scientific sector ICAR/17) of the University of Florence, the Diocese of Pitigliano-Sovana-Orbetello and the Diocesan Museum Palazzo Orsini in Pitigliano, began in March 2020. Action aimed at safeguarding cultural heritage and in line with the idea of a *diffuse museum* (Aiello, 2020b). Two relevant historical emergencies such as the church of the convent of St. Francesco in Pitigliano and the church of St. Maria in Sovana refer to the first museum pole in Pitigliano (Stefanini, et al. 2021).

2.1 The case study of St. Francesco church, Pitigliano

The Convent of St. Francesco, located outside the urban center of Pitigliano, is in a state of ruins today (fig. 01). In fact, the building, which was built in the XVI century to a design by Antonio da Sangallo il Giovane, was soon abandoned in the early years of the XVIII century under the pressure of the Napoleonic suppressions, leading to a gradual process of decay. In the second half of the 1900s the Diocese implemented a parceling out of the convent complex and remained the owner of only the church.

There are still many elements of interest of the ruin, in addition to its architectural definition, that lead us to focus attention on this building again.

The first phase of the study was to, as is customary, prepare an integrated survey project, which in 2019 approached a three-dimensional modeling of the actual state with care taken to keep the textural and chromatic data as faithful as possible to the actual appearance of the ruin (fig. 02) (Lecci et al. 2021). At the same time, research was carried out at the Uffizi *Gabinetto* of Drawings and Prints, a valuable fund for those interested in architectural design and the studies made by Renaissance architects.

Fortunately surviving the events of about half a millennium are two papers precisely concerning the San Francesco in Pitigliano, where the architect in the early period of his professional activity sketches two plans of the building. From some reconstructions of the activity and the placement of the drawings it is plausible to think that the church in 1522 was already definitely built.

The drawing depicts, on the recto of the page, the plan layout of the convent complex of St. Francesco, consisting of two cloisters around which the buildings are attested (fig. 03). Accompanying the project sketch is a legend indicating the function of the various buildings. What remains to this day of the entire convent is solely the church part. Church designed with a single nave with leaning against it on the long side three polygonal chapels extroflexed with internal apse. Note also that the church was planned to have a vestibule with three entrances from which to enter, now lost.

The study of Sangallo's drawing, given the differences in the church between the project and its present state, has guided the research toward a more thorough investigation of the project itself, taking an interest in how the building was conceived and how it should have looked in its original state (Aiello, 2020a).

The drawing seems to plan an overall idea and that the realization therefore according to the document could have been synchronic. The survey also provided us with a reading of the parts attributable to the original layout and thus compatible with the plan found in the Uffizi *Gabinetto* of Drawings and Prints.

The functional distribution of the architectural complex was identified directly from the legend of the original sketch. An initial graphic elaboration was carried out that could communicate this information more clearly and immediately, placing the 16th century design sketch at the center and explaining the dislocation of the rooms by highlighting them and their wording, as specified by the architect in the legend (fig. 04).

More extensive archival research identified designs that could be compared with that of St. Francesco in terms of characteristics and style, attempting to delineate the possible elevation thought up by the architect.

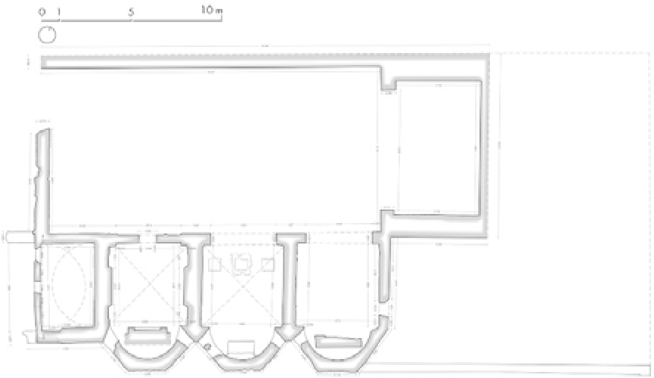

Fig. 2: Plan of the church of the convent of San Francesco in Pitigliano. Graphic elaboration obtained from the survey and developed by the arch. Luca Pasqualotti in his Architecture degree's *Abitare il Paesaggio Storico* (Pasqualotti, 2020).

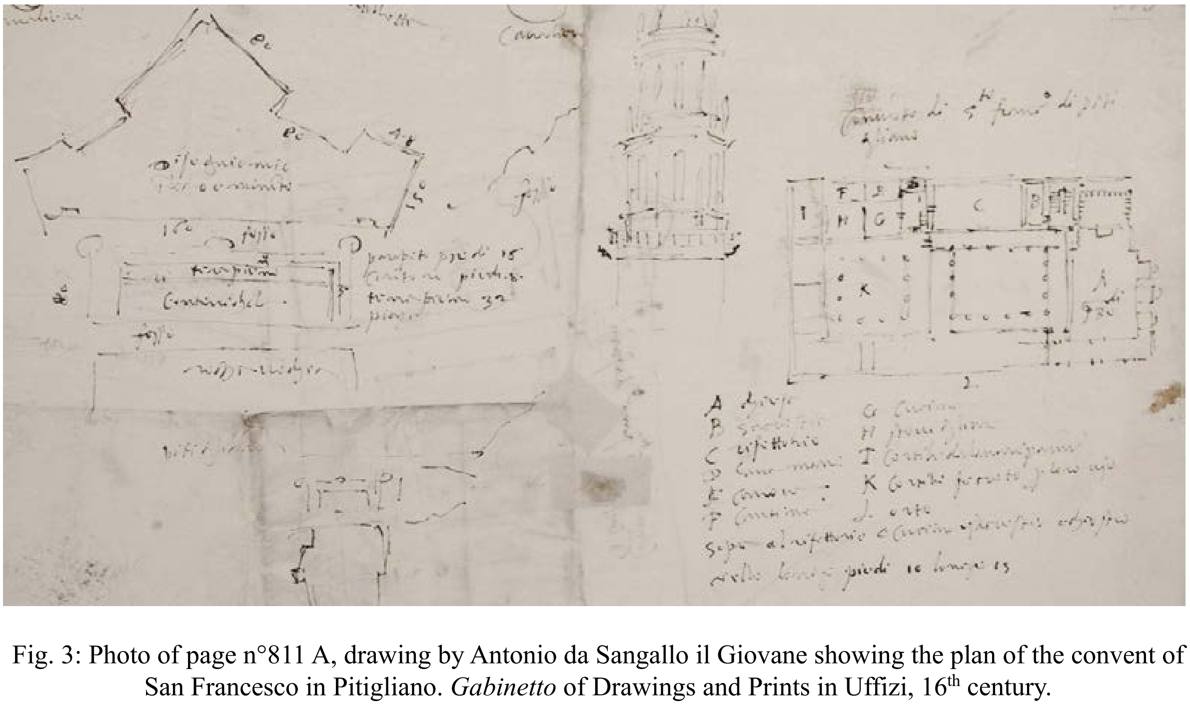

Fig. 3: Photo of page n°811 A, drawing by Antonio da Sangallo il Giovane showing the plan of the convent of San Francesco in Pitigliano. *Gabinetto* of Drawings and Prints in Uffizi, 16th century.

On the survey and the iconographic document, the metric-proportional study of the entire plan layout was carried out, with the aim of verifying whether the project, even if in the form of a sketch, had been conceived according to proportional ratios and/or according to specific mensural canons.

Such a possible positive finding would on the one hand have helped the reading of the architectural portion visible today and on the other hand would have added information about the figure of the architect himself, regarding his modus operandi as a architectural designer. The analysis was based on the planimetry, from which the design geometries were highlighted from the proportional diagrams of the two cloisters. These were then investigated for the existence of any measurement modules between them (fig. 05) (Pasqualotti, 2020). Analyzing the length and width ratios of the greater cloister revealed an internal scanning in squares of sides equal to the span of the intercolumn of the portico. This correspondence thus revealed the existence of a modularity that, aggregated in a ratio of 4:5, punctuates the entire composition of the cloister itself. The modular quantity derived from this ratio was extended to the entire plan development of the complex, bringing out the same correspondence between module and project, thus suggesting that the architect had a clear proportional geometric structure of reference (fig. 06) (Zerbini, 2022).

Fig. 4: On the left: Graphic reworking of the project sketch by Antonio da Sangallo il Giovane; on the right: visualization of the sketch showing the different functions of places.

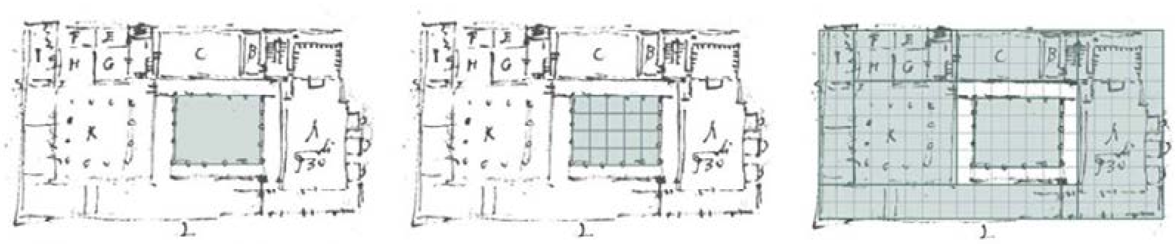

Fig. 5: Compositional-proportional studies performed on the project sketch of the plan of San Francesco's convent in Pitigliano.

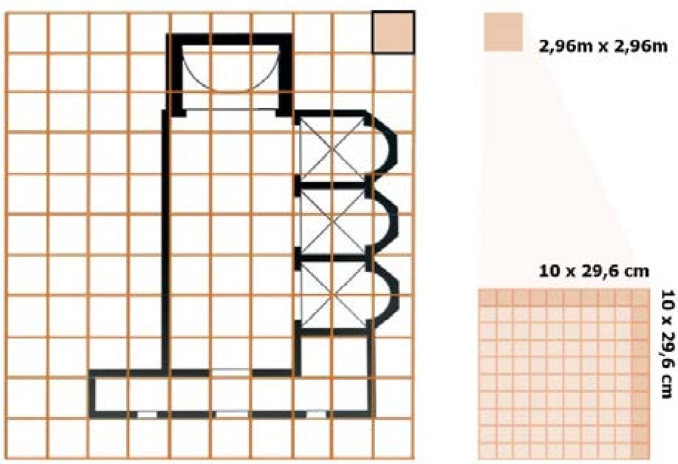

Fig. 6: Compositional-proportional study on the plan of the church through the modular grid obtained from the previous study.

The proportional geometric protocol then applied directly to the survey of the surviving structure revealed a direct match even in the elevations, which are still recognizable today. The building consistency, therefore, has been identified in its main characteristics of heights and distributions.

Missing at this point a stylistic reference to associate with the compositional one to trace the design idea. In this regard, compositional constraints of the surveyed structure were sought, such as portals, still recognizable facade openings, and traces of the ante-facade vestibule. It was then observed that the portals of access to the vestibule and the presence of a central rose window, would have conditioned the elevation of the vestibule itself, which was meant to allow direct light intake. For these reasons, the vestibule designed by Sangallo was assumed to be a single-register element, over which the gable of the church rises.

The result obtained was the subject of three-dimensional modeling, which from the plan design shows the construction of the building according to the proposed hypothesis and finally overlaps with the model inferred from the survey, of the church in its present state (fig. 07).

Two models of a different nature are thus obtained, the first is produced from a survey of the actual state, while the second is produced from a design model, constrained planimetrically and determined in elevations by the proportions introduced by the plans of the Sangallo il Giovane, and its analogous projects.

The final idea was to produce holographically, the superimposition of the two models and the representation of the document testifying to the design intention of the Sangallo il Giovane.

2.2 The case study of St. Maria church, Sovana

The small town of Sovana is characterized by the central Pretorio square and the ruins of the church of the patron saint San Mamiliano. It, believed to be the first church-cathedral of Sovana, is placed directly on the remains of an Etruscan and then Roman building almost bordering the Pretorio square whose northern edge is defined by the side of the church of Santa Maria.

It perhaps to be identified as that Santa Maria, which is consecrated by Bishop Ranieri of Tuscania in 1208, is certainly mentioned already in the will of Count Ildebrandino Aldobrandeschi, called *il Rosso*, of 1284, and recorded in the Decimari of 1296. In 1321-24, it was looted and possibly damaged by the Sienese in 1410 and by the people of Pitigliano in 1434. Around 1558, the construction, on the initiative of Grand Duke Cosimo I de'Medici, of the Loggia with archive building, later to become Palazzo Burbon del Monte, deprived it of its facade, limiting access to only the side portal, open to the square (fig. 08).

The interior of the church is of the basilica type, with three naves divided by polygonal pillars supporting wide round arches. The nave is divided into three bays by Gothic transverse arches, on which the wooden trusses of the roof are set. In the center of the presbytery, raised on a few steps, is the famous ciborium (VIII-IX century), the only example of its type in Tuscany, referable to the pre-Romanesque period (fig. 09) (Rivetti, 2018).

In the work being presented, it is interesting to consider the urbanistic placement of the church in relation to the whole plan the plant. The latter consists of the square and a series of water distribution infrastructures that affect the last terracing where the entire city is set. The church, therefore, is in line with the oldest route that leads directly to the site of the present cathedral. Along this route, in the proximity of the apse of St. Maria's itself is the Public Fountain, currently facing the square, and a wash house at a lower level than the Fountain, adjacent, however, to the extroversion of the church's apse. In further analyzing the archival documents in the Technical Report of the Superintendence for the consolidation works of the church in 1984 it appears that in the apse outside during the excavation an empty archway was found, probably a possible ancient water access route connected to the water system described above (fig. 10).

The continuing problems inherent in rising damp that affected the interior of the church induced to investigate what kind of water structure was present of the area at the time before the church was built. In 2021, thanks to the INGV (National Institute of Geophysics and Volcanology) of the CNR in Florence, it was possible to resort to a geophysical exploration inside and outside the church by means of an electromagnetic radar technique (Ground Penetrating Radar, GPR) survey at 300 MHz and 800 MHz. This made it possible to investigate the stratigraphic conformation and the presence of any structures in the subsurface. The results obtained indicate that there is a depressed area under the church with a compluvial development at the bottom, probably backfilled with material similar (tuffaceous elements) to that of church construction. The compluvium appears to be directly in axis with the apse and its opening to the outside described above, still present today, and a collector placed in the direction of the present wash houses (fig. 11).

The water line, therefore, running from the cathedral to the main square, suggested the possibility that it was a permanence of water system of the classical period, also given the baths of the villa under San Mamiliano. The geophysical survey, moreover, returned a different density of material between the area of the aisles and the central nave of the church opposite the apse, delineating a well-defined rectangular area that ends in conjunction with the two rows of pillars. Opposite the present chancel, a very large apsidal form can be discerned that opens and extends the entire length of the church. This materializes a kind of double-apsidal plan with a central basin and an inflow channel that were placed in axis with the entire external water system (fig. 12).

Regarding the problem of continuous rising damp that still affects the structure today, it is shown that water continues to pass through by capillarity. It is noted how the level of humidity is distributed on the floor forming a hemicycle opposite to that of the apsidal basin of the church. These results gave the possibility to advance hypotheses about the previous use of the area by focusing on possible references to nymphaea of urban areas of Roman cities or classical in general, tried to connect the various outcrops of water adduction.

To make visible all that the instrumentation identified and highlighted, the choice was made not to make a copy of the church itself as such, but to structure a possible evolution from the Classical hypogeum layout to a conversion of the structure into a religious site of the early medieval period. The choice of 3D reconstruction is emphasized by the choice of the use of holographic representation, which through moving scenes, comprehensively depicts the steps in the history of the city of Sovana (Stefanini, et al. 2022).

3. RESULTS

Operationally, the holographic representation, is actualized through the support of the holographic showcase, an instrument formed by a monitor that contains the images or video to be projected. They are reflected on the glass faces of a hollow pyramid trunk and recomposed in the center. The operation is based on the theoretical principle of projective geometry, whereby the image, or video, contained in the monitor is projected onto the transparent surfaces inclined at 45° of the prism, directly applying the principles of projectivity (homology) (Lecci, et al. 2019).

Interestingly, at a strictly operational and technical stage, a properly theoretical principle is being materialized into a result provided by theory. The principles of projective geometry make it possible to faithfully recreate an image or video animation of digitally made objects that appear via optical effect, in a three-dimensional view at the center of the pyramid (Yamanouchi, et al. 2016). To create the holographic projection, it was necessary to make a video that would show all the stages of the research previously described and be able to communicate the story of the building clearly and directly. The work involved writing a storyboard of the research contents and making them the protagonists of the images to be produced, structuring a storytelling to be included in the holographic showcase. To do this, the 2D and 3D material obtained from the survey was used, with which a real narrative plot was developed for the creation of the video animation (Gabellone, 2014).

The storyboard made it possible to sequence all the steps to be told, hierarchizing the information and, at the same time, managing its timing, effects, and steps. In the case of the church of St. Francesco, the paper document becomes the protagonist of a three-dimensional reconstruction of the project that then gradually reifies into the remaining structure of that architectural idea of which we have the trace sketched as a starting point. Geometric analysis of the plan follows until the building is made visible according to the architect's compositional ideas, finally arriving of what remains of the walls of the present ruin (fig. 13).

In the case of the church of St. Maria, on the other hand, the narrative starts from the dissolving of the interior and exterior walls of the church until it arrives at the level of the floor, beyond which the reconstructive hypothesis of that hypogeous environment, known only through the studies carried out on the subsoil, is depicted. Thus, what is not visible is made visible, leaving an idea, a curiosity about what is hidden under the thick walls of the Sovana church that we still see today (fig.14).

3.1 The choice of hologram projection

Using high technology and new methods of digital representation such as holography, we expect to develop more explanatory and engaging narratives (Luschi, et al. 2023). Holograms become a form of interactive and educational visualization, closer to reality by distancing themselves from the use of the support of visors (VR) that isolate from the outside world.

With the implementation of the above-described videos in the holographic showcases inside the Diocesan Museum of Palazzo Orsini in Pitigliano, it was possible to give visibility to the museum and its inaccessible external archaeological sites, making them virtually visitable (figs.15,16).

The museum reality has the purpose of both musealization and being able to have effective communication with visitors. The goal is to present new forms of communication that allow the dissemination of knowledge about the historical-archaeological heritage. Allowing the involvement of increasingly diverse user targets, offering a complete and satisfying visit (Lecci, et al. 2022).

4. CONCLUSIONS

The results that have emerged from the two approaches and experiences are of different tenors. The first that of the church of St. Francesco is the attempt to pursue an idea that leaves its trace from the beginning for the conception of the drawing, to its realization. In between these two major terms is an activity of logical reconstitutions of the project idea that is verified in parallel, both by the drawing and the preliminary sketch, and by the result whereby the extreme terms make the intermediate procedure more and more plausible.

The second experience, on the other hand, there is an evolution to be made visible, still, and partly inaccessible. The technology used puts us in a position to extrapolate a drawing. This drawing is a fact that, however, must be compared with the actual drawing of the church of St. Maria.

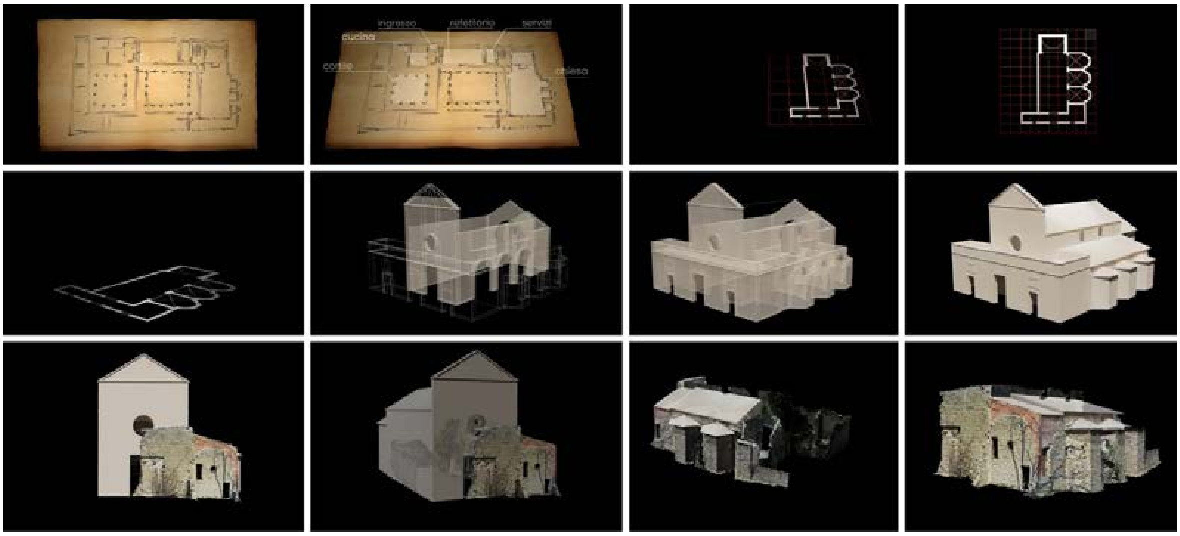

Fig. 13: Some frames in sequence of the video elaboration of St. Francesco's convent in Pitigliano, created to be projected inside the holographic showcase.

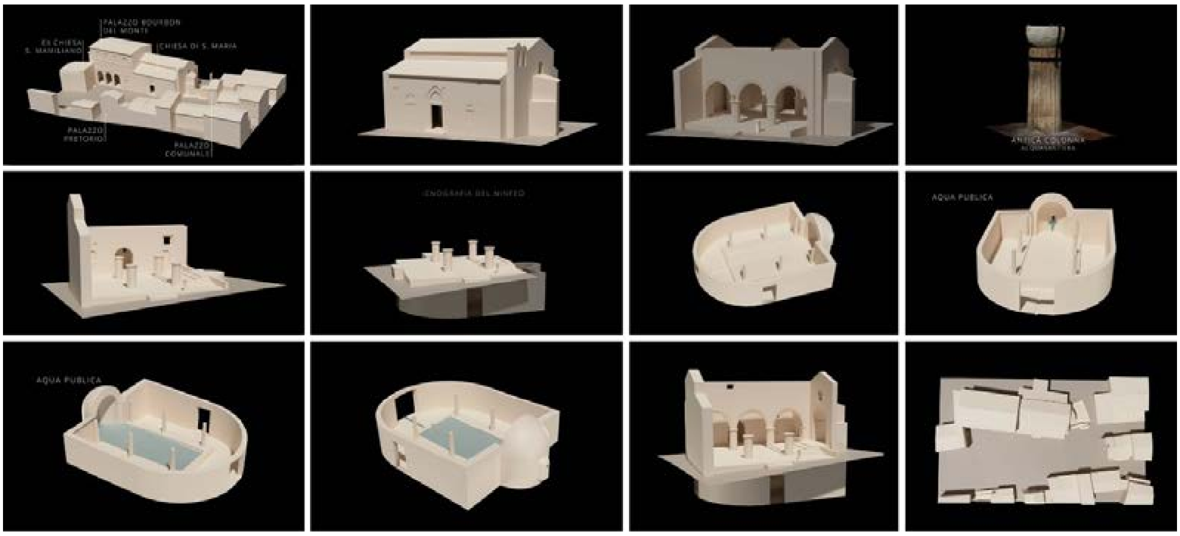

Fig. 14: Some frames in sequence of the video elaboration of St. Maria in Sovana, created to be projected inside the holographic showcase.

Fig. 15: The showcase shows the holographic projection of the video, as indicated by the sequence of frames.

Here it is that between these two moments a logic must intervene introduced precisely by a digital model that mediates the positions, the hypotheses and makes them visible in a becoming understandable and consistent with what are the scientific data placed at the end of it.

So, if in the first case there is a drawing of a project and then a verification of that data through a model, in the second case we have two survey models of a different nature working together and helping to verify the evolutionary stages of a site. Focusing not on the representation of the object itself but of an evolution of an idea and a resemantization of urban spaces.

The digital copies, then, managed to show the effectiveness of a research and its different moments of in-depth reconstruction of hypotheses, returning a unicum that is coherent and somehow re-presenting the becoming of these architectures, in the passage of time.

ABSTRACT: *Nowadays, despite the growing attention to indoor environmental quality and comfort, existing workplaces still often fail to meet employees' expectations and needs, affecting their well-being and productivity. In order to improve management decisions, crucial insights can be provided by the timely correlation of objective workplace conditions, observed by sensors, and subjective workers' feedback, collected through Ecological Momentary Assessment (EMA) method. This paper presents a prototypical Digital Twin for the assessment of workplace performance from an occupant-centric perspective, based on the integration of IoT, BIM and Semantic Web technologies. Following the definition of relevant use cases and requirements a layered system architecture is presented and the prototype implementation is discussed. For capturing the workplace's environmental properties, a sensor network based on the Zigbee communication standard is proposed due to its data transmission efficiency. The measured data, converted in the lightweight MQTT protocol, are streamed to an InfluxDB time series database where they are stored along with the incoming workers' feedback collected as survey responses with a dedicated web application. These time series data are queried and transported into a developed web platform for integrating BIM and RDF data within the standardized structure of Information Containers for linked Document Delivery (ICDDs). Inside this platform, the IFC model of the workplace, the measured data from the sensors, and the worker generated RDF data according to the WOMO ontology for occupant-centric workplace management are linked. The capabilities of the workplace Digital Twin prototype are finally demonstrated querying the linked heterogeneous data to fulfil workplace management tasks in a case study provided at the end of the paper.*

KEYWORDS: *Digital Twin, Workplace performance assessment, Well-being and productivity, Linked Data, Information Container for linked Document Delivery (ICDD), Semantic Web, Internet-of-Things (IoT).*

1. INTRODUCTION

Providing high-quality indoor workplaces that meet their occupants' needs is a challenge of utmost importance for Facility Managers (FM) because of the critical impact they have not only on employees' quality-of-life, health and well-being (Vischer and Wifi, 2017), but also productivity (Al Horr, Arif, Kaushik, *et al.*, 2016). However, although the growing adoption of Information and Communication Technologies (ICT) to control and automate building systems (e.g. HVAC, lighting, access, etc.) has enabled an unprecedented granularity and interactivity in the operation of workplaces, evidence suggest that they still fall short of their occupants' expectations (Abbaszadeh *et al.*, 2006). To address this issue, occupant-centric approaches for control and operation of buildings have been recently proposed, shifting the technology-centred paradigm to the recognition of the user, with its individual and dynamic physiological and psychological requirements, as the most critical component in the occupant-building system (O'Brien *et al.*, 2020).

Recent research focused on supporting managers in the assessment of workplace performance providing them a constant holistic understanding of employees' individual activities, preferences, and conditions within their physical and social work environment. In this regard, effective solutions have been proposed for the timely

Alessandro Bruttini, Philipp Hagedorn, Felix Cleve, Vito Getuli, Pietro Capone, Markus König, *A Semantic Digital Twin Prototype for Workplace Performance Assessment*, pp. 1193-1205, DOI 10.36253/979-12-215-0289-3.118

collection of occupant- and building-generated data and their semantic integration, processing, and visualization using Building Information Modeling (BIM), sensor networks and Semantic Web technologies (Abdelrahman, Chong and Miller, 2022; Donkers, de Vries and Yang, 2022a). However, the development and implementation of these approaches for workplace management purposes are still in their early stages due to limitations in domain knowledge representation, and heterogeneous data integration strategies that need further investigation.

In order to address these issues, this paper presents the concept of a semantic Digital Twin for the integration and exploitation of heterogeneous workplace data, built on the findings of previous contributions by the authors. The research framework and workplace domain knowledge formalization are discussed in Bruttini *et al*., (2022), while the storage and processing of semantic data pivots on the use of standardized information containers (ISO 21597-1:2020) through a dedicated web platform whose effectiveness has been demonstrated in asset and project management use cases (Sigalov *et al.*, 2021; Hagedorn, Liu, *et al.*, 2023). In the followings, after the discussion of the findings of relevant related works, the system development, prototypical implementation and case study demonstration for a workplace performance use case are provided.

2. BACKGROUND

Over the past decade, the pursuit of the benefits obtainable with data-driven management and control of the built environment with the specialization of the concept of “Digital Twin” for the AECO sector, has witnessed an exponential growth (Sacks *et al.*, 2020). The use of Sematic Web technologies and the diffusion of the Linked Building Data (LBD)[1] approach paved the way for the integration of heterogeneous information from diverse knowledge domains, hence overcoming the initial limitations of BIM. In particular, the possibility to observe building operational conditions, e.g., indoor environmental quality (IEQ) factors and systems status, and contextually evaluate them against the way the occupants behave and perceive a given space, enabled an unprecedented understanding of building-occupant complex interactions, starting the long-awaited paradigm shift towards occupant-centric approaches in building management and operation (O’Brien *et al.*, 2020).

In the following paragraphs, the findings and limitations of recent relevant studies related to occupant-centric building operation and workplace performance assessment are reported. Then, a review on sensor network solutions for building monitoring is presented and the state-of-the-art for the semantic integration of building data is discussed.

2.1. Occupant-centric building operation and workplace performance assessment

An indoor workplace represents a complex system characterized by dynamic mutual interactions between the physical space and its occupants. Therefore, to assess workplace performance, quantifying the extent to which it supports workers’ activities and meets their needs and expectations is crucial. In this regard, extensive literature investigated the impact of different physical and non-physical factors on workers’ satisfaction, productivity, and well-being, from workplace IEQ parameters (Al Horr, Arif, Katafygiotou, *et al.*, 2016) to workspace layout (Kim and de Dear, 2013) and the degree of user perceived control on the environment (Luo *et al.*, 2016).

To monitor how these and other heterogeneous factors affect the workers, both building objective properties, observed by sensors, and workers subjective conditions must be timely collected and integrated. For the latter, indirect approaches based on inferences from historical building systems’ data (e.g., lighting usage for visual quality assessment) are making way to the collection of direct occupant feedback through smartphone and web applications and wearable devices (Nagy *et al.*, 2023). For this purpose, the Ecological Momentary Assessment (EMA) approach (Shiffman, Stone and Hufford, 2008) initially developed for medical and social researches, is progressively replacing Post Occupancy Evaluation (POE) for the collection of frequent, real-time occupants’ feedback directly from their workplace environments via the use of micro-surveys (Engelen and Held, 2019).

Nonetheless, a system that enables the semantic integration, processing, querying and visualization of building- and worker-generated data is necessary to support occupant-centric workplace management and performance assessment. In this regard, recent contributions showed the feasibility and opportunities provided by the adoption of BIM, sensor networks and semantic web technologies for the integration of static and dynamic domain-

[1] W3C Linked Building Data (LBD) Community Group - https://www.w3.org/community/lbd/ - (accessed 12/07/2023)

specific data for IEQ and occupant experience assessment (Abdelrahman, Chong and Miller, 2022; Donkers, de Vries and Yang, 2022b, 2022a). However, since indoor workplace management purposes still need to be fully addressed with specific solutions, the authors developed a framework and an ontological representation of worker's conditions and activities in indoor environments which form the conceptual basis of the workplace digital twin prototype proposed in this paper (Bruttini *et al.*, 2022).

2.2. Sensor networks for building monitoring

For the contextualization of subjective worker's data, his surrounding environmental conditions must be objectively observed through a sensor infrastructure which provides for sampling, transferring, and storing of the sensed data. In recent years, Internet-of-Things (IoT) technology has established as the main solution for the implementation of such sensor networks. Most of them make use of a similar multi-level hardware architecture that addresses the above-mentioned challenges. Kifouche *et al.* (2017) describes three levels, the sensor-, gateway- and base-station-level. Li *et al.* (2023) add a further application-layer for data visualization interfaces.

Concerning the sensors, both wired and wireless solution can be deployed. While the former can be more reliable, it needs additional cabling and therefore lacks in flexibility (Tanasiev *et al.*, 2021). Hence most of the studies use wireless solutions, relying on sensor devices that consist of a sensing unit, a microcontroller and a radio adapter for the data transmission. As sensing unit, anything from the widely used temperature and humidity sensors up to a motion or CO_2-level sensor is possible. A microcontroller reads out its data and sends them to a gateway via Wi-Fi, Bluetooth (Li *et al.*, 2023), Zigbee (Kifouche *et al.*, 2017) or LoRa (Kifouche *et al.*, 2017; Tanasiev *et al.*, 2021). As wireless sensors are mostly battery powered, power management is a crucial aspect, finding the right balance between power consumption, bandwidth, and transmission range. While some studies assemble their own sensor devices on a prototypical base, there are approaches as well that make use of out of the shelf sensor devices with proper device housing (Chamari, Petrova and Pauwels, 2023).

The gateway is placed on site and acts as a translator receiving data from the sensors and routing them into the backend system. Thus, the selection of the radio technology and communication protocol, together with the building substance and materials, substantially effects the network range, determining the number of gateways needed for a seamless coverage inside the building (Kifouche *et al.*, 2017). As used within several works (Kifouche *et al.*, 2017; Tanasiev *et al.*, 2021; Li *et al.*, 2023), it is suitable to implement the gateway with a low cost SoC computer like a Raspberry Pi, which connects via Ethernet with the backend system.

Detached from the installation on site, the backend system can be deployed anywhere else, even in the cloud. It implements a software solution for processing and storing the forwarded data. While earlier works made use of individually designed solutions (Kifouche *et al.*, 2017), recent studies showed the effective adoption of the machine-to-machine (M2M) and IoT protocol called Message Queuing Telemetry Transport (MQTT) (Tanasiev *et al.*, 2021; Chamari, Petrova and Pauwels, 2023; Li *et al.*, 2023). Eventually, besides relational databases such as MySQL(Kifouche *et al.*, 2017; Tanasiev *et al.*, 2021; Zhang and Beetz, 2022; Li *et al.*, 2023), for storing sensor observations the adoption of NoSQL, time series databases and RDF data stores is growing especially in semantic information model applications (Chamari, Petrova and Pauwels, 2023).

2.3. Linked Data and information containers for semantic Digital Twins

With the recent advent of the Digital Twin paradigm in the AECO sector, viable solutions for the integration of BIM with both static and dynamic data for the real-time representation of physical built assets became crucial. In this regard, several studies proved that the adoption of Semantic Web technologies and Linked Data approach enable the deployment of semantic Digital Twins where building information can be enriched via linking with heterogeneous domain-specific data, whose representation is in turn demanded to dedicated ontologies (Mavrokapnidis *et al.*, 2021; Eneyew, Capretz and Bitsuamlak, 2022).

However, in a context where a standardized approach for the creation and maintenance of Digital Twins is still missing and systems' requirements are subject to frequent transformation, using BIM data and models as common basis for the implementation of domain-specific Digital Twins with a modular approach can provide the much-needed flexibility and scalability. Kosse *et al.*, (2023) argue how modular Digital Twins can be implemented with the use of standardized information containers which provide a model for storing and exchanging heterogeneous information. In particular, as shown in Polter and Scherer (2023), and Zinke *et al.* (2023), Information Containers for linked Document Delivery (ICDDs), compliant with the ISO 21597-1 (2020), are suitable for this purpose since they implement a vendor-neutral data structure which integrates, besides payload documents to be exchanged, distributed linked data. Moreover, supporting the Linked Data approach, their interconnection to web standards such as HTTP and REST is easily implementable, while Semantic Web technologies enable data retrieval through SPARQL queries. Arbitrary data can be modeled using an ontological layer that can be stored in the container or as web resources, while a specific linking structure supplements the capability of the container to host a Digital Twin. Furthermore, as demonstrated Senthilvel and Beetz (2021), the possibility to nest and interlink ICDD individual container modules opens to a scalable system-of-systems approach where compatibility is ensured by the containers' conformity to ISO 21597.

Likewise, in previous research the authors showed the feasibility and versatility obtainable with the adoption of ICDD containers for the storage, integration, querying and visualization of building and domain-specific information with the development of a dedicated web platform. With differences in implemented functions and user interface, the proposed approach proved effective for different use cases, including infrastructure asset management (Hagedorn, Liu, *et al.*, 2023), and smart contracts-based automated payment and contract management (Sigalov *et al.*, 2021). On this basis, as detailed in the followings, a customized version of the mentioned ICDD platform is proposed for the implementation of the presented workplace digital twin prototype.

3. RESEARCH FRAMEWORK AND METHODOLOGY

The present study is part of a broader research effort which aims at the realization of a data-driven workplace management framework finalized to the enhancement of workers' well-being and productivity through capturing and understanding the dynamic worker-workplace interactions. To achieve this goal, a workplace semantic digital twin, able to integrate heterogeneous occupant- and building-generated data for workplace management purposes, is proposed. With reference to Fig. *1*, this paragraph describes the study's methodology, from the system conceptualization to its prototypical implementation to a room-scale case study.

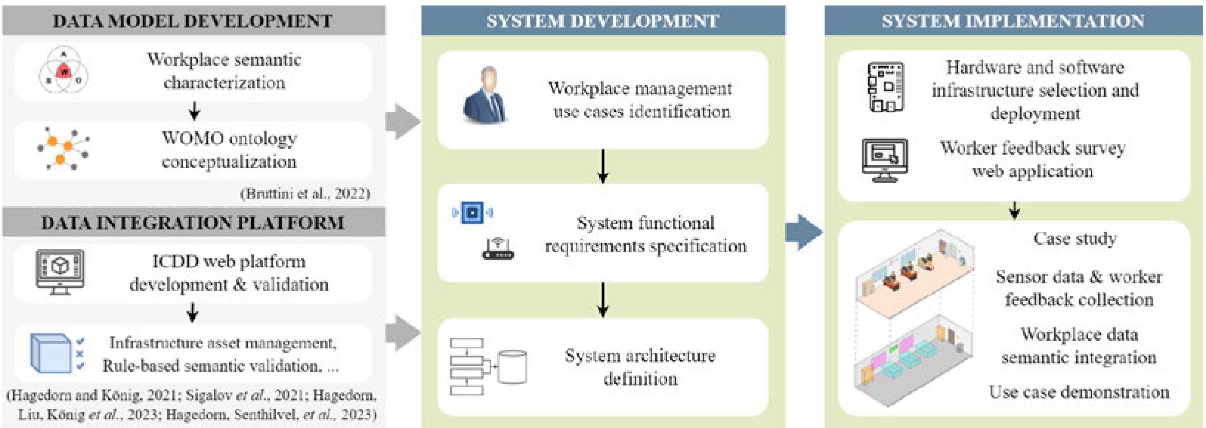

Fig. 1 Research methodology

As discussed above (see §2), the development and implementation of the proposed system stems from previous authors' contributions. The formal representation of workplace knowledge, characterized as the intersection of the worker-building-activity semantic domains, is provided in the Occupant-centric Workplace Management Ontology (WOMO) presented in Bruttini *et al.*, (2022). Workers' objective and subjective features, along with their current activity, are described and interlinked through feedback instances, hence related to the correspondent building spaces and conditions. These are represented by reusing well-established ontologies, such as the Building Topology Ontology (BOT)[2] and Semantic Sensor Network ontology (SSN)[3]. In turn, for the semantic storage and integration of the aforementioned heterogeneous workplace data, standardized information containers (ISO 21597-1, 2020) are adopted. Therefore, the workplace knowledge base, comprising of its IFC model, workers' and sensors' data, is realized through an ICDD container and semantic data integration,

[2] https://w3c-lbd-cg.github.io/bot/ - (accessed 12/07/2023)

[3] https://www.w3.org/TR/vocab-ssn/ - (accessed 12/07/2023)

querying, visualization, and rule-based validation are enabled by a dedicated web platform developed by the authors (Hagedorn, Pauwels, *et al.*, 2023; Sigalov *et al.*, 2021; Hagedorn, Liu, *et al.*, 2023; Hagedorn, Senthilvel, *et al.*, 2023).

The system development involved three main steps, namely: use cases' identification, requirements definition and architecture conceptualization. Then, the criteria for the selection of the hardware and software solutions for the system prototype implementation are described, including the development of a custom web application for the collection of workers' feedback. Eventually, the capabilities of the prototype are evaluated for a case study office room. A workplace performance assessment use case is tested through the querying and visualization of the collected workers' feedback and contextual observed environmental conditions.

4. SYSTEM DEVELOPMENT

4.1. System use cases

According to the research framework's overarching goal and to the scope and purposes that drove the workplace domain knowledge formalization within the WOMO ontology (Bruttini *et al.*, 2022), the system shall inform and support managers' decisions for the improvement of employees' well-being and productivity, providing insights from the correlation between workers' subjective feedback and workplaces' objective conditions. For this purpose, three general use cases have been identified, namely:

- *Workplace performance assessment* – Evaluation of how a workplace supports or hinders its occupants through the correlation of workers' subjective feedback with the objective indoor environmental conditions.
- *Workplace issue discovery* – Evaluation of the factors that contribute to the occurrence of unsatisfactory conditions and identification of latent issues that affect workers' needs (e.g., privacy, focus, lighting, etc.).
- *Worker preference clustering & Spatial recommendation*: Recognition and evaluation of recurrent data patterns and correlations, and implementation of artificial intelligence-enabled methods for learning and predicting ideal conditions for worker groups or profiles (e.g., based on environmental preferences, activity needs, etc.), and for the recommending solutions for underperforming spaces or occurred issues.

The presented system prototype implementation focuses on the *workplace performance assessment* use case, leaving the remaining to future developments.

4.2. System requirements

The system requirements, on which the following system architecture conceptualization and prototype implementation is based, are listed below per functional area:

- *Building-generated data collection* – To monitor workplace's indoor environments, the sensors' typology and communication protocol shall favour easy, flexible, and affordable deployment while providing reasonable accuracy.
- *Occupant-generated data collection* – The collection of worker objective and subjective data shall be using voluntary feedback responses to timely micro-surveys developed according to the EMA methodology. Feedback time and location are mandatory, while customizable feedback request's generation (e.g., scheduled, voluntary), survey's prompts and rating scales shall be granted. Collection of workers' momentary health indicators (e.g., heart rate), environmental preferences (e.g., thermal quality), and self-assessed conditions (e.g., productivity) shall be enabled along with their current activity.
- *Time series data handling and storage*: Both the transmitted building- and occupant-generated data shall be stored and organized in a store specialized for time series data. The database structure shall not be constrained in terms of data sources (i.e., sensors, feedback interfaces) and structure (i.e., building observed properties, worker data and survey fields), and shall allow data storage efficiency (i.e., down sampling), querying and aggregation.
- *Data semantic integration, querying and visualization*: Heterogeneous static and dynamic workplace data shall be integrable to realize an evolving workplace knowledge base where information is semantically structured and interlinked according to acknowledged ontologies, and reasoning, querying, and visualization are enabled. This shall include, but not be limited to, the geometries and properties of building spaces and elements (i.e., IFC model), sensors' observations and workers' feedback.

4.3. System architecture

On these assumptions, a comprehensive four-layered system architecture has been drawn as shown in Fig. *2*. At the bottom, the *physical layer* represents the physical workplace from which the data describing the building operational and environmental properties (e.g., air temperature, window opening, etc.) are collected by the deployed sensors, and workers' objective and subjective data (e.g., location, environmental preference, activity, etc.) are provided via momentary feedback. This layer transfers the data to the upper *data storage layer* where two functionally distinct stores are identified: one dedicated to dynamic data (i.e., timeseries sensors' observations and workers' feedback); the other, dedicated to consolidated data (e.g., aggregated sensor observations) and less frequently changing or static building information. The latter forms the system's core knowledge base, where workplace heterogeneous information (e.g., BIM model, organizational data, timeseries, etc.) are stored according to appointed ontologies and hence semantically interlinked.

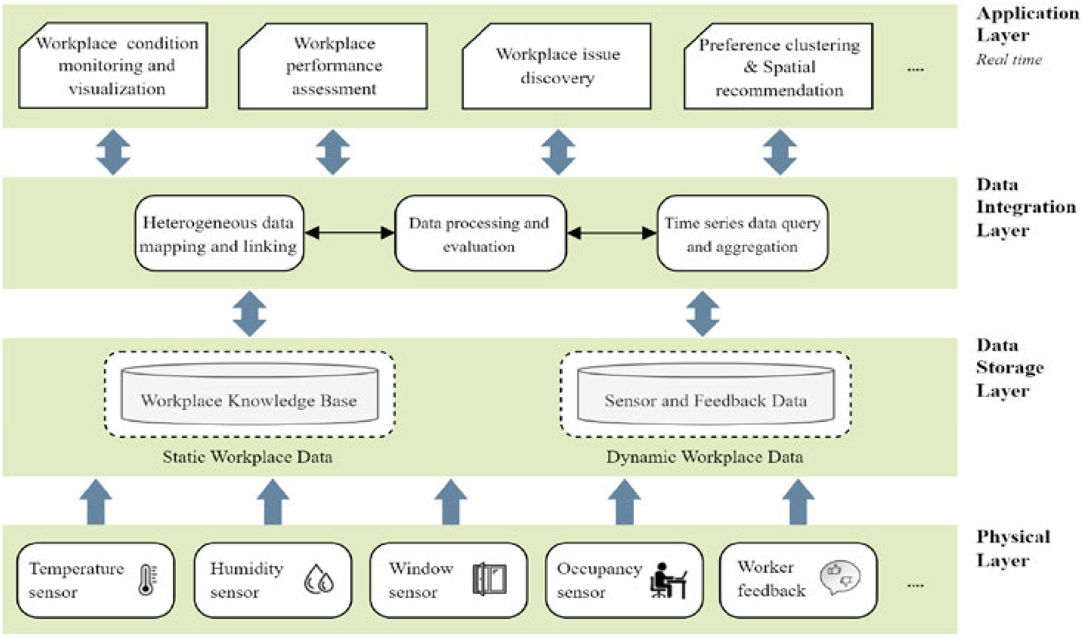

Fig. 2 Workplace digital twin system architecture

In turn, the *data integration layer* provides access to the workplace static and dynamic data, allows for their semantic integration and processing, and mediates the incoming requests from the top *application layer*. This last layer provides the user, i.e., manager, with the digital twin-based services that shall serve the identified use cases, such as: workplace condition monitoring and visualization; building-activity-worker data correlation for workplace performance assessment, issue discovery and spatial recommendation.

4.4. System prototype implementation

This paragraph describes the hardware and software choices taken for the system prototype implementation. As shown in Fig. *3*, the physical workplace can be represented as the combination of several workspaces (i.e., building's spaces) that shares spatial, organizational, or functional properties at different scales and are occupied by the workers during their daily working routines (e.g., a part of an open space, a single room, a workstation, etc). For this implementation, the system's targeted workspaces consist in private or shared office rooms with a gross floor area not exceeding 50 m^2. For workspace properties monitoring, a wireless network based on the Zigbee communication standard has been chosen due to the acknowledged performances in terms of network reliability, ease of deployment and affordability of compatible commercial devices in smart building applications. Three types of sensors have been selected to monitor objective workspace properties, namely: temperature and humidity sensor for the thermal environment; contact sensor for window status; motion sensor for occupancy detection and count. All types of sensors are battery-powered, can be installed without screws and transmit data wireless, allowing for fast and flexible deployment, substitution, and maintenance. A Raspberry Pi[4]

[4] https://www.raspberrypi.com/products/raspberry-pi-3-model-b/ - (accessed 14/07/2023)

SoC provided with a universal USB Zigbee gateway is appointed as network coordinator and transmits sensor data to the system backend via Ethernet connection. Moreover, the mesh topology of the Zigbee network allows for the addition of power-supplied devices acting as repeaters (e.g., smart plugs), hence providing redundancy and easy range extensibility.

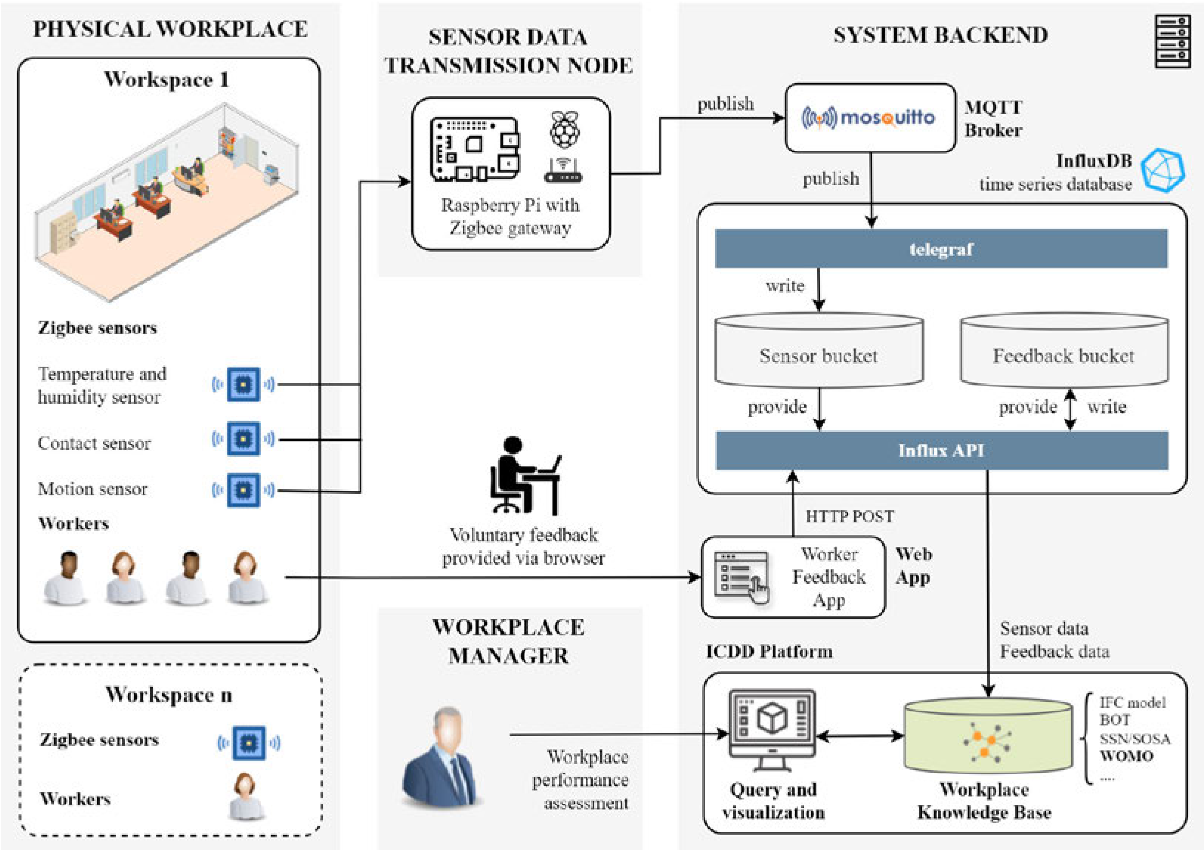

Fig. 3 Workplace digital twin system prototype implementation scheme

The encoding and transmission of the sensors' data has been demanded to the MQTT protocol due to its suitability in IoT applications that requires lightweight, machine to machine, message exchange. The sensors' observations (i.e., actual measurements and metadata) are gathered from the gateway, encoded into individual message packages, and published via MQTT protocol on dedicated topics, one for each sensor, to an Eclipse Mosquitto[5] broker instantiated at the system backend. On the same server, an InfluxDB[6] timeseries database instance connected with an agent (i.e., telegraf [6]) to the MQTT broker and subscribed to all relevant topics receives and stores the sensor-generated data into a dedicated bucket.

For the collection of workers' data, a web application presenting a one-page survey form has been developed. Accessing the form via browser, workers can provide feedback instances on a voluntary base. The survey interface is designed to allow fast responses in order to prevent survey fatigue bias. For this reason, worker ID and current location, corresponding to their allocated workstation, are preset and not editable by the responder. The other survey fields allow for multiple choice response and can be customized to query for the current worker activity and to express their environmental preferences and self-assed conditions. The survey web application uses the HTTP POST method and the Influx API to transmit and write the collected responses to timeseries records within a dedicated feedback bucket in the InfluxDB database.

The last component of the prototype implementation consists in the aforementioned web platform through which the heterogeneous workplace data are stored in a dedicated ICDD container, are semantically interlinked according to predefined ontologies and hence processed, queried, visualized. Here, the workplace IFC model, comprising of the geometrical and functional information necessary for the description of the identified

[5] https://mosquitto.org/ - (accessed 14/07/2023)

[6] https://www.influxdata.com/; https://www.influxdata.com/time-series-platform/telegraf/ - (accessed 14/07/2023)

workspaces, forms the foundation of the workplace digital twin knowledge base. Dedicated platforms' functions retrieve sensors' and workers' data from the timeseries database and stores them as RDF triples accordingly to the SSN ontology. In turn, the building information contained in the IFC model are mapped to BOT ontology classes (i.e., `bot:Space` and `bot:Element`) and linked to sensors' observations and workers' features, preferences, activities and feedback according to the WOMO ontology. Eventually, the resulting knowledge graph can be queried within the platform, and dedicated services provide for the visualization of the results to support workplace performance assessment use cases.

5. CASE STUDY

In this section, the capabilities of the presented prototype are demonstrated with a room-scale case study that involved the collection of worker feedback and sensor data over a period of one week. The collected data are integrated with static workplace information stored in a correspondent ICDD container (e.g., IFC model), then queried and visualized for a performance assessment use case using the dedicated web platform. The appointed room is a shared office in availability of the Chair of Computing in Engineering at the Ruhr University Bochum (Bochum, Germany). The office and case study setup specification are shown in Fig. *4*.

Workspace specification

Workspace type	Shared office
Workstations (Employees)	4 (4)
Lenght x Width x Height	7,35 x 6,00 x 3,75 m
Area	44,10 m^2
Volume	165,38 m^3

Observed properties & Sensors

Air temperature and relative humidity	1x Temperature and humidity sensor (height = 0,70 m)
Occupancy number	4x Presence sensor (1x workstation)
Window status	2x Contact sensor (1x window)

Sensor network characteristics

Network coordinator	Raspberry Pi 3 Model B connected via ethernet to internal network
Zigbee gateway	Phoscon ConBee II Universal USB Zigbee 3.0 gateway

Worker feedback colletion

Workers involved	4 - Allocated to the office
Feedback strategy	Web application (browser) Voluntary (>= 4 times/day)
Test duration	1x Work week (10-14/07/2023)
Worker data	6 - ID, location, activity category and type, thermal preference, self-assessed productivity

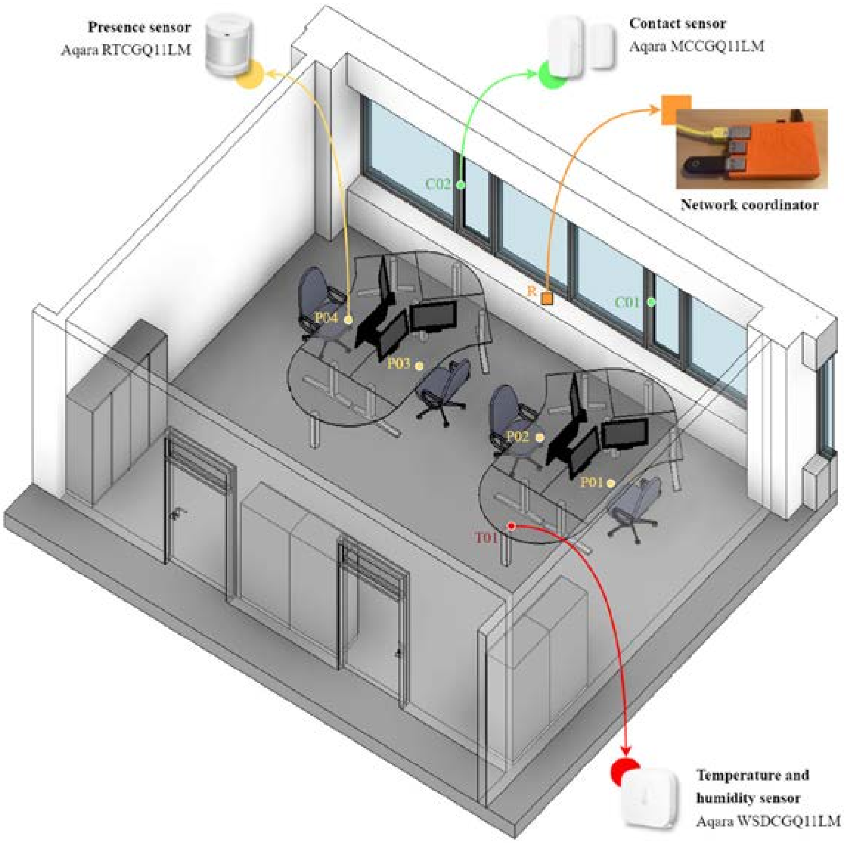

Fig. 4 Case study setup

5.1. Sensor network setup

The deployed sensor network consists of commercial products based on the Zigbee standard and widely adopted in smart building applications. The main characteristics of the installed components are reported below, along with their vendor and model to allow for specification retrieval:

- *Air temperature and humidity sensor (x1)* – It is positioned under the work plane of one of the desks in order to: avoid direct exposure to sunlight or radiators' heat emission; avoid obstruction to other objects; observe occupants' thermal micro-environment (i.e., height 0,70m) during work without being exposed to their body heat emission. [Aqara WSDCGQ11LM]
- *Contact sensor (x2)* – They return the open/closed status of each operable window. [Aqara MCCGQ11LM]

- *Motion sensor (x4)* – They use passive infrared (PIR) detection and are positioned under each of the desks' work planes. The sensor field-of-view is partially obstructed so that the detection of false positives is minimized. Presence at workstations is aggregated to determine room occupancy. [Aqara RTCGQ11LM]
- *Network coordinator* – A Phoscon ConBee II universal USB Zigbee 3.0 gateway connects the sensors and can support other Zigbee compatible devices from different vendors. The gateway is installed on a Raspberry Pi 3 Model B, connected via ethernet to the backend. In turn, on the Raspberry Pi runs an open source Zigbee2MQTT[7] bridge that enables network configuration (i.e., device pairing, removal and setting) with a graphical user interface accessible via browser. The bridge encodes the incoming sensor data into MQTT messages that are published to the Eclipse Mosquitto MQTT broker instance at the backend. The topics' hierarchy focuses on the sensors, and presents three levels: argument, sensor type and ID (e.g., "sensors/contact/c01" for contact sensor "C01"). Therefore, decoupling the sensors' deployment from the network configuration, higher flexibility is provided. Sensor metadata (e.g., observed window) are stored in the workplace knowledge graph.

Eventually, an InfluxDB agent, telegraf, is configured to connect to the MQTT broker, subscribe to all the topics of interest (i.e., "sensors/#"), decode sensor messages' payloads and write the related observations in timeseries within the predisposed sensor bucket.

5.2. Worker feedback web application

The collection of workers' feedback involved the four employees assigned to the case study office for one week (i.e., five workdays, 10-14th July, 2023). A web application has been implemented to collect their momentary feedback as responses to a single-page survey form (Fig. 5). Survey fatigue bias has been minimized presetting the workers' IDs and location and limiting the survey's queries to three. First, the specification of the current activity category and type is requested among five options: solo work, call, group work, break, or other unspecified activity. Then, the expression of the worker preference towards the perceived thermal quality is requested in a three-points scale: prefer cooler, no change, or prefer warmer. Eventually, the self-assessed productivity shall be indicated among not productive, normal or very productive. Rating scales' mid-points represent satisfaction with the environment and baseline productivity. To submit the feedback, at least one query must be responded. The survey response data are posted to Influx DB and stored as timeseries in the dedicated feedback bucket. The subjects involved have been informed about the research purposes, have agreed to voluntarily provide the feedback data and allow for their anonymized use and dissemination.

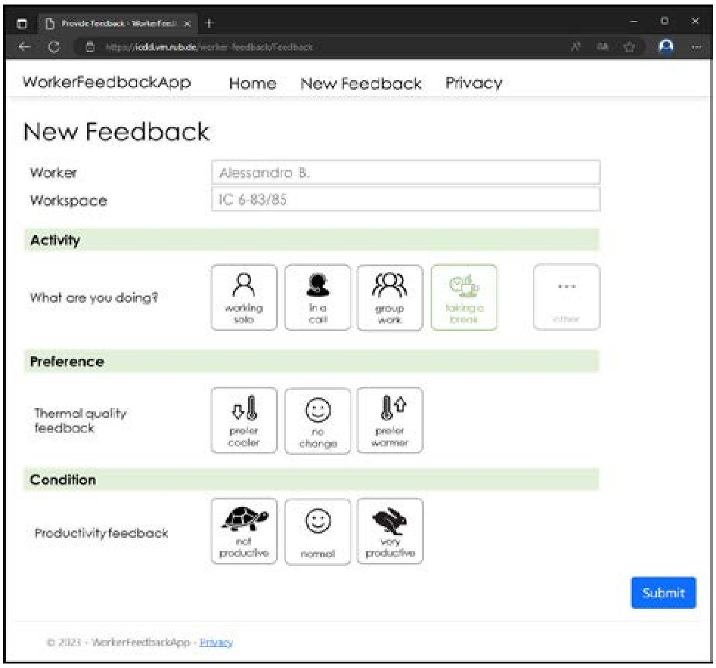

Fig. 5 Worker feedback web application – Survey form

[7] https://www.zigbee2mqtt.io/ - (accessed 17/07/2023)

5.3. Workplace performance assessment

The case study evaluation of the workplace digital twin prototype has been carried out in terms of its capabilities of integration, querying, and visualization of heterogeneous data (i.e., sensors, workers, building) for workplace performance assessment. For this purpose, a use case related to the assessment of the perceived thermal quality has been specified in form of the following competency questions (CQs):

CQ1: *How has a workspace performed for thermal quality in a certain period?*

CQ2: *Which workspace's environmental conditions are related to the reported thermal preferences?*

To address the above CQs, a customized "workplace performance dashboard" service has been implemented within the discussed ICDD web platform (Fig. *6*). On the left-hand panel an authorized user can retrieve and access all the resources and contents organized in separate ICDDs containers, one for each identified workspace (i.e., case study office "IC6-83+85"). In the *Ontology Resource* folder, the data structures necessary for the semantic formalization of the containers contents, link and domain knowledge are stored. The *Payload documents* folder contains the workspace IFC model and the proxy documents corresponding to each installed sensor. In turn, these can be accessed to retrieve the related observations from the timeseries database. Besides, the reified worker, feedback, sensor data and internal links are stored in the *Payload triples* folder.

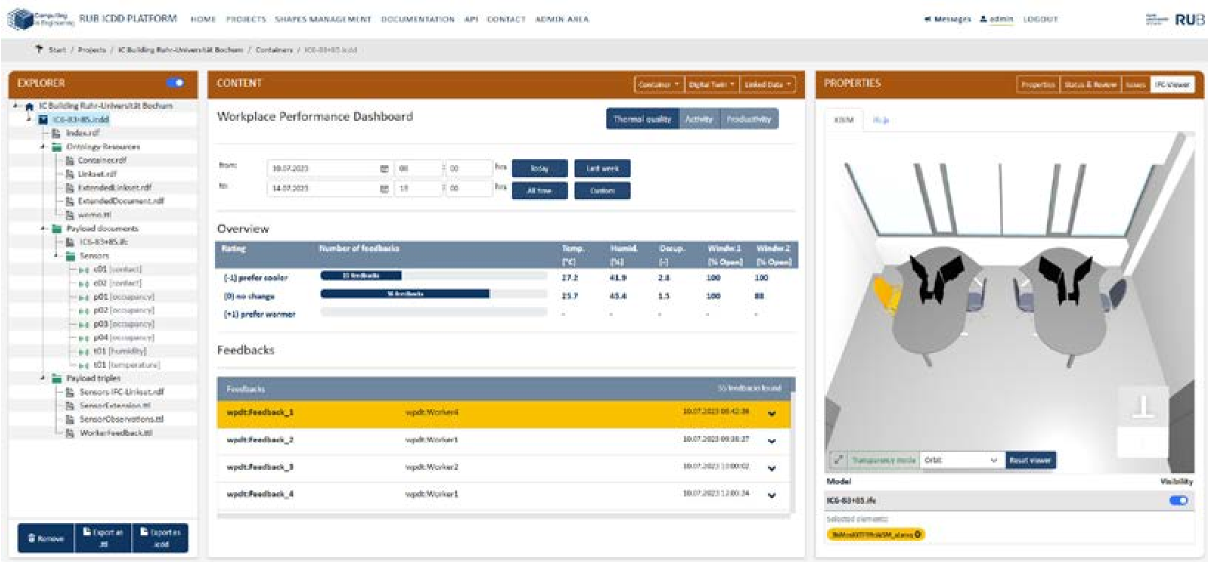

Fig. 6: Workplace performance dashboard (ICDD web platform)

In the central panel the user is provided with a graphical interface for querying and visualizing the data. The proposed approach for workplace performance assessment is centred on the evaluation of the conditions perceived by the employees and expressed with their feedback responses, hence the user has two filtering options to reduce the scope of the query: first, the object of the assessment must be chosen among preferred workspace environmental properties, activities performed by the workers or their experienced conditions; then, the target time interval must be specified. For the presented use case, feedback data are filtered for *thermal quality* preferences expressed within the data collection period of 10-14th July, 2023. In the *Overview* section the distribution of the responses is then returned according to the adopted rating scale and in relation to the mean values of the sensor observations at the corresponding feedback times. Therefore, the manager can not only assess the workplace performance in terms of overall thermal quality (CQ1) but also understand which conditions contributed the occupants' thermal comfort and take better informed actions to mitigate the occurrence of unsatisfying conditions (CQ2). In this regard, the bidirectional link established between the sensor and feedback data with the corresponding element of the workspace IFC model showed in the right-hand viewer contributes to enhance the visualization of the queried data. In fact, selecting one retrieved feedback instance the workspace element related to its source location is highlighted; conversely the selection of another linked element in the model can be used for further filtering the query results (i.e., per workstation).

6. CONCLUSIONS

The improvement of workers' well-being and productivity in existing indoor workplaces can be achieved with the adoption of occupant-centric approaches based on the understanding of the complex building/worker interactions. For this purpose, this paper presents the concept of a semantic digital twin that enables the linking and contextual interpretation of building, sensor, and worker data to support workplace management use cases. The system requirements are identified along with a comprehensive four-layered architecture, and the system's prototypical implementation is discussed. The adoption of commercial Zigbee devices and the MQTT standard protocol for data communication are proved effective for the deployment of an affordable, flexible, and scalable sensor network. An InfluxDB database is implemented to efficiently store and easily access both sensor and feedback timeseries data, the latter collected with a custom developed web survey application. The core digital twin services related to the semantic integration, querying and visualization of the heterogeneous workplace data are realized with the adoption of standardized ICDD containers and Semantic Web technologies, enabled through a custom developed web platform. Eventually, the system prototype's capabilities for the assessment of workplace performance are demonstrated with the correlation of workers' thermal preferences and workspace condition observed for the case study.

At this development stage, the proposed concept still presents several limitations that shall be addressed with further research. The extension of the digital twin prototype in terms of number of monitored workspaces, building and worker features considered, employees involved, and feedback collection period is currently undergoing to test it against a building-scale application scenario. Furthermore, additional platform's services are under development to investigate semantic reasoning opportunities that the system can provide for workplace issue discovery and spatial recommendations.

A SYSTEMATIC REVIEW OF DIGITAL TWIN AS A PREDICTIVE MAINTENANCE APPROACH FOR EXISTING BUILDINGS IN THE UK

Modupe B. Sobowale
School of Natural and Built Environment, Department of Civil Engineering, Faculty of Engineering and Physical Sciences, Queens University Belfast

Dr Faris Elghaish & Dr Tara Brooks
School of Natural and Built Environment, Department of Civil Engineering, Faculty of Engineering and Physical Sciences, Queens University Belfast

ABSTRACT: *Digital Twin (DT) developments and applications in the Architectural Engineering Construction (AEC) Industry are emerging. However, insufficient publications synthesised the existing literature on DT of existing buildings, including energy retrofit and challenges as part of Net-zero strategies. When developing DT systems, it is vital to include the existing buildings primarily captured in 2-Dimensions (2-D) static data. To date, the implementation of DT has been minimal in applications in existing buildings in the UK. Despite DT benefits for maintenance (O&M) managers, facilities management (FM) as a comprehensive source of consistent data for predictive maintenance. This study explored the challenges faced by DT adoptions in existing buildings through a systematic review of the extant literature. A systematic approach is adopted to search the Scopus database using relevant keywords such as "Digital Twin.", "Built Environment" and "Existing Buildings.". the study focused on publications from the past five years (2018 to 2023) and prioritised articles in Scopus. The findings of this paper showed that the practitioners, O&M managers, and academics in built environments need more proper knowledge and technical expertise on digital twins as part of Industry 4.0 (I4.0). Evidence from the literature resulted in low empirical case studies and applications. The complexity of real-time data integration and interoperability were highlighted as part of the challenges despite the need for comprehensive knowledge of DT in the built environment. Scarce publication on the study was noted. The directions for comprehensive solutions and future research on digital twin applications in existing buildings towards achieving efficient energy retrofits, cost reductions, and net-zero goals were highlighted.*

KEYWORDS: *Digital Twin, BIM, Data, Buildings, Energy, Management.*

1. INTRODUCTION

The emergence of Industry 4.0 has shifted the trajectory in the built environment. Digital Twin (DT) is essential to implement Building 4.0 (Delgado et al., 2023). There is more interest in DT technology as a building block of the metaverse and a vital pillar of Industrial 4.0 that needs to be harnessed (Hassani, Huang, & MacFeely, 2022). What is the place of DTs in constructed facilities projects? (Khallaf, Khallaf, Anumba, & Madubuike, 2022). The Digital Twin framework is based on Building Information Modelling (BIM) and a newly created plug-in to receive real-time sensor data from the physical instance (H. Hosamo, Hosamo, Nielsen, Svennevig, & Svidt, 2023). The built environment needs to move from a static sustainability assessment to a DT- based and IoT dynamic approach to turn climate and environmental challenges into opportunities and support the sustainability decision processes throughout the whole building's life cycle (Tagliabue et al., 2021). DT has become a 'hot topic' among academic circles and commercial communication in the industry. However, the DT is often misunderstood or misused as it is 'trendy'(Zhou, Zhang, & Gu, 2022).

Why DT instead of a traditional monitoring system? Traditional or human monitoring systems resulted in wastages, siloed documentation, and incorrect monitoring activities (Agrawal, Thiel, Jain, Singh, & Fischer, 2023; Khalil, Stravoravdis, & Backes, 2021; Sagarna, Otaduy, Mora, & Leon, 2022). Change is required, and DT could solve these problems better. The awareness of the interaction of humans and DT is vital to eliminate costs, strategic misalignments, misallocation of resources, and unrealistic expectations from DTs due to DT technology's immaturity (Agrawal et al., 2023).

DT is needed for prediction and stimulation due to the inability of the 2-Dimensioal (2D) or 3-Dimensional (3D)-BIM) data on its own to give a suitable platform for prediction. The local and global market dynamic changes require more robust and innovative operational BIMs in the AEC-FM sectors. The static 3D model needs an active approach (Harode, Thabet, Jamerson, & Dongre, 2023). However, the existing maturity models lack DT implementation comprehensively and quantitatively (Chen et al., 2021). The levels and advancement of digitalisation in the AEC industry have different capabilities. The AEC industry is fragmented into the pillars of

Industry 4.0: the Internet of Things (IoT), big data, augmented reality, advanced visualisation, Virtual Reality (VR) and simulation, additive manufacturing, system integration, cloud computing, autonomous systems, and cybersecurity (Pour Rahimian, Dawood, Ghaffarianhoseini, & Ghaffarianhoseini, 2022). There are issues with minimising the cost and manual labour of the automated segmentation of individual instances for more efficiency and valuable outcomes for geometric digital twins (Agapaki & Brilakis, 2021).

The global goals to address environmental challenges in the construction industry and operational assets' life cycles warrant a change of approach. The concept of digital twins' application as one of the solutions has a knowledge gap for its adoption in the industry. Integrating IoT, BIM and AI as parts of the digital twin to automate the monitoring and control of emissions from existing assets evidence interactive trends and patterns from collected data through the integration of machine learning. It enhances facility management as a potential for net-zero targets. However, there are limitations, such as digital shadow usage instead of real-time digital twins (Arsiwala, Elghaish, & Zoher, 2023). Nearly Zero Emission Buildings (NZEBs), reducing the energy consumption of the existing building is necessary, and the need to manage energy consumption is supported (Agostinelli, Cumo, Guidi, & Tomazzoli, 2021; Francisco, Mohammadi, & Taylor, 2020; Kaewunruen, Rungskunroch, & Welsh, 2019; Tang et al., 2023). Still, the viability of digital twins' financial and technical implementation has been questioned. However, the BIM-Digital Twin integration for detailed energy stimulation was used in a case study in the United Kingdom (UK); it was proven that digital twin implementation has the potential for a 23-year return period for renewable technology for an existing building (Kaewunruen, Rungskunroch, et al., 2019).

The DT-based approach could provide an adaptive comfort model, energy-saving strategies, and building comfort optimisation. Exploiting the digital twin approach supports sustainability decisions through the whole adoption cycle for climate issues and environmental challenges; it can be used for energy-saving in different types of buildings (Tagliabue et al., 2021). The effectiveness of implementing a digital twin for asset management is lacking for adoption in the housing sector and industry practitioners for predictive monitoring in buildings (Arsiwala et al., 2023). Existing research indicates that DT is still needed in stimulation during system run-time and different lifecycle phases in academic and industrial communities (M. Liu, Fang, Dong, & Xu, 2021).

With all the above in mind, this paper aims to develop a direction for research on digital twin applications in existing buildings towards achieving the net-zero target. The objectives are 1) to explore the challenges in using DT in existing buildings? And 2) to investigate how the built environment sector could use predictive maintenance system-based DT in the UK. The rest of the paper sections are 2) the adopted methodology in the study, 3) digital twins research for predictive maintenance, 4) research significance and contributions, and 5) the conclusion and recommendations for future studies to leverage the adoption of DT for predictive maintenance in the built environment.

2. METHODOLOGY

According to Webster and Watson (2002), the literature review aims to uncover the past to identify the gaps and chart future directions by identifying aspects that research should focus on. The benefits of using a systematic literature review in this paper are: 1). to identify where evidence may be lacking, contradictory or inclusive, and 2). justify why a problem is worthy of further study (Aromataris & Pearson, 2014). See Figure 1.

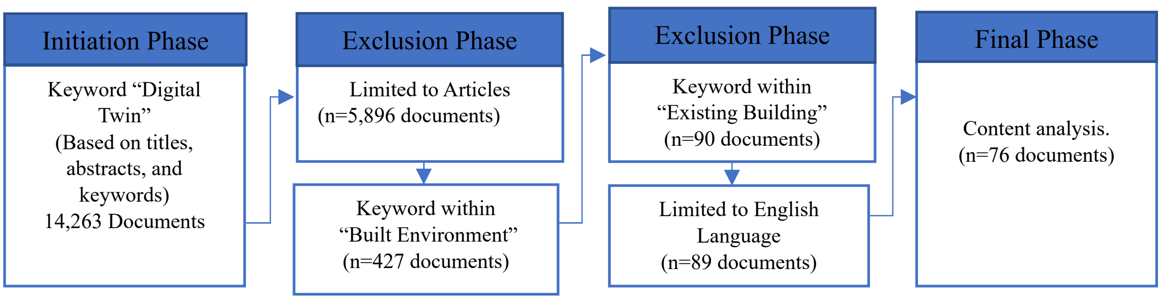

Fig 1: Systematic Selection Flowchart

The systematic review methods framework is based on the Initiation, Exclusion, Exclusion and Final phases criteria based on research studies by Kitchenham et al. (2010) and Mastan, Sensuse, Suryono, and Kautsarina (2022). For the inclusion and exclusion stage, Scopus was used to filter relevant keywords for the study to reduce the likelihood of bias, as the largest database of peer-reviewed research compared with Google Scholar or Web of Science and PubMed. The keywords searched from titles and abstracts were "Digital Twin", "Built Environment", and "Existing Building" as the relevant terms to the research study and the domain, which were used on papers published over a timeframe between 2018 and the present.

Articles were chosen from different journals written in English. The selected articles were then narrowed to 76 articles in the Scopus database using the process described in Figure 1. The articles were categorised broadly into 1). BIM-DT Maturity Model 2). DT in the AEC industry 3). DT for Maintenance of Buildings 4). DT for Net Zero in Existing Buildings (NZEB) 5). DTs for Facility Management 6). DTs for Energy Management. However, the emphasis was an overview analysis of the DT technology for existing buildings management within the AEC industry. NVivo software was used for the systematic content review and visualisation analysis. The NVIVO software aided rigorous data extraction, evaluation, and categorisation of the large amount of data generated by the 76 selected articles.

3. DIGITAL TWINS RESEARCH FOR PREDICTIVE MAINTENANCE

The following sub-sections will show cases of the attributes and challenges of DT adoptions within the articles selected. These are: 1). BIM-DT Maturity Model 2). DT in the AEC industry 3). DT for Maintenance of Buildings 4). DT for Net Zero in Existing Buildings (NZEB) 5). DTs for Facility Management 6). DTs for Energy Management for an overview of limitations faced within the built environment.

3.1 BIM-DT Maturity Model

The emergency of real-time connectivity and deployment in an environment increases the potential for DT concepts in the built environment. Noted to be in an early stage of adoption, the analysis indicated unrealised and unexploited possibilities of the DT concept for building management; further studies as a baseline were recommended (Deng, Menassa, & Kamat, 2021). BIM and DTs are disruptive technologies to be embraced by the construction industry due to the recent increase in advanced automation and autonomous technologies at the organisation, and need to be adequately leveraged (Sepasgozar et al., 2023). Notably, DT proved to be a valuable tool for the entire lifecycle management of buildings since BIM cannot handle the sensory information and complexities of existing buildings (Banfi, Brumana, Salvalai, & Previtali, 2022).

Existing BIM standards (ISO 19650) were proposed to promote a better interoperable digitalised built environment to develop DTs in the AEC sector (Nour El-Din, Pereira, Poças Martins, & Ramos, 2022). DT-BIM-based model reduced load bearing and risk in existing highway infrastructures. However, concerns were information collection and analyses for inspection, maintenance planning, and data sharing and visualisation limitations. The BIM-based model provided solutions and insights for high-quality construction and maintenance to minimise rapid degradation and component failures in infrastructures. Owners and stakeholders would achieve higher operational efficiency and sustainability outcomes over the life cycle, especially the expensive phases (Kaewunruen & Lian, 2019). DT-BIM-based model is recommended for the whole life-cycle mitigation of risks and uncertainties of exposure to extreme weather conditions for construction industry stakeholders (Kaewunruen, Sresakoolchai, Ma, & Phil-Ebosie, 2021).

Integrations of human-centred approaches, Virtual Design Construction (VDC), digital twin and artificial intelligence will transform the future of the AEC industry and create research opportunities. The integrations can simultaneously optimise, predict, and provide significant cost savings for the industry work processes, which should be noted for the main line of future research (Rafsanjani & Nabizadeh, 2023). BIM, IoT, and AI-supported systems are beneficial for prediction and data-driven retrofitting strategies, a step towards achieving the net-zero targets (Arsiwala et al., 2023). Multi-layer DT called BIM-IoT-Data integration (BIM-IoTDI) indicated capabilities to overcome interoperability and be suitable for smart buildings (Eneyew, Capretz, & Bitsuamlak, 2022). AI, DTs, and scanning technologies are valuable for maintenance strategies. However, some challenges are associated with technological, cultural, market and regulatory factors (Çetin, Gruis, & Straub, 2022).

Two-directional interactions between humans and computers should be part of the development to reach a high maturity level. Further studies, including advanced technologies like AI, BIM, and Geographic Information System (GIS) cloud computing, are essential to cope with the complex urban challenges of multidisciplinary DTs (Masoumi, Shirowzhan, Eskandarpour, & Pettit, 2023). Automation and robotisation are resources for management improvement in construction and existing buildings-the BIM data are programmed to a robot and visual format as the digital twin of the real-world building revealed valuable results that need further studies on the data reliability, interoperability of the BIM and 3D-Robot connections, and update of the BIM model based on robot feedback (Pauwels, de Koning, Hendrikx, & Torta, 2023). Likewise, the Mobile BIM Technology (MBT) functions can help researchers and practices in digitalisation, lean construction, evaluation perspectives and data-driven approaches to enable DT. Legal and security perspectives should be considered (Jowett, Edwards, & Kassem, 2023).

The proposed DT and Cloud BIM-Extended Reality (XR) platform development using the Scan-to-BIM-to-DT process to a 4D multi-user live app to improve building comfort, efficiency and costs was validated for energy improvements for existing buildings and façade renovations (Banfi, Brumana, Salvalai, et al., 2022). Implemented DT used scan-to-BIM with sensor data as an Industry Foundation Classes (IFC) BIM platform to monitor the structural health of the building walls. It can benefit FMs for planning and maintenance activities and the long life cycle of a building (Longman, Xu, Sun, Turkan, & Riggio, 2023). The lack of a clear process roadmap is partially a factor. Still, Digital Twin Construction was proposed as a comprehensive construction mode that prioritises closing the control loops instead of an extension of BIM tools integrated with sensing and monitoring technologies (Sacks, Brilakis, Pikas, Xie, & Girolami, 2020). DT cannot be limited to the focused aspects like 3D modelling, monitoring, and visualisation of DTs (Masoumi et al., 2023). Tagliabue et al. (2021) supported shifting from a static sustainability assessment to a digital twin-based and IoT-enabled dynamic approach for real-time evaluation, sustainability criteria control, and user-centred viewpoint in the built environment. A roadmap is required to support decisions and policymakers to aid implementations for the next ten years (2030) (Sepasgozar et al., 2023).

It should be noted that DTs are extensions of engineering information (EI) leveraging modern information and communications technology (ICTs) and do not have their unique technical characteristics (Zhou et al., 2022). The integration of DT roles as an observer, analyst, action executor and decision-maker is useful in helping practitioners systematically plan DT deployments, clearly communicate goals and deliverables, and lay out a strategic vision (Agrawal et al., 2023). Digital Twins are the future of the metadata required for a socio-technical collaborative and sustainable ecosystem based on a virtual representation of the physical instance in a real-time operational state superseding static 3D- Building Information Modelling or traditional 2D of assets for the multidisciplinary AEC domains for operational efficiency and cost reduction (Pregnolato et al., 2022) updated information to analyse and optimise ongoing design, planning and production, lean construction, and data-centric construction management (Sacks et al., 2020).

The widespread traction of DTs for constructed facilities projects reveals the benefits of DTs as the ability to reduce operating costs and human error, automate energy demand, manage assets throughout their lifecycle, and structural health monitoring in real-time (Khallaf et al., 2022) with robot-Assisted reality capture in larger spaces (Xu, Xia, You, & Du, 2022). The application of DTs and Machine Learning helps predict and analyse prestressed steel structures needed for intelligent monitoring techniques and control methods to ensure safety (Z. Liu, Yuan, Sun, & Cao, 2022). IoT and DT connection and integration produce real environments to boost automation, Industry 4.0 transformation and cost-effectiveness (Al-Dhlan, 2021) with robot-assisted reality capture in larger spaces (Xu et al., 2022). Likewise, DTs in the UK are used for highway asset management to achieve minimum human input and have very high accuracy (Jiang, Ma, Broyd, Chen, & Luo, 2022).

Multi-layer DTs proved to be a valuable tool for the entire lifecycle management of buildings since BIM cannot handle the comprehensive DT technology that can be supported with socio-technical approaches to reach maturity. The integration of IoT with DT has proven to be valuable with the application of DTs in the multidisciplinary AEC domains, even though some challenges were indicated in Tables 1-5.

3.2 DT in the AEC Industry

The articles in Table 1 are on DT research in the AEC Industry and the challenges encountered. Infrastructure assessment and construction management were highlighted.

Table 1. Articles on DTs studies within the AEC Industry.

Author/Year	Focus of Study	Employed Tools	Challenges /Limitations
(Camposano, Smolander, & Ruippo, 2021)	Awareness of DT of Built assets relative to the software ecosystem	Interpretive analysis of semi-structured interviews	Inter-organizational relationships, data sharing, and technical expertise
(Çetin et al., 2022).	Adoptions of digital technologies in social housing	Multiple- case study Circular Economy Digital Twins framework	Technical, cultural, market and regulatory issues. Misalignment of supply and demand. Data quality and sharing
(Eneyew et al., 2022)	Interoperability of smart-building DTs	BIM-IoT Digital integration	Autonomous query decision and data sharing

(Jowett et al., 2023)	Mobile BIM technologies taxonomy in field BIM interactions with construction management functions	A longitudinal case study over 12 months, two project workshops, expert interviews and an industry survey at project, enterprise, and industry levels.	Lack of delineation between related terms used.
(Kaewunruen et al., 2021)	Vulnerability assessment and risk-based maintenance of infrastructures	BIM-DT based model	Automated interaction of data, 3D modelling human resources and standards, IT software natural and human risk assessments.
(Longman et al., 2023)	The implementation of DTs to support structural health monitoring (SHM).	Scan-to-BIM approach in IFC-BIM platforms.	Data integrations and project infrastructure
(Nour El-Din et al., 2022)	Status of DTs and the evolution of the concept of DTs for construction Assets	Systematic Review	Lack of data standardisation
(Pauwels et al., 2023).	Live semantic data transfers from building digital twins for robotic navigation	BIM-based model	Automation, data reliability and standards
(Rafsanjani & Nabizadeh, 2023)	Cost-saving DT capabilities in construction and operational phases	VDC-DT based model + VR+AR	Technical expertise, Compatible software, Automation, Human-centric scenarios, real-time data senses and analysis.
(Sacks et al., 2020)	Digital twin information systems to achieve closed-loop control systems to monitor construction.	Conceptual analysis	Lack of comprehensive information system and knowledge

3.3 DT for Maintenance of Buildings

Table 2 comprises articles on building maintenance and the challenges of adopting DTs. Emphases are mostly on historical building restoration.

Table 2. Articles on DTs exploration for maintaining structural buildings.

Author/Year	Focus of Study	Employed Tools	Challenges /Limitations
(Ali, Alhajlah, & Kassem, 2022)	The status and future trends in building information modelling (BIM)	Systematic literature review (SLR) methods through co-occurrence and co-citation analysis.	The complexity of the project, integration of components and data
(Banfi, Brumana, Landi, et al., 2022; Khalil et al., 2021)	Data categorising in the digital documentation of heritage buildings	HBIM model	Protection and longevity of heritage buildings data. Interoperability and BIM standardisation or extended reality environments and data formats.
(Cardinali et al., 2023; Moyano, Carreño, Nieto-Julián, Gil-Arizón, & Bruno, 2022; Noronha Pinto de Oliveira e Sousa & Correa, 2023).	Digital twins for heritage buildings.	Historic building information modelling (HBIM) geometric model.	Data acquisition constraints and difficulties, the scale of the building.
(Daniotti et al., 2022).	BIM-DT Based Interoperability for efficient renovation in buildings	BIM-DT based model	Data integration and standardisation processes
(Pan, Braun, Brilakis, & Borrmann, 2022)	How to enrich geometric digital twins of buildings, particularly emphasis on capturing small vital entities in buildings	3D point cloud + AI-based image segmentation	Variation in objects, data collection and occlusion of the environment
(Porsani, de Lersundi, Gutiérrez, & Bandera, 2021)	Evaluates of an automated or semi-automated BIM to BEM workflow in buildings	BIM-BEM model	Technical expertise, large and complex buildings
(Sagarna et al., 2022)	Documentation and displaying inspection-related information in BIM models to generate a dynamic information model in buildings.	Innovative BIM model-State of Conservation Assessment BIM Model (SCABIM)	Dynamic open-source data integration, technical workforce, and equipment

4. RESEARCH SIGNIFICANCE AND CONTRIBUTION

The research's significances are to remove silos and allow data and information sharing for effective and holistic implementation and interactions that reduce wastage and costs in retrofitting and energy consumption in existing buildings as one of the largest energy consumptions. The research would add insights into energy retrofit and management cost as part of Net-zero strategies in the UK.

Analysing the existing literature on DT attributes and challenges provides a glimpse into the reality of insufficient research studies on DT globally, especially in the UK; 25 articles from the UK were within the research scope. The analysis would contribute to the body of knowledge in the UK and globally. The literature pointed out the confusion of DT as an extended branch of BIM. However, DT has been revealed as a multi-objective and multi-scale technology field within the I4.0 that requires an advanced analytical approach through data and stimulation to support comprehensive and predictive decision-making to save costs and wastages. The door is widened for researchers to explore viable solutions to overcome the challenges uncovered in the literature to leverage DT benefits within the built environment.

The research would contribute and benefit suppliers (technologies and platforms), homeowners, landlords, policymakers, operation and maintenance (O&M) managers, facilities management (FM), and the research community to reduce costs with predictive decisions based on proactive maintenance rather than reactive maintenance. It will replace speculative retrofitting actions with factual insights for different types of existing structural buildings, occupancy behaviour and locality. There are reasonable limitations within the period of the systematic review and the platform used to select optimal articles based on the research topic due to the low number of publications. However, more publications could have been added from other platforms like Google Scholar but not peer-reviewed to ascertain the quality required to maximise the value of the review.

5. CONCLUSIONS AND FURTHER RESEARCH

Digital Twins can integrate information from multiple sources to replicate the operation of the physical spatial asset in real-time for stimulations and predictive insights**.** The application of digital twins is still in an emergency phase as a valuable digital technologies advancement, especially with the built environment and the AEC industry in the UK. There needed to be more publications on the research topic. The paper set out two objectives: 1) to explore the challenges in using DT in existing buildings. And 2) to investigate how the built environment sector could use predictive maintenance system-based DT in the UK.

DT needs to be more understood and consistent in the application or technical tools usage from literature. In addition, practitioners, AEC managers and academics need more proper knowledge and technical expertise on digital twins as part of the I4.0, as evidence from the literature resulted in low empirical case studies. The complexity of real-time data integration and interoperability were highlighted as part of the challenges. Digital Technologies can be pardoned as a common word for I4.0, are the enabler of all societies and organisations' productivities, previously a buzz, now overtaken by Artificial Intelligence (AI). The direction to advance digital twins' adoptions in existing buildings towards achieving net-zero goals is realism 1). Training for applicable practitioners in the built environment for the AEC industry. 2). Affordable computations and simulation tools and systems 3). Cloud-based architecture infrastructure and services 4). Data integration and interoperability 5). Open sources collaboration 6). Socio-technical influences and sustainable policies.

Finally, based on the literature, predictive maintenance system-based DT with intelligent analysis supported comprehensive and consistent solutions for rehabilitation, operation, and maintenance management of existing building life cycle management. However, more steps are needed to leverage the benefits: the future case study for the built environment sector to use predictive maintenance system-based DT in the UK are 1). the depth of knowledge of DT with professionals in the built environments, 2). A standard benchmark framework for DT adoptions 3). Available and accessible computations simulation tools, and systems 4). Funding for the research 5). Socio-Technical influences and training.

ABSTRACT: *In supporting the economic growth, Indonesian government has instructed to develop 201 National Strategic Infrastructure Projects, including Ameroro Dam Project. Located in Southeast Sulawesi, the construction process faced many engineering challenges with conventional monitoring methods, such as potentially delayed action plan and hindered decision making due to insufficient progress visualization data, inadequate real-time monitoring data, and unintegrated engineering data. Therefore, Project Management Information System (PMIS) dashboard is utilized as a Digital Twin innovation to overcome these challenges and optimize the project delivery. This study presents a case study approach on how PMIS could optimize the progress monitoring in Ameroro Dam Project. This PMIS Dashboard is integrated with Building Information Modelling, Digital Survey, Geospatial Data, and Project Management Data that supports the decision making as it provides more reliable data. This study illustrates the comparative study between conventional method and PMIS efficiency for a better project management. The effectiveness of PMIS can be seen as the integrated data is utilized to plan a construction working methods, along with monitoring the project schedule. Moreover, the visualization helps the engineers for a risk mitigation with the project performance display. Eventually, the paper concludes by the PMIS dashboard optimization for real-time progress monitoring in dam project, leading to more efficient infrastructure construction project management.*

KEYWORDS: *BIM, Digital Twin, Construction Working Methods, Geospatial Data, Progress Monitoring, Project Management.*

1. INTRODUCTION

As an agricultural country, the presence of Dam has always been considered as one of the most important infrastructures in Indonesia. As one of the most crucial engineering infrastructure, Dam is primarily used for water supply, flood control, agricultural irrigation, and hydroelectric power generation (Kalkan, 2014). Despite its many functions, the construction of Dam project is considered very complex. The construction of Dam project involves a large number of people with various objectives, interest, and disciplines to perform interdisciplinary activities. Moreover, time and physical resources limitations have added another dimension of complexity for dam project (Mahato & Ogunlana, 2011). However, many construction projects in Indonesia still apply traditional methods of project management which frequently caused a low productivity and waste a significant amount of time and resources due to poor prioritization and poor multi-tasking. Not only in Indonesia, but globally, construction is one of the biggest industry in the world that matters for the world economy. However, it has a long record of poor productivity. McKinsey (2020) reports the construction industry represents 13% of global GDP, but the productivity growth in construction only reach 1% annually for the past two decades. As shown in Figure 1, is significantly less than the productivity growth of the global economy, approximately 2.8% a year.

The low productivity in construction caused by many factors, one of which in slow innovation and digitalization. As it can be seen on Figure 2, the digitization index in construction is ranked as the lowest 2 among other industry. Currently, many construction projects are still using traditional monitoring systems which is impossible to implement timely checks and repairs (Woo, 2010). Previous studies also identified several limitations of conventional monitoring methods such as the absence of project visualizations that can hinder the decision making, affected the project quality, time, and costs.

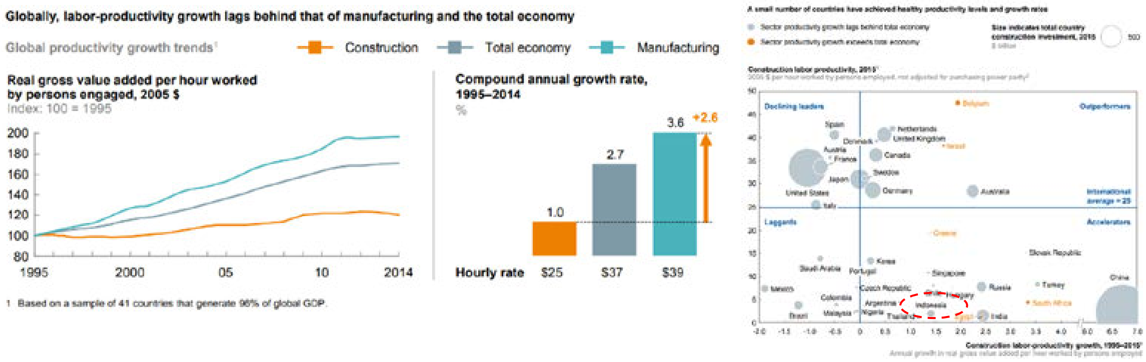

Figure 1. Global Labor Productivity Data (McKinsey Global Institute, 2017)

Figure 2. Industry Digitization Index (McKinsey Global Institute, 2016)

As the construction projects are getting more complex, it needs more advanced and integrated tools to improve the construction process. Along with the advancement of information technology (IT) that have been rapidly evolving, Digital Twin and Building Information Modelling (BIM) are some of the latest technologies that are useful in terms of improving project management in construction. Digital Twin can be referred as a concept originated with the Internet of Things (IoT) that represents digital simulation within an IT platform by integrating physical feedback data, artificial intelligence (AI), and machine learning (Bi, 2022). Furthermore, Digital Twin contributes to smart construction in achieving economic and sustainability goals (Istanbullu, Wamuziri, & Siddique, 2022). As it improves the productivity in construction sector through digitalization, many studies discussed about the implementation of Digital Twin and BIM in the construction project. However, the least amount of research discussed the best practices of Digital Twin utilization for infrastructure project management, specifically dam project. Therefore, this paper aims to perform a digital construction innovation namely Project Management Information System (PMIS) dashboard as a Digital Twin platform and analyze the project management effectiveness based on a real case study of a dam project. Finally, some recommendations of PMIS future development are proposed in the conclusion for future infrastructure projects.

2. LITERATURE REVIEW

2.1 Project Management

In order to success in delivering the expected project delivery, a good practice of project management should enable organizations to execute the project effectively and efficiently. Project management can be described as the implementation of knowledge, skills, tools, and techniques to project activities to meet the project requirements. Project management is accomplished through the correct execution and integration of the project management process identified for the project (Project Management Institute, 2017). Especially for construction project which involves many aspects, a good project management practice is required to ensure the project can be delivered on time. Moreover, construction project management can be described as a multidimensional discipline that requires accurate consideration of various crucial aspects, including cost, quality, schedule requirements, as well as social and environmental impacts, and broader stakeholder interests (Ke, Zhang, & Philbin, 2023).

2.2 Project Monitoring

To achieve the project goals, there are several crucial things in practicing project management, one of which is monitoring. Especially for dams construction, monitoring is considered critical since deformation may occurred as a result of erosion, water load, hydraulic gradients, and water saturation (Kalkan, 2014). Besides, monitoring can be described as collecting, calculating, assessing measurement and trends to enhance the process improvements (Project Management Institute, 2017). It can be concluded that project monitoring is fundamental aspect for successful project management and decision-making. However, despite the importance of project monitoring, many construction projects currently constrained by the inadequacy of traditional monitoring system. Traditional monitoring methods are considered inaccurate, time-consuming, and labor-intensive because they rely on large-scale manual operations that will lead into project delays and cost overruns (Nakanishi, Kaneta, & Nishino, 2021). Therefore, a good project monitoring system in a complex construction project is considerably important. For instance, continual monitoring is required to give the project management team with insight into the project's health and indicates any areas that might require special attention (Project Management Institute, 2017). It is because successful construction projects are identified by the level of awareness of project progress or work performance. Moreover, a progress monitoring system should comply the information requirement for real-time progress and decision making (Teizer, Lao, & Sofer, 2007). Ideally, monitoring may fasten the decision makings with its reliable data. The monitoring activities process should enable stakeholders acquire a comprehensive overview of the project's existing condition, identify issues for corrective action, and estimate future performance in terms of time and cost (Project Management Institute, 2017). As numbers of research have been conducted to reduce the gap between traditional monitoring and real-time monitoring, several approaches have been proposed for a better project management in construction monitoring.

2.3 Project Management Information System

Semi or fully automated data collection and analysis process can be a support in making quick and accurate decisions. Fortunately, technological advancement has been striving to improve the construction monitoring system in recent years. Numerous emerging automated data collection, analysis, and visualization techniques also have been utilized to develop systems for digitized real-time progress monitoring (Nakanishi, Kaneta, & Nishino, 2021). Thus, the implementation of PMIS can be considered effective to improve the project management in a complex project. According to Project Management Institute (2017) PMIS required to collect, analyze, and use the information to accomplish the project objectives and realize the project benefits. Moreover, PMIS also provides access to Information Technology (IT) software tools such as scheduling software, that allows stakeholders to track planned dates versus actual dates, report variation between the progress performance against the schedule baseline and estimate the effects of modifications to the project schedule model. Beside the integration between the volume of data and information, PMIS also includes scheduling software that has the capability to help plan, organize, and adjust the sequence of the activities; it also expedites the process of building a schedule model by generating start and finish dates based on the inputs of activities, network diagrams, resources, and activity durations (Project Management Institute, 2017).

2.4 BIM and Digital Twin

As it can fulfill the aspects of the PMIS, the idea of collaborating BIM and GIS shows a great potential as a Digital Twin to improve the project management process. In the last few years, BIM known as a collaborative working method for the creation and management of a construction project (Acebes, Testa, Alonso, & Curto, 2023). BIM can be defined as a three-dimensional view that represents the building data to achieve the summary and integration of various information in construction (Yue, 2023). Furthermore, project progress cost, construction clashes and situation can be accessed through the animation in BIM. These functions are in line with the PMIS which include spreadsheets, simulation software, and statistical analysis tools to assist with cost estimating (Project Management Institute, 2017). However, the utilization of BIM only could not satisfy the PMIS objectives. While BIM tools provide excellent representations for product design, they often lack essential features necessary for construction when it comes to Digital Twins (Bao, Guo, Li, & Zhang, 2018). Digital Twin can be defined as a virtual representation of a physical asset that can reflect its current status. The data is collected through sensors and other monitoring devices embedded within the structure and transmitted to the virtual model in real-time (Ma, et al., 2020). The implementation of Digital twins ensures the final result to be more accurate and reliable. Through accessing to this real-time data, stakeholders can quickly identify and respond to issues as they arise, leading to increased efficiency and productivity (Jiang, Guo, & Wang, 2021). In this case, BIM can be utilized for visual management tools as the base information for Digital Twin to provide a high-level representation of buildings and their assets by integrating the physical and digital world (Hosamo, et al., 2022). Besides, Digital twin construction creates a data-centric way of construction management by combining BIM technology, lean construction thinking, the digital twin concept, and artificial intelligence (Bandara, Ranadewa, Parameswaran, & Eranga, 2023). Hence, the availability of current and historical data on the digital twin enables predictions of future behavior which beneficial for operation and maintenance phase from the infrastructure asset (Sivalingham, Sepuvelda, Spring, & Davies, 2018). Some technologies such as GIS and digital surveying are also utilized to obtain the real-time data of Digital Twin. Moreover, the presence of PMIS as digital twin may improves the overall project management performance as it displays the visualization of current project state, detect the potential risk, shows the project performance, as well as enhance the collaboration between stakeholders. However, as many observers addressed about the development of BIM and Digital Twin, none of the observers discussed about the best practices for dam project. This perspective is important since dam construction is considered very complex and required a good project management system. Hence, the proposed research is to identify the Digital Twin best practice for dam project, as well as analyzing the effectiveness for project management.

3. METHODOLOGY

The methodology used on this research is based on a case study approach of Ameroro Dam from the perspective as the general contractor for project management purposes during the construction. The obstacle inherent in the construction phase is that the monitoring process is still conventional, resulting the data obtained not being real-time, although this phase is critical for monitoring project performance to ensure quality, budget, and schedule. Therefore, the step to overcome this limitation is by doing digitalization with PMIS. The PMIS will automatically collect and process the data such as BIM Model, Digital Survey data, and project data for the input data. As the result, the PMIS platform will present the project data in a more effective way, especially to support the project management and decision-makings.

3.1 Case study description

As an agricultural country, the agricultural sector plays a crucial role and contributes to the country's economy. According to data from Central Bureau of Statistics, Indonesia produces 31,36 million rices in 2021, and the government plans to increase the rice production targets up to 300.000 tons in 2024. Therefore, to support this policy, the Ministry of Public Works mandated to construct 65 priority dams through the National Strategic Project, one of which is Ameroro Dam Project. The Ministry of Public Works assigned the construction of this project to Hutama Karya as one of the Indonesia's leading state-owned enterprises for the main contractor. Ameroro Dam is built as the 2nd dam in South East Sulawesi Province to increase the number of water reservoirs in Indonesia in order to support food security programs and water availability. This dam was designed to be a multipurpose dam, with a total capacity of 54.15 million m^3 and an inundation area of 212.89 Ha. With the project value of 38 million USD, Hutama Karya covers the scope of works namely spillway, access road, bridges, hydromechanical and electrical, and supporting and facility buildings. With a project duration of 945 days, Hutama Karya faces a complex project management to finish Ameroro Dam Project such as targeted to accelerate from the project schedule, remote access to the project, and managing communication with stakeholders in remote area. Therefore, an effective monitoring system is required by the organization to manage this project throughout the project life cycle. The required features to support the project monitoring are collected and combined into a platform to form the PMIS dashboard. The utilization of PMIS dashboard helps Hutama Karya as the main contractor to enhance the project management during the construction process. The PMIS is based on Building Information Modelling (BIM) and Geographic Information System (GIS) and is integrated with other company's strategic platforms, which supports the data requirements for the project to provide a more reliable data, especially during the decision-making process.

Figure 3. Ameroro Dam Project

3.2 Project management information system

The existence of PMIS has significantly improved project management by delivering a more accurate construction process and a better project visualization for construction monitoring. The features available on the PMIS dashboard does not have any specific benchmarks and are developed according to the company's business process needs. The framework in Figure 4 shows the workflow from data collection to processing and output production of PMIS. The primary data such as BIM Model, Digital Survey Data, and Project Data is utilized as the foundation of PMIS dashboard which in this case study is built in the base of a GIS platform, thus geospatial map is becoming the base layer of the information. The production of BIM Model is required and processed with georeferenced coordinate system, inserted to be a raw data for Geo-BIM feature. The Geo-BIM referred to in this paper is the integration of the BIM Model with GIS, hence, to simplify further discussion it will be referred as Geo-BIM. On the other hand, Digital Survey obtained with Photogrammetry methods by using Drone Mapping. This digital surveying operation will produce point clouds and processed into Digital Terrain Model (DTM), Digital Surface Model (DSM), and Orthophoto as a raw data for Geo-BIM. Afterwards, the superimposed BIM Model and Orthophoto in the GIS platform will be beneficial as the progress visualization feature for project monitoring. Moreover, this PMIS dashboard is also equipped with video surveillance from live CCTV that will support the stakeholders for doing construction monitoring remotely. For a better understanding on how PMIS works for the project management process, it will be explained in Figure 4 as shown below.

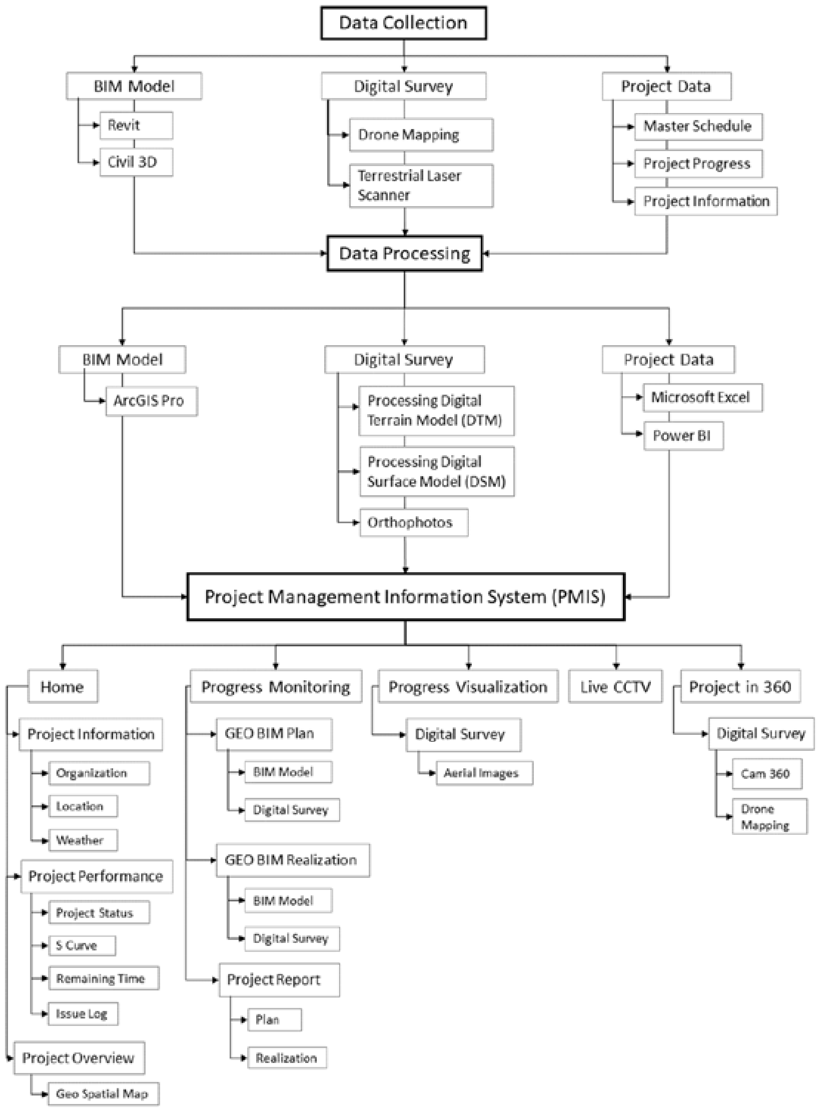

Figure 4. PMIS Flowchart

3.3 Data Collection

As a basis input for PMIS dashboard, data collection is undertaken using two methods namely manual methods with total station and 2-dimensional engineering drawings and digital methods by utilizing digital survey, BIM, and project data. The digital data collection includes Digital Surveying process to obtain the geographic data, real-time data, and making the BIM Model for the visualization and calculation needs.

3.3.1 Manual Data Collection

The conventional method of surveying is undertaken by surveyor using a Total Station Topcon GTS 230 and it took approximately 1,5 hours for 1 hectare. The manual surveying is undertaken by 2-3 surveying engineers. Furthermore, the 2-dimensional engineering drawing usually made at least 1 day for each drawing as shown on Figure 5.

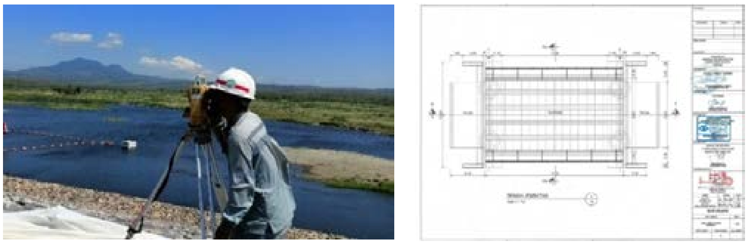

Figure 5. Manual Data Collection with Total Station and 2D Engineering Drawing

3.3.2 PMIS Data Collection

3.3.2.1. Digital Survey

At the earliest stage of the construction, Digital Survey was conducted by BIM Engineer to obtain geographic data to be superimposed with the engineering drawings. The digital surveying process is carried out with Photogrammetry method by using Drone Mapping that will perform aerial surveying and generate a collection of images of the object. The raw data was collected using a drone DJI Phantom 4 Pro V.20 shown in Figure 6. The surveying methods was started by arranging the flying route of the drone and setting up the overlapping rate between each image. Furthermore, Digital Survey method considered effective as it took only 15 minutes approximately for the area of 15 hectares per flight mission with 100 meters of altitude and produced Digital Elevation Model and Orthophotos as the output. This method is conducted regularly, and the data will be embedded on the PMIS dashboard for project monitoring needs.

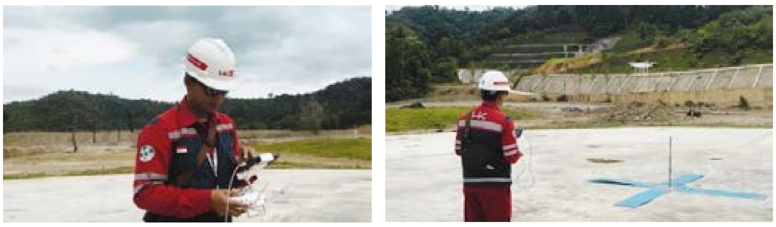

Figure 6. Digital Survey process with Drone Mapping

Figure 7. Photogrammetry Flight Mission

3.3.2.2. Building Information Modelling

During the construction process, Building Information Modelling (BIM) plays an important role as the project visualization. Hence, the BIM Model is an important input data for the PMIS dashboard, which can be later integrated with GIS. The data collection process started with the BIM 3D Model creation based on the detailed engineering drawings using BIM Authoring tools. Afterwards, the coordinate points from the digital survey are inputted on the BIM 3D Model, so that this model has georeferenced data that can be integrated with GIS later on the PMIS Dashboard. The process for generating shop drawings from BIM 3D model only requires 4 hours to finish each drawing. This 3D model is also required to provide the design overview for stakeholders, as well as being the basis for decision-making in solving any clash problems.

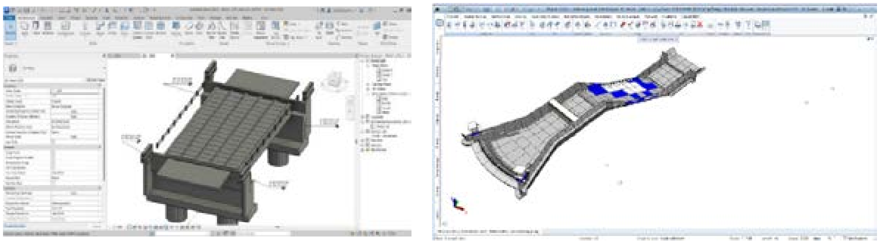

Figure 8. Georeferenced BIM Model

3.3.2.3. Project Data

Besides, the PMIS dashboard also integrated with project data such which compiles stakeholders name, project milestones date, location, and project remaining time to be showed in the project information. Moreover, the PMIS dashboard also integrated with project engineering data such as master schedule, monitoring schedule, 4D scheduling from BIM, plan and realization of project cost that becoming the focal point of the dashboard which will be featured as the project performance.

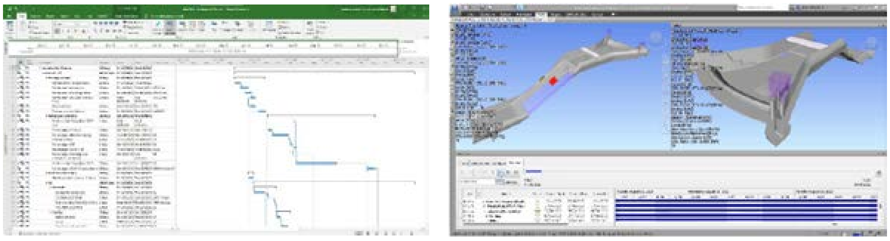

Figure 9. Integrated Project Schedule Data

3.4. Data Processing

3.4.2. Manual Data Processing

For the surveying phase, Total Station obtained RAW data such as distance and elevation level, and the output will be inputted manually on Microsoft Excel and processed in CAD software. Moreover, for the schedule data, the conventional method needs to input manually on Microsoft Excel or Microsoft Project for the monitoring purpose. This process usually requires 6 hours long to produce Cross Section data as a support for Project Monitoring.

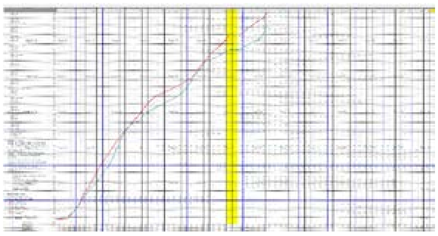

Figure 10. Project Master Schedule

3.4.3. PMIS Data Processing

The graphic visualizations on this dashboard are supported by collaborating platforms and software which data kept in cloud-based or on-premises server. In this case, the company use both, the combination between cloud-based and on premises server because the data is interlinked. Nowadays, digital platforms are build based on collaboration which helps them to grow stronger with the ability on showing other platforms data through open API and interlinked data. As well in this PMIS dashboard, beside using open API to connect the BIM model data, the connector between platforms is developed in spreadsheets that previously arranged with required fields based on each visual requirement. Thus, the information inserted is categorically and historically inputted regarding the visual representation needed in the dashboard then transformed into bar graphs, doughnut graphs or gauge charts.

3.4.4. Project Information

The project information as the basic data, compiles stakeholders name, project milestones date, location, weather condition, and remaining time that becoming the focal point of the dashboard. In the framework of project management, the remaining time shows in countdown to ensure the initial attention of the stakeholders are concerning on how the time and progress are in the right direction, otherwise the rest of information provided in this dashboard will be able to support the necessary decision making to guarantee the timely delivery of the project.

Figure 11. Project Information Data Processing

3.4.5. Project Performance

Project Performance is used to determine if a project is in the Excellent, Warning, or Critical category based on the actual and anticipated project cost value, income realization, and plan. The Project Performance contains many information and integrated with the project engineering data such as master schedule, monitoring schedule, plan, and realization of project cost. Firstly, these databases are inputted in Microsoft Excel and processed on ArcGIS Pro. Then the dashboard is created on ArcGIS Dashboard Enterprise, and these S curve dashboards are inputted in PMIS dashboard through the ArcGIS Experience Builder.

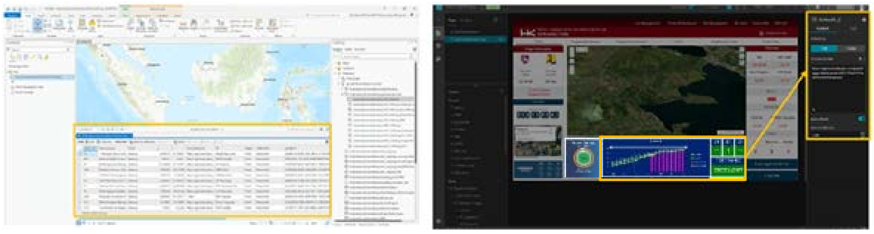

Figure 12. Project Performance Data Processing

3.4.6. Geo-BIM

During the data processing, the Digital Survey data which obtained from Drone Mapping will be processed to be superimposed with the BIM 3D Model. The output produced from the drone mapping were subsequently translated into Orthophoto and Digital Elevation Model (DEM) to be processed in Agisoft metashape. Afterwards, DEM can produce 2 outputs, namely Digital Terrain Modelling (DTM) and Digital Surface Modelling (DSM). DTM could be processed as a contour and can be developed as cross section and top surface in Autocad Civil 3D to produce cut and fill volume calculation for progress monitoring. Meanwhile the DSM or Digital Survey Modelling will be processed as 3D Object. The 3D object will be inputted in ArcGIS and overlayed with the BIM Model to see the construction progress, as shown on Figure 13 and 14.

Figure 13. Orthophoto Data Processing

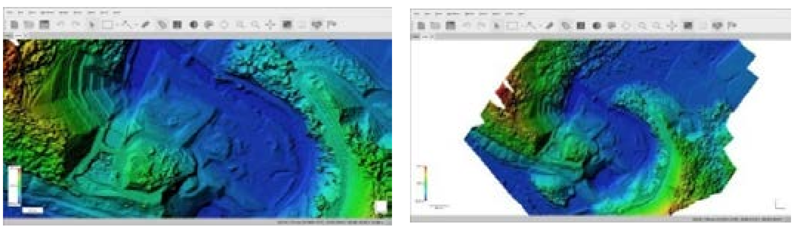

Figure 14. Digital Elevation Model (DEM) Data Processing

3.5. Result and Discussion

After the data processing, many outputs showcased as the result of PMIS. The final output contains project performance, Geo-BIM, and Live CCTV which beneficial as the progress visualization and enhance the decision-makings during the construction progress. This dashboard usually used as project management plan by project stakeholders namely project manager, site engineer manager, engineers, and head-office management team to identify the current project status and regular monitoring purposes during the coordination meeting.

3.5.2. Project Performance

The main page of PMIS dashboard allows us to identify the current project status and project performance. It includes the project information such as project value and time of completion, project remaining time, project location, and the weather. The project performance feature also integrated with the project master schedule, showcasing the S Curve of the project progress. Moreover, it completed with the Schedule Performance Index (SPI), Cost Performance Index (CPI), and Efficiency Performance Index (EPI) which will resulting as the project performance conclusion, as shown on Table 1. Moreover, it also completed with the project data such as financial data, QHSSE data, Issue log and action plan.

Table 1. Project Performance Formula

	SPI	EPI	CPI
EXCELLENT	>1	>1	>1
WARNING	>1	<1	<1
CRITICAL	<1	<1	<1

SPI = Schedule Performance Index

EPI = Efficiency Performance Index

CPI = Cost Performance Index

This formula is referred as Project Forecasting, that is utilized as a monitoring tool that ease the project management team to identify risks and take actions, as well as allocate the resources early. The result can be seen on the PMIS main dashboard which aims to increase the project team's awareness of current project status as shown on Figure 15.

Figure 15. Project Performance

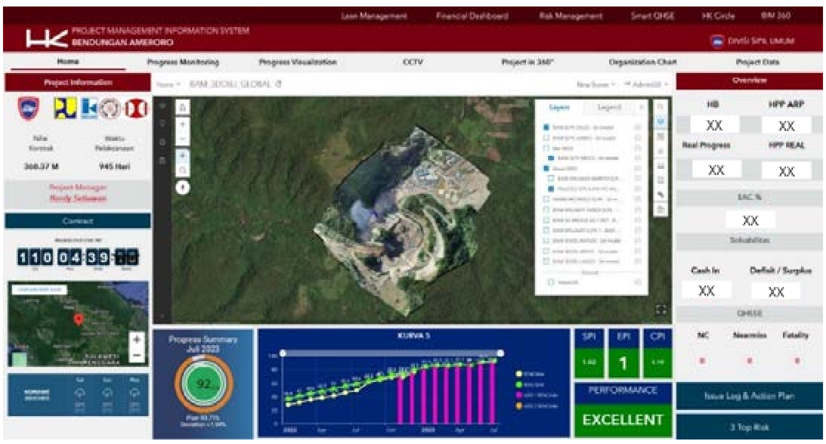

Figure 16. Ameroro Dam Project Performance on PMIS Dashboard

3.5.3. Progress Visualization

The aerial images produced from the Drone Mapping are shown in Progress Visualization feature as an overview of the construction progress. This feature is beneficial for regular monitoring purposes to ensure many points on the site that are difficult to reach manually, so that if there are any construction issues such as initial cracks occur, it can be detected and anticipated immediately.

Figure 17. Progress Visualization

3.5.4. Progress Monitoring with Geo-BIM

As a result of the integration between BIM 3D Model and digital data, Geo-BIM was obtained as one of the features of PMIS. In addition, the results from digital survey namely geospatial data, orthophoto, and 3D objects can be superimposed with the BIM Models and site progress data to be integrated in PMIS as digital twin to the existing conformance to the plan accurately with the appropriate coordinates as shown in Figure 18. Moreover, this feature also enables us to make a comparison between the planned construction action plan on the current month versus the realization of construction action plan, which both visualized in BIM overlayed with orthophoto. Manual methods monitoring can only use ms project in terms of scheduling and cannot provide overlay visualization data. Meanwhile, the progress monitoring using PMIS provides Geo-BIM that combined with the project schedule, that can be created for weekly action plan. Each realization progress will be inputted into the Geo-BIM as overlayed data. Then the result of this sumperimposed data can be compared for regular monthly monitoring to identify the deviations. Therefore, if there is any deviations, a strategy can be made to catch up the project schedule. Hence, the integration between photogrammetry with BIM Model accelerates the construction monitoring process as well as making the action plan with the help of the digital twin as the project visualization. Thus, this integration assists stakeholders on decision makings more accurately and quickly.

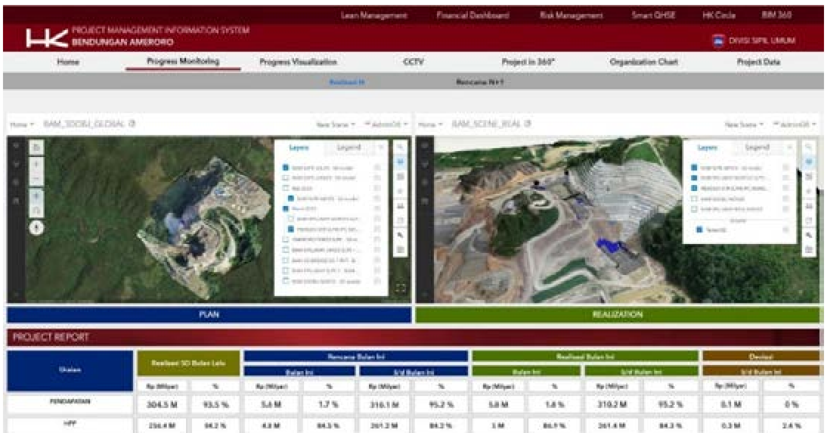

Figure 18. Progress Monitoring with Geo-BIM

3.5.5. Live CCTV

There is a Live CCTV feature which integrated with site project cctv support the progress monitoring purposes. Moreover, this Live CCTV feature enable the stakeholders to do real-time monitoring remotely during the construction process. The CCTV units are strategically placed in the production and construction areas, showing not only the current activities but also assisting safety manager to ensure accident prevention with real time monitoring from the control room.

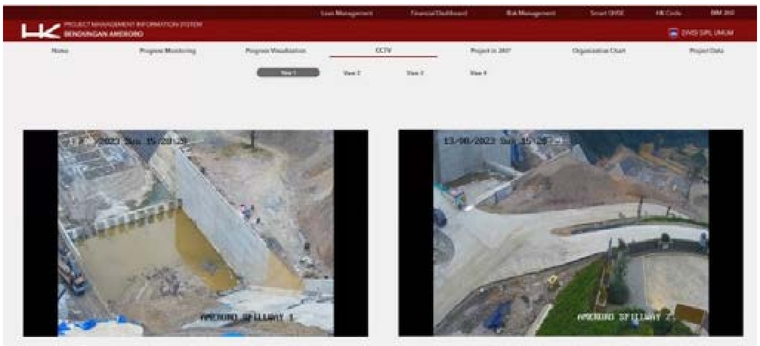

Figure 19. Live CCTV

3.5.6. Comparative Analysis

As we can see from the data above, the manual methods of project monitoring require a lot of time and manhour, rather than the digital monitoring through the PMIS. The comparative analysis below is affected by many factors. On the quantitative side, it affected by manpower and manhour needed during the data collection and processing, with formula as illustrated below:

Data Collection Time Productivity Rate for every 1 hectare

$$Productivity\ Rate = \left|\frac{\sum Manual\ Survey\ time\ (min)}{\sum Digital\ Survey\ time\ (min)}\right|$$

$$Productivity\ Rate = \left|\frac{90\ \ min}{1{,}5\ \ min}\right| = \boldsymbol{60x}$$

Data Collection Manpower Efficiency

$$Efficiency\ Rate = \left|\frac{\sum Manual -\ Digital\ Survey\ manpower\ (people)}{\sum Manual\ Survey\ manpower\ (people)}\right| x\ 100\%$$

$$Efficiency\ Rate = \left|\frac{(3-2)\ peoples}{3\ peoples}\right| x\ 100\% = \mathbf{33}\%$$

Data Processing Time Efficiency

$$Efficiency\ Rate = \left|\frac{\sum Ms\ Project + BIM\ (hours)}{\sum Ms\ Project\ (hours)}\right| x\ 100\%$$

$$Efficiency\ Rate = \left|\frac{8\ hours}{16\ hours}\right| x\ 100\% = \mathbf{50}\%$$

Data Processing Productivity Rate

$$Productivity\ Rate = \left|\frac{\sum 2D\ Drawings\ time\ (hours)}{\sum BIM\ Drawings\ time\ (hours)}\right|$$

$$Productivity\ Rate = \left|\frac{8\ hours}{4\ hours}\right| = \boldsymbol{2x}$$

On the other side, the utilization of PMIS also shows significant difference in terms of output quality, especially to support the project monitoring and decision-makings as shown on table 2.

Table 2. Comparative Result of Project Management between using PMIS and non-PMIS

Factors	Project Management without PMIS	Project Management using PMIS
Data Collection	Consisted of single-sourced data. The process requires longer time to collect data from many involved parties	Consisted of integrated data, which more comprehensive between time and visualization. The data automatically updated by the Engineer with a faster time.
Project Monitoring	Manual monitoring requires longer time and cannot be schedule-based since the realization progress from the surveying data is not integrated.	Project Monitoring with PMIS allows the integration between GIS, BIM, and Project Schedule to be superimposed into monthly overlayed data for regular monitoring purpose
Building Information Modelling	It is unintegrated with the geospatial data so clash detection with the site cannot be checked	It can be overlayed with the digital survey data to see the conformance with the existing site as well as beneficial for progress monitoring
Project Performance	The management team in project or headquarter may be unaware with project current status by the unavailability of updated project performance data	Increase the management team awareness of project current status and beneficial to make a corrective action plan
Decision Makings	Requires a longer time by the unintegrated and less updated data and the absence of visualization,	The availability of updated project data and visualization provide more reliable data and fasten the decision-makings
Historical Data	The engineering data are unintegrated and may be lost after the project finished	The historical engineering data are stored and integrated in one platform
Limitation	Requires longer time	Highly dependent to online internet network

4. CONCLUSIONS

The presence of PMIS as a Digital Twin plays a crucial role during the project monitoring in ensuring the timely delivery of a construction phase of a project. It can be concluded from the results above; the quantitative data shows the digital monitoring is more effective than conventional monitoring during the data collection process. In terms of time, digital monitoring improves the productivity by 60x faster than the manual method, with manpower efficiency of 33%. Moreover, the implementation of BIM improves the productivity up to 2x faster than the conventional methods and cut the time efficiency by 50%. From the qualitative side, PMIS consisted of integrated data which more comprehensive between time and visualization, rather than without PMIS that consisted of single-sourced data. In terms of the output quality, the integration of BIM and GIS provide more reliable data to support the decision makings by the presence of updated project data and visualization, that can be overlayed with the digital survey data. Moreover, the project performance feature increase awareness of project current status that ease the project management team to identify risks, take actions, and make the corrective action plan. PMIS is going to be a major difference in asset management aspect, with the collected database from construction phase have been prepared to be handed over to the asset manager as the reference for maintenance activities. Meanwhile with the conventional methods, unintegrated engineering data are subjected to be scattered after the project finished. Therefore, it can be concluded that the utilization of PMIS accelerates stakeholders' decision through data driven decision making while reduce and mitigate risk of cost overruns as early as possible with the findings on project monitoring. Future recommendation of the historical project data which collected in PMIS is expected for future project management plan, especially for project with the same characteristic. Besides, the PMIS utilization is improving collaboration and understanding of the project situation through Digital Twin with the data intensive communication and eliminate the inefficient process with remote monitoring. All in all, the digital twin technology nowadays has shown a significant role on providing the efficiency and optimizing the productivity on construction industry where each stakeholder should spot the benefit for their organization. Likewise, in Hutama Karya, PMIS capabilities currently in use are highly adaptable to future development and updating according to organizational needs and technological advancement. Hence, not only the tools are evolving but also the people need to be agile and adaptive to maintain its effectiveness to support company's business process excellence.

5. ACKNOWLEDGEMENTS

A grateful acknowledgment is delivered to PT Hutama Karya (Persero) and Ameroro Dam Project as the fund and research support for the PMIS dashboard as a Digita Twin reesarch. The continuous support from the company's management has driven to many improvements and development to the research and the use of the PMIS dashboard in supporting the project management for all the companies' projects around Indonesia.

HUMAN-IN-THE-LOOP DIGITAL TWIN FRAMEWORK FOR ASSESSING ERGONOMIC IMPLICATIONS OF EXOSKELETONS

Abiola A. Akanmu, Adedeji O. Afolabi & Akinwale Okunola
Myers-Lawson School of Construction, Virginia Tech, Blacksburg, VA, USA.

ABSTRACT: *Exoskeletons are increasingly being recognized as ergonomic solutions for work-related musculoskeletal disorders in the construction industry. However, users of active back-support exoskeletons are susceptible to various physical and psychological risks, which could be exoskeleton type-or task-dependent. A test bed is needed to enable deployment and assessment of risks associated with exoskeleton-use for construction tasks. This study aims to develop a human-in-the-loop digital twin framework for assessing ergonomic risks associated with the use of active back-support exoskeletons for construction work. A literature review was conducted to identify risks associated with exoskeletons and the technologies for quantifying the risks. This informed the development of a system architecture describing the enabling technologies and their roles in assessing risks associated with active back-support exoskeletons. Semi-structured interviews were conducted to identify construction tasks that are most suitable for active back-support exoskeletons. Based on the identified tasks, a laboratory experiment was conducted to quantify the risks associated with the use of a commercially available active back-support exoskeleton for carpentry framing tasks. The efficacy of the digital twin framework is demonstrated with an example of the classification of exertion levels due to exoskeleton-use using a 1D-convolutional neural network. The study showcases the potential of digital twins for comprehensive ergonomic assessment, enabling stakeholders to proactively address ergonomic risks and optimize the use of exoskeletons in the construction industry. The framework demonstrates the significance of evidence-based decision-making in enhancing workforce health and safety.*

KEYWORDS: *Digital twin, ergonomics, exertion, exoskeletons, risk assessment, sensing technologies, work-related musculoskeletal disorders.*

1. INTRODUCTION

The United States Bureau of Labor and Statistics reports that the construction workforce continues to experience a higher rate of work-related musculoskeletal disorders compared with workers in other industry sectors combined. The back is one of the most affected body parts. Back-related injuries account for about 43% of all work-related musculoskeletal disorders (BLS, 2023). Exoskeletons are emerging as potential solutions to WMSDs. Specifically, active back-support exoskeletons, a class of exoskeletons, have been shown to reduce the risks of overexertion which is one of the triggers of back-related injuries. For example, studies have revealed a reduction in muscle activity (Theurel et al., 2018), discomfort in the body parts (Gonsalves et al., 2021; Kim et al., 2019), rate of exertion (Alemi et al., 2020; Baltrusch et al., 2021), and range of motion (Cumplido-Trasmonte et al., 2023) due to exoskeleton-use. These benefits are motivating construction contractors to explore active back-support exoskeletons for construction work. However, studies have also mentioned that exoskeleton-use on construction sites could trigger unintended consequences such as loss of balance or fall risks (Alabdulkarim et al., 2019; Kim et al., 2019; Massardi et al., 2023), physical discomfort and pain (Gonsalves et al., 2023; Gonsalves et al., 2021), fatigue (Theurel et al., 2018), and restricting movement when climbing ladders (de Looze et al., 2016; Kim et al., 2019). These highlight the likely task-specificity of exoskeletons. In addition, the unintended consequences could also be specific to exoskeleton types (Fox et al., 2020; Kim et al., 2019). With the increase in commercially available exoskeleton solutions, a testbed would be beneficial to support the testing and assessment of the solutions for construction tasks. This has downstream implications for enabling real-time monitoring of exoskeleton-use during construction, which could inform strategies for reducing unintended risks.

Sensing technologies provide opportunities to measure risks associated with exoskeleton-use (Akanmu et al., 2020; Ogunseiju et al., 2021). Data from sensing technologies could be modeled and analyzed to extract insights that can be mapped to workers' virtual replicas and controls (e.g., rating meters). This digital representation could be used by stakeholders (e.g., project and safety managers, and manufacturers) to develop control strategies such as deciding on the contextual use of exoskeletons (i.e., most suitable application tasks and duration of use), suitable exoskeleton types, and modifications to exoskeleton design. This digital representation is referred to as the human-in-the-loop digital twin which is a two-way symbiotic relationship between physical entities (e.g., workers and exoskeleton) and their virtual representative in which humans initiate the control (N. Zhang et al., 2022). The implication is that the ergonomic consequences of workers' postures while using exoskeletons can be obtained in real-time which can enhance their ability to control or self-manage their exposures (Ogunseiju et al., 2021). Thus, this paper presents a digital twin framework for assessing the risks associated with exoskeleton-use for construction work. A review of the literature was conducted to identify risks associated with exoskeleton-use and

Abiola Akanmu, Adedeji Afolabi, Akinwale Okunola, *Human-in-the-Loop Digital Twin Framework for Assessing Ergonomic Implications of Exoskeletons,* pp. 1233-1244, DOI 10.36253/979-12-215-0289-3.121

the sensing technologies for quantifying the risks. The risks enabled the development of a system architecture to support the development of a human-in-the-loop DT framework that can inform decisions to support the sustainable use of exoskeletons in construction. Construction workers are interviewed to identify tasks that would benefit from active back-support exoskeletons. The efficacy of the DT framework is demonstrated with an example of predicting risk of exertion due to the use of an active back-support exoskeleton for one of the tasks. This study motivates discourse on human-in-the-loop Digital Twins for construction applications. The study highlights the extent to which physiological risks associated with exoskeleton-use can be predicted.

2. BACKGROUND

2.1 Exoskeletons for Construction Work: Risk and Assessment Techniques

Studies have shown that exoskeletons have intended benefits and unintended consequences. For instance, exoskeletons are prospective innovative ergonomic interventions aimed at reducing overexertion in various parts of the body (Gonsalves et al., 2021). This may in turn reduce the occurrence of WMSDs among construction workers (Akanmu et al., 2020). There is evidence that exoskeletons can reduce back muscle activities by 23 - 35% (Abdoli-e and Stevenson, 2008). Other benefits revealed in the literature include reduced discomfort to the body parts (Alemi et al., 2020), increased productivity, financial gains, and work retention (Kim et al., 2019), and increased ability to lift heavier loads and perform repetitive tasks (Mahmud et al., 2022). Despite these benefits, there are some unintended consequences associated with exoskeletons. Exoskeletons have been known to trigger risks broadly classified in Table 1 as physical and psychological risks. The physical risks include joint hyperextension, instability and fall risk, muscle fatigue, bruising, skin and soft tissue injury, and increased cardiovascular demand and metabolic cost (Howard et al., 2020; Massardi et al., 2023; Theurel et al., 2018). For example, skin irritation or chemical burns could occur if an exoskeleton battery leaks corrosive materials to the user (Howard et al., 2020). In addition, due to the added weight of the exoskeleton, the user's center of gravity may be significantly impacted causing balance problems and a diminished recovery rate (Alabdulkarim et al., 2019). Gonsalves et al. (2021) showed that exoskeletons result in discomfort in the chest and thigh regions. Previous research has indicated that exoskeletons can redirect loading from one part of the body to another (Picchiotti et al., 2019). For example, during overhead work, exoskeletons reduce the muscle activity in the shoulder and the back of the arm but increase muscle activity in the lower back, abdomen, and legs (Theurel et al., 2018). Besides, usability, self-efficacy, and safety could be negatively impacted because the exoskeletons could get caught around wires and may affect work postures (Baltrusch et al., 2021). Exoskeletons are sometimes incompatible with some personal protective equipment such as safety harnesses (Gonsalves et al., 2023). Previous studies (Omoniyi et al., 2020; Siedl et al., 2021) have also identified psychological risks such as decreased situation awareness/distraction, cognitive overload, fear of the device, and overconfidence in the device. Various sensing technologies, such as inertial measurement units and electromyographs, have been employed to quantify these risks. Similarly, objective measures from the sensing technologies have been validated with subjective assessment instruments such as the NASA Task Load Index and Berg Balance Scale. These are highlighted in Table 1.

Table 1: Risks and assessment techniques of exoskeletons.

Categories of risks	Risks	Objective Assessment	Subjective Assessment	Related Studies
Physical risks	Joint hyperextension	Inertial measurement units; Cameras	Local Perceived Pressure scale; Borg Rating of Perceived Exertion scale	(Theurel et al., 2018)
	Instability and Fall risk	Pressure insoles; Force plates	Berg Balance Scale	(Alabdulkarim et al., 2019; Kim et al., 2019; Massardi et al., 2023)
	Muscle fatigue	Electromyography	Borg Rate of Perceived Pain Scale; Borg Rate of Perceived Exertion Scale	(Theurel et al., 2018)
	Hygiene issues/Bruising, Skin and soft tissue injury	Biocompatibility tests	Usability questionnaires e.g., System Usability Scale	(Howard et al., 2020; Massardi et al., 2023)
	Cardiovascular demand	Electrocardiogram; Photoplethysmogram	Workload assessment questionnaires e.g., NASA Task Load Index (TLX)	(Moyon et al., 2018; Theurel et al., 2018)
	Metabolic cost risk	Indirect calorimetry	Questionnaires for workload assessment (e.g., NASA TLX), Rating perceived exertion (RPE) with the Borg Category Ratio (Borg CR-10)	(Alemi et al., 2020; Baltrusch et al., 2021)

	Usability of the device (e.g., perceived discomfort, chest pain, catch and snag risks)	Eye tracker; Electromyography	Focus groups; Usability questionnaires; Borg CR 10 scale; Body part discomfort scale	(Gonsalves et al., 2021; Kim et al., 2019; Ogunseiju et al., 2022)
Psychological risks	Decreased situation awareness/ Distraction	Eye tracker	NASA-TLX	(de Looze et al., 2016; Delgado et al., 2020)
	Exertion	Electrodermal activity sensor	Rating perceived exertion (RPE) with the Borg Category Ratio (Borg CR-10)	(Man et al., 2022; Theurel et al., 2018)
	Fear; Lack of trust	Electromyography; Photoplethysmogram; Electrodermal activity sensor	Interview; Self-developed questionnaires; subjective psychological impact test	(Omoniyi et al., 2020; Upasani et al., 2019)
	Cognitive overload	Electroencephalography; Eye tracker; Electrodermal activity sensor	NASA-TLX; MF (M-VAS) and boredom (B-VAS)	(Cumplido-Trasmonte et al., 2023)
	Overconfidence effect	Camera Videos; Optical tracking system (OTS)	Focus groups; Questionnaires (e.g., Modified Spinal Function Sort)	(Baltrusch et al., 2021; Siedl et al., 2021)

2.2 Digital Twin for Ergonomic Risk Assessment

In recent years, there have been increasing explorations of DT for diverse applications including workforce health and safety. Sharotry et al. (2022) developed a DT to track the biomechanical fatigue in operators caused by repetitive action in lifting activities. The study analysed changes in the joint angles in workers' body joints using a dynamic time-warping algorithm. Another study (Greco et al., 2020) presented an ergonomic risk mapping of DT workstations using a wearable motion capture system and inputting in virtual simulated environments. With the DT, the authors were able to identify risk indexes related to working postures, exerted forces, material manual handling and repetitive actions, and sources of biomechanical overload. In construction, Ogunseiju et al. (2021) developed a DT framework for improving self-management of ergonomic risks. However, scarce studies have explored the assessment of exoskeleton-use using a DT environment. Furthermore, Greco et al. (2020) opined that existing DT frameworks have limited roles for users or stakeholders. Humans play vital roles in workplace systems; therefore, supporting technologies should be designed to facilitate their input (Sharotry et al., 2020).

3. METHODOLOGY

The approach employed in conducting this study is shown in Figure 1. First, a review of the risks associated with exoskeletons and the technologies for measuring the impact of the risks was conducted (Section 2.1). This informed the development of an architecture of a human-in-the-loop DT system for assessing risks associated with active BSEs. Semi-structured interviews were conducted to identify construction tasks that would benefit from the use of active BSEs. A laboratory experiment was conducted to quantify the risks associated with using active BSEs. This informed the development of an example of a DT-based model for assessing the risk levels of exertion during exoskeleton-use. These are described as follows:

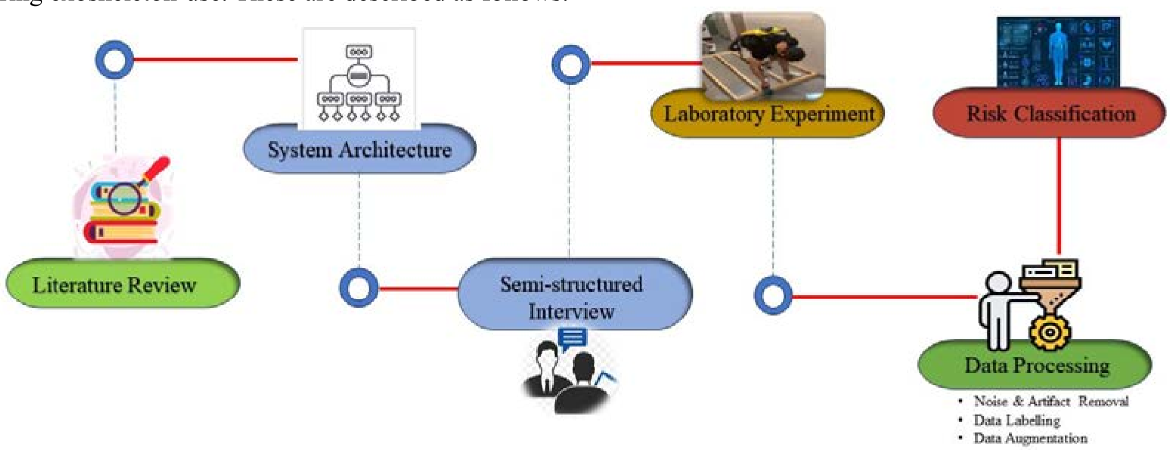

Fig. 1: Overview of research methodology.

3.1 System Architecture

The system architecture shown in Figure 2 is built to illustrate the proposed human-in-the-loop DT framework. The system architecture shows the enabling technologies and their role in supporting the assessment of ergonomic risks associated with exoskeleton-use. The architecture comprises six layers include physical layer, data layer, data transmission layer, storage layer, application layer, and access layer. These are described as follows:

3.1.1 Physical layer

The physical layer comprises sensing technologies and physical devices. The sensing technologies support capturing of physical and psychological risks, and environmental characteristics of work areas. The physical risks include local muscle fatigue, fall risk, joint hyperextension, and metabolic risk which can be measured using electromyography (EMG), pressure insole, inertia measurement unit (e.g., comprising of accelerometers, gyroscope, and magnetometer), and calorimeter respectively. The psychological risks include cognitive overload, lack of trust, and decreased vigilance which are measured using an electroencephalogram, electrocardiogram, photoplethysmogram, and eye tracker respectively. The workspace or site conditions can be captured using environmental sensors such as temperature and humidity sensors and image-based sensors such as cameras and laser scanners. Physical devices include reality technologies such as virtual and augmented reality devices, and other data acquisition technologies for collecting subjective data to evaluate the aforementioned objective measures. Reality technologies support the development of risk-free simulated construction site environments where workers can practice work with different exoskeletons.

3.1.2 Data layer

Data from the physical layer are captured in the data layer. The data layer contains the data generated from the sensors and physical devices, such as raw acceleration and angular velocity from the IMU, brain waves from EEG, electrical conductance of the skin from EDA sensors, eye fixations from eye trackers, muscle activity from EMG, and temperature and humidity from temperature and humidity sensors. Subjective data (such as perceived cognitive load, rate of exertion, and discomfort levels) are also stored in the data layer. This layer also contains videos of construction work and general characteristics of the work area that might explain or influence risk factors of WMSDs.

3.1.3 Data transmission layer

The data transmission layer transfers data from the data layer to other layers for storing, modeling and analysis, and DT representation. Different communication technologies could be used in this layer, such as short-range transmission technologies e.g., Wi-Fi, Bluetooth, Zigbee, near-field communication (NFC), and Zwave, and long-range transmission technologies e.g., 3G, 4G long-term evolution (LTE), and low-power wide-area networks.

3.1.4 Storage layer

This layer consists of cloud services that store data received from the data transmission layer and application layer. Heterogenous data from these layers are gathered and stored in a cloud storage system for exchange or sharing with other layers. The data or information can be beneficial for extracting other insights that can help improve the health and safety of workers. Depending on the stakeholders and their information needs, multiple repositories may be included. As such, different access rights may be provided. For instance, a data analyst may need access to label subjective data obtained from the data layer to enable assessments involving risk classifications. A safety/health manager may be provided access to data that can inform impact on workers' health while impacts while a project manager may be provided access to data relating to impact on productivity.

3.1.5 Application layer

This layer includes algorithms and applications for processing and analyzing data obtained from the storage layer. The data are processed and represented in formats that can be used by decision-makers in the access layer (Section 3.1.6) for decision-making. For example, to assess workers' levels of exertion from their electrodermal activity (EDA) signals, this layer will use signal processing algorithms, feature extraction, and deep learning networks (e.g., conditional generative adversarial network, recurrent neural network, and long short-term memory), and visualization algorithms. Signal processing algorithms such as discrete wavelet transforms and adaptive predictor filtering methods will be used to reduce artifacts from the EDA signals. A symmetric multilayer perception model for extracting features will be used to extract informative features from the EDA signals. The extracted features will be fed into deep learning networks (e.g., conditional generative adversarial network, recurrent neural network, and long short-term memory) to classify the EDA signals into the levels of exertion. Finally, visualization algorithms will be used to augment the levels of exertion on a virtual replica of the worker and a rating meter.

3.1.6 Access layer

In the access layer, stakeholders can visualize the impact or extent of the risks as a virtual replica of the worker and a rating meter. This layer includes the following: (1) beneficiaries of the DT platform and (2) how they access the DT platform. The beneficiaries may include safety managers, project supervisors, and product manufacturers. Safety managers may want to understand if the workers are reaping the intended health benefits of the technology. Project supervisors may want to know the impact of the technology on project performance. Both stakeholders could use the feedback to work with manufacturers to plan more suitable designs for their projects. The stakeholders can monitor the performance of the workers via interactive dashboards and web applications. The performance of the workers will be shown in the form of their virtual replica and a rating meter to interpret the risks. For example, the levels of exertion associated with an exoskeleton (e.g., no exertion, low exertion, medium exertion, and high risk) that is computed in the application layer, will be shown as different colors in a virtual replica and rating meter (e.g., green, yellow, and red human). In this way, the project stakeholders can understand the type and extent of the risk, which could inform decision making such as which type of exoskeleton to use for what task, how long the exoskeleton should be used for the task, and changes that should be made to the device to better adapt it to construction work.

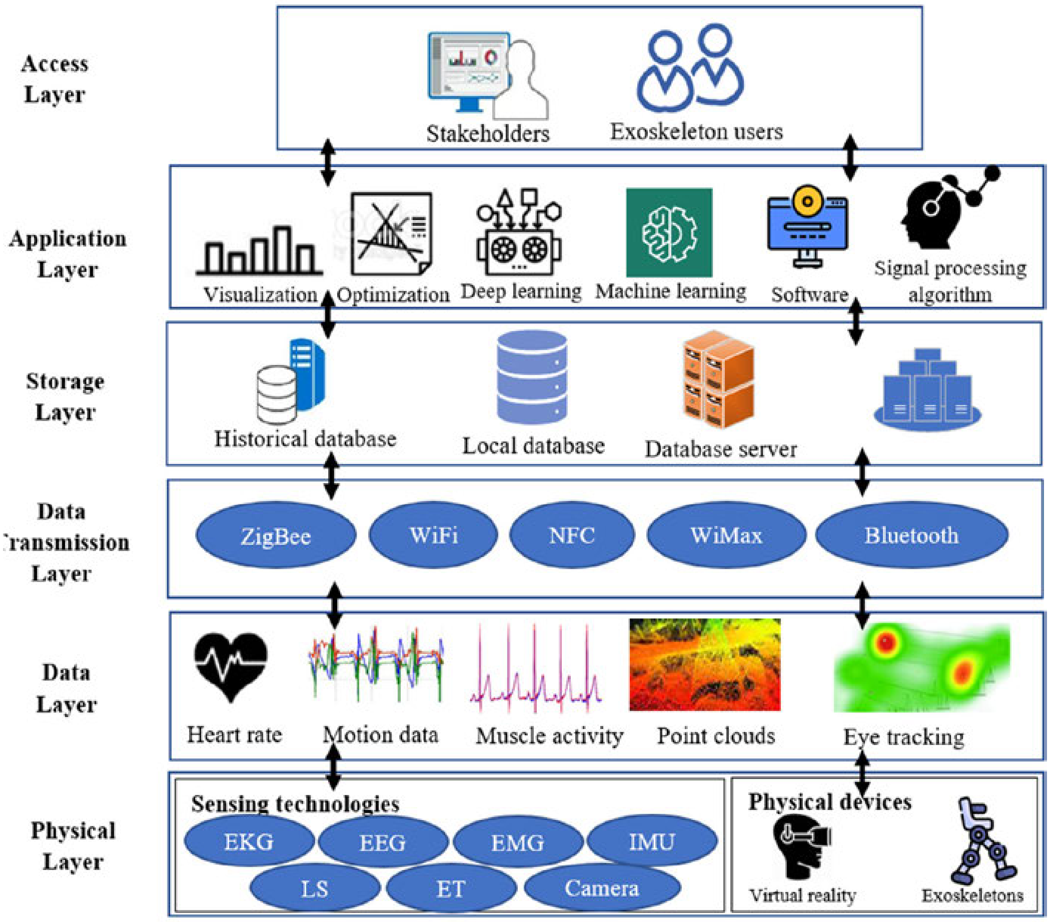

Fig. 2: System architecture.

3.2 Semi-Structured Interview

Semi-structured interviews were conducted with industry practitioners (n=8) to understand the construction tasks that would benefit from the use of active back-support exoskeletons. A purposive sample was used to identify and select potential participants who could provide valuable insights to the study. The research team selected participants with experience in construction safety, and technology implementation in the construction industry. The interviews were conducted over Zoom and recorded. The transcripts of the interview were coded and emerging themes were identified. An inter-coder reliability test was conducted on the coded data using the Cohen-Kappa coefficient. Cohen-kappa coefficient of 0.90, indicating a strong level of agreement, resulted from the assessment.

3.3 Experimental Procedure, Participants, and Data Collection

Sixteen students were recruited to participate in a carpentry framing activity; one of the activities identified from Section 3.2 as beneficiaries of active back-support exoskeletons. The participants reported no prior issues related to musculoskeletal disorders that could affect their performance in the study. The experiment was approved by the Virginia Tech Institutional Regulation Board (IRB: 19-796). The task involved the following: (1) measuring timber planks (i.e., four 1”x4”x47” planks and two 1”x4”x70” planks) needed to construct a 47”x70” frame; (2) assembling the measured timber materials as shown in Figure 3; (3) nailing the assembled timber frame using a nail gun; (4) lifting and moving the erected frame, which weighs approximately about 40lbs, to an upper floor via staircase for installation on the upper floor; and (5) installing the frame by aligning the frame with an existing wall. The participants completed these tasks while wearing CrayX, an active back-support exoskeleton from German Bionics. Their electrodermal activity was measured using Emotibit, an open-source biosensor. The data was collected at 50Hz i.e., 50 data points per second. After performing the framing task, each participant was presented with Borg’s rating of exertion scale (Borg CR-20) and asked to provide subjective ratings of their perceived exertion for the entire task. The Borg scale ranges from 6 (not exhausting) to 20 (extremely exhausting) (Albert et al., 2021; Borg, 1982). The participants’ ratings of perceived exertion were measured using the Borg’s exertion rating scale (Borg CR-20) which ranges from 6 to 20, where 6 represents no exertion and 20 represents maximum exertion. Figure 3 shows participants performing framing tasks with the exoskeleton and the biosensor. The task was video recorded.

Fig. 3: Participant performing framing task while wearing an exoskeleton and EEG cap.

3.4 Data Preprocessing

3.4.1 Noise and artifact removal

The collected EDA signals were filtered to remove the noise and artifacts. A low pass filter with a cut-off frequency of 4 Hz was employed to remove the noise. A Gaussian filter was used to smoothen and attenuate the artifacts. MATLAB was used for this purpose.

3.4.2 Data labeling

Using the time-stamped video, EDA data corresponding to each participant’s tasks were sorted and structured. The ratings of 7– 11, 12 – 14, and 15 – 20 were represented as low exertion, medium exertion, and high exertion, respectively (Chowdhury et al., 2019). The sorted EDA data of each participant was labeled based on their intensity class as shown in Table 2.

Table 2: Classes, labels, and data points.

Classes	Labels	Percentages of participants (%)	Number of data points
Low Exertion	LE	70	50759
Medium Exertion	ME	12	6823
High Exertion	HE	18	14072

3.4.3 Data augmentation

The EDA data of the minority classes were augmented due to the imbalanced nature of the datasets. Studies have shown that balanced datasets result in the Synthetic Minority Oversampling Technique (SMOTE) being employed to balance the EEG data of the minority classes with the majority classes (Sowjanya & Mrudula, 2023). For example, from Table 2, the ratio of the datasets in the LE, ME, and HE classes (i.e., Low Exertion, Medium

Exertion and High Exertion respectively) is 7:1:4. As shown in Table 3, more datasets were generated with SMOTE to balance the datasets of the minority classes (i.e., Medium Exertion and High Exertion) with the class with the most datasets (i.e., Low Exertion).

Table 3: Classes, labels, and data points (raw and balanced).

Classes	Labels	Number of raw data points	Number of balanced data points
Low Exertion	LE	50759	50759
Medium Exertion	ME	6823	50759
High Exertion	HE	14072	50759

3.5 Risk Classification

This study employs a 1-D convolutional neural network to classify the EDA data into the above-mentioned classes (i.e., LE, ME, and HE). 1-D CNN is suitable for 1D signals whose applications have high signal variations (Y. Zhang et al., 2022). The network comprises an input layer, a convolution 1-D layer, a batch normalization layer, a Rectified Linear Unit (ReLU) layer, a dropout layer, a maxpooling layer, a fully connected layer, a softmax layer, and a classification layer. The convolution layer applies filters to the input data obtained from the input layer and extracts distinctive features using 10 filters of width 10. The batch-normalization layer improves the stability and speed of training the network by normalizing the input to each layer. The ReLU layer applies a non-linear activation function to the output of the batch-normalization layer. The dropout layer helps to prevent overfitting of the model. The maxpooling layer down-samples the output of the dropout layer. In the fully connected layer, a linear transformation is applied to the input vector through a weight matrix so that every input influences every output of the output vector. The softmax layer takes in the output from the previous layer and presents a vector that illustrates the probability of the class that the input belongs to. The classification layer presents the results of the softmax layers as classes of the assessed risks. The network was trained using the Adam optimizer (Karim et al., 2019). Due to the size of the dataset, 300 epochs were used. The learning rate was set to 0.01.

The balanced data was split as follows: 70% of the data was set aside for training, 15% of the data was also set aside for validation and 15% was intended for testing the trained model. MATLAB R2023a, installed on a machine with NVIDIA GeForce RTX 2080 GPU and 16GB memory, was employed for the classification. Commonly used metrics for assessing the performance of machine learning models were employed in this study. These include accuracy, precision, recall, and F1-score (Bangaru et al., 2021).

4. RESULTS AND DISCUSSION

4.1 Construction Tasks for Active Back-Support Exoskeleton-Use

The results of the semi-structured interview were represented in the form of a word cloud. Word clouds are graphical representations of the frequency of concepts or keywords that are significant in discourses (Adu, 2019). The word cloud in Figure 4 provides a quantitative and visualized method to illustrate the key construction tasks suggested by the participants to benefit most from active back-support exoskeletons. The most mentioned tasks include plumbing, carpentry, steel, drywall and rebar installation, and labor work. The least mentioned tasks include ceiling, electrical, scaffolding, and flooring work, mason, and ceiling work. The suggested tasks support reporting of industry databases (BLS, 2023) and research studies (Antwi-Afari et al., 2023; Gonsalves et al., 2023) that identified back-related injury as a concern in the construction industry. Some of the tasks suggested by the practitioners (e.g., carpentry work, rebar installation, concrete work, and masonry) were also identified by (Kim et al., 2019) as being suitable for exoskeletons. Similarly, Gonsalves et al. (2023) identified framing and plumbing as being more suitable for back-support exoskeletons.

Fig. 4: Word cloud of construction tasks that would benefit from active back-support exoskeletons.

4.2 Example of Prediction of Level of Exertion from Exoskeleton-Use

This study presents an example of predicting the levels of exertion due to exoskeleton-use. This section presents the performance of the 1-D convolutional neural network in classifying the levels of exertion during exoskeleton-use for a framing task.

4.2.1 Model performance evaluation

The accuracy of the 1D-CNN in classifying the levels of exertion due to exoskeleton-use for the framing task is 82%. The confusion matrix for the model is illustrated in Figure 5. The matrix shows that the model performed better in detecting the ME and HE classes than the LE class. For example, the model detected classes ME and HE with 100% accuracy and LE class with 67%. Furthermore, 37% of the LE class is mostly confused with the HE class.

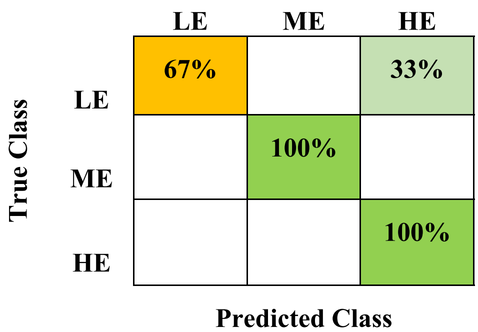

Fig. 5: Confusion matrix showing classification accuracies of levels of exertion due to exoskeleton-use.

From the precision (see Table 4), it can be observed that out of the times ME and HE classes were predicted, the model was correct 100% of the time. However, out of the times HE class was predicted, the model was correct 67% of the time. For the recall, out of all the times the HE class was predicted, only 75% of the class was correctly predicted.

F1-score explains a model's ability to both capture classes (recall) and accurately capture the classes (precision). The F1-score of the ME class is 100%, meaning that the model has a balanced ability to accurately capture all the ME classes from the data. However, in the case of the F1-scores of the LE and HE classes which are 80% and 75% respectively, the model will have a mixed reaction. For the LE class, while the model may be correct 67% of the time, all the LE class predicted will be correct. The findings of this study have shown the effectiveness of 1D-CNN in classifying EEG signals (Alzahab et al., 2021). The lowest F1-score obtained in this study is still high and can be compared to other construction-related studies (Xiong et al., 2022).

Table 4: Performance metrics for ID-CNN for the classes.

Classes	Precision	Recall	F1-score
LE	67%	100%	80%
ME	100%	100%	100%
HE	100%	60%	75%

4.2.2 Level of Exertion and Digital twin

The digital twin of the exoskeleton-users and the rating meter (shown in Figure 6) shows the level of exertion resulting from the results of the model. The digital twin shows an exoskeleton-user experiencing medium exertion. The meter comprises a pointer and three different colors, red, yellow, and green indicating high, medium, and low exertion respectively. The pointer reflects the level of exertion which is currently shown as medium exertion. Related studies have shown the possibilities of creating similar interfaces for data acquisition as a human-in-the-loop digital twin (Locklin et al., 2021). This exoskeleton risk assessment dashboard can also be extended to show the muscle activity, cognitive load, and fall rating of the exoskeleton user. This vital data collected via sensors can be useful for supervisors and managers to monitor workers while using the exoskeletons.

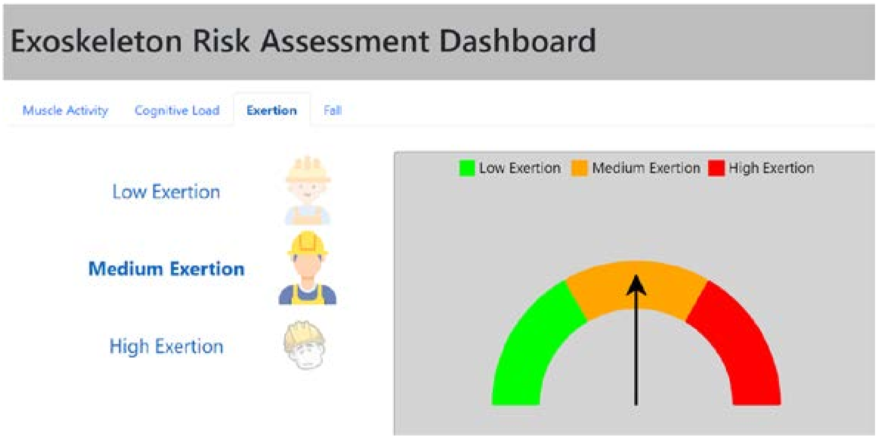

Fig. 6: Dashboard showing digital twin representation of the level of exertion.

5. CONCLUSIONS, LIMITATIONS AND FUTURE WORK

This study aims to investigate a digital twin framework for assessing the risks associated with exoskeleton-use for construction work. A review of the literature was conducted to identify risks associated with exoskeleton-use, and objective and subjective methods for assessing the risks. A system architecture was developed to illustrate the enabling technologies and their roles in supporting the proposed framework. Results of interviews with construction workers identified carpentry framing task as one of the construction tasks that can benefit from active back-support exoskeletons. Electrodermal signals were collected during the experimental simulation of the framing task with an active back-support exoskeleton. 1D-CNN trained to classify electrodermal data demonstrates the potential of the DT framework to predict the exertion levels of exoskeleton users during framing tasks. This study contributes to the scarce literature regarding the use of digital twins for assessing the suitability of exoskeletons for construction work. The study demonstrates the role of physiological sensing and machine learning techniques in facilitating the implementation of the digital twin framework. Furthermore, this study sets precedence for research involving the use of digital twins for performance monitoring of exoskeletons during construction work. Such efforts could promote the sustainability of exoskeleton solutions in the construction workplace. This study had some limitations which are currently being addressed in an ongoing study. Firstly, EDA data was generated from students engaged in a laboratory-based simulation of framing tasks. The use of experienced construction workers could produce data that can help develop prediction models that are generalizable for the construction population. Secondly, only the exertion levels using the EDA data was modeled to demonstrate the digital twin framework. Further work will involve other sensing technologies and the prediction of other physical and psychological risks. Future studies will also involve a user assessment of the digital twin framework with intended users.

URBAN CENTERS MANAGEMENT: A DIGITAL TWIN APPROACH

Alessandra Corneli

Department of Construction, Civil Engineering and Architecture, Polytechnic University of Marche Ancona, Italy

Marianna Rotilio

Department of Civile, Construction-Architectural and Environmental Engineering University of L'Aquila L'Aquila, Italy

ABSTRACT: *The management of the built environment is a topic that requires reference to the management of complex systems. In fact, the variety of domains involved means that the management of urban centers is not only complicated, and therefore it is not enough to model a set of rules that are representative of phenomena related to the real environment. Not only that, but what is evident is that emergency management lacks the ability to access real-time information that could be decisive. Having tools that provide real-time data, that reprocess it, and that are able to provide an enriched and slightly predictive view of what is happening offers the possibility of having a real impact in the management of the built environment. In this sense, digital twins are a valuable approach to achieving the desired results. Digital twins through the integration of technologies such as lnternet of Things (IoT), simulators, Artificial Intelligence (AI), and Augmented Reality (AR) technologies make it possible to develop systems capable of exploiting the concept of collective intelligence, in a digital version, through a large number of heterogeneous agents working according to stigmergic mechanisms. This research work aims to propose its own architecture of digital twins for the management of resilient urban centers, with particular reference to the management of post-earthquake reconstruction scenarios.*

KEYWORDS: *Digital twin, urban environment management, urban centers, smart cities, emergency management, BIM.*

1. INTRODUCTION

The 2030 Agenda for Sustainable Development (Agenda, 2030) has set 17 Goals among which Goal 11 is defined as follows "Make cities and human settlements inclusive, safe, resilient and sustainable." In addition, there is a recent trend that identifies an increasing population shift to urban centers. According to the United Nations, over 55 percent of the world population inhabited cities in 2008, with the percentage expected to rise to 68 percent by 2050 (UN 2019). All of this implies the need to rethink cities focusing not only on the sustainability of these centers of aggregation but also with the intention of making them resilient to change and responsive to unexpected events.

It should be noted that urban centers, cities are complex organisms (De Toni et al., 2013). This implies that it is impossible to manage the processes affecting them through rules, but a holistic and integrated approach is needed. One approach that has been pursued for years to the problem of managing urban centers is the development of smart cities. The term smart city is said to have first appeared in the middle of the 1990s, when the cities promoted themselves after introducing new information and communication technology (ICT) infrastructure or e-governance services, or when attracting technology companies to provide new economic growth to the region (Hollands, 2008). Anyway, a smart city should go beyond the mere use of ICT systems. It is expected that a smart city should improve the quality of life of its citizens, while simultaneously simplifying the management of the city. In some cases of developing smart cities the term "smart" was referred to an automated mechanism introduced to perform the desired activity within a given domain (Ahad et al., 2020). Other smart city paradigms relate technology more directly with innovation and human capital development, based on the concept that technology can give a city's constituents the power to innovate, create, participate in society and solve problems collectively for the common good (Angelidou, 2015). In any case the current research on smart city does not fully address the complex nature, conflicts and interdependencies of the smart city objectives (Shamsuzzoha et al., 2021).

Meanwhile in recent years we assist the rise of Building Information Modelling (BIM) approach in a wider way than the one that wants it to represent but a small part (a narrow building-level view) within the wider environmental context. BIM's massive introduction into the processes of the built environment has led to a higher level of digitization of all kinds of information, as this approach allows the achievement of high performance only when embedded in digital systems and platforms. This evolution of BIM should be carefully framed within a paradigm that factors in people, processes and new emerging technologies in an increasingly interconnected world (Boje et al., 2020).

In this scenario it is expected that residents of future smart cities will be exposed to unprecedented amounts of

real-time information on a daily basis (Du et al., 2020). This data also coming directly from people and equipment and assets can contribute to the development of a stigmergic system. Stigmergy is a communication method used in decentralized systems by which individuals in the system communicate with each other by modifying their surroundings and leaving traces (Debreu Netto et al., 2015). Indeed, the scenario of the 21st century is increasingly characterized by interactions between the physical and virtual worlds, thanks to the progressive creation of a global connective space with a high intensity of information flows, the potential of Information Communication Technology (ICT), as well as the Internet of Things (IoT), of Big Data, Virtual and Augmented Reality, and the spread of progressively more powerful computational devices, whose high processing capabilities, albeit without discretion, are being defined, namely the so-called Artificial Intelligence and Machine Learning, and related predictive algorithms (Cinquepalmi and Pennacchia, 2020). All this leads to a currently emerging paradigm and that is the Digital Twin (DT) paradigm. Other industrial sectors than construction have been developing digital twin-based concepts over the past decade, but this approach has made its first appearances in the AECO sector only over the past few years. Digital twins are a digital replica of their real counterparts. A DT is always a representation and for this reason unlike its physical counterparts, it is not an all-or-nothing proposition. DTs can be tailored so as to choose to collect information only about features that have value for the stakeholders involved or for the aim it is developed for. There is a crucial aspect in DT that differs them from simulation models and even common smart cities paradigm (Fig. 1) and it is prediction. Numerous examples have shown how digital twins can continuously monitor operations and identify abnormal behaviors, allowing human operators to react promptly and reduce downtime (Arup, 2019). In any case in the longer-term, it is evident that no single DT will be sufficient for modern complex cities: in a smart city scenario, independent DTs of various assets will need to communicate and cooperate, providing feedback to a central decision making "hub" or city-level decision makers (Pregnolato et al., 2022).

This paper presents a framework for implementing digital twins in urban centers. Building on what DA (Silva et al., 2018) showed as a technology for the smart city, our proposal is to include a reasoning layer through real-time data, which is one of the aspects that differentiates DT from the rest: short- to medium-term forecasting to provide decision support to the decision makers involved. The scenario that is particularly referred to is that of emergency management. Since city management requires dealing with complexity the digital twin is the ideal method to take into account different data and analysis in an integrated way. Starting with an analysis of the scientific bibliography concerning the digital twin and smart cities illustrated in the next section, the article aims to focus on real-time management and the insights that DTs can offer to support the management of the unexpected. Case study on which to implement the proposed framework will be presented.

2. LITERATURE REVIEW

Performing a search on the Web of Science, using the keywords "digital AND twin* AND "urban" AND "cit*" in

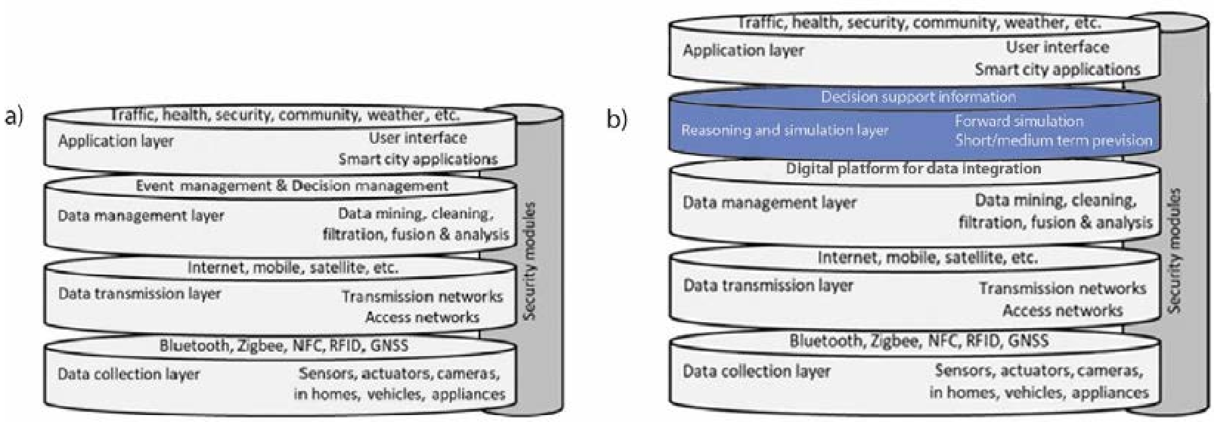

Fig. 1: a) Smart city architecture proposed by Silva et al., 2018; b) DT architecture whose fundamental layer that differentiates this from Smart Cities is the Reasoning and simulation layer that allow for short/medium term previsions supporting prompt decision-making particularly significant during emergencies.

a time range from 2006 to the present, yielded a total of 379 articles, most of them in the area of Computer Science (21.1%) and Engineering (17.8%)(Fig. 2). Particularly in relation to the latter area, there were only 153 papers in total (Fig.2). Furthermore, the metric analysis showed that most of the publications are concentrated in the last

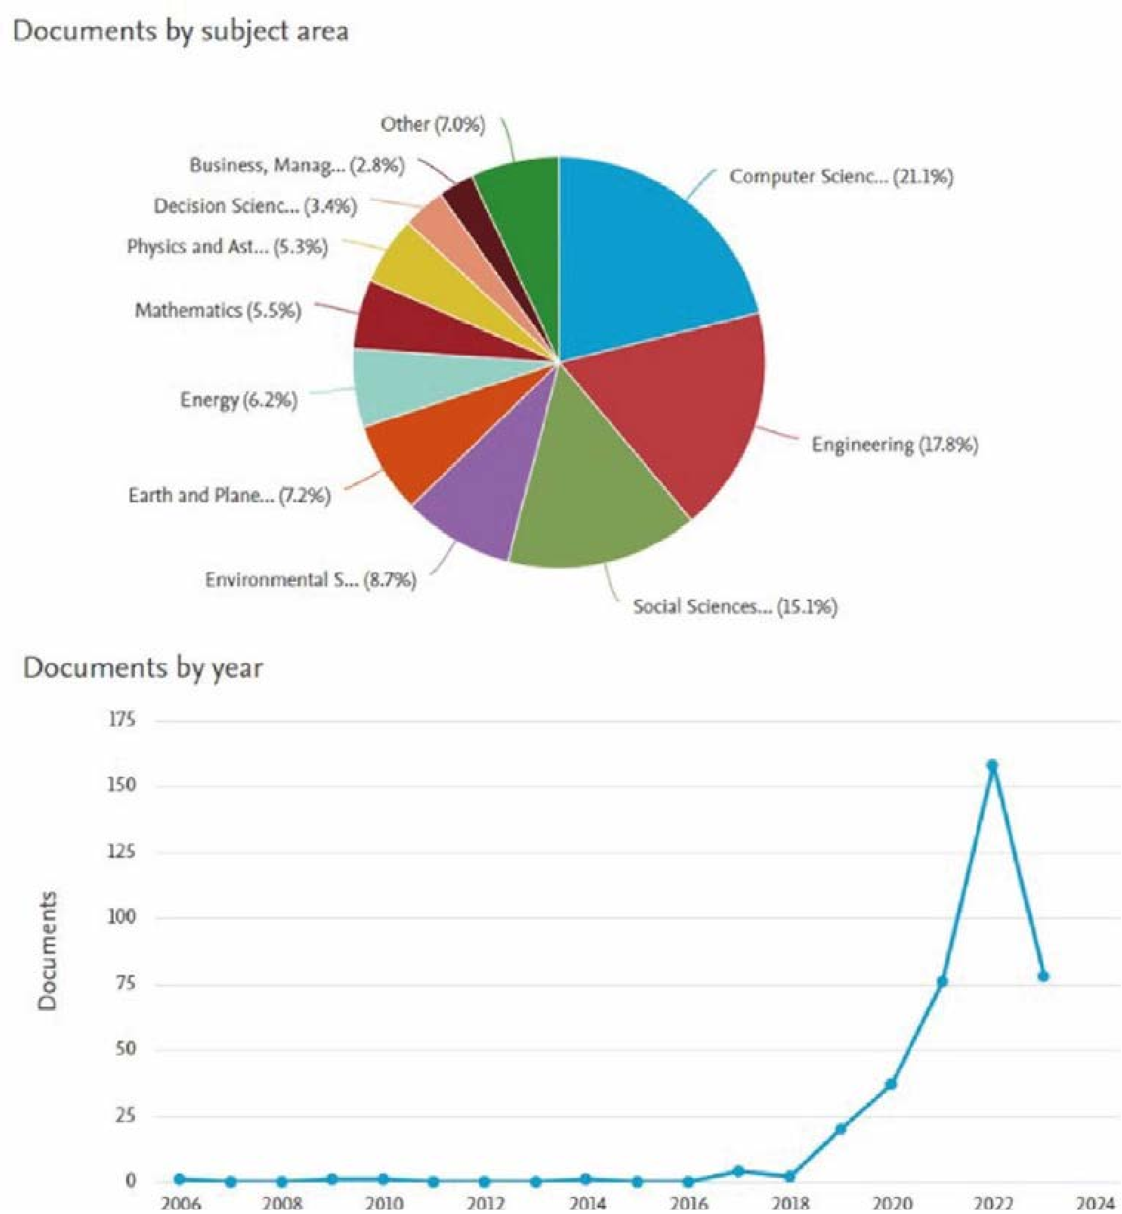

Fig. 2: The graph above shows the number of papers containing the terms “digital”, “twin” and “urban” in the period from 2006 to 2023 divided by subject area. The graph below instead shows the trend (referred to the same period of time) of papers with the same key words comprised in the area of Engineering. The spike in the adoption of certain terms from the years 2021-2022 is evident.

five years, i.e. from 2018 to the present (Fig. 2). This data highlights how the topic is of recent interest in the international scientific community. From the 153 articles identified, a screening was first carried out by reading the titles of the articles and discarding those of no interest. Subsequently, the abstracts were read and the search areas were identified. These ranged from the topic of infrastructure and urban mobility to that of the construction and built environment. For each area, an article of particular interest to the study was identified, argued below and summarized in Table 1.

Gang Yu et al. (2021) focus on urban infrastructure, proposing a digital twin framework for the operation and maintenance of tunnels. Haishan Xia et al. (2022) analyze the BIM GIS relationship within the digital twin framework used to support smart city development. The study is also conducted in the area of infrastructure, in relation to rail transport. Salem and Dragomir (2022), on the other hand, develop a literature analysis of the construction project management using digital twin approach. Lv et al. (2022), Corrado et al. (2022) and Nica et al. (2023) carry out their research in the field of urban planning, also from a sustainable perspective (Corrado et al., 2022; Nica et al. 2023). In particular, Lv et al. reflect on the importance of using DTs urban platform to improve the future planning vision. Yu et al. (2023) analyze the support that new digital technologies can offer in the creation of smart cities, as does Wenhua Huang et al. (2022) in relation to the Internet. Other areas of interest are those concerning the use of the Digital Twin for the management of the built environment (Rotilio et al., 2023) and urban mobility (Yeon et al., 2023).

The research performed showed that the topic of DT in support of smart cities is an area of study of recent interest within the international scientific community and that it is addressed in specific areas, lacking a global and multidisciplinary approach. This research gap highlights how further research is needed, which this article aims to help bridge. Indeed, the main objective of the research presented here is to provide a framework that, based on a DT approach, supports the management of the complex contexts typical of post-disaster reconstruction in which many issues and disciplines converge. A demonstrator will be presented for framework validation.

3. RESEARCH METHODOLOGY

The proposed application framework for the development of DTs to support the management of urban centers begins with the identification of needs. It should be kept in mind that a DT however comprehensive is always a representation of certain components of reality. For this reason starting from the identification of needs or we could say critical issues for which decision support is desired can begin to design the digitization of the real world. This analysis can only start from the dialogue with the stakeholders concerned, the administrators of the territory (Public Administrations) and the decision makers who will then be the end users of the product.

The critical issues and needs thus identified lead to a second analysis concerning which aspects, parameters or agents need to be monitored in order to collect data useful for managing the identified issue. The connection in fact between the real world and the digital world is given by the Data Integration Layer (that will be better explained in the next section) which collects data through the use of the most suitable technologies. The choice of the latter also comes from a thorough analysis not only of what data needs to be collected but also of the context, the instrumentation possibilities of the environment, the data transmission technologies themselves, etc. Once the data have been collected and integrated with each other, we move on to the use phase.

As previously mentioned what makes a digital twin different from simulation systems is the ability to make short- and medium-term predictions by exploiting collective intelligence. To do this, it becomes necessary to identify the best tools for this intelligence to emerge and be recognizable and interpretable. Artificial intelligence tools, Bayesian networks, and game engine-type agent simulators are some of the possible means of interpreting data by highlighting patterns or recognizing behaviors, applying multifactor interaction knowledge on problems, or performing high repetitions of random simulations to probe all possible scenarios. Depending on the data collection method, the subsequent possible processing also varies and thus the choice of the two components of the DT is strongly influenced.

Finally, the last aspect that profoundly affects the system is how the information resulting from the processing can be transmitted to the relevant stakeholders. The first choice to be made is whether it will be information used in the back office or directly on site. In both cases, the solution involving the implementation of a cloud platform is the best since it allows more immediate access to the data even from smartphones. In the case of information displayed directly on site in addition to the previously mentioned smartphones, solutions involving augmented, diminished or mixed reality can also be used. Although tools for displaying information as holograms are not yet widespread on a large scale, the power of superimposed visualization is for many applications of extreme importance. However, it should be kept in mind that recently registration techniques are being developed such that overlay visualization can be achieved even with the much more common smartphones.

In the following paragraph the application of what was introduced in the methodology will be translated into the architecture of the proposed system.

4. A FRAMEWORK FOR THE IMPLEMENTATION OF DIGITAL TWIN IN URBAN ENVIRONMENT

We are sometimes faced with some confusion in differentiating simulation systems from actual digital twins. There are two main characteristics that put together determine and differentiate a DT from the rest: real time and short- and medium-term prediction. The forecasting capability that is the one that most characterizes a DT is achieved by an intelligence component that can predict unexpected situations and propose optimized solutions based on data from the physical layer in real time. The proposed integration methodology for an optimal DT implementation involves the development of a framework architecture that consists of four layers added to the physical one: the data acquisition layer, the data integration layer, the digital twin modeling layer and finally the user interface layer renamed the presentation and service layer (Fig. 3).

The physical layer refers, in this case, to the urban environment that is the object of the digital twin. Buildings, roads and facilities of cities are all considered since this will enable a valuable support to decision. The different level of scale of assets covered and the multi-domain visualization of information integrated with each other will provide a look at all crucial aspects at once.

Data acquisition layer (Data collection layer in Fig.1-b) is a functional representation of the interface between the physical layer and the framework and is aimed to fetch data to digital models. In this layer are managed gathering technologies and transportation data protocol parsing. Data can be divided into two distinct categories: static and dynamic data. Static data are related to the configuration of context, thus not changing continuously. It includes preliminary survey data and characterization of physical asset (e.g. BIM and GIS models, Point Cloud models, etc.). The purpose of collecting these data on an urban scale is to report a representation of the built environment as built and in its current state of preservation. Given the heterogeneity of the type of constructions objects of the representation (buildings, roads, bridges, infrastructure) data will also have heterogeneous formats and sizes, as well as different scales of representation of the data. Dynamic data on the other hand are related to observations about relevant aspects for the behavior simulation of the physical system. Dynamic data are typically transported in XML or JSON format. Cameras, wireless sensors, citizens' smartphones can all contribute to the acquisition of

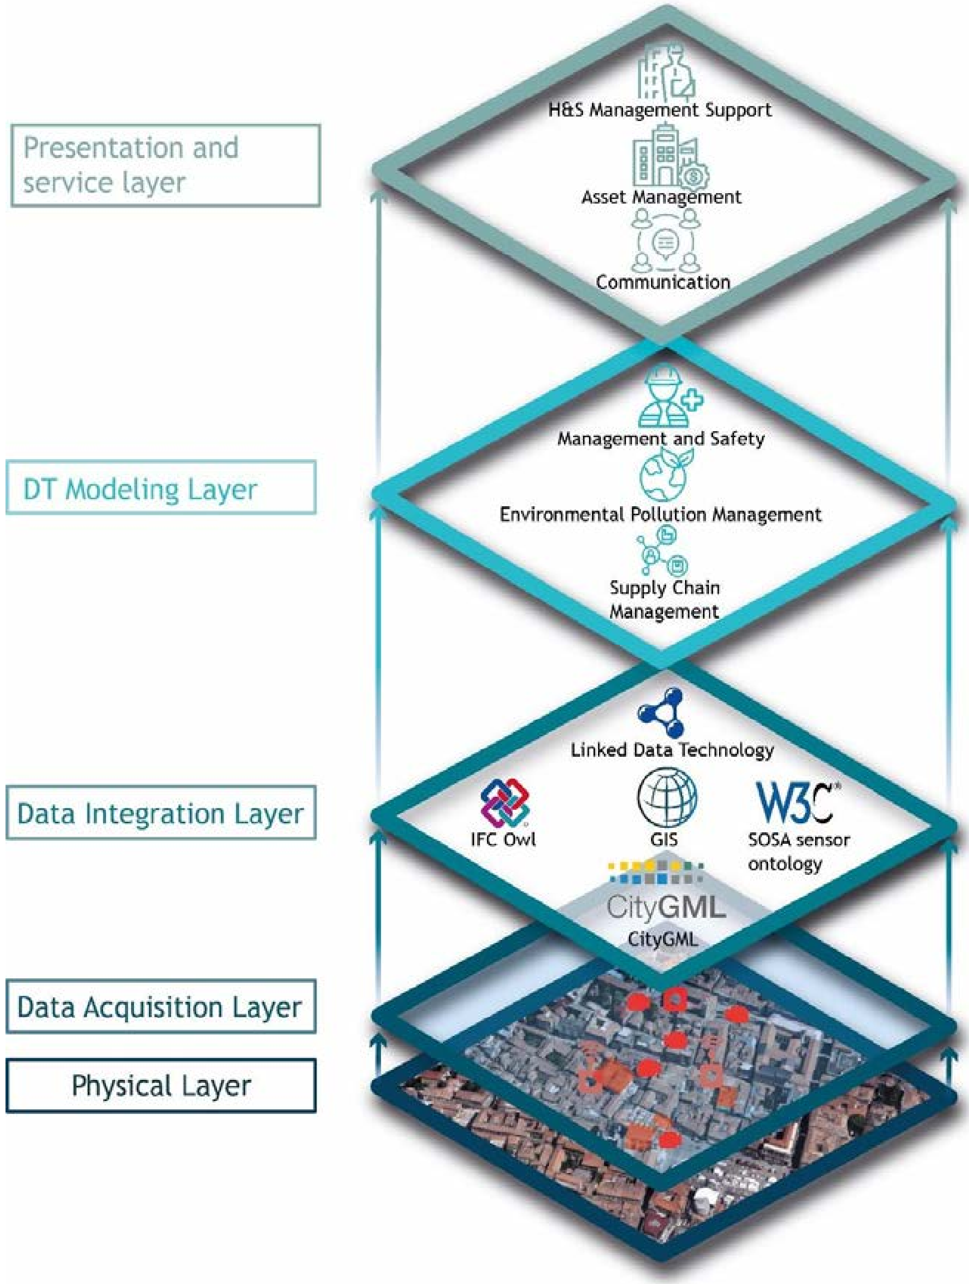

Fig. 3: DT for uban centres proposed architecture.

dynamic data, and by wisely choosing their placement these help create a stigmergic environment in which it is the assets, equipment, and people themselves (whether workers or citizens) that supply the DT with data.

Representation could be solved with the adoption of the Semantic Sensor Network Ontology (SOSA). SOSA ontology is recommended by the World Wide Web Consortium (W3C) for describing sensors and their observations, the involved procedures, the studied features of interest, the samples used to do so, and the observed properties, as well as actuators. Procedure for data acquisition optimization are fundamentals so as to avoid huge amounts of useless gathered data to analyze and improve the efficiency of the system.

Data Integration Layer will be in charge of integration of data at different scales (such as BIM and GIS representations), of different formats, and multidisciplinary. Beside this first task of data integration layer it has to be taken into consideration that most of popular data models (e.g. IFC, CityGML) do not claim to be based upon a formal Top Level Ontology since they have been developed pragmatically over years, and have been validated by practice. After the definition of the industrial exchange format IFC (Industry Foundation Classes), an important step in the direction of extending the scope of building data models is the recent introduction of IfcOWL ontology standard which is the Web Ontology Language format of IFC. This advance goes towards the embracement of Web of Data technologies to model the context of interest (buildings and assets). On the same line, research methodological approach is inspired by the expected benefits obtainable with Web of Data technologies such as the ability to granularly link data from different models. Web of Data consists of two technologies that are built upon the basic Web then relying on Universal Resource Identifiers (URIs) and Hypertext Transfer Protocol (HTTP): Semantic Web: RDF (Resource Description Framework) for graph-based data representation, and OWL (Web Ontology Language) for specification for shared conceptual models; Linked Data: Principles for specifying the interrelations and access across different datasets.

Both technologies contribute to the specification of the shared meaning of entities, one of the crucial problems in interoperability. This approach allows to support the integration of BIM models represented in IfcOWL with other building data referred to various ontologies directly in RDF; so many XML-based formats will also be supported such as CityGML-based format (for city scale representation) or sensor and observations data ontologies.

Then there remains the issue of data that are unstructured or do not have their own ontologies. This aspect for what concerns DT at the urban scale is extremely relevant since the vastness and heterogeneity of the elements taken into account makes the possibility of interfacing with multidisciplinary and multiscale data very realistic. A powerful framework therefore having to take this into account should contain the possibility of including new ontologies for both data and semantic links between structured and unstructured data. The framework proposed envisages the possibility of sharing data stored in RDF repository on the Web so that users can access them in a granular manner. Besides graph-based data model, schema/ontology languages, serialization formats, and query/reasoning languages, should provide a RESTful API technology for clients to interact with data.

Data Integration Layer can be mapped to Data Transmission Layer in Fig. 1-b because they methods shown also provide the means by which to communicate some of the data itself.

DT modeling layer (Data management layer plus Reasoning and simulation layer Fig. 1-b) is a virtual layer ideally containing the Digital Twin model or models. These differ according to the purposes for which they are implemented (e.g. in Fig.3 one DT for supply chain management, one for environmental pollution management and the last for H&S management). This layer contains the digital copy of the asset and the simulation tools for behavior forecasting. In the framework here proposed DTs are thought to be distributed over the cloud and connected to the framework via the internet. Different DTs are implemented by using domain specific algorithms and tools and are fed by Data Integration Layer through the REST Interface. Any DT internal structure is highly dependent on its specific domain and scope. Nevertheless, it must have a normalized external interface to link itself into the framework. Such interface is minimal and includes following data flows (usually in XML/JSON format): first configuration parameters and variables, time synchronizing clock, input and output streaming and exposed variables shared with the framework.

Finally, the presentation and service layer (Application layer Fig. 1-b) is a virtual layer on top of the framework that enables interaction with people/stakeholders. It corresponds to the RESTful API interface for retrieving information from the model integration bus. This layer is designed as a layer for distributing information to external management systems and specific user interfaces. This layer allows interaction with the population, thus also defining the DT as a tool for improving communication with and active participation of the citizenry. On the other hand, this layer is also the one that allows customers or decision makers to visualize data and possible suggested corrective actions. Again, the services toward which one can strive are diverse: three possible outputs of DTs are shown in Fig.3, namely support for site safety management, support for decision makers involved in real estate asset management, and communication with the public. It is at this level that the services that the digital twin will take care of are defined in detail, and so in a reverse engineering effort we start from here to understand at the root what data will need to be collected to meet certain set purposes.

5. CASE STUDY: L'AQUILA

The application for the proposed framework is the municipality of L'Aquila, in Abruzzo region, Italy. L'Aquila is a municipality that well represents the previously mentioned concept of complexity. First of all, it is a city that is located in an earthquake zone and periodically subjected to earthquakes that then result in subsequent states of emergency. L'Aquila is a historic city, and this entails two fundamental aspects: on the one hand, the city's housing stock is likely to be more fragile, less resilient to change, and with historical and artistic value to be preserved at the same time. On the other hand, its being an ancient city means that some infrastructure especially in the city center has drawbacks: narrow streets, uneven paving. All these aspects put together make the DT paradigm a very efficient and comprehensive method for dealing with problems.

The case we wanted to focus on is the implementation of a digital twin for safety support at construction sites and more specifically with regard to prop removal operations. In the most common post-earthquake scenarios, there is a frequent need to realize temporary shoring mainly for safety purposes, related to the use of the buildings themselves and of the adjacent public spaces (Fig. 4). Despite being conceived as temporary, the shoring is frequently intended to last more than a decade, often without undergoing revision or maintenance. Frequently they also create hindrance to the viability and free road travel because they occupy portions of public land. It is for this reason that their removal for the execution of recovery operations is a particularly delicate phase. This first demonstrator aims to test the ability of the proposed framework to integrate urban impact models of a construction site taking into account criticalities related to the removal of temporary shoring. The dismantling of this system is of great interest because it determines significant impacts in reconstruction sites, both in terms of operators' safety and organization and management.

The proposed DT will work by projecting short- and medium-term forecasts based on data streams generated by monitoring networks. These networks enable early warning strategies based on real-time predictive analysis of collected data, while also performing high-speed and qualitative simulations to assess specific risks and behaviors. The sensor network defines a fourth-level monitoring system, that is, a system that can estimate the location and extent of damage and use this data to determine the state of the overall structure, and thus its level of safety. The reference models are a simplified version of the FEM model simulator, linked to the HBIM model of the building aggregate, or structurally connected set of buildings. The DT thus implemented will work on three types of data sources: [a] sensor data from a network of sensors installed in the building aggregate and on temporary shoring, with the intent of monitoring relative displacements of structural elements, subsidence, and deformations, and [b] data communicated in real time through the sensors, arising from neighboring construction sites related to ongoing activities and positioning, vehicles and thus additional vibrations generated, and [c] contextual data communicated in real time related to urban processes that may interfere with or be jeopardized by the simple execution of temporary shoring removals or collapses.

This will enable the DT to provide valuable support during the reconstruction phase when the dismantling of temporary shoring may lead to the definition of deformation close to sudden collapse conditions. At the same time, the DT will integrate and interpret the data from the sensor network based on the three previously identified sources and generate an early warning if the limit values are exceeded. In this way, the decision maker will be informed and will be able to activate the necessary measures: stop work, if necessary, and evacuate the surrounding area. In addition to this, the DT integrated in a communication platform with the population will provide information about the works in progress so as to provide support to the citizen. Indeed, the latter could change his or her route by car if the site's workings block the passage or his or her walking route also in relation to the possible dust emissions reported by the DT. Finally, the continuous application of DT during the management and operation of the building stock could facilitate the transition from scheduled maintenance to an "on-demand" approach, in which the building itself communicates the necessary maintenance actions. Specifically, during the execution of consolidation work, the building aggregate will be equipped with a network of sensors aimed at conducting structural monitoring. The collected data are exploited to verify the performance of the buildings over time, allowing a continuous assessment of their safety and the opportunity to plan appropriate rehabilitation activities to reduce their vulnerability. The results in terms of process innovation introduced by the proposed research will support actors involved in the reconstruction and management of smaller historic centers, particularly site safety coordinators to coordinate and plan removal work.

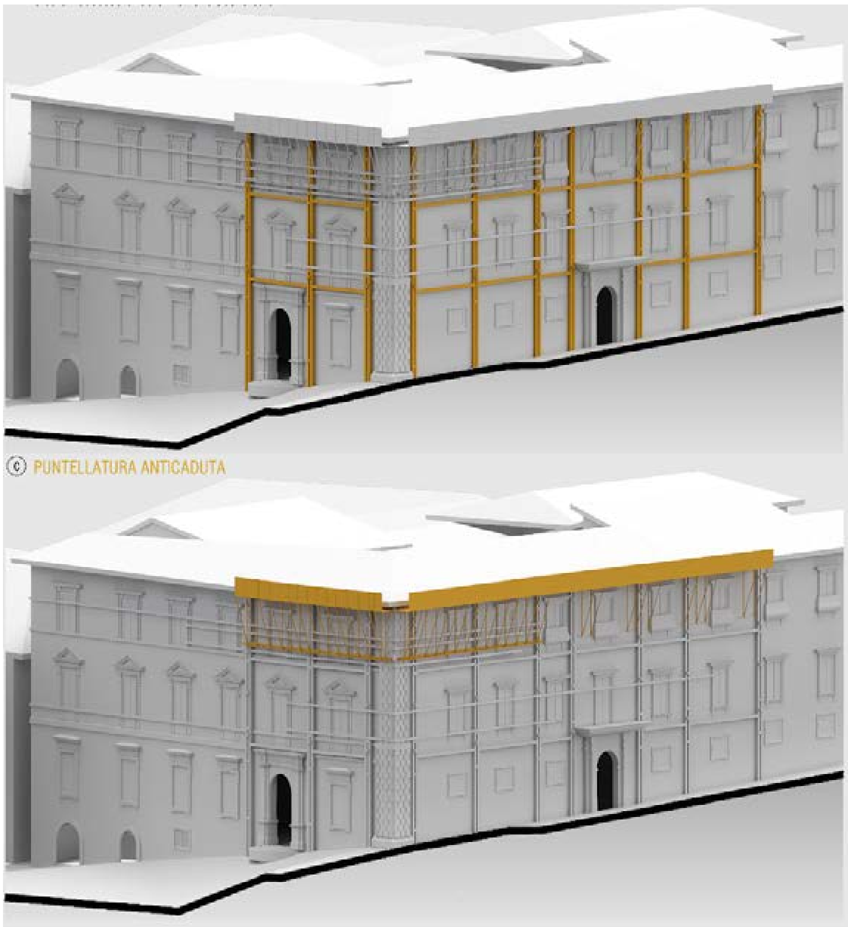

Fig. 4: Examples of shoring in HBIM for a historic building.

6. CONCLUSION

This paper presents a framework for implementing a digital twin in an urban environment that by its definition is characterized by complexity. The scenario chosen is that of post-earthquake emergency management and subsequent reconstruction phases. The configuration of an integrated system such as DTs that collect real-time data directly from the physical context allows for stigmergic systems. These imply that it is directly the environment, or rather the agents within it, that leave information on the ground for other agents. Inolte the DT through real-time simulation systems and data analysis is able to provide short- and medium-term forecasts that ensure decision support, both for stakeholders involved in land management, for those responsible for the construction and repair phases, and for the community.

DIGITAL TWINS FOR SMART DECISION MAKING IN ASSET MANAGEMENT

Chady Elias & Raja R.A. Issa

Rinker School of Construction Management, University of Florida, USA

ABSTRACT: *This study discusses the classification of Digital Twins (DTs) and their use in the Architecture, Engineering, Construction, and Operations (AECO) industry, the differences between building information modeling (BIM) and DT are emphasized and platforms for implementing DTs are compared. DTs are quickly gaining traction in the AECO industry because they create the ability to interact virtually with all physical smart devices in the built environment. The need for replicas goes all the way back to the 1960s, when NASA created physical replicas of spaceships and connected them to simulators to develop workshop solutions on the ground. DTs are simply building blocks of the metaverse that act as a real-time digital copy of a physical object. Based on data from the physical asset or system, the physical twin (PT), a DT unlocks value in supporting smart decision-making by combining artificial intelligence (AI) with the internet of things (IoT).*

KEYWORDS: *Digital Twins; Internet of Things; Artificial Intelligence; Asset Management.*

1. INTRODUCTION

Digital Twins (DTs) are quickly gaining traction in the AECO industry are quickly becoming synonymous with smart cities because they create the ability to interact virtually with all physical smart devices. DTs allow us to integrate in a physical environment data and information on what is happening in that environment thus converting that physical environment into a virtual one, that can be used in real time, or in aggregate, to facilitate the analyses of physical spaces.

In the AECO industry, the focus on DTs has increased due to the proliferation of digitalization and integration processes. For example, there has been a marked growth in the development of Building Information Modeling (BIM), but while BIM has instigated the digitalization and integration of design and construction information, its utility for smart decision-making in the postconstruction stage is limited as the data and information captured in BIM outputs are static. Consequently, the need for technology that enables dynamic optimization of BIM data and operational data has grown. DTs have shown early promise in the AECO industry to elevate BIM from static to actionable and dynamic virtual models.

2. BACKGROUND

The path from building information modeling (BIM) to DTs involves the integration of multiple data sources (see Fig. 1).

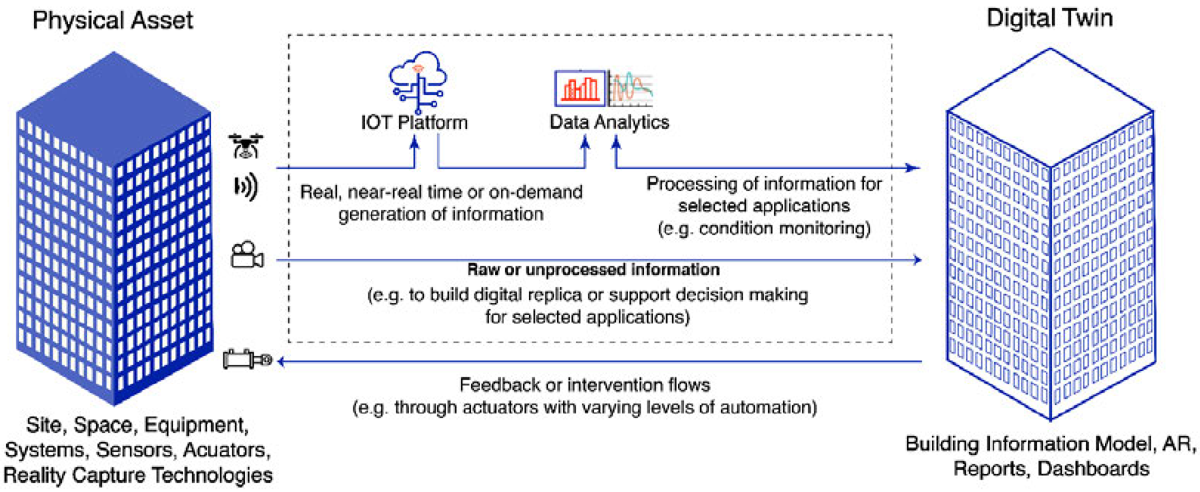

Fig. 1: Essential components to create a DT of a building (Adapted from Khajavi et al. 2019)

2.1 Building Information Modeling (BIM)

BIM as a digital technology continues to stimulate new workflows in the AECO industry. The capabilities of BIM to generate three-dimensional visualizations, and data rich models have resulted in its extension to facility lifecycle activities including facility management, operations and maintenance (O&M), commissioning and close-out, energy management, and space management, all key aspects of FM (Becerik-Gerber et al. 2012). Major progress has been made in the efficient transfer of design and construction data to FM systems, e.g., Computerized Maintenance Management Systems (CMMS), by using open standards, e.g., Construction Operation Building information exchange (COBie). Identification and specification of the required data during the facility design stage and requiring appropriate BIM deliverables is essential to developing models which are beneficial to facility managers. The data allows facility managers to analyze operational data while allowing owners a complete view of their assets (Asare et al. 2021).

Selecting the proper BIM level of development (LOD) is crucial in successfully developing a DT. The LODs for sharing building information models with project participants, as prescribed in the American Institute of Architects (AIA) E202 contract (AIA 2022), range from LOD 100 to LOD 500 (see Table 1). BIM, specifically the LOD 500 model, is the foundation of the Existence DT. The next step in the integration of BIM, FM and O&M lies in the development of DTs.

Table 1. AIA E202 LODs (AIA 2022)

§	Levels of Development (LOD)
4.2	**100:** The Model Element may be graphically represented in the Model with a symbol or other generic representation. but does not satisfy the requirements for LOD 200. Information related to the Model Element (e.g., cost per square foot. tonnage of HVAC, etc.) can be delivered from other Model Elements.
4.3	**200:** The Model Element is generically and graphically represented within the Model with approximate quantity, size, shape, location, and orientation.
4.4	**300:** The Model Element, as designed, is graphically represented within the Model such that its quantity, size, shape, location, and orientation can be measured.
4.4.1	**350:** The Model Element, as designed, is graphically represented within the Model such that its quantity, size, shape, location, orientation, and interfaces with adjacent or dependent Model Elements can be measured.
4.5	**400:** The Model Element is graphically represented within the Model with detail sufficient for fabrication, assembly, and installation.
4.6	**500:** The Model Element is a graphic representation of an existing or as-constructed condition developed through a combination of observation, field verification, or interpolation. The level of accuracy shall be noted or attached to the Model Element.

2.2 Internet of Things (IoT)

The internet of things (IoT) presents us with opportunities for transforming work and everyday life. The IoT is at the intersection of the physical and digital worlds, with all kinds of devices harnessing the power of interconnectivity to provide seamless experiences for businesses and consumers alike. To reach its full potential, IoT has to shift from continuing to provide incremental value amid siloed clusters to unlock its vast potential value as a fully interconnected IoT ecosystem. This will require an integrated IoT network within and across all industries. The main obstacle to be confronted is the cybersecurity risk which detrimentally impacts the trust needed to integrate IoT applications and networks. For smart cities, as with other applications, the expected solution lies in the merging of IoT and cybersecurity to form a new, integrated system (Greer et al. 2019).

2.3 Digital Twins (DTs)

A DT is comprised of three principal parts: a physical system in real space, the physical twin (PT); a virtual system in cyberspace, the DT; and the connection between real and cyber space for transferring data and information using cyber-physical systems and the internet of things (CPS/IoT). A DT creates an accurate digital model of the physical system in cyberspace that can accurately replicate and simulate the behavior of the PT. According to Tao et al. (2018), a DT can also provide a digital footprint of products by integrating geometry, structure, behavior, rules and functional properties. Salvador Palau et al. (2019) noted that DTs can also be considered as intelligent agents with prediction, communication, and data preprocessing capabilities.

Kritzinger et al. (2018) distinguished the various digital forms and categorized them as digital model, digital shadow and DT based on the automated dataflow between them (see Fig. 2). The Digital Model is a digital representation of an existing or planned physical object that does not use automated data exchange between the physical object and the digital object. Changes in the state of the physical object have no direct impact on the digital object and vice versa. The Digital Shadow is derived from the Digital Model and represents one-way data flow between the state of an existing physical object and a digital object. A change in state of the physical object leads to a change of state in the digital object, but not vice versa. The DT is characterized by automated bi-directional data flow between the physical and digital objects, which possess intelligence and decision-making capabilities that enable the automated feedback loop to the physical entity. A change in state of the physical object directly results in a change in state of the digital object and vice versa.

The combination of the PT and its corresponding DT is the fundamental building block of fully connected and flexible systems that are able to learn and adapt to new demands. Some of the DT roles include remote monitoring, predictive analytics, simulating future behavior, and optimization. To fulfil these roles, DTs rely on certain capabilities that exist across all of them. These required DT capabilities are summarized as follows (Redelinghuys et al. 2020):

- Acquire PT state - The DT must be able to acquire data from a variety of sensor types (e.g., temperature, pressure and vibration sensors and counters or PLC registers) from the PT. The PT sensor data collected is refined and enriched (e.g., through combination and adding context) into information sets that describe the state of the PT.

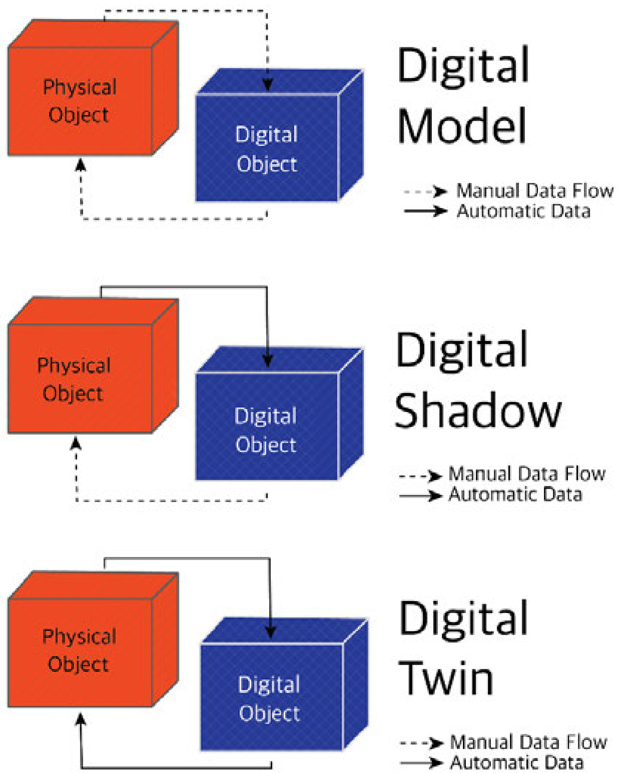

Fig. 2: Evolution from Digital Forms to Digital Twins (Adapted from Kritzinger et al. 2018).

- Maintain Information Repository - The state information obtained from the PT sensors is stored for easy access through the internet. This repository typically relies on Cloud-based storage, since large volumes of data may be stored for long periods of time.

- Simulate operation - The simulation of the PT's operation, i.e., predicting its future behavior from a given starting state and selected set of conditions, is required for some of the envisioned roles of the DT including the evaluation of new processes and different operation schedules.

- Emulate operation - Using emulation to imitate and visually represent or reproduce the action or function of the PT in real-time using feedback from embedded sensors.

Changes in the physical process will impact the digital world through the feedback of real-time embedded sensors and actuators. Using this data feedback, digital models can be used to interpret the behavior of machines or systems, and predict future state from real-time and historical data, as well as experience and knowledge. The core elements of a DT are the models and data. CPS, and the technologies required for developing CPS, are considered as a necessary foundation for implementing DTs.

Major challenges to adopting DTs include global connectivity, data integration and interoperability, data standardization, security and integrity, real-time performance and reliability, as well as barriers to its implementation and legacy system transformation (Attaran and Celik 2023). These challenges play a fundamental role in the development of DTs, as the connections between the PT and its corresponding DT typically rely on internet enabled connectivity.

3. CLASSIFICATIONS AND LEVELS OF MATURITY

There is not one single definition for what a DT is or the capabilities it provides. There are numerous types of DTs and levels of functionality based on the needs or the organization or project and the maturity of the data available. The development of a DT is a continuum, with the model evolving with the addition of new data and capabilities, the following classifications were developed by KPMG (2022) to indicate the level of functionality of the DT based on the types and level of data and capabilities that the system provides (see Figure 3):

- Existence twin: Furnishes principal project information, e.g., details on asset location and properties, enabling a single source of truth for asset data across the project. Traditional CAD and BIM systems are examples of an existence twin. This DT definition differs from that of the Kritzinger et al. (2018) classification of the evolution from digital forms to DTs.

- Status twin: Provides information on the status and condition of assets as detected by embedded IoT sensors. This can provide important insights into construction quality and progress, as well as asset health status over its lifecycle, and enables prediction of future performance based on the data collected.

- Operational twin: Allows for a real-time view of the project and the operational asset. This can provide critical insights into real-time performance and risks, both during construction and operations, and it enables more informed decision-making.

- Simulation twin: Enables teams to assess the impact of different design, construction, and operational decisions, allowing optimization of improvements in cost, performance, and risk. A simulation twin enables better and more thorough planning and can help minimize the risk of costly design and construction errors and faulty operational control changes.

- Cognitive twin: Uses AI and real-time data collection to analyze data, make decisions and optimize operational performance. This enables refinements made in real-time based on live data to adapt to existing conditions.

These classifications imply that an organization does not need to develop a highly advanced and complex model to see value from investing in DT technologies. For example, existence and status DTs can provide important project management insights on the physical configuration, properties, budget and cost, and as-built condition of a project and its component assets.

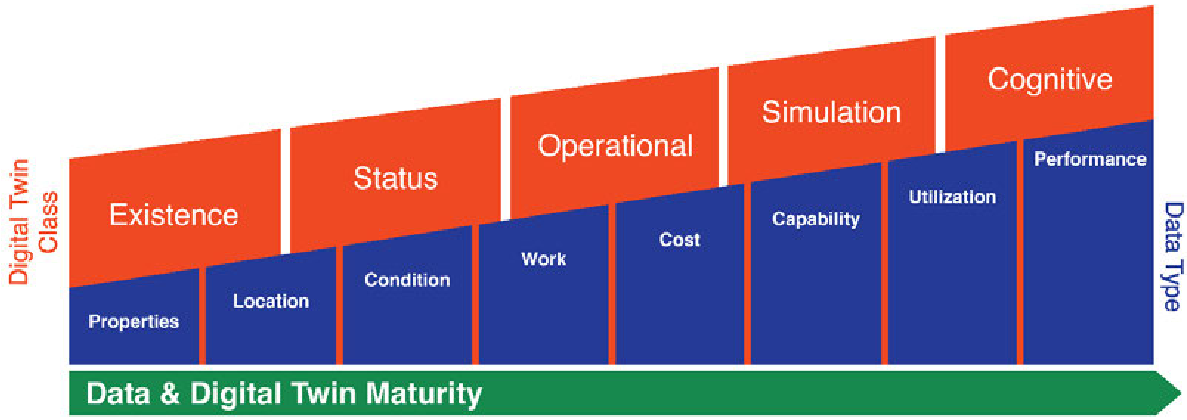

Figure 4. Data and DT Maturity (Adapted from KPMG 2022)

4. DIFFERENCES BETWEEN BIM AND DT

The building information model focuses on replicating the physical asset throughout the asset's lifecycle, while the DT replicates and enables a connection with the physical asset during operations. In BIM, there is total split between the digital and the physical asset, while, for DTs this split is distorted due to asset instrumentation and data synchronization between the physical and the digital asset. BIM is used in the three main phases of the built asset's lifecycle, design, build, and operations (Brilakis et al. 2019), while the DT is focused primarily on operations. These models have varying degrees of detail for their specific use-cases, i.e., built asset design, design-construction coordination, optimal asset delivery, and facility management. For DTs, there are no standard specifications for model detail or fidelity available. BIM has limited support for asset monitoring and control and for asset performance simulations during operations, while the DT does not consider discipline coordination for built asset delivery (Delgado and Oyedele 2021).

5. PLATFORMS FOR IMPLEMENTING DTs

There are three categories of data platforms for implementing DTs (Adamenko et al. 2020):

1. IoT Platforms: They provide data connectivity between the real and virtual world. Typically equipped with resources that establish connection between networked devices and the applications that process and/or visualize the data. Examples include Azure Digital Twins and IoT, Amazon Web Services IoT TwinMaker, Siemens MindSphere and Eclipse. DT design with such tools is more data-based. They provide a user interface (UI) for data modeling.

2. Gaming Engines: These platforms facilitate the development of executable video game-like applications. Their high-end visualization capabilities can be combined with IoT Platforms to achieve user-friendly DT applications. Examples include Unreal Engine, and Unity 3D. They require extensive programming to model DT data.

3. Commercial modeling and Simulation Platforms: These tools typically support design and implementation of system-based DTs. Examples include ANSYS, Autodesk Tandem, NVIDIA Omniverse, Microsoft Azure and Unreal Engine. They each provide a user interface (UI) for data modeling, e.g., Digital Twin Definition Language (DTDL) based on JSON-LD for Azure models, and the Universal Scene Description (USD) language for the Omniverse platform.

6. CONCLUSION

DTs provide a new outlook for smart decision-making in the AECO industry. From an operations and maintenance perspective, DTs can provide a dynamic view of facility status, enable operational control, support scenario planning and testing, and afford overall operational intelligence. To achieve high-performing DTs for smart decision-making, it is important to develop high-quality BIM outputs and supplement them with high-fidelity data. This requires a clear understanding of the different types of DTs, the tools for developing them, as well as knowing how and where to apply DTs. A macro-level roadmap to transforming BIM to DTs has been presented. As adoption of DTs increases, it is important to address the issues of standardization of DT design and implementation. This includes testing implementation tools and methods towards identifying the creation of DTs that can truly make decision-making in the AECO industry smarter.
